- Overall strain includes global rearrangement of the fibers and tightening of the weave. Tightening of the weave with increasing strain may partially explain the increase in SR and ISR values, and their leveling off after the first few percent strain.
- Strain gages are intended for application to smooth, flat surfaces; these conditions are not met when the gages are attached to woven geotextiles where the gages pass over multiple weaves in both the machine and cross-machine directions. The height and length of these "bumps" may be expected to change throughout the test as the reinforcement is strained. This change in degree of flatness of the gage may modify the gage resistance, thus affecting the output.
- The strain gages were not attached to a single geosynthetic fiber oriented in the direction of straining. They were attached to three parallel slit film strips or three parallel filament bundles, and the gages crossed strips and filament bundles oriented perpendicular to the

direction of strain. The independent action of the parallel slit-films or filament bundles to which the gages were attached can be expected to influence gage performance.

- d) In the in-soil tests, it is possible, even likely, that the geotextile sheets were arched very slightly when tested. The presence of such an arch, while unconfirmed, would result from the soil not being perfectly flat when the UCD specimen was constructed or from deformation of the soil during loading. During straining this arch may be increased, removed, or reversed, depending upon specimen behavior. Any change in the reinforcement orientation would influence the gage reading. This effect may be compensated for by attaching complementary gages directly opposite each other on each side of the geotextile specimen.

With the exception of item (d), these complicating factors are inherent to the nature of woven geotextiles and must be recognized as contributors to uncertainty when interpreting strain gage data.

Because the gages attached to the geotextiles did not accurately record overall strains, to estimate the true strain in a geotextile from strain gage measurements, it is necessary to apply a correction factor, CF. Such a factor can be computed by taking the reciprocal of SR and ISR (i.e.,  $CF_{SR} = 1/SR$  and  $CF_{ISR} = 1/ISR$ ). Emphasizing typical test results, instead of the full range of variation presented in Table 3, we believe representative correction factors for the geotextile reinforcements and strain gages used in our program are as follows:

Table 4: Correction factors.

Strain (%)	YL - series gages		PA -series gages
	0.5	4 - 6	0.5
$CF_{SR}$	2.5-1.0	1.7-1.0	2.5-1.4
$CF_{ISR}$	5 - 1.7	2.0-0.9	2.5-0.9

The selection of representative correction factors is somewhat subjective, and is based upon our assessment of the quality of all of the tests conducted in the program, and involves some engineering judgment. Because of the spread in CF values, and the somewhat subjective nature in their selection, it is impractical to select a single correction factor to apply to a given strain gage reading. Instead, if correction factors are to be applied, we recommend a probable range be computed for the corrected strain gage measurement, and that this range be used in estimating overall geotextile strain from strain gage measurements. When using strain gage data to estimate true geotextile strains, our test program illustrates that the potential for error is greatest at low strains (less than 1%). This is unfortunate because for geosynthetic reinforced walls, for example, reported typical strain values are often of this magnitude (Allen et al., 1992; McGown et al., 1993).

In our program, the difference between the measured overall geotextile strain and that measured with strain gages is similar to that reported by Allen et al., (1992) for a 12.6 m high instrumented geotextile reinforced wall. The reinforcements and strain gages used in our program were the same or similar products and by the same manufacturers as those used by Allen et al. For measuring overall geotextile strain in the field, Allen et al., used mechanical extensometers. The extensometers tended to record greater strain than the electrical resistance strain gages in almost all cases.

Despite the apparent limitations and inaccuracies associated with using strain gages to measure overall and incremental strain of geotextiles, the test results provide evidence that strain gages can be effectively used to measure strain distribution and creep of geotextiles confined in soil, Figures 5, 6, and 7. The effectiveness of using strain gages to measure strain distribution and to record creep in geotextiles, as was found in our laboratory program (Boyle, 1995a), was also observed by Allen et al., (1992) in a full scale instrumented wall. Therefore, despite the inability to use strain gages to determine the true strain in geotextiles with confidence, strain gages appear to be useful instruments for determining the distribution of strain along woven geotextiles and for recording creep.

### 3 CONCLUSIONS

In this study, in the first few percent strain, i.e., at strains typically observed in geosynthetic reinforced walls, strain gages underrecorded by 20% to 80% both total and incremental strain. The degree of underrecording decreased at strains between 4% and 8% strain, and the incremental strain ratio was on the order of 1.0 in some cases. Because of the inaccuracies involved, we suggest that a range of probable geotextile strain values, not a single value, be reported when adjusting field strain gage data. This is an especially important consideration at small strains, e.g., less than 1%.

Despite our inability accurately measure the true geotextile strain using strain gages attached to woven geotextiles, we did find that strain gages could be effectively used to identify the distribution of strain along the geotextiles. Strain gages were also found to be effective for monitoring creep in geotextiles.

### ACKNOWLEDGMENTS

This research was funded by the Washington State Department of Transportation, and their financial support is greatly appreciated. We thank T.M. Allen for his many helpful discussions and M. Gallagher for his assistance in conducting the laboratory tests.

# Soil Confinement Effect on Stress-Strain Properties of Geosynthetics

Z. Yuan, R. H. Swan, Jr., and R. C. Bachus  
GeoSyntec Consultants, Atlanta, Georgia, USA

V. Elias  
Earth Engineering & Sciences, Inc., Baltimore, Maryland, USA

**ABSTRACT:** A confined extension test device was designed and fabricated for measuring the response of geosynthetic materials confined in soil. A series of confined extension tests was performed on each of five selected geosynthetic materials using the confined extension test device. Each test series consisted of one unconfined extension test and two confined extension tests, each conducted at a different level of normal stress. The test data were presented in the form of stress versus strain curves. Using the test data, secant moduli at select strain levels were calculated. A comparison was made between unconfined and confined moduli for each geosynthetic material to quantify the soil confinement effect on stress-strain properties. A comparison was also made between the relative increase of moduli at the same strain level among the five geosynthetic materials to demonstrate the different responses of these geosynthetic materials under soil confinement.

**KEYWORDS:** confined extension test, soil confinement, geosynthetics, geogrids, geotextiles, stress, strain, modulus.

## 1 INTRODUCTION

In the design of geosynthetic-reinforced soil structures, the tensile strength and modulus of the reinforcing material are important design parameters. These two parameters are commonly obtained from the wide-width tensile test, described in the American Society for Testing and Materials (ASTM) Standard Test Method D 4595. This test is conducted under unconfined (i.e., in-air) conditions which do not fully simulate field conditions. Under field conditions, the geosynthetics are almost always confined within soil. Questions have been raised regarding the potential beneficial effects on the stress-strain properties of the geosynthetics due to soil confinement.

To address these questions, several researchers have studied the effect of soil confinement on stress-strain properties of various geosynthetic materials using different test devices. These devices include: (i) the in-soil test device developed by McGown et al. [1982] and modified by Wilson-Fahmy et al. [1993]; (ii) the zero-span test device by Christopher et al. [1986]; (iii) the pullout test device by Holtz [1977] and Juran et al. [1991]; (iv) the modified triaxial test device by Ling et al. [1991] and Wu [1991]; (v) the plane strain unit cell device (UCD) by Boyle [1995]; (vi) the automated plane strain reinforcement (APSR) cell by Whittle et al. [1993]; and (vii) the modified direct shear test machine by Leshchinsky et al. [1987]. Characteristics of these test devices were described in detail in the final report to the Federal Highway Administration (FHWA) by Yuan et al. [1997].

After an extensive literature review and several series of test trials using different in-soil confined extension test devices, it was found that an in-soil test apparatus based on the initial design by McGown et al. [1982] including the revisions by Wilson-Fahmy et al. [1993] could be modified to provide a nearly constant strain rate and a nearly constant tensile load over the confined test specimen length. Using this device, the confined response of a geosynthetic material measured using the in-soil test apparatus can be directly compared with the unconfined response (ASTM D 4595) of a geosynthetic material to assess the overall effect of soil

confinement. This led to the decision to design and fabricate a new device which is conceptually similar to the in-soil test apparatus for use in a comparative testing program. Using the modified device, herein referred to as the confined extension test device, the confined stress-strain response of geosynthetics at different confining stresses were compared with the unconfined response of the same geosynthetic to evaluate the effect of soil confinement.

## 2 TEST PROGRAM

### 2.1 Testing Materials

The materials used in the testing program included five geosynthetic and two soil materials. A brief description of each geosynthetic material and its ultimate wide-width tensile strength as tested in accordance with ASTM D4595 are summarized in Table 1. Beach sand and silty sand were

Table 1. Summary of geosynthetic properties.

Geosynthetic Materials	Description	Tensile Strength (kN/m)
Geosynthetic PP-10	Staple-filament needle-punched polypropylene nonwoven geotextile	19.7
Geosynthetic PP-11	Slit-film and multi-filament polypropylene woven geotextile	70.1
Geosynthetic PP-12	Mono-filament polypropylene woven geotextile	40.3
Geosynthetic PE-13	Extruded polyethylene geogrid	86.0
Geosynthetic PET-14	Polyester geogrid	85.5

used as the two soils in the testing program. For each of the two soil materials, a particle-size analysis was performed; results are shown in Figure 1. Based on the

Figure 1. Particle-Size distribution curves for beach sand and silty sand.

results of particle-size analyses, the beach sand and silty sand were classified as SP (poorly-graded sand) and SM (silty sand), respectively, in accordance with the Unified Soil Classification System. A standard Proctor compaction test and direct shear tests were also performed on each of the two soils; results are summarized in Table 2. The

Table 2. Summary of compaction and direct shear test results.

Soil Material	Maximum dry unit weight and optimum moisture content (ASTM D 698)	Peak shear strength parameters <sup>(1)</sup> (ASTM D 3080)
Beach sand	16.1 kN/m <sup>3</sup> at 11.5%	30° and 0.5 kPa
Silty Sand	15.4 kN/m <sup>3</sup> at 21.5%	34° and 7.6 kPa

direct shear tests were conducted on remolded beach sand and silty sand specimens compacted to 95 percent of maximum dry unit weight at optimum moisture content. Tests were conducted at normal stresses ranging from 14 to 63 kPa and a displacement rate of 1 mm/min.

## 2.2 Test Equipment

A new confined extension test device was designed and fabricated. As mentioned previously, the confined extension test device is conceptually similar to the in-soil test apparatus developed by McGown et al. [1982] and modified by Wilson-Fahmy et al. [1993]. These earlier devices consisted of a stationary confining box while a moving box was developed by the authors. The detailed cross-section drawing of the confined extension test device

is shown in Figure 2. The device consisted of the following major components:

1. a rigid supporting table with overall plan dimensions of 1,070 mm in length by 710 mm in width;
2. a confinement box with internal dimensions of 430 mm by 305 mm in plan and 150 mm in depth;
3. a flexible pneumatic diaphragm loading device (air bladder system) at the top and bottom of the confinement box for applying normal stresses to the test specimen; and
4. a 150-mm diameter hydraulic cylinder for applying tensile loads to the geosynthetic specimen.

The hydraulic cylinder was mounted on the front of the supporting table. A constant rate of strain was achieved by manually adjusting the rate of air or hydraulic flow into the hydraulic cylinder. A constant load test or a confined creep test can be conducted by maintaining a constant pressure within the hydraulic cylinder.

The confined extension test device was calibrated through several series of preliminary and calibration tests prior to being used for the confined extension testing program. These tests were conducted to evaluate: (i) the friction between the confinement box and steel rollers; (ii) the uniformity of strain distribution along the geosynthetic specimen length; and (iii) the reproducibility of test results. The results of the calibration tests are detailed in the final report to FHWA and indicate that: (i) the friction between the confinement box and steel rollers did not vary with confining pressures and the maximum friction was approximately 40 N; (ii) the strain distribution along the geosynthetic specimen length was approximately uniform for a normal stress up to 138 kPa; and (iii) the confined extension test device produced similar results for three specimens of a given geosynthetic subject to the same test conditions.

## 2.3 Testing Procedure

A testing procedure was developed to conduct confined extension tests using the confined extension testing device. This testing procedure consisted of the following steps:

1. *Preparation of Test Specimen:* Soil was compacted into the lower half of the confinement box above the lower air bladder system to form the lower confining layer. A previously prepared geosynthetic specimen with each end of the specimen cast in a low-temperature curing epoxy resin was placed on top of the confining soil layer. The two clamp ends of the geosynthetic specimen were then connected to the corresponding clevis as shown in Figure 2. A pretension force was then applied to the geosynthetic specimen to eliminate slack within the geosynthetic specimen. Additional soil was compacted into the upper half of the confinement box to form the upper confining layer. The upper air bladder system was then installed on top of the upper confining layer.
2. *Apply Normal Stress:* A normal stress was applied to the test specimen by pressurizing the upper and lower air bladder loading systems simultaneously.
3. *Apply Tensile Loads:* After the application of normal stress, the geosynthetic specimen was loaded under a

Figure 2. Details of confined extension test device.

constant rate of displacement as measured on the front specimen clamp.

Tensile loads were measured at the front and rear end of the geosynthetic specimen using two electronic load cells. Displacements at the front and rear ends of the geosynthetic specimens were measured using two linear variable differential transformers (LVDTs), each connected to a "tell-tail" wire which was attached to the geosynthetic specimen within the confinement box. Load and displacement data were recorded using a computer data acquisition system.

There were five major test variables involved in the testing procedure established for conducting confined extension tests. These variables were: (i) pretension force; (ii) strain rate; (iii) aspect ratio; (iv) thickness of the confining soil; and (v) boundary friction on the upper and lower surfaces of confining soil. The first three test variables were selected in accordance with ASTM D 4595 as follows:

1. **Pretension Force:** A total pretension force equal to 1.25 percent of the expected breaking force was applied to each geosynthetic specimen. However, the total pretension force was not less than 45 N or greater than 222 N in any case. The pretension force was applied to the geosynthetic specimen prior to placement of the upper confining soil layer.
2. **Strain Rate:** A constant rate of strain of 10 percent per minute was applied to the geosynthetic specimen in the confined extension test.
3. **Aspect Ratio:** An aspect ratio of 2:1 was used for geotextile specimens with a specimen width of 200 mm. For the geogrid, the test specimen was trimmed in such a way that it had a length containing at least two complete apertures in the direction of testing and a width containing at least five ribs in the cross-test direction.

The soil thickness and boundary conditions were selected

based on the results of two preliminary confined extension tests, as will be described below.

The effect of soil thickness on the confined response of geosynthetics was investigated through a series of confined extension tests on Geosynthetic PP-10 confined between two layers of beach sand with thicknesses ranging from 10 to 76 mm. The test results, as shown in Figure 3, indicate that there was little difference among the confined responses of Geosynthetic PP-10 when it was confined between 25- to 76-mm thick soil layers. However, the effect of soil confinement was reduced when the thickness of the soil layer was reduced to 10 mm due to the fact that cracks developed throughout the thickness of the soil layers, resulting in partial confinement of the geosynthetic specimen. To provide full confinement of the geosynthetic specimen, a soil thickness of 76 mm was then selected for all of the confined extension tests in this study.

Figure 3. Responses of Geosynthetic PP-10 confined within various thicknesses of beach sand layers.

The effect of the boundary friction on the confined response of geosynthetics was investigated through a series of confined extension tests on Geosynthetic PP-10, each test conducted under one of the following two boundary conditions:

1. Condition 1: no lubrication between the air bladder and confining soil while the confinement box was allowed to move; and
2. Condition 2: lubrication between the air bladder and confining soil while the confinement box was fixed to the supporting table during testing.

The lubrication was achieved by placing two layers of lubricated latex membranes on the contact surface between the bladder and confining soil. In each test the geosynthetic specimen was confined between 10-mm thick beach sand layers in order to directly compare the effect of the boundary condition. The test results, as shown in Figure 4,

Figure 4. Confined responses of Geosynthetic PP-10 under lubricated and unlubricated boundary conditions.

indicate that the confined stress-strain curves of Geosynthetic PP-10 are very similar when tested in accordance with conditions 1 and 2. Because of the small difference between these results, condition 1 was selected for the boundary condition during the testing program.

### 3 TEST RESULTS

Ten test series were conducted in the testing program. Each test series consisted of one unconfined and two confined extension tests on one of the five selected geosynthetic materials. Each geosynthetic material was confined within beach sand (Test Series 1 through 5) or silty sand (Test Series 6 through 10) under two different normal stresses (69 and 138 kPa). For each test, tensile loads and displacements were measured at the front and rear end of the geosynthetic specimen by load cells and LVDTs, respectively, and recorded using the computer data acquisition system. The load and displacement data were subsequently used to develop the tensile force (i.e., load

divided by initial specimen width) versus strain (i.e., total displacement divided by initial specimen length) curves.

To quantify the improvement due to the soil confinement, secant moduli at 1, 5, and 10 percent strain levels and peak strength were calculated for each test and summarized in Table 3. For this paper, the secant modulus at 5 percent strain was selected to quantify the effect of soil confinement. The improvement of secant moduli at 5 percent strain was plotted versus confining pressure for each geosynthetic material confined in the beach sand and in the silty sand as shown in Figures 5 and 6, respectively.

Figure 5. Confinement effect of beach sand on secant modulus at 5 percent strain.

Figure 6. Confinement effect of silty sand on secant modulus at 5 percent strain.

In these plots "improvement" is defined as the ratio of the confined secant modulus to the unconfined secant modulus at a strain level of 5 percent. These figures clearly demonstrate that the Geosynthetic PP-10 is significantly affected by soil confinement and the other four geosynthetic materials are less affected by soil confinement. The comparison between Figures 5 and 6 indicates that the confinement effect of the beach sand is greater than that of the silty sand.

Table 3. Summary of confined extension test results.

Test Series Number	Geosynthetic Material <sup>(1)</sup>	Confining Material <sup>(2)</sup>	Confining Pressure (kPa)	Modulus at 1% Strain (kN/m)	Modulus at 5% Strain (kN/m)	Modulus at 10% Strain (kN/m)	Peak Strength (kN/m)

			69	1174.8	1046.3	875.7	97.7
			138	1397.9	1250.4	984.9	105.1

Notes: (1) For Geosynthetics PP-10, PP-11 and PP-12, each test specimen was 200 mm in width and 100 mm in gage length. For Geosynthetics PE-13 and PET-14, each test specimen had two full apertures in the machine direction and five ribs in the cross-machine direction.

(2) For each confined extension test, the geosynthetic specimen was confined between two 76-mm thick layers of beach sand or silty sand.

#### 4 CONCLUSIONS

A confined extension test apparatus was designed, fabricated, calibrated, and used in a comparative testing program. The advantages of the test apparatus fabricated for this study include: (i) ease of the test set-up; (ii) well-defined boundary conditions; and (iii) ease of test interpretation. Based on the results of the calibration tests, a nearly uniform distribution of tensile strain along the specimen length was achieved. Because of this relatively uniform distribution, the confined stress-strain response of the geosynthetic was readily obtained from the measured data and used for a direct comparison with the unconfined response of the geosynthetic to evaluate the effect of soil confinement. Further evaluations can be performed using this device to study the effects of full and partial confinement and creep behavior of geosynthetic materials.

Based on the results of the ten confined extension tests series, the following conclusions can be drawn:

1. Soil confinement significantly improves the moduli and strength of Geosynthetic PP-10. As the confining pressures increases, the moduli and strength of this material similarly increases. The 5 percent moduli of Geosynthetic PP-10 increased by approximately 200 to 400 percent when confined in the beach sand and 50 to 300 percent in the silty sand under confining pressures of 69 and 138 kPa.
2. Under the same confining pressure, the confined response (i.e., modulus and strength) of Geosynthetic PP-10 in beach sand is greater than that of Geosynthetic PP-10 in silty sand.
3. There is a noticeable effect of confinement with respect to the confined response for the two woven geotextiles and two geogrids (Geosynthetics PP-11, PP-12, PE-13, and PET-14) when confined in the beach sand and in the silty sand; the increase of the 5 percent moduli ranged from approximately 5 to 30 percent among Geosynthetics PP-11, PP-12, PE-13, and PET-14 at a normal stress of 138 kPa. These increases can be considered significant with respect to unconfined moduli of the same materials although considered less significant when compared with the increase of the 5 percent moduli for the nonwoven geotextile (Geosynthetic PP-10).
4. Improvement of the confined stress-strain properties for a given geosynthetic material may be primarily related to: (i) internal friction between fibers or yarns; (ii) alignment of curved fibers or yarns (i.e., tortuosity); and (iii) interlocking of soil within openings or apertures of geosynthetics.

#### ACKNOWLEDGEMENTS

The research presented in this paper was supported by the FHWA. The support of the FHWA is greatly appreciated. The authors would like to thank Drs. B. Christopher, R.M. Koerner, and R.D. Holtz for their comments on the original

report of this research program submitted to the FHWA on which this paper is based.

**ABSTRACT:** Concurrent with a product development program, a review of the testing of reinforcements was conducted. Review of more than 100 published articles revealed that: (1) Researchers have identified 14 issues of concern to the design engineer as well as the manufacturer of geosynthetic reinforcements. (2) The geosynthetic and geotechnical community have not fully exploited the technical resources (data base and knowledge) of the textile industry. (3) Data for reinforcement products is inconsistently reported, resulting in potential misinterpretation. (4) Little research has been conducted on the testing of high performance geosynthetic reinforcements. This paper will review the above and present a test methodology that: (1) addresses the issues of concern, (2) is based on detailed research and experimentation, (3) is easily verified, is repeatable and reproducible.

**KEYWORDS:** Mechanical properties, tensile strength, modulus, testing, woven fabrics, knit fabrics, specifications.

## 1 INTRODUCTION

Much research has been conducted on the type of wide width testing represented by ASTM D4595 and ISO 10319 in hopes of establishing a relationship between laboratory testing and the plane strain conditions a geosynthetic experiences in use. The references cited in this paper represent the key portion of the work that deals with some aspect of wide width testing of geosynthetics. 53 references in the literature explore wide width testing. Less than 10 address reinforcements and 5 of the 10 report serious concerns about current methodology and the results of its application to high strength materials (Haliburton 1978; Myles et al. 1986; Rowe et al. 1986; Leschinsky et al. 1990; Brand et al. 1991). In the period from 1977 (Finnigan 1977) through the present, 14 issues of concern have been identified with the testing of reinforcements with many of these concerns yet unresolved. The research reported here focuses specifically on the testing of textile products employing high tenacity industrial quality multifilament textile yarns from such polymers as polyester (PET), polyamide (nylon), and polyvinyl alcohol (PVA).

The specific concerns about testing of reinforcing products expressed in the literature are: (1) the effect of sample gauge (length) on reported values including tensile strength, extension and modulus, (2) the effect of test speed, i.e. strain rate on reported values: one specific issue is the difference between ASTM at 10% and ISO at 20% per minute, (3) the effect of fabric structure (weave) on reported values, (4) the effect of jaw or grip types on reported values, (5) the control of sample slippage in grips, (6) the amount of tolerable slippage in clamping devices, (7) the accuracy of various extension measurement systems,

(8) the effect of the extension measurement system on the reported values, (9) the effect of sample width on reported values, (10) the effect of preload on reported values, (11) the definition, measurement and reporting of modulus, (12) which modulus is important?, (13) what portion of the sample does a reported modulus represent?, (14) is there a demonstrated relationship between single end yarn test values and fabric test values?

The research reported in this paper is directed toward developing a repeatable and reproducible test method for textile reinforcements. This presentation focuses on 8 of the concerns. The issues addressed are sample length, sample gauge (area of extension measurement), method of extension measurement, fabric structure, test preloads and modulus. Reference is made but specific research is not reported for jaw types, slippage, sample width and yarn to fabric relationship. The investigation includes both conventional roller grip systems and pressure clamping systems. The pressure clamping system incorporates a technique used in other disciplines for very strong materials. This technique is the application of sacrificial tabs to the clamping area of the specimen, thus permitting very high jaw pressures without specimen damage. A second modification to test protocol involved the use of long samples, 0.508 m between grips. Long samples have two benefits, first the sample geometry is similar between roller and tab systems and longer samples reduce the effect of variation in test speed on results. It is important to note that, the techniques employed in this work are applicable to conventional textiles produced from multifilament yarns based on polymers whose glass transition point is at or above the testing temperature. It is the authors opinion that the techniques in the test method that produce meaningful

information for very strong textiles will not be necessary for other textile based geosynthetics such as nonwovens or separation membranes. A specific caution applies to robust fabrics produced from polypropylene yarns. While the variations in test results caused by variation in testing speed can be substantially neutralized for fibers, yarns and fabrics produced from nylon and polyester, the same cannot be said for polypropylene textiles unless tests are conducted at temperatures below  $-10^{\circ}\text{C}$ . Given an accurate description of applicability, technique, preparation, equipment, and clear and accurate reporting requirements, this methodology can be incorporated in the standard test methodologies already extant in the geosynthetics industry.

## 2 RESULTS OF THE INVESTIGATION

### 2.1 The Importance of Fabric Structure on the Testing of High Strength Reinforcements.

Several researchers have noted that the structure of a product has a profound impact on the performance of that product in a testing protocol. Research can be interpreted to describe the structure of the reinforcement (fabric) as the dominant condition of the testing protocol (Rowe and Ho 1986). This concept is confirmed by a text sponsored by the NGO (Balkema 1986), which conducts a detailed discussion of the effects of fabric and yarn crimp, sample width, and cross contraction under load in confined and unconfined tests with the conclusion that the structure of

the fabric and the size of the sample will dominate the protocol and dictate the hierarchy of the results. Figures 1 and 2 present comparative test results for two groups of fabrics. For both groups all conditions are uniform except sample structure. Figure 1 presents 6 fabrics produced to the same performance specification, (5 of these fabrics employ a common warp in different structures, the sixth was produced separately). Figure 2 presents an additional 5 fabrics, all from a common warp of a different polymer. The wide variation in the curves and the shape of the curves demonstrates the dramatic effect of fabric structure on the results from a tensile test. Fabric structure is manipulated by the designer/producer to achieve a performance level. Test conditions cannot "correct" the impact of structure on results because structure clearly has

Figure 1. Performance Variation of Polyester Fabric Structure

Figure 2. Performance Variation of PVA Fabric Structure an impact on performance.

### 2.2 The Effect of Preloads on Test Results

Three widely referenced test methods for the reporting of geosynthetic properties are ASTM D4595, ISO 10319:1993 and BS 6906. Subtle differences in test conditions and important differences in reporting exist between the methods. Both ISO and the British Standard cite a maximum preload of 1% of breaking strength while ASTM allows 1.25% not to exceed 0.73 kN/m. The ASTM method appears more conservative for very high strength materials: however, ISO and BSI recommend stress strain curves that

include any initial elongation established in the application of preload. ASTM allows the presentation of data without reporting the initial elongation and acknowledges in a note that ASTM does not have agreement on the point of origin (zero position). Myles (1986) clearly defined the logic and the method in which to record the test initiation, a "daylight" point and total offset to be used for calculation

Figure 3. Stress-Strain Curve with Complete Test Results

of secant and tangent moduli as shown in Figure 3.

The test methods cited above are employed equally for a wide range of geosynthetics. The significance of tensile strength and modulus are not the same for all classes of geosynthetics. Unreported stress, strain and modulus data on a filter is not a concern to the designer. Any such unreported data on products used in critical structures is, or should be, a significant concern. One illustration of the importance of accurate reporting is the effect of preloads. Figure 4 presents the effect of preload variation on a set of identical samples tested on roller grips. The significance of geosynthetic performance at low strain is increasingly recognized as significant to the working range of successful construction projects (Craig 1997, Fakher et al. 1996). Current specifications are frequently governed by strength requirements at strains of 5%. Because testing preload has such profound effect on reported data at low strain values, it is essential that the design engineer have both a good understanding of test protocol and accurate data in order to employ reinforcements in such designs. Figure 4 demonstrates that application of a 222 N preload results in a 15 to 20% increase in reported load at 5% strain and that

successively higher preloads more than double T5 values. Ultimate strength is nearly independent of preload; however, there can be a modest decrease in ultimate strain as preload increases. Figure 5 demonstrates that preloads

Figure 4. Effect of Preload on Identical Samples Using Roller Grips

Figure 5. Effect of Preload on Identical Samples Using Tab Grips

produce the same data inflation in the tab system that was seen in figure 4 for roller testing. Figure 6 presents 2 widely different fabric structures produced to the same specification tested under no preload and under a high preload using roller grips. Clearly preloads inflate data regardless of fabric structure or gripping system. When employing roller grips, the use of preload in testing of very strong geosynthetic reinforcements is obviously necessary in order to remove slack and to seat samples in the testing device. The recording of preloads applied in testing of very strong geosynthetic reinforcements is important, and the full reporting of extension when applying preloads is essential to insure data is presented in complete form. The reporting of tests performed on high strength textiles should

are related to segments of the stress strain curve. The ISO and BSI definitions are compatible with ASTM in language; however, the ISO and BSI curves, with the reporting of extension from test initiation, clearly include data that ASTM excludes. The point is that the reporting of a value at 2% or 5% strain on a secant calculated from a body of data that omits part of the specimen extension data should be of little value to the designer of a critical structure.

During the execution of a test, data for the entire curve can be recorded. With the salient data available for analysis, information concerning any, and every, segment of the load elongation curve can be observed. Initial modulus should be defined as the linear portion of the test curve from the initiation point to the point where the curve

Figure 6. Effect of Preload Regardless of Structure, Using Roller Grips

include test initiation, daylight point and the total offset as mentioned by Myles (1986).

### 2.3 The Definition of and Reporting of Modulus

Due to poor agreement between sources, the definitions of modulus can be problematic for the authors of specifications and test reports on reinforcing geosynthetics. The problem is the selection of the portions of the curve to be included in the calculations. ASTM D4595 defines initial tensile modulus as “the ratio of change in tensile force per unit width to a change in strain (slope) of the initial portion of the force per unit width strain curve.” ASTM also defines offset modulus and secant modulus in similar terms with the clear intent that all of these concepts

Figure 7. Measurement of Initial Modulus Data Using Tab System with No Applied Preload

shifts to non linearity. Figure 7 presents 2 best fit lines for 2 segments of a stress strain curve. Segment (a) represents 0 to 1%. Segment (b) represents 1 to 2%.

### 2.4 The Effect of Sample Gauge on Test Results

One of the principle concerns of the research community in its review of wide width testing on reinforcements was the effect of sample gauge. The authors conclude that the 100 mm sample gauge has proven to be inadequate for reinforcements. Finnigan (1977), Sisson (1977) and Van

Leeuwen (1977) all cited standard testing protocols for strong fabrics as the textile strip method in which sample length was typically 2 to 4 times the width. Recognition that the strip concept of sample configuration is most appropriate for strong tensile members is recognized repeatedly throughout the literature, ASTM D5035, a strip test, is representative of the standard method for testing strong textiles and employs long thin specimens. The NGO (Balkema 1986) provide discussion of the mechanisms of testing and effects of gauge, width and structure. The concept of long sample lengths is common to the textile industry reflecting the producers understanding that short sample lengths inflate strength and extension while deflating modulus. Pan et al. (1997) showed that a small variation in length of textile reinforcements had a large effect on results. Experiments were conducted using long samples, up to 0.508 m, in the sacrificial tab method in search of a neutral gauge for multifilament textile products using polyester, polyamide or other industrial fibers. Data indicates that a small variation in length of textile reinforcements has a large effect on results. The experiments indicate that for multifilament textile products using polyester, polyamide or other industrial fibers both the effects of sample length and of variations in test speed are greatly reduced by long specimens. Figure 8 presents the effect of strain rate on initial modulus as a function of specimen length. Initial modulus is defined as "the linear portion of the test curve from the test initiation point to the point where the curve shifts to nonlinearity". Figure 9 presents the effect of strain rate on segment (3%-ULT)

Figure 9. Effect of Strain Rate on Segment (3%-ULT) Modulus

modulus as a function of specimen length and Table 1 presents a comparison of standard deviation for initial and segment modulus.

Table 1. Comparison of Standard Deviation for Initial and Segment Modulus

45.7	2	1.0	1.3

## 2.5. Strain Measurement

The measurement of strain in testing of geosynthetics is widely acknowledged to be difficult and it is particularly so for the high strength materials used in reinforcements. The ISO method dictates that the extensometer be capable of measuring the distance between two reference points on the specimen without any damage to the specimen or slippage in relation to the specimen and resulting in a measurement representing the true movement of the reference points. The four strain measurement techniques cited in the literature and the ISO test method are mechanical, optical, infrared or electrical devices. Mechanical devices include both crosshead movement (displacement of the clamps) and lvdt's (linear displacement measurement devices) or mechanical devices attached to the specimen. Optical devices include video and laser systems. All of which observe a small section of the specimen. The principle issues are specimen damage, rate of strain and confirmation of accuracy. The experiences reported by Brand and Pang (1991) and Leschinsky and Fowler (1990) define the difficulties experienced in accurate measurement of strain on very strong geosynthetic materials regardless of device type, and reflect the broad concern that accuracy needs to be verified by comparison of two or more measurement techniques. Figure 10 presents a comparison of curves from specimens in which extension was recorded simultaneously for both displacement and an optical device. The excellent agreement at low strain is most significant to the designer

Figure 10. Effect of Extension Measurement Device Using Tab System

of reinforced structures.

Specimen damage or distortion that influence test results can be evidenced in two principal forms. Sample slippage in clamps resulting in partial or major deformation can influence test results necessitating that the specimen be discarded. More frequent is the seating slippage typical of roller devices and the slight distortion of samples in the clamp area in normal strip tests. In both instances, accurate measurement and recording of strain is essential to determine whether the slippage materially affects the results. Figure 11 compares the results of identical specimens with data recorded by lvdt and by crosshead.

Figure 11. Effect of Extension Measurement Device Using Roller Grips

The crosshead data presentation shows initiation and the process of sample slippage during the test. The lvdt data is presented from preloaded initiation only and masks the slippage and elongation at initiation. It is interesting to note that the device has the effect of truncating the stress strain curve at ultimate while recording consistent data at low loads.

Figure 7 illustrates that for non slipping grips, crosshead displacement data from a correctly calibrated instrument will provide strain information for an entire sample geometry rather than a small nonrepresentative sector. Some practitioners have expressed concern about the accuracy of displacement measurement. The conventional testing machine does experience deformation in the

conduct of a tensile test. Error introduced by this deformation is corrected by subtracting machine displacement from the data. To demonstrate accuracy we tested a calibrated aluminum bar. The specified modulus of the specimen was 68.95 GPa. Strain gages recorded a modulus of 68.1 GPa. Crosshead displacement recorded modulus of 54.0 GPa. Displacement values corrected for machine deformation were 68.4 GPa, essentially zero error. Tests conducted on fabrics with loads at 31.1 kN and extension of 12 to 16% experienced machine deformation of less than 0.1%. Failure to correct for this deformation results in test error of less than 0.5% leading to the conclusion that displacement is an accurate measurement.

Finally, rate of strain is shown to be problematic in measurement as it is calculated as a percentage of sample gauge (a length measurement). For those geosynthetics that can be tested in a 100 mm length by 200 mm width geometry, the speed of the test is easily recorded by conventional means. High strength materials are typically tested in the much different longer than wide geometry, dictated by equipment load capacity and clamping devices. Brand and Pang (1990) report that strain rate for an entire sample tested by roller grips was typically 6% not the expected 10% prescribed by the method ASTM D4595. The NGO, Balkema (1986) explains that the phenomena occurs because of differences in strain characteristics in different portions of the specimen. Strain in the vicinity of the clamps is plane in nature while strain in the center of the sample tends to be linear. Goswami et al. (1996) present variation in strain for different sites on the specimen as the norm for textile type materials. The necessity to observe either the total area or a large portion of the specimen to accurately record strain rate necessitates the simultaneous employment of a combination of techniques such as displacement and optical devices and a mandatory comparison of the data. The definition of sample length, the strain measurement gauge used, the strain measurement system used and the observed test speed must be clearly reported.

## 2.6 Jaws, grips and other devices

Strong geosynthetics such as reinforcements experience great difficulty in sample gripping. Experienced researchers (Haliburton 1978; Myles 1986, 1987; Rowe et al. 1986; Richardson et al. 1987; Leschinsky and Fowler 1990; Brand and Pang 1991) cite grip failure as a key concern. The principal test methods, ASTM, ISO and BSI, recognize the issue of the difficulty of sample gripping and permit the utilization of roller or capstan grips. Roller grips typically require sample lengths of 1.829 m, width up to 0.203 m and typical spacing between rollers of 0.508 m. Because the sample geometry used in rollers is larger than most extension measurement tools, it seems obvious that displacement could be a critical measure of sample strains.

Unfortunately, the large amount of slippage that occurs in roller grips throughout the test negates the application of these techniques for low strain values in roller testing, although displacement can be quite accurate in recording ultimate strain. Equally problematic is the application of other devices. Typical optical devices observe a pencil line wide strip 0.203 m high, and mechanical/electronic devices also observe a very narrow, 0.101 m long section of a specimen with the result that when applied to roller tested specimens, these extension measurement systems represent the area observed and not the specimens performance.

Roller grips have several other awkward characteristics beside large sample geometry including the need to permit a sample to seat itself. The process of seating, also described as the application of preload, involves a certain extension of the sample. Accurate reporting requires that this extension be recorded as per Figure 3. Another issue of difficulty caused by large sample geometry of 1.829 m length, 0.508 m grip separation and sample widths up to 0.203 m is incompatibility with the general definition of wide width sample geometry: 100 mm gauge length by 200 mm width. In terms of strain measurement, this definition results in the apparent observation of, and reporting on, of a 0.101 m section of a 0.508 m or longer sample. Leschinsky and Fowler (1990) and Brand and Pang (1991) reported that different areas of a fabric were seen to extend at different rates and that any 100 mm by 200 mm section of a large sample would not be representative of the sample, or the product. The phenomenon that extension is not uniform over a large sample is documented elsewhere in textile literature (Goswami et al. 1996).

Sample widths vary according to the test device load capability, but in every case an equal number of yarn ends should be tested in each specimen of a sample or a testing program. In our work the separation from center of barrel to center of barrel was fixed at 0.508 m. Extension was measured by displacement or lvdt with the lvdt found to be acceptable for measurement of low strain values but strongly influenced by sample geometry at ultimate. Figure 9 compares identical specimens with extension recorded by displacement compared to lvdt. The lvdt could be observed to distort the specimen, break fiber and prematurely fail the specimen at very high strain.

The jaw used in the sacrificial tab system employed in our work is a hydraulic clamp with a wide pressure range. For very strong fabrics with tensile exceeding 700 kN/m, grip pressures exceeded 20.7 MPa insuring control of slippage in the grips. The typical specimen length exceeds 0.610 m permitting mounting of 0.0508 m sacrificial tabs on each end of the specimen and leaving a 0.508 m separation between clamps. As in roller testing, sample width is dictated by load cell capability but in every case an equal number of yarn ends is maintained between specimens.

## 2.7 Sample preparation

Care is taken in mounting samples in grips to avoid skew. Sacrificial tabs of light metal are adhesive bonded on both sides of specimens destined for pressure clamps, with tab separation of a minimum of 0.508 m. Adhesives are selected to have minimal influence on samples. For many light load fabrics, under 130 kN/m, protective tabs are unnecessary.

The sample preparation technique attempts to achieve yarn (and filament) alignment. The sacrificial tab permits very high pressures across the clamped face of the specimen which prevents the specimen from slipping out of the clamp. Simultaneously, the soft adhesive that binds the tab to the sample permits some relative slippage within the specimen permitting the maximum degree of uniform alignment and engagement of a high proportion of the filaments in the specimen. Slippage is observed in the two procedures at different times. Slippage is first observed on rollers in the early stages of the test, continues through much of the procedure and reduces to nil when approaching ultimate. Slippage is observed in pressure clamps at the end of the test. This small distortion develops late in the test and allows the continued loading of a majority of the filaments in the specimen.

## 3 CONCLUSIONS

The following conclusions are presented in the same order as the listing of the 14 concerns. 1. For textiles with uniaxial orientation of strength members (yarns), sample length influences test results. Shorter lengths inflate tensile values while deflating modulus. A practical solution to insure comparable results is to employ sample lengths in pressure grips that are comparable to roller grip separation distances. This permits the observation of similar geometry of the specimens. 2. Increased test speed inflates results; however, longer samples reduce the effect. Polyolefin materials are far more greatly affected by variation in speed. 3. Fabric structure dominates testing. Manipulation of other testing aspects: polymer, fiber form, test speed, sample geometry, grips, or protocols cannot reduce the impact of structure on fabric performance. 4. Test grips are part of a system and each system, roller or pressure can be employed to achieve accurate and repeatable results. 5. Slippage is also part of the system when testing strong materials and is in fact desirable in order to achieve consistent and meaningful results. 6. Tolerable slippage is observed and recorded by developing correlation between extension measurement systems. 7. Extension measurement is a critical element and a contentious issue in testing of high strength fabrics. Certain devices, lvdts, can be satisfactory for part of the test and may invalidate another portion of the test. There is a potential lack of confidence

in, or familiarity with, displacement and its influence of sample geometry and speed. Accurate displacement measurement can be performed simultaneously with other measurements and compatibility of two measurements insures good understanding of the test process and the recognition of flawed results. The test operator must take care to report the strain measurement gauge and the sample length, particularly when these measurements are different. 8. Extension measurement is defined by sample geometry, test speed, the physical area the device measures and the location of the device on the sample. Extension measurement techniques must be reported in detail to avoid undue masking of results. 9. Strong reinforcements are essentially uniaxial in orientation with each strength member (yarn) parallel to the next. In strip testing, whether 1.016, 0.203 or 0.0508 m in strip width, the entire sample is gripped and width does not play a significant role in the test except where the grip system is incapable of achieving uniform pressure. For reinforcements, sample width identifies the limits of the apparatus, not the reinforcement. In all cases testing must insure that an equal number of yarn ends are tested from sample to sample within a nominal specimen width. 10. Preload is a necessary element in testing of strong materials if roller systems are used. If not properly reported, preloads can mask test result information. 11-13. Modulus is the second contentious issue in testing of reinforcements. Clearly the meaningful moduli are related to certain segments of the data curve. In terms of reinforcements for critical structures it is not agreed whether the meaningful value is a secant of a very large segment or the actual value of a specific segment, for example: the modulus of the segment between 2% and 5% strain. 14. The relationship between single end yarn data and fabric performance is clearly evident; however, the relationship is not represented by a simple ratio. Some of the influences on the translation efficiency of a yarn strength to a fabric are: processing conditions, fabric structure, and testing systems. For a given product from a specific system, the relationship of yarn to fabric is a constant.

# GEOSYNTHETIC REINFORCEMENT: ARE GEOTEXTILES AND GEOGRIDS INTERCHANGEABLE?

C. Joel Sprague, P.E.  
Sprague & Sprague Consulting Engineers, Greenville, SC, USA

**ABSTRACT:** Geosynthetically reinforced soil structures have become acceptable, cost-effective alternatives to conventional geotechnical structures. Yet, it is interesting to note that many geosynthetically reinforced soil structures are specified in such a fashion that only geogrid but not geotextile reinforcement may be used, or vice versa. Why is this? This paper explores this question using tables and charts of relevant, performance-oriented properties and a survey of more than 50 State DOT and FHWA engineers questioned about their preferences related to the use of geotextiles and geogrids for reinforcement applications. In general, there appear to be no overriding technical or economical reasons to rely on proprietary, product-specific designs/specifications when using geosynthetic reinforced soil structures. Conversely, there are several arguments for the widespread use of generic design, specification, and procurement procedures.

**KEY WORDS:** geotextiles, geogrids, reinforcement, specifications

## 1 INTRODUCTION

Though the use of tensile inclusions in soil structures dates back several thousand years to the construction of religious structures in ancient Babylonia, it was only three decades ago that Henri Vidal, a French architect, pioneered modern earth reinforcement techniques. These techniques involved the incorporation of resisting elements into a soil mass to complement the soil's compressive strength and together to act in a composite fashion to improve the mechanical properties of the soil mass. Vidal patented his system, which used steel strips to provide the reinforcement, and named the system "Terre Armee" in France and "Reinforced Earth" in the United States. The first Reinforced Earth wall was constructed along California State Highway 39 in 1972.

Mitchell and Villet (1987) detailed and expanded on this historical perspective, noting that beginning in the early 1970's, experimentation using geotextiles as soil reinforcement was conducted in Europe and the United States. The U.S. Forest Service constructed full-scale wrapped-face walls in the Siskiyou and Olympic National Forests using geotextiles in 1974 and 1975 and developed construction and design guidelines based on this experience. Under FHWA sponsorship, highway departments in New York, Colorado, and Oregon constructed geotextile reinforced walls in the early 1980's. These geotextile reinforced walls were compared to walls constructed with steel inclusions and all were found to perform well.

This success attracted other candidate forms of plastic inclusions such as geogrids. Beginning in about 1984, Tensar geogrids were introduced specifically for soil reinforcement. These geogrids were manufactured of

polyethylene - a different polymer than used in the geotextiles. Polypropylene and polyester were the polymer of choice for geotextiles.

Since 1986, the use of reinforced soil systems, which are also called mechanically stabilized earth (MSE), in the United States has significantly increased. The primary types of MSE systems which have emerged include: mechanically stabilized earth walls (MSEW); reinforced soil slopes (RSS); reinforced embankments over soft foundations (RESF); and reinforced liners and caps. MSEW and RSS have become especially important in highway construction as their use reduces the required width of new right-of-way and facilitates construction within existing limited right-of-way. RESF are recognized as a cost-effective alternative to traditional techniques for constructing earthen embankments over low strength foundations. Additionally, critical environmental applications of geosynthetic reinforcement have emerged, including the reinforcement of landfill and lagoon liner and cap systems on steep slopes and over weak subgrades or underlying voids.

Free draining granular material is the preferred backfill material in reinforced soil structures. Therefore, the use of reinforced soil structures - primarily MSEW and RSS - has been somewhat limited in cases where high quality backfill material is not readily available. Mitchell and Zornberg (1994 & 1995) observed that the inherent low strength, moisture instability, possible volume changes, and creep potential, along with the corrosive potential of saturated soils, are common concerns associated with the use of fine-grained, cohesive backfills. They further noted that as successful experiences are documented and consistent design methodologies are developed for these poorly

draining backfills, even greater growth in the use of reinforced soil structures will be possible.

Clearly, there has been substantial acceptance of geosynthetic reinforced soil structures and much of the growth has been the result of aggressive marketing by companies providing candidate geosynthetic soil reinforcement materials. Therefore, much of the experience gained to-date is with those reinforcement materials which are marketed most aggressively and "packaged" with proprietary designs. Yet, this growth has been fraught with argument as competing proprietary systems claim superior performance or dependability. In response, independent researchers and Federal and State engineers have advanced the development of generic design techniques and material specifications such as AASHTO (1997) MSEW specifications and the FHWA's RSS guidelines by Berg (1993) and the DEMO 82 educational effort discussed by DiMaggio (1996). This new generation of generic design techniques and specifications recognizes the suitability of both geotextiles and geogrids for soil reinforcement.

This paper details the key issues associated with the use of geosynthetics as soil reinforcement and provides comparative data for common reinforcing geosynthetics. Additionally, required product documentation, relative costs, and a summary of geosynthetic reinforcement use by state Departments of Transportation (DOT) are presented.

## 2 REINFORCEMENT DESIGN INPUTS

### 2.1 Overview

Geosynthetic reinforcement systems incorporate geotextiles and/or geogrids as horizontal layers within a soil backfill to resist outward movement of the reinforced soil mass. The geosynthetic interacts with the soil by adding a tensile force and this tensile force is transferred to the soil mass through unique geosynthetic/soil interaction mechanisms. Both tensile force and soil interaction must be determined for each candidate geosynthetic.

### 2.2 Allowable Tensile Strength

The allowable tensile strength of a geosynthetic is input into reinforced soil analyses in order to determine the reinforced factor of safety. Allowable geosynthetic design strengths must be determined by testing and analysis methods that account for the long-term dimensional stability and durability of the full geosynthetic structure. Dimensional stability is characterized by the ability of the geosynthetic to sustain long-term load in-service without excessive creep strains. Durability factors include site damage, chemical degradation and biological degradation. These factors may theoretically cause deterioration of either the geosynthetic's tensile elements or the geosynthetic/soil stress transfer mechanism of the geosynthetic structure according to Berg

(1993). To account for dimensional stability and durability, allowable tensile strength,  $T_a$ , for the geosynthetic is determined using a partial factor of safety approach such as Equation 1 from Berg (1993).

$$T_a = T_{ult} / (FS_{CR} \times FS_{ID} \times FS_{CD} \times FS_{BD} \times FS_{JNT}) \quad (1)$$

$T_a$  = allowable geosynthetic tensile strength;

$T_{ult}$  = ultimate geosynthetic tensile strength;

$FS_{CR}$  = partial factor of creep deformation;

$FS_{ID}$  = partial factor of safety for installation damage;

$FS_{CD}$  = partial factor of safety for chemical degradation;

$FS_{BD}$  = partial factor of safety for biological degradation;

$FS_{JNT}$  = partial factor of safety for joints.

The allowable tensile strength,  $T_a$ , is often referred to as the long-term design strength, or LTDS. (Long-term allowable design load, or LTADL, is also used by some.) Many geosynthetic manufacturers can provide typical LTDS values for each of their candidate reinforcement materials. It is important to recognize that these "typical" LTDS values reflect factors of safety derived from laboratory and/or field testing which may or may not simulate the project conditions under consideration. Therefore, the designer must consider whether the partial factors of safety inherent in any "typical" LTDS value are applicable.

### 2.3 Partial Factors of Safety.

The partial factors of safety used to calculate the allowable tensile strength of the geosynthetic are intended to address the issues which provoke the greatest arguments between competing reinforcing systems. These factors of safety are either based on laboratory/field testing of the candidate material or are assigned based on "default" values derived from worst-case experience. An example of default values as recommended by Berg (1993) and typical testing-derived values is shown in Table 1.

Table 1. Typical Geosynthetic Reinforcement Default and Testing-Derived Values for Partial Factors-of-Safety

FS	Partial Factors of Safety					Composite
	ID	CR	CD	BD	J/S	
Default	3.0	5.0	2.0	1.3	2.0	78
Tested	1.2	2.0	1.1	1.0	1.01	2.64

KEY: FS=factor of safety; ID=installation damage; CR=creep; CD=chemical degradation; BD=biological degradation; J/S=joint/seam

The magnitude of default values virtually assures that a material supplier will do product-specific testing to derive the factors of safety to be used to calculate allowable tensile strength. If one were to use only default values, the

candidate geosynthetic would be able to claim an allowable tensile strength equal to only 1/78th of the ultimate tensile strength of the material. Certainly, this would likely make the candidate material uneconomical. Conversely, product-specific testing can be done to clearly define the unique limitations of a material without excessive conservatism. Guidance is commonly given in well written specifications such as Berg (1993) on how to determine factors of safety through laboratory/field testing. For example, one state DOT (WSDOT,1996) requires that ASTM D 5818 be the basis for  $FS_{ID}$  and that ASTM D 5262 along with a detailed data extrapolation technique be the basis for  $FS_{CR}$ . Additionally, this DOT gives a general approach to determining  $FS_{CD}$  and  $FS_{BD}$  based on the geosynthetic polymer.  $FS_{JNT}$  is not addressed, so presumably joints/seams are not permitted. It is important to note that the use of partial factors of safety does not identify any combined effects of the various forms of degradation. In the future, FS values derived from testing that examines the combined, and perhaps synergistic effects of two or more forms of degradation will be used. These types of testing are currently under development.

As shown in Table 1, using factors of safety derived from testing, the allowable tensile strength would typically be on the order of 38% of the ultimate (i.e. composite  $FS=2.64$ ), rather than the 1.2% of ultimate resulting from the use of default values. Composite factors of safety for calculating LTDS are commonly range from 2.0 to 4.0, depending primarily on the polymer.

Figure 1. Geosynthetic Strength Characteristics

## 2.5 Creep.

As shown in Table I, creep potential is usually the greatest "factor" in LTDS calculations. Characteristic strength properties and associated creep limits of various geosynthetic types are presented in Figure 1. Creep potential limits the allowable tensile strength to no more than the creep limited load and strain. Therefore, as shown

in Figure 1, PET geosynthetics can safely mobilize higher strengths and strains than can PE or PP. This explains the generally lower composite factor of safety used to calculate LTDS for PET geosynthetics ( $FS = 1.8 - 2.0$ ) versus that used for PE or PP ( $FS = 3 - 4$ , or more).

## 3 GEOSYNTHETIC/SOIL INTERACTION

### 3.1 Overview

As noted earlier, along with tensile strength, a geosynthetic's interaction with the soil must be characterized as a part of the design process. Geogrids mobilize a different kind of interaction with the soil than the frictional behavior relied on by geotextiles. Instead of a continuous frictional surface, geogrids have large openings, or apertures, which allow the soil to be continuous through the inclusion. Geogrids transfer stress to the soil through passive soil resistance on transverse members of the grid and limited friction between the soil and horizontal surfaces of the geogrid. Geotextiles transfer stress to the soil through the friction created across its entire surface area.

Two types of soil/geosynthetic interaction must be quantified: pullout and direct shear. In both cases, the quantification of stress transfer must be accomplished through laboratory testing. As with Factors of Safety, specific guidance, especially on the range of normal loads to be used, is commonly given in well written specifications on how to determine pullout and direct shear coefficients through laboratory/field testing.

### 3.2 Pullout Resistance.

Pullout coefficients are used in stability analyses to compute mobilized tensile force at the front and tail of each reinforcement layer in MSEW and RSS systems. According to Berg (1993) design of MSEW and RSS for permanent applications requires evaluation of long-term pullout performance with respect to three basic criteria:

1. pullout capacity should be adequate to resist the design tensile force with an appropriate factor of safety; and
2. allowable displacement should be greater than the relative geosynthetic to soil displacement required to mobilize the design tensile force; and
3. the pullout load should be smaller than the critical creep load.

The long-term pullout interaction coefficient is quantified by laboratory testing such as is outlined by Berg (1993). For geotextiles, this simply requires a quick effective stress pullout test since only surface friction is involved. For geogrids, sufficient long-term junction strength must be considered in addition to or as a part of pullout testing, since soil bearing on transverse ribs may be an important component of grid pullout resistance. This may require

creep testing of the junctions or the entire soil/grid system or cutting transverse ribs to remove the junctions from the testing. Therefore, much more testing may be required in order to qualify a candidate geogrid for pullout resistance as compared to a geotextile. The  $C_i$  value from pullout testing is used to calculate the bond length behind a critical failure surface using Equation 2.

$$L = PO_{ult} \text{ or } PO_{0.75 \text{ in}} / (2 \times C_i \times \sigma \times \tan\phi) \quad (2)$$

Where:

$L$  = bond length beyond a failure plane;  $\sigma$  = normal load;  $\tan\phi$  = the tangent of the soil's friction angle;  $C_i$  = interaction coefficient (See Tables 2a and 2b);  $PO_{ult}$  = the highest load resisted by the embedded reinforcement; and  $PO_{0.75 \text{ in}}$  = the pullout capacity associated with a movement of less than 0.75 inches (19mm) of the leading edge of the reinforcement sample.

Table 2a: Typical Short-term Geosynthetic/Soil Interaction Coefficients for Pullout,  $C_i$

	Clay	Sand	Clay	Sand	Clay	Sand
W,PP,GTX	0.60	0.90	0.65	0.90	0.70	0.90
W,PET,GTX	0.70	1.00	0.80	1.00	0.90	0.95
W,PET,GG	n/a	0.90	n/a	1.00	n/a	1.00
EX,PE,GG	>0.7	>0.9	>0.7	>0.9	>0.7	>0.9

KEY: W=woven; EX=extruded; PP=polypropylene; PET=polyester; GTX=geotextile; GG=geogrid; n/a=not available. Based on Cowell & Sprague (1993); Collin & Berg (1993); unpublished reports

Cowell and Sprague (1993) provided the following general conclusions based on extensive pullout testing:

1. Geogrids and geotextiles having similar strength properties also have similar ultimate pullout capacities and coefficients of interaction.
2. The pullout capacity at 0.75 inches of displacement for the geotextiles tested was significantly lower (50 to 67%) than that obtained for geogrids of similar strengths.

3. Junction strength of geogrids and the contribution to pullout resistance contributed from transverse ribs does not have a significant affect on pullout performance. (See long-term values in Table 2b)

One additional conclusion can be drawn concerning the sensitivity of a design to variation in  $C_i$ . If equation 2 is solved for length, given a required pullout, it can be shown that for  $C_i$  in the range of 0.7 to 0.9, a minimum length of 1 m controls for reinforcement layers below approximately 1 m of soil depth.

### 3.2.1 Pullout in the Design of RSS Structures.

The ultimate load is taken to be less than or equal to the LTDS and from this the bond length required is calculated. A factor of safety, typically on the order of 1.5, is applied to this length. In RSS applications, strains are typically controlled by using a 10% creep limit strain in the selection of the LTDS. RSS structures can tolerate more movement than MSEW, therefore  $PO_{0.75 \text{ in}}$  is not typically used for RSS.

### 3.2.2 Pullout in the Design of MSEW Structures.

For the design of MSEW structures, especially those with concrete facing panels, not only is the required bond length calculated as with RSS structures, but the limiting strain of the wall face can be critical. It is important to check if the LTDS can be mobilized within a limiting strain in order to assure that wall face movements remain within tolerable limits. Therefore, both the  $C_i$  and the  $PO_{0.75 \text{ in}}$  must be checked to see how they may affect the design.

### 3.3 Direct Shear.

Direct shear coefficients are used in checking the factor of safety against sliding of an overlying soil mass. This sliding is a consideration in all reinforced soil systems. Soil/geosynthetic direct shear resistance is determined by laboratory testing. As can be seen in Table 3, geotextiles and geogrids are both highly efficient in transferring interface shear stresses, especially with sand.

Table 3: Typical Geosynthetic/Soil Interaction Coefficients for Direct Shear,  $C_s$

Interface with Soil	Normal Stress					
	500 psf		750 psf		1000 psf	
	Clay	Sand	Clay	Sand	Clay	Sand
W,PP,GTX	0.60	0.85	0.60	0.90	0.60	0.90
W,PET,GTX	0.75	0.90	0.80	0.95	0.90	0.95
W,PET,GG	0.80	0.90	0.85	0.95	0.90	0.95
EX,PE,GG	>0.9	>0.9	>0.9	>0.9	>0.9	>0.9

KEY: W=woven; EX=extruded; PP=polypropylene; PET=polyester; GTX=geotextile; GG=geogrid. Based on Koutsourais, et al (1991); The Tensar Corp. (1986); unpublished reports

MSEW designs may also require quantification of the geosynthetic/facing connection strength using large-scale pullout testing for each unique geosynthetic/facing combination. Still, experts continue to debate the magnitude of the forces, if any, which are exerted at the face.

#### 4 DOCUMENTING GEOSYNTHETICS

Consideration and approval of candidate geosynthetics by owner/agency personnel requires that the geosynthetic supplier provide sufficient evidence of the proposed material's suitability and additional evidence of the manufacturer's/supplier's capabilities. The Federal Highway Administration (FHWA) requirements for documentation in all submittals are detailed by Berg (1993) as follows:

- \* History of material development.
- \* Current capability to supply material.
- \* Polymer and additive composition of geosynthetic.
- \* Practical applications of material.
- \* Representative list of users.
- \* Typical LTDS and interaction values.
- \* Typical unit costs.
- \* Laboratory test data, comprehensive literature review, and the interpretation and extrapolation used to determine the partial factor of safety should be presented for:
  - Creep performance: Range of loads for 10000 hours.
  - 75 year creep extrapolation.
  - Installation damage.
  - Ultimate strength.
  - Chemical resistance.
  - Biological degradation.
  - Joint (seam/connection) strength.
  - Long-term pullout coefficient.
  - Direct sliding coefficient.

#### 5 COST CONSIDERATIONS

An important factor in the increasing acceptance of a technology is increasing cost-effectiveness. Although there are many factors associated with the as-built cost of any geosynthetic reinforced soil structure, including project size, backfill type, and contractor familiarity to name a few, it is useful to examine the relative material costs associated with various candidate geosynthetic reinforcements. Commonly, geogrids are somewhat more costly per unit LTDS than are woven geotextiles but, geogrids may be more cost-effective for providing lower initial strain levels and higher soil interaction, if needed. Typical pricing of geogrids ranges from 0.0015 to 0.001 \$/m<sup>2</sup> per unit LTDS for low to high strengths, respectively. Woven geotextiles commonly range from .001 to .006 \$/m<sup>2</sup> per unit LTDS.

As note earlier, the FHWA has taken the lead in providing guidance in the implementation of generic design techniques and material specifications associated with geosynthetic reinforced soil systems. Still, individual owners/agencies are free to exercise their own judgements as to the appropriateness of following the FHWA lead. Tables 4a and 4b summarize a telephone survey of state Departments of Transportation (DOTs) conducted by the author in the fall of 1996. The survey solicited responses on the use of geosynthetic reinforced soil structures, reinforcement preferences, and reasons why preferential specifications may be used on any given project.

Table 4a. Survey of State DOTs - Use of Geosynthetic Reinforced Soil Systems

U.S. Region	Number of States Using Reinforced Soil System								
	MSEW			RSS			RESF		
	C	T	n/u	C	T	n/u	C	T	n/u

Mid-Atl.	0	2	2	2	0	1	4
Southeast	3	6	2	3	0	3	4
Midwest	1	4	0	5	0	1	5
Southwest	1	5	0	1	2	2	4
Plains	0	4	0	2	2	3	4
West	0	4	1	3	1	3	4
Far West	2	3	3	2	3	2	2
States Responding	44	44	44	44	43	43	43

KEY: Gtx=geotextile; GG=geogrid; Gen.Future=plan generic use in future  
NOTE: RI,NV,PR did not respond. 5 states did not indicate a preference. 6 states did not state a reason for a preference.

Tables 4a and 4b reveal the following trends:

1. Most Departments of Transportation (DOTs) are commonly using at least one form of geosynthetic reinforced soil structure.
2. Geogrids have been the most often used geosynthetic reinforcement to-date, largely because of vendor/consultant influences and greater experience with these materials.
3. Many DOTs intend to use non-preferential, more generic design/specification approaches in the future.

A further indication of the acceptance of and support for geosynthetic reinforced soil structures is the recently initiated effort to develop manuals and software and teach associated courses on mechanically stabilized earth technology. Geosynthetic reinforcement and associated design/construction technologies will be presented. This effort is called Demonstration Project No. 82, or Demo 82 for short, and has as its explicit purpose according to DiMaggio (1996): "to optimize the acceptance and implementation of mechanically stabilized earth technology in routine design and construction practice."

## 7 CONCLUSIONS

Generally, geotextiles and geogrids are interchangeable in reinforcement applications. It appears that there are no overriding technical or economical reasons to rely on proprietary, product-specific designs/specifications when using geosynthetic reinforced soil structures. Conversely, the following observations support the use of generic design, specification, and procurement procedures:

1. Geotextiles and geogrids have been successfully used for over 2 decades in all types of reinforced soil structures.
2. Generally accepted design techniques have been developed which are equally compatible with geotextiles and geogrids.
3. Geotextiles and geogrids have been tested and found to provide suitable and comparable tensile and soil/geosynthetic interaction properties.
4. Geotextiles and geogrids can be quickly tested to confirm compliance with generic project-specific requirements.
5. A wide range of suitable, proven products is available representing the full range of strength/strain/interaction properties typically required in reinforced soil structures.
6. Many owners/agencies now commonly using geosynthetic reinforced soil structures are inclined to encourage more generic design, specification, and procurement of geosynthetic reinforcement in the future to assure fairness and cost-effectiveness.

The generic design, specification, and procurement of geosynthetic reinforced soil structures appears to evolve naturally as the designer/owner gains sufficient understanding of and experience with the associated technology.

## ACKNOWLEDGMENTS

The author would like to thank David Andrews of Synthetic Industries for his valuable review of the original report upon which this paper is largely based.

# Effect of End-Restraint in Geogrid-Soil Structures

H. Ochiai, N. Yasufuku, and T. Kawamura  
Department of Civil Engineering, Kyushu University, Fukuoka, Japan

T. Yamaji  
Ministry of Transport, Tokyo, Japan

T. Hirai  
Mitsui Petrochemical Industrial Products, Ltd., Tokyo, Japan

**ABSTRACT:** Reinforcing effects of geogrid-soil structures depend on the end-restraint condition of the geogrid. Two types of end-restraint, fixed-end and sliding-end, were experimentally investigated by using a prototype shear apparatus that has been developed for this purpose. Main conclusions are: 1) In order to obtain a significant effect of reinforcement, one end of each geogrid in the soil structure should be fixed on the facing of the soil structure in such a way that the geogrid and the soil in the moving soil mass do not move relative to each other, and 2) For the fixed-end type, there exists an additional confining effect which increases the normal stress on the potential sliding plane in addition to the effect due to the tensile force of geogrid.

**KEYWORDS:** Reinforcement, Geogrids, End-restraint

## 1 INTRODUCTION

Earth reinforcement techniques have become useful and economical solutions to many problems in geotechnical practice but there are some points concerning the reinforcing mechanism of soil-reinforcement system that

need to be clarified.

In geogrid reinforced soil structures, such as the one shown in Figure 1, the end-restraint condition of the geogrid may have considerable influence on the reinforcing effect. In this research, two types of end-restraint, fixed-end and sliding-end, have been investigated experimentally by using a small prototype shear apparatus which has been developed for this purpose. An expression has been proposed to evaluate the reinforcement effect quantitatively.

## 2 MODEL OF END-RESTRAINT

The two types of end-restraint investigated are shown in Figures 1a and 1b.

**Fixed-end:** Figure 1a shows the fixed-end type of restraint. One end of the geogrid is fixed on the facing and the geogrid and the soil in the moving soil mass do not move relative to each other.

**Sliding-end:** Figure 1b shows the sliding-end type of restraint. The geogrid is not fixed on the facing and the geogrid and the soil may move relative to one another.

## 3 TEST APPARATUS AND TEST PROCEDURE

### 3.1 Test apparatus

The apparatus has two bellofram-cylinders on the right and left sides to model the types of end-restraint. In the fixed-end type, the left side of the geogrid is fixed to the upper box and the tensile force of geogrid is provided by the right bellofram-cylinder. In the sliding-end type, the tensile force of geogrid is provided by both sides of the bellofram-cylinder.

A sketch of the test apparatus and the shear box are shown in Figure 2, details can be found in Ochiai et al (1996). The shear box is rectangular in shape and is of size 200 × 200 × 380mm. The shear box has two halves, the

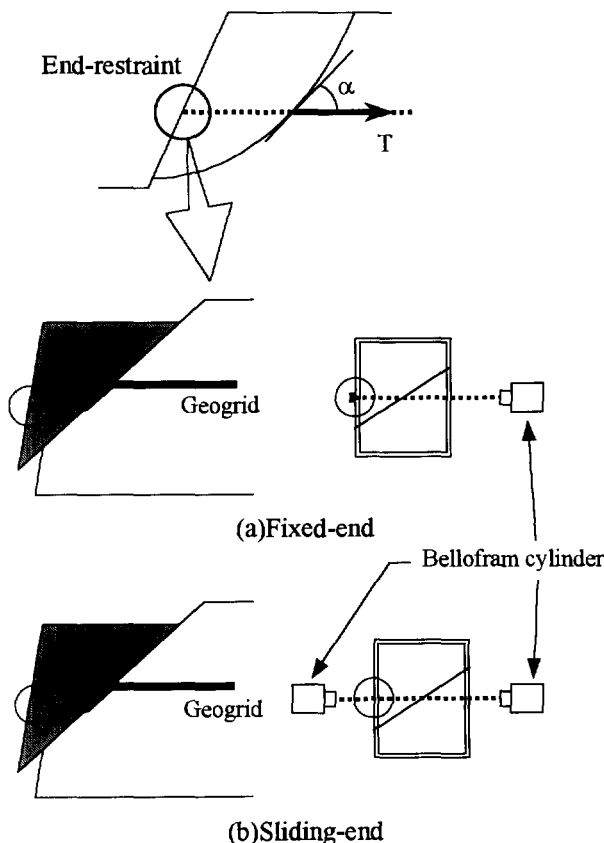

Figure 1. Model of end-restraint in in-situ and laboratory test conditions

upper box and the lower box, with a common sliding plane. The two halves of the shear box are connected and guided by frictionless linear motion bearings on the sliding plane. Three types of shear boxes with different sliding angles are prepared for this study. The shear force,  $S$ , along the sliding plane is provided by the vertical surcharge load. The normal component of the tensile force on the geogrid on the sliding plane is canceled out by the reaction on the linear motion bearings. Therefore, the normal component of reinforcement effect due to tensile force of geogrid,  $T \cdot \sin \alpha \cdot \tan \phi$ , cannot be mobilized in the tests.

### 3.2 Specimen

Dry Toyoura sand, which is a standard sand used for testing

in Japan, was used and four kinds of geogrids with varied shape properties were used as reinforcement materials. The physical and strength properties of sand are shown in Table 1 and Figure 3 respectively. The strength values of sand were obtained using the test apparatus shown in Figure 2 for the conditions of the relative density,  $D_r=90\%$ , and the sliding angle,  $\alpha=30^\circ, 40^\circ, 50^\circ$ .

The geogrid measurements are defined in Figure 4 and the properties of geogrids are summarized in Table 2.

### 3.3 Test procedure

Sand is poured through multiple sieves in order to construct a homogeneous specimen. The relative density of the sand,  $D_r$ , is about 90%. After applying a constant tensile force to

(a) Test apparatus

## 4 TEST RESULTS AND DISCUSSION

### 4.1 Effect of end-restraint

Figure 5 shows the typical relationships between shear force on the sliding plane,  $S$ , and shear displacement,  $D$ , obtained from a series of tests. The same tendency is observed in the fixed-end and sliding-end types. The curves in Figure 5 are approximated by hyperbolas given by the equation

$$S = \frac{D}{a \cdot D + b} \quad (1)$$

$a$  and  $b$  are constants in which  $1/a$  is the asymptotic line of the curves and is approximated as the maximum value of shear force,  $S_m$ , on the sliding plane. The relationships between the ratio,  $S_{m(F)}/S_{m(S)}$ , and the normal stress on the sliding plane,  $\sigma_n$ , are shown in Figure 6 in which  $S_{m(F)}$  and  $S_{m(S)}$  are the maximum values of shear forces for the fixed-end and the sliding end tests respectively. The maximum value of shear force for the fixed-end test is larger than that of the sliding-end test. Higher reinforcing effects in fixed-

Figure 5. Relationships between shear force,  $S$ , and shear displacement,  $D$

Figure 6. Relationships between  $S_{m(F)}/S_{m(S)}$  and normal stress,  $\sigma_n$

end tests were observed in both small normal stress values and large tensile force of geogrid. The reinforcing effects in sliding-end test is not mobilized, especially in small normal stresses,  $\sigma_n$ , because there is little friction between geogrid and soil.

The maximum values of shear stress measured in the tests are used to investigate the reinforcing effect in the two types of end-restraint conditions. The maximum value of shear stress on the sliding plane is calculated as

$$\tau_m = \frac{S_m}{A'} \quad (2)$$

where  $A'$  is the area of the sliding plane. Typical test results are shown in Figure 7. For sand samples, the relation between  $\tau_{m(N)}$  and  $\sigma_n$  is a straight line through the origin with an inclination of  $\tan\phi$  as shown in Figure 3;

$$\tau_{m(N)} = \sigma_n \cdot \tan\phi \quad (3)$$

in which  $\phi$  is the internal friction angle of sand.

For geogrid-reinforced sand, the relationship will, in general, be expressed as follows;

$$\tau_{m(R)} = \tau_1 + \{(1 + \beta) \tan\phi\} \sigma_n \quad (4)$$

where  $\tau_1$  is the intercept on the  $\tau_m$  axis and  $\beta \cdot \tan\phi$  is the increment in slope of the reinforced lines from the sand line. The values of  $\tau_1$  and  $\beta$  depend on the end-restraint conditions. The value of  $\tau_1$  in the sliding-end type is approximately equal to zero, whereas the value in the fixed-end type changes with the tensile force of geogrid,  $T$ , as shown in Figure 7. The values of  $\beta$  in the two end-restraint

Figure 7. Relationships between maximum shear stress,  $\tau_{max}$ , and normal stress,  $\sigma_n$

Figure 8. Relationships between  $\beta$  and tensile force,  $T$

conditions are summarized in Figure 8 where  $\beta$  is approximately equal to zero in the sliding-end type and has a constant value in the fixed-end type irrespective of the tensile force of geogrid,  $T$ , i.e.

$$\text{Fixed-end: } \tau_1 \neq 0, \beta \neq 0 \quad (5)$$

$$\text{Sliding-end: } \tau_1 \approx 0, \beta \approx 0 \quad (6)$$

In conclusion, a significant effect of reinforcement cannot be obtained in the sliding-end type. In order to obtain a significant effect of reinforcement, the geogrid should be fixed on the facing of the soil structure in such a way that the geogrid and the soil in the moving soil mass do not move relative to each other.

## 4.2 Evaluation of reinforcement effect in fixed-end type

### 4.2.1 Evaluation of $\tau_1$

The design of the apparatus is such that the normal component of tensile force on the sliding plane is not transmitted to the soil and therefore a component of reinforcement effect,  $T \cdot \sin \alpha \cdot \tan \phi$ , due to tensile force of geogrid,  $T$ , cannot be mobilized in the tests. Therefore, the observed reinforcement effect due to the tensile force,  $T$ , is a component along the sliding plane,  $\tau_1$ .

(a) Different tensile forces of geogrid,  $T$

(b) Different sliding angles,  $\alpha$

Figure 9. Comparison between experimental results and calculated values of  $\tau_1$

$$\tau_1 = \frac{T}{A'} \cos \alpha \quad (7)$$

The calculated values from Equation (7) and the experimental results in Figure 7 are almost the same as shown in Figures 9a and b. Therefore, Equation (7) well expresses the experimental results under different tensile forces,  $T$ , and sliding angles,  $\alpha$ .

### 4.2.2 Evaluation of the coefficient $\beta$

The  $\beta$  in Equation (4) can be considered to be a coefficient for the increment in normal stress on the sliding plane due to the placement of geogrid in soil. The coefficient  $\beta$  will therefore depend on the density of the soil and the shape of geogrid. A shape index,  $R$ , for evaluating the shape characteristics of the geogrid has been proposed by the authors (Ochiai et al, 1996) as follows;

$$R = \frac{2t(B+L) \frac{A}{B \cdot L}}{A} = 2t \left( \frac{1}{B} + \frac{1}{L} \right) \quad (8)$$

Figure 10. Description of measurements in the shape index

where notations in Equation (8) are shown in Figure 10. It is noted that the value of  $R$  represents the effects in which the soil is confined into the aperture of geogrid, and is pressed by the surface of geogrid. Four kinds of geogrids with different values of  $R$  were used in this study. A unique  $\beta$ - $R$  relationship can be observed by comparing the shape index  $R$  and the coefficient  $\beta$  as shown in Figure 11.

In fixed-end tests, where the geogrid and the soil in the moving soil mass do not move relative to each other, the geogrid restricts the deformation of soil and therefore an additional normal stress,  $\beta \cdot \sigma_n$ , is induced on the sliding plane as illustrated in Figure 12. This effect of soil reinforcement may be called the confining effect (Ochiai et al 1996).

Thus, the maximum value of shear stress,  $\tau_{m(F)}$ , measured in the fixed-end tests may be expressed as

$$\tau_{m(F)} = \frac{T}{A'} \cos \alpha + (1 + \beta) \sigma_n \tan \phi \quad (9)$$

Figure 11. Relationship between  $\beta$  and shape index, R

Figure 12. Condition of normal stress around the geogrid

## 5 REINFORCEMENT EFFECT IN GEOGRID-SOIL STRUCTURES

The test apparatus used in this study was designed such that the normal component on the sliding plane of tensile force of geogrid,  $T \cdot \sin \alpha$ , is directly transmitted to the lower box and not to the soil. Therefore, the normal component of reinforcement effect due to the tensile force of geogrid,  $T \cdot \sin \alpha \cdot \tan \phi$ , is not mobilized in the test. However, this component of reinforcement effect is considered to exist in in-situ conditions and is therefore added to the value obtained from the laboratory test. Thus the maximum values of shear stress in geogrid-soil structures may be expressed as follows;

$$\tau_{m(F)} = \frac{T}{A'} (\cos \alpha + \sin \alpha \cdot \tan \phi) + \{(1 + \beta) \sigma_n\} \tan \phi \quad (10)$$

where  $\beta \cdot \sigma_n$  is an additional normal stress on the sliding

plane induced by the restriction of soil deformation due to the placement of geogrid in soil.

## 6 CONCLUSIONS

A series of tests has been performed to clarify the effect of end-restraint in geogrid-soil structures. It has been concluded that:

1. In order to obtain a significant effect of reinforcement, one end of the geogrid should be fixed on the facing of the soil structure in such a way that the geogrid and the soil in the moving soil mass do not move relative to each other.
2. For the fixed-end type, there exists an additional confining effect which increases the normal stress on the potential sliding plane in addition to the effect due to the tensile force of geogrid. The maximum value of shear stress,  $\tau_{m(F)}$ , in the geogrid-soil structure may therefore be expressed as

$$\tau_{m(F)} = \frac{T}{A'} (\cos \alpha + \sin \alpha \cdot \tan \phi) + \{(1 + \beta) \sigma_n\} \tan \phi$$

**ABSTRACT:** This paper aims at rationally explaining the mechanical behavior of the soil structure reinforced by geosynthetics. The attention is paid to confining effect by the geosynthetics under shearing in this paper. The confining effect is interpreted as the mechanical interaction such that the reinforcement material works so as to prevent dilative deformation of soils. Then, elasto-plastic constitutive models which can describe the dilative deformation of soils under shearing are introduced and applied to the finite element simulation of the mechanical behavior of soil structure reinforced by geosynthetics. A full-scale in-situ model test, which was carried out in Kanazawa, Japan, is chosen to analyze. After verification of applicability of employed methodology to the analysis of the model test, the computed results are compared with the monitored behaviors of the soil structure reinforced by geosynthetics in the model test.

**KEYWORDS:** Geosynthetic reinforcement, Dilatancy of compacted soils, Elasto-plastic model, Finite element simulation

## 1 INTRODUCTION

The behavior of the soil structure reinforced by geosynthetics is governed by the mechanical interaction of soils and geosynthetic materials. In the numerical simulation of the behavior of such soil structure, appropriate modeling of its mechanical interaction is required. The authors tried to explain the reinforcement mechanism by geosynthetics throughout a series of finite element numerical simulations for a full scale in-situ model test (Ohta et al, 1996), where soils were simply modeled as non-linear elastic materials by employing the hyperbolic constitutive relation. However, observed behaviors in the in-situ model test could not be well explained. Particularly, the development of strain localization, which was prominently observed in the test, could not be well expressed. This has led the authors to feel the importance of introducing the contraction/dilatation characteristics of soils under shearing into the numerical simulation. Then, this paper focuses on the dilatancy characteristics of soils and the reinforcement mechanism is tried to be interpreted as that the geosynthetics work so as to confine the dilation of soils under shearing. The elasto-plastic models for soils are introduced to describe the dilatancy characteristics of compacted soils of which the reinforced soil structure is composed. An idea to specify input parameters needed in the analysis for the compacted soils is proposed and a series of finite element simulations of full scale in-situ model test are carried out. Finally the results obtained are

compared with monitored behaviors in the test.

## 2 MODEL TO DESCRIBE DILATANCY OF COMPACTED SOILS

### 2.1 Sekiguchi and Ohta's Model

A model employed in this paper is the elasto-plastic constitutive model proposed by Sekiguchi and Ohta (1977). This model had been primarily developed for naturally consolidated-saturated clays and can be regarded as an extension of the original Cam Clay model. The shear behavior of heavily over-consolidated clays is represented by strain-softening material with dilation in this model. The positive volumetric strain (dilation) which the model yields varies with the over-consolidated ratio,  $OCR$ . Higher  $OCR$  produces greater dilation under shearing. When this model is applied to the compacted unsaturated soils that tend to dilate under shearing, some idea on how the compacted soils can be modeled as the heavily over-consolidated saturated clays is required. The section 4.2 is devoted to evaluate the material properties of compacted soils as the heavily over-consolidated clay.

When this model is incorporated into a finite element code, a problem arises, that is, the conventional judgement criterion by Hill (1958) cannot distinguish the subsequent loading (elasto-plastic response) in the strain softening region from the unloading (elastic response). Asaoka et al. (1994) introduce a new criterion which can judge the

subsequent loading in the strain-softening region. The new judgement criterion is employed here and is briefly summarized as follows.

When the plastic strain increment is given by the following associated flow rule as,

$$\dot{\epsilon}_{ij}^p = \Lambda \frac{\partial f}{\partial \sigma_{ij}}, \quad (1)$$

proportional constant  $\Lambda$  can be expressed in terms of plastic strain increment as,

$$\Lambda = \frac{L}{X}, \text{ and } L = \frac{\partial f}{\partial \sigma_{ij}} C_{ijkl}^e \dot{\epsilon}_{kl}^p, \\ X = \frac{\partial f}{\partial \sigma_{ij}} C_{ijkl}^e \frac{\partial f}{\partial \sigma_{kl}} + h, \text{ } h = \frac{\partial f}{\partial \sigma_{ij}} \delta_{ij}, \quad (2)$$

where  $\dot{\epsilon}_{ij}^p$  is the incremental plastic strain tensor,  $\sigma_{ij}$  is the stress tensor,  $C_{ijkl}^e$  is the elastic stiffness tensor,  $f$  is the yielding function. In the case of Sekiguchi and Ohta's model, the yielding function  $f$  is given as,

$$f = MD \ln \frac{p}{p_0} + D \eta^* - \epsilon_{ij}^p \delta_{ij} = 0, \quad (3)$$

where  $M$  is the critical state parameter,  $D$  is the dilatancy coefficient proposed by Shibata (1963),  $p$  and  $p_0$  are mean stresses at the current state and at the reference state, respectively,  $\eta^*$  is generalized deviatoric stress ratio defined by

$$\eta^* = \sqrt{\frac{3}{2} \left( \frac{s_{ij}}{p} - \frac{s_{i_0 j_0}}{p_0} \right) \left( \frac{s_{ij}}{p} - \frac{s_{i_0 j_0}}{p_0} \right)}, \text{ } s_{ij} \text{ is the deviatoric stress tensor } (= \sigma_{ij} - p \delta_{ij}).$$

Now, since the plastic coefficient  $X$  of Eq.(2) always stays positive, the loading or unloading can be judged by the sign of scalar function  $L$  of Eq.(2) as,

loading (elasto-plastic)	if $L > 0$	
neutral	if $L = 0$	(4)
unloading (elastic)	if $L < 0$	

This judgement criterion is incorporated into the finite element program, DACSAR (Iizuka and Ohta, 1987). 4-node quadrilateral constant strain element is employed in the finite element discretization. Fig.1 indicates the verification of F.E. program. Computed effective stress paths of triaxial undrained shear are compared with theoretical curves where  $q$  is the deviatoric stress by

$$q = \sqrt{\frac{3}{2} s_{ij} s_{ij}}.$$

Figure 1 Stress paths of Sekiguchi and Ohta's model

## 2.2 Drucker and Prager's Model

Another model employed is the elasto-plastic constitutive model of which the yielding function is Drucker and Prager's type. This model always yields the dilation without strain-softening. The amount of dilation is determined by the input parameters,  $c$  and  $\phi$  regardless of how much the soils are over-consolidated. Drucker and Prager's yielding function is given as,

$$f = \alpha I_1 + \sqrt{J_2} - k = 0, \quad (5)$$

where  $I_1$  is the first invariant of stress tensor ( $I_1 = p$ ),  $\sqrt{J_2}$  is the second invariant of deviatoric stress tensor ( $\sqrt{3} \sqrt{J_2} = q$ ) and  $\alpha$  and  $k$  are constants relating with the cohesion  $c$  and the internal friction angle  $\phi$  as,

$$\alpha = \frac{\tan \phi}{\sqrt{9 + 12 \tan^2 \phi}} \text{ and } k = \frac{3c}{\sqrt{9 + 12 \tan^2 \phi}}. \quad (6)$$

The associated flow rule is employed and the model is incorporated into the finite element program, DACSAR. Fig.2 compares computed effective stress paths of triaxial undrained shear with theoretical ones. Good agreements are obtained.

Figure 2 Stress paths of Drucker and Prager's model

## 3 SIMULATION OF FULL SCALE IN-SITU MODEL TEST

### 3.1 Full Scale In-situ Model Test

A full scale in-situ model test was conducted during the period from July, 20, to August, 8, '92 in Kanazawa, Japan, in order to investigate the reinforcement mechanism by geosynthetics (Nishimoto et al., 1992, Ohta et al., 1996). A beam shaped soil structure reinforced by geosynthetics was designed and the resistance capability of the structure against the bending moment was investigated. Fig.3 shows the side view of the test embankment that was 2.75 m high, 42.5 m long and 4.5 m wide, including supporting berm. In the construction of the test embankment, the soil was spread over up to 10 cm thickness and compacted sufficiently by the vibration roller. The degree of compaction was controlled by the dry unit weight

measured by RI (radioisotope) method. The geosynthetics (Adem#G-6, Maeda Kohsen Co.) were placed at every 50 cm. The experiment began by removing steel H piles, which were supporting the reinforced portion by geosynthetics, in the order by the number in Fig.4. The deformation of the reinforced soil structure was measured by photographic observation of the position changes of markers installed at every 25 cm interval on the side of the embankment. The measured maximum deformation at each step is summarized in Table 1. In the experiment, when the #10 steel H pile was removed at Step 9, the structure failed.

### 3.1 Applicability of Constitutive Models

The soils were sampled from the test site and served to one-dimensional compression (oedometer) tests and constant volume shear box (CV-SBT) tests in the laboratory. The soil samples were consolidated in the shear box by the vertical pressure of 39.2, 78.4, 156.8 and 313 kPa and then were sheared under the constant volume. Fig.5 shows the effective stress paths obtained from CV-SBT tests for undisturbed compacted soil samples. Experimental effective stress paths in Fig.5 are quite similar to typical behaviors of over-consolidated clays. The authors believe that constitutive models which can explain dilation of a soil element are applicable to the compacted soils, when the effective stress paths in Fig.5 are compared with those in Figs.1 and 2.

Figure 5 Effective stress paths of compacted soils

### 3.2 Evaluation of Material Parameters Needed in Analysis

The soils used in the full-scale test were sampled from the site and were prepared at the water content of 20, 23, 25, 27 and 30 %. These loose disturbed soils were served to CV-SBT tests. The soils were consolidated in the shear box by the vertical pressure of 39.2, 78.4, 156.8 and 313 kPa and then were sheared under the constant volume. The results obtained are shown in Fig.6, where the upper figure of Fig.6 presents the relationship between the dry unit weight  $\rho_d$  and the consolidation pressure  $\sigma'_v$  and the lower one shows the equivalent 'undrained' strength,  $s_u$ , obtained from CV-SBT for very loose disturbed samples. The increase rate of 'undrained' strength results in  $s_u/\sigma'_v = 0.234$ .

Next, the undisturbed compacted soil samples of which natural water contents varied from 20.6 to 23.4 % in-situ were served to the consolidation and shear tests in the same manner. The plots of test results for undisturbed samples are added to Fig.6 and then Fig.7 is obtained. The plots for undisturbed samples seem to form straight lines with in-situ water contents as shown in Fig.7. When these lines are extended to compression lines obtained from consolidation tests in the shear box for very loose disturbed samples, the equivalent pre-consolidation pressures  $\sigma'_{v0}$  can be estimated. Thus, the equivalent pre-consolidation pressures  $\sigma'_{v0}$  and the equivalent over-consolidation ratios can be specified for in-situ compacted soils as in Table 2.

The 'undrained' strengths ( $\blacktriangle$ ) obtained from shear tests for undisturbed compacted samples can be converted to its equivalent N.C. 'undrained' strengths by using the following equation,

$$\left(\frac{s_u}{\sigma'_{v0}}\right)_{NC} = OCR^{-\bar{\lambda}} \left(\frac{s_u}{\sigma'_v}\right)_{OC} \quad \text{and} \quad \bar{\lambda} = 1 - \frac{\bar{c}_s}{C_c} \quad (7)$$

where  $C_c$  and  $\bar{c}_s$  are gradients of compression lines in Fig.6 and the equivalent swelling line in  $e - \log \sigma'_v$  space of Fig.7. Thus converted strengths are plotted in the lower figure of Fig.7 as  $\blacksquare$  and agree with the broken line indicating  $s_u/\sigma'_v = 0.234$ .

Then, input parameters needed in Sekiguchi and Ohta's model can be specified as follows. The N.C. undrained

strength obtained from the constant volume shear box test has been theoretically derived from Sekiguchi and Ohta's model as (Ohta et al., 1985),

$$\left(\frac{s_u}{\sigma'_{v0}}\right)_{NC} = \frac{1+2K_0}{3\sqrt{3}} M \exp(-\Lambda), \quad (8)$$

where  $K_0$  is the coefficient of earth pressure at rest,  $M$  is the critical state parameter ( $=\frac{6\sin\phi'}{3-\sin\phi'}$ ,  $\phi'$ : effective internal friction angle) and  $\Lambda$  is the irreversible ratio (see, Iizuka and Ohta, 1987). Therefore, by employing the empirical relations:  $M = 1.75\Lambda$  (Karube, 1975),  $K_0 = 1 - \sin\phi'$  (Jaky, 1944), Eq.(8) can be expressed as the function of only  $\phi'$  shown in Fig.8. Now, since the increase rate of strength  $(s_u/\sigma'_{v0})_{NC}$  is given as 0.234 in Fig.6, the effective internal friction angle is specified as 27.5 degree for in-situ compacted soils. Other parameters needed in Sekiguchi and Ohta's model are also specified in the manner shown in Fig.9. Thus obtained input parameters are summarized in Table 3. In the numerical simulation, since the equivalent pre-consolidation pressures of in-situ compacted soils vary in wide range from 931 to 2058 kPa as in Table 2, two cases ( $\sigma'_{v0} = 980$  kPa: Case 1, 1960 kPa: Case 2) are considered.

Figure 6 Experimental relation of  $\rho_d$ ,  $\sigma'_v$ , and  $s_u$

Triaxial CU tests were also carried out for undisturbed soil samples. The results obtained are summarized in Table 4 and the input parameters ( $c'$  and  $\phi'$  in terms of effective stress) needed in Drucker and Prager's model can be specified. However, two test results shown in Table 4 happened to quite differ each other. Therefore, two cases in the numerical simulation are considered as shown in Table 4.

### 3.3 Comparison of Finite Element Simulations

The finite element mesh employed in the simulation of the full-scale in-situ model test is shown in Fig. 11. The 4-node constant strain finite element and the forward incremental calculation scheme are used. The supporting portion indicated by shaded part in Fig.7 is removed following the order in the experiment as shown in Table 1. Table 6 indicates the step number when the axial force of a

bar element exceeded its strength and the structure failed. In Figs.12, the computed predictions and the monitored behaviors are compared above positions of steel H piles of No.2 and No.5 (refer to Fig.4), in which the horizontal axis in the figure represents the step number shown in Table 1. The labels G1, G2 and G3 indicate the geosynthetics placed, that is, G1 is at the upper layer, G2 is at the middle layer and G3 is at the lower layer. As seen from figures, the monitored deformations are larger than our predictions. It would be because the geosynthetics hung down in experiment when the support was removed and then soils between geosynthetics were loosened. Figs.13 illustrates the contours of shear strain distribution. The results of Case 1 (Sekiguchi and Ohta's model) and Case 4 (Drucker and Prager's model) are chosen to be compared with the monitored result in Fig.13, because there was not much differences between results of Case 1 and Case 2 nor between results of Case 3 and Case 4. Fig.13(d) is added to be compared with the numerical result of the hyperbolic model which does not consider the dilation under shearing (Ohta et al., 1996). At earlier step such as at Step 2, the hyperbolic model does not explain the sharp distribution of strain localization which is observed as in Fig.13(a). The dilatancy models seem to qualitatively explain the monitored development of strain localization from earlier

(a) Observed shear strain distribution

step. In the case of Sekiguchi and Ohta's model, the shear strain localization concentrates in narrower zone, which is closer to monitored tendency, but distributes in wider region in the case of Drucker and Prager's model. However, the quantitative agreement with monitored distribution of shear strain has not been achieved. The authors guess that it is because the soils were considerably loosened resulting in being less stiff when the steel H piles were removed.

#### 4 CONCLUDING REMARKS

A beam shaped soil structure reinforced by geosynthetics was designed to investigate the resistance capability of the structure against the bending moment and was constructed as a full-scale model test. The monitored behavior of the full-scale model test and its numerical predictions are compared. In numerical simulation, dilatancy models are introduced in order to capture the development of strain localization in the beam shaped soil structure reinforced by geosynthetics. Specification procedure of input parameters needed in the models is presented. The compacted soils used in the full-scale model test are represented by the over-consolidated clays equivalent to them. It is found that dilatancy models qualitatively explain the monitored behaviors in the field model test. However, the above results were obtained for a rather unique test setup and more precise examination on general applicability of dilatancy models is required.

annual evaporation exceeds the annual precipitation. Hence, the design allowed for no phreatic surface in the backfill.

The shear resistance of the concrete blocks was included in determining the depth of reinforcement required and excluded in determining the reinforcement force required.

The design of the hockey-field wall was based on the same principles, as outlined above. The detail of this wall is shown in Figure 2.

Figure 2: Specified detail of hockey field wall

FIGURE 2

The depth of the reinforcement geotextiles was specified as 2.4m (0.49 H), for the highest section of 4.9m high. The bottom part of the wall was reinforced using woven multi-filament polyester geotextiles with a maximum tensile strength of 50 kN/m. The upper part was reinforced with woven polyester geotextiles of a maximum tensile strength of 25 kN/m. The height of wall reduced along the length of the wall, and at a height of 2.6m, the wall reverted to a gravity structure. Hence this backfill was not reinforced, but 500mm deep blocks were used over the lower section of the wall.

The design was based on a 1:4 slope of the fill at the top of the wall.

### 3. FAILURE DESCRIPTION

#### 3.1 Athletics track wall

The facing blocks of the wall collapsed, as a result of the lower blocks being sheared by the horizontal deformation of the wall and reinforced backfill. At the top of the fill extensive large cracks formed, upto 75mm

wide. Heavy rainfall resulted in sheet flow runoff from the field flowing into some of the cracks.

Immediately after the collapse of the athletics track wall, seepage was noted over the lower 700mm of the backfill, in areas where stormwater had not flowed into the tension cracks of the soil.

The deformed soil mass kept moving vertically over the next few weeks, until a vertical displacement of around 0.7m existed at 2.4m to 2.8m from the back of the wall. This position coincided with the trench for the irrigation pipes of the sportsfield, and the edge of the athletics track subsoil drainage. Sections of the pipes had been repaired in the past, and the pipe junctions were pulled apart by the movement of the failed wall. The foundation of the concrete blocks had rotated by around 14°, and moved laterally. The deflected reinforced soil mass remained intact for numerous months, before being removed by excavation for remediation of the wall.

#### 3.2 Hockey field wall

The facing of the wall next to the field light mast collapsed over a 20m section, with a portion of the surcharge slope at the top of wall lying on top of the collapsed blocks. A 7m long section adjacent to this moved horizontally by over 150 mm, and opened up a 75mm wide tension crack near the top of the surcharge slope. The concrete blocks near the bottom of this wall section were also extensively cracked.

To the south of the light mast the wall supported a car park with a wall height of 3.74m and a wall slope of 70°. The area 2.5m behind the top of the wall settled by around 100mm, and a crack of 20mm wide existed at the back of the settled area. The wall had an outward bulge of between 130mm and 170mm near the mid-height. These measurements can not be exactly quantified, as no completion survey had been carried out on the wall, upon completion of construction.

### 4. AS-CONSTRUCTED DETAILS

#### 4.1 Athletics track wall

The detail of the as-constructed wall is shown in Figure 3. This detail applies over most of the wall length. The end sections of the wall of lower height had no geotextile in the backfill, but a larger and heavier concrete block was used.

The bottom layers of reinforcement geotextile were missing in the fill, as well as the top layer of reinforcement geotextile. The short layer of non-woven geotextile at the top of the wall was installed to minimise the risk of erosion gullies forming behind the blocks.

This wall had a short section where no geotextiles were installed in the backfill, but the rest of the wall backfill was reinforced with either three or four layers of a woven multi-filament polyester geotextile with a tensile strength of 25kN/m.

Figure 3: As-constructed athletics track wall

The backfill to the reinforced section as well as under the athletics track, consisted of a silty clay to clayey sand, with a Plasticity Index varying between 24 and 32, and a liquid limit above 43. The soil also classified as medium expansive on the van der Merwe chart for active soils. The tested shear strength of the soil is:

$$\phi' = 26,3^\circ$$

$$c' = 6 \text{ kPa}$$

#### 4.2 Hockey field wall

The detail of the as-constructed wall is shown in Figure 4 and Figure 5.

The wall in Figure 4 was specified to be constructed as per the athletics track wall detail, to a maximum height of 3.74m. The car park at the top of the wall started 2m from the back of the wall, at the highest section of the wall. The depth of the reinforcement geotextiles was specified as 1,8m deep, and they were installed to that depth. The spacing and type geotextiles were however not installed to specification, with sections of the wall having the erosion control geotextile replacing sections of the upper two layers of

Figure 4: As-constructed hockey field wall, below carpark

reinforcement geotextiles. The tensile stiffness of the non-woven geotextile is between 20% to 30% of that of the woven reinforcement geotextile specified.

The wall in Figure 5 was built to a maximum height of 3.7m, compared to a design height of 4.9m. The toe of the wall and the breakpoint of the top of the slope above the wall were fixed, resulting in a steeper surcharge slope at the top of the wall. This slope varied between 17° and 25° to the horizontal, compared to the 14° design slope. The backfill to the wall, as well as the slope above the wall, consisted of a clayey sand to gravely silt.

Figure 5: As-constructed hockey field wall, below sloped section

Laboratory analyses of soil samples from both walls confirmed that they were active soils, with a low shear strength, similar to the backfill of the athletics track wall. The reinforcement to the backfill varied considerably over the highest portion of the wall. A 20m section of the highest wall collapsed, while other sections deflected excessively. During reconstruction of the wall, a layer of alluvial soil was also exposed near the base of the reinforced fill where the wall had collapsed. The sections

where the wall had been designed and built as gravity walls, performed satisfactorily. The slope at the top of the wall was less than 14°.

## 5. BACK ANALYSIS:

The failures of the walls was back analysed, based on the following design deviation conditions:

- Reduced shear strength of poor backfill.
- Incorrect reinforcement geotextiles position.
- Geometry deviation.
- Seepage through backfill.

Each condition was analysed separately, and then in combinations, to determine the impact on the wall stability, resulting from the non-compliance's with the original design. The analysis was carried out using a dual wedge analysis program.

### 5.1 Reduced Shear Strength and Position of Geotextiles

Due to the variation of moisture content in South African soils between summer and winter, the 'cohesion' measured in laboratory tests on active soils (high PI), is seldom realised in the field over the long term. Hence the case of no cohesion was included in the analysis, as the walls had stood for nearly three years. For the back analysis, the full concrete block shear strength (including mechanical interlock) was included.

Wall I = Athletics track

Wall II = Hockey field

P/R = Ratio of provided to required

<b>Case – Poor Backfill:</b>	<b>P/R</b>
<b>Wall I</b>	
As-Constructed (3 layers)	0,86
As-Constructed (4 layers)	1,00
Geotextile spacing as specified	1,36

#### **Wall II – Collapse**

As specified slope at top, bottom geotextile missing	0,64
As specified slope at top, geotextiles as specified	2,5

#### **Wall II – Deflected**

As-Constructed (overall stability)	1,19
As specified geotextiles	1,87
As-constructed (force in geotextiles)	1,11

The analysis shows that the reduced shear strength of the soil plus the incorrect spacing of the geotextiles brings the wall close to ultimate limit state for wall I, and "beyond" ultimate limit state for the collapsed wall II. The deflected wall II results in service loads in the geotextiles with a margin of only 10% above what would be normally considered a maximum for the ultimate limit state for the geotextiles used. Geotextiles loaded to this level are expected to give rise to large deflections and excessive creep. This was clearly the case on site.

The reduced shear strength of the soil on its own is unlikely to result in a state of collapse. For a collapse to occur, one would expect the ratio of provided to required to be well below 1,0.

The "temporary situation," where a cohesion of 6kPa is effective, results in a reduction in the stresses of the geotextiles by a factor of 2.5. Also, the factor of safety for overall stability of Wall I is 1.9 and Wall II is 2.3. Hence, no stability or deflection problems would be expected. This was the case for a period of three years from construction.

### 5.2 Geometry Deviation

Wall II has a further complication, where the slope above the wall was constructed at a slope, which is very close to incipient failure, for a shallow sloughing failure. It can be shown that should such a failure be mobilised, that the upper 1.0m height of the wall, as built, would be at a point of incipient failure. Such a slide results in the top of the wall being pushed over, releasing the clamping effect of the blocks at the front of the geotextiles. Hence, the local stability at the top of the wall is at the limit of equilibrium, where the slope at the top of the wall approached the shear strength of the fill. ( $c' = 0\text{kPa}$ ).

The overall stability was also analysed, based on variation of the angle of the upper slope. The result of this analysis is shown below:

<b>Case – Poor Backfill:</b>	<b>P/R</b>
25° slope at top, as specified geotextiles	0,79
17° slope at top, as specified geotextiles	0,95
14° slope at top, as specified geotextiles	1,15

### 5.3 Seepage

The effect of a phreatic surface in the reinforced backfill to the wall was analysed. For this a simple  $r_u$

$$= \left( \frac{\sigma}{\gamma_w h_w} \right) \text{ factor was used on the lower failure surface}$$

of the dual wedge analysis. Using a value of  $r_u=0,1$ , the following results were obtained.

#### Case: Poor Backfill with Phreatic

Surface:	P/R
As-Built (3layers)	0,82
As-Built (4 layers)	0,91
Geotextiles – as specified	1,15
Geotextiles as specified, granular backfill	2,3

Again, it can be seen that a phreatic surface alone would probably not have been sufficient to collapse the wall.

From the above analyses, it can be concluded that in order for the wall to fail, at least two non-compliance's to the original design were required. On this basis the following scenarios were identified as having resulted in the collapses:

Wall I (Athletic track): Missing geotextiles at the base of the wall in conjunction with low shear strength soil.

Wall II (Hockey wall): Steep surcharge slope, in conjunction with low shear strength soils.

Incorrect spacing of geotextiles with the low shear strength soils lead to serviceability failure of the carpark wall.

## 6. REMEDIATION OF THE WALLS

### 6.1 Athletic Track Wall

The athletics track wall was rebuilt, using an imported granular fill. The fill was reinforced with five layers of a woven polyester geotextile with a tensile strength of 50kN/m, at a uniform depth of 2.5m into the fill. Due to space constraints, the excavation next to the athletics track had to be temporarily supported, using driven soil anchors. In the area where the soil remained very wet, subsoil drains were installed at the interface between the clayey soil and the imported granular fill. The owner of the sportsfield was also requested to carry out leakage

tests on the irrigation system to minimise the risk of saturation and erosion due to leaking water pipes.

### 6.2 Hockey Field Wall

The section of the hockey field wall that had been built too low, and had not deflected excessively, was reinforced with either one, two or three rows of 6m long soilnails, spaced at 1,6m horizontally. These soilnails consisted of 20mm diameter galvanised high tensile steel bars encased in grout.

The number of nails depended on the extra height of wall to be placed ontop of the existing wall, and the final height of the wall. The maximum wall raise was 1,8m ontop of an existing 3,1m high wall. The nails were designed to ensure overall stability of the wall, and the added wall height was reinforced with woven polyester geotextiles. These geotextiles were specified to have a tensile strength of 50kN/m, spaced at 680mm vertical centres and 2,5m deep. A silty sand was specified for the backfill.

The collapsed wall sections, and sections where the backfill and wall had deflected excessively (visibly), were rebuilt. The poor shear strength of the soil dictated that the depth of the geotextiles needed to be 77% of the final wall height. The granular fill used for the reinforced fill allowed the use of a cheaper woven polypropylene tape multi-filament geotextiles with a tensile strength of 35kN/m over the upper 3,5m of the wall, and a woven polyester geotextiles of 50kN/m for the lower section.

All the above work was completed by end of 1996, and has been performing satisfactorily to date.

## 7. CONCLUSIONS

From the above, the following conclusions can be drawn:

- Geotextile reinforced backfill walls are structures that are robust to variations from the design specifications.
- Collapse of such a structure is usually as a result of two or more substantial deviations from the design specifications.
- Geotextile reinforced retaining walls have a ductile and a brittle component. The brittle component is the facing, while the backfill acts as a ductile component of the structure.

## ACKNOWLEDGEMENTS

The authors wish to thank the owners of the retaining walls, as well as the wall contractors, for their permission to publish this case history.

T. Koga

Kyushu Railway Company (JR Kyushu)

**ABSTRACT:** The first prototype preloaded and prestressed geogrid reinforced soil bridge pier was constructed to support temporary railway girders. An abutment of geogrid-reinforced soil retaining wall, which was not preloaded nor prestressed, was also constructed. The behavior of the pier and the abutment during and after construction and in service was carefully observed. By preloading and prestressing, the gravel backfill of the pier became very stiff against static and dynamic load compared to the abutment. Cyclic triaxial loading tests on the backfill gravel were performed to understand the contribution of the preloading and prestressing to the high performance of the pier.

**KEYWORDS:** Preloading, Prestressing, Geogrid-reinforced soil, Bridge pier, Full-scale loading test, Cyclic triaxial test

## 1 INTRODUCTION

A new construction method, the preloaded and prestressed (PLPS) reinforced soil method, has been proposed; a reinforced backfill is made very stiff against vertical load by vertical preloading and prestressing (Tatsuoka et al. 1996a.)(Figure 1). A similar method taking advantage of preloading has been proposed by Adams (1997), but it does not take advantage of effects of prestressing. The mechanisms of the PLPS method, which will be mentioned later, were demonstrated by tests on a full-scale model embankment and creep-relaxation tests on large triaxial specimens of the backfill gravel (Uchimura et al. 1996).

In this paper, the construction and the behavior of the first prototype PLPS geogrid-reinforced soil bridge pier is

reported. This pier was constructed in the summer of 1996 to support temporary railway girders and has been opened to service since the summer of 1997. The comparison of the behavior between the PLPS pier and an ordinary geogrid-reinforced soil abutment, which was not preloaded nor prestressed, proved that preloading and prestressing can restrain three kinds of vertical compression of the backfill: creep compression under long-term static compressive load; the amplitude of compression by dynamic loading (i.e. transient cyclic loading); and residual compression by many times of cyclic loading.

Cyclic triaxial loading tests on the backfill gravel was performed to understand the effects of preloading and prestressing on the behavior of the pier under cyclic load in service. The results showed that when a very well compacted backfill is sufficiently preloaded and prestressed at an appropriate stress level, the settlement at the pier crest and the reduction in the tie rod tension caused by many times of cyclic loading can be very small.

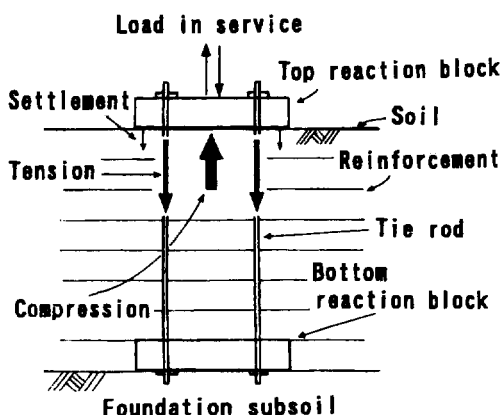

Figure 1. A schematic diagram of preloaded and prestressed reinforced soil (Tatsuoka et al. 1996a.).

## 2 OUTLINE OF PLPS METHOD

### 2.1 Construction Procedures

The typical construction procedures are as follows (Tatsuoka et al. 1996a):

1. The sub-soil is improved if necessary, usually by in-situ cement-mixing; a pile foundation is not used because of its high cost.
2. A rigid bottom reaction block, which is usually a reinforced concrete (RC) block, is constructed at the

bottom level of the backfill.

3. Four steel tie rods are installed vertically with their bottom ends anchored to the bottom reaction block.

4. The backfill is constructed, being reinforced with geogrid and involving the tie rods within it. Usually, well-graded gravel is used. Good compaction of the backfill is essential.

5. A top reaction block is constructed on the top of the completed backfill.

6. Hydraulic jacks are set at the top ends of the tie rods, supported by the top reaction block.

7. The backfill is preloaded by using the jacks. To develop as large as possible compression of the backfill during this stage, high preload kept constant for a long period or many times of cyclic loading may be applied.

8. The load is decreased from the preload level to a prescribed non-zero prestress level.

9. The top ends of the tie rods are fixed to the top reaction block (usually by using nuts), and the jacks are removed. After this, a vertical stress remaining in the backfill in equilibrium with the tie rod tension works as prestress.

## 2.2 Mechanisms

The mechanisms of this method could be summarized as follows (Tatsuoka et al. 1996a) :

1. The backfill needs to be reinforced to support much higher preload than an unreinforced backfill.

2. The preloading and subsequent unloading makes the backfill stiffer and nearly elastic against external loads applied on the top reaction block. The amount of unloading from the preload level should be larger than the maximum design load; otherwise, the compressive stress activated in the backfill during service may exceed the maximum stress during preloading, resulting in occurrence of larger plastic deformation of the backfill. On the other hand, the load should not be decreased to a very low level or zero to avoid swelling and associated softening of the backfill (Tatsuoka et al. 1996b).

3. The compressive prestress activated in the backfill under prestress condition leads to high stiffness, thus a high integrity, of the backfill.

4. The load working on the top of the backfill is always in equilibrium with the sum of the external load applied on the top reaction block and the tie rod tension. Therefore, when external compressive load is applied, the reduction in the tie rod tension associated with vertical compression of the backfill results in a reduction of load increment on the backfill. This mechanism decreases the backfill settlement.

5. Large part of the tensile strains in the reinforcements induced by preloading remains after the load is decreased to the prestress level. Therefore, the reinforcement can confine the backfill more efficiently.

6. If a well compacted backfill is preloaded by sufficiently large load for a long period, relatively large creep

deformation develops in the backfill, resulting in very small long-term rate of the relaxation of the tie rod tension under the prestressed condition..

7. The backfill may deform in the simple shear mode during a seismic event. When the backfill is very well compacted, large dilatation of the backfill may occur associated with seismic shear deformation. But such dilatation is restrained by the tie rods, resulting in a considerable increase in the tie rod tension and compressive stresses in the backfill. Therefore, a high seismic stability can be expected.

## 3 PROTOTYPE PLPS GEOGRID-REINFORCED SOIL BRIDGE PIER

### 3.1 Design and Construction

The first prototype PLPS geogrid-reinforced soil bridge pier was constructed to support two 16.5 m long steel bridge girders for a single railway track in Fukuoka City, Japan (pier P1 in Figure 2a). The bridge is planned to be used for about three years from August 1997. The cross-section of the pier is 6.4 m x 4.4 m, and the height of the backfill is 2.7 m. The design dead load by the girder weight and live load by train loads including impact load are 196 kN and 1,280 kN, respectively.

On the other hand, one of the abutments for the girder was constructed as an ordinary geogrid-reinforced soil retaining wall (GRS-RW) without preloading and prestressing (abutment A2 in Figure 2a).

First, a subsoil of an about 9 m-thick very soft clay deposit was improved by in-situ cement-mixing forming nine 9 m-long 0.8 m in diameter cement-mixed soil columns (Figure 2b). In addition, the whole cross-section of the pier was improved by cement-mixing for the 1 m-thick surface soil layer to form the bottom reaction block. The lower ends of four steel tie rods, which were originally produced for prestressed concrete, were anchored into the cement-mixed soil columns for a length of 4 m. The nominal yield tensile force of each tie rod is 1,034 kN.

The backfill was constructed with a help of gravel-filled bags stacked along the four sides of each gravel layer, while wrapping around the bags with the reinforcement. A well graded gravel of crushed sandstone ( $D_{max} = 30$  mm,  $D_{50} = 0.9$  mm,  $U_c = 16.5$ ,  $\phi = 60^\circ$ ) was used. A hand-operated 30 kg-vibration compactor and a hand-operated 60 kg-tamper were used to compact the backfill; larger machines could not be used because of small available working space. A geogrid reinforcement of polyvinyl alcohol coated with polyvinyl chloride (PVC) was used, whose nominal rupture strength is 73.5 kN/m and the nominal stiffness is 1,050 kN/m at strains less than 1 percent. The arrangement of the reinforcement was determined for a GRS-RW with one facing at the end under

Figure 2. a) A bridge construction project involving the first prototype PLPS reinforced soil pier; b) detail of the pier; c) arrangement of the instrumentation described in this paper (Tatsuoka et al. 1996b).

plane strain condition with the same height as the actual pier, instead of the actual pier having a rectangular prismatic shape. As the result, the vertical spacing of the reinforcement was designed to be 30 cm. However, the pier has two pairs of wall faces in two orthogonal directions; therefore, each cross-section having one pair of wall faces were designed independently. By overlapping the two cross-sections, the actual average vertical spacing of the reinforcement became 15 cm.

The construction of the backfill took five days by a team of five workers. Preloading started ten days after casting the top reaction RC block (5 m-long, 2.4 m-wide and 0.8 m-thick). Then, full-height rigid facings were cast-in-place on the four wall faces. The total construction period was about 1.5 months. The construction cost for the pier was about a half of that for an equivalent conventional RC pier supported by a pile foundation.

The abutment A2 was constructed by the same method using the same materials as the pier, except that it has only one wall face retained by reinforcement with a vertical spacing of 30cm, and the both sides are exposed slopes (1.5:1.0 in H:V) without a facing.

### 3.2 Instrumentation

For the measurement of vertical compression, four stainless anchor plates for the pier and two plates for the abutment were embedded at the bottom of the backfill (Figure 2c). Brass rods placed inside PVC pipes were vertically installed through the backfill and connected to the anchor plates at the lower ends. The vertical displacement of the top of the rods relative to the top of the backfill have been measured with displacement transducers. The average compression of the pier and the abutment was calculated based on these measurements.

The tie rod tension has been measured with electric resistance strain gages attached to the tie rods. The earth pressure has been measured at the center (P01) and near the tie rods (P02) at the bottom level of the backfill with strain-gage-type pressure transducers of 20 cm in diameter. The tensile strains of the reinforcement have been measured by strain gages attached to the grid at 32 points. Strains in horizontal two directions, orthogonal each other, have been measured separately.

### 3.3 Preloading

For a period of ten week days, preload was applied by using four hydraulic jacks (Figure 3). The total net preloading period was 72 hours, however, because the preloading was allowed only during daytime due to a restraint at the site. During nighttime, the tie rods were fixed to the top reaction block with the backfill under prestressed condition.

In the first day, the vertical load was increased step by

step up to 1,960 kN (from the origin to Point 1 in Figure 4); each step consisted of a load increment of 196 kN applied within 2 minutes or less and a pause keeping the load constant for 30 or 60 minutes. In the fifth day, the load was decreased to 905 kN (Point 10), followed by reloading. In the sixth day, the load was increased to 2,350 kN (after Point 11). In the seventh day, the load was decreased to zero (Point 13), followed by reloading. In the tenth day, the load was decreased to about 1,100 kN (Point 16) and then the backfill was left under prestressed conditions for three days. Finally, the load was increased to 2,350 kN (Point 17), maintained for three hours, decreased again to 980 kN (Point 18), and since then, the backfill has been left under prestressed condition.

Figure 4 shows the relationship between the total tie rod tension,  $T$ , and the backfill compression. During the preloading stage, the tie rod tension was the same as the amount of the preload working on the crest of the backfill. A total settlement of 8 mm occurred through the whole preloading period. During unloading and reloading by 1,400 kN in the last day, the rebound and re-compression were nearly the same and equal to only 0.4 mm, indicating a very high stiffness and nearly elastic deformation of the backfill. According to Tatsuoka et al. (1996a), the Young's modulus  $E$  for vertical elastic strains of such gravels measured by triaxial tests can be expressed as  $E = E_0 \cdot (\sigma_v / p_0)^m$ , where  $m=0.57$  and  $E_0$  is the  $E$  value when the vertical stress  $\sigma_v$  is equal to  $p_0 = 98$  kPa. Based on this relationship, by fitting the theoretical elastic rebound and reload curves to those measured with the pier,  $E_0=400$  MPa is obtained. The theoretical curve for elastic settlement is also plotted to start from the origin in Figure 4; this curve indicates the elastic component of the compression. The plastic component of the compression is obtained as the difference between the elastic component and the integrated value of the instantaneous compression increments caused at each loading step. The difference between the total compression and the instantaneous (elastic plus plastic) component is the time-dependent (viscous) component. The viscous component is found to be more than a half of the total compression and its ratio to the total compression increases with the load level. Therefore it is important to remove potential creep deformation of the backfill by sufficient preloading.

It may also be seen from Figure 4 that the average stiffness of the backfill when reloaded from Point 10 is noticeably smaller than the value when reloaded from a higher load level (e.g., from Point 7). Moreover, the average stiffness when reloaded from the zero load (from Point 13) is smaller than the above. This behavior is likely due to the effects of swelling and softening of the backfill when the load is decreased largely or to zero. This result shows the importance of maintaining sufficiently high prestress in the backfill (Tatsuoka et al. 1996b).

Figure 5 shows the relationship between the total tie rod

tension and the earth pressure measured at the center (P01) and near the tie rods (P02) at the bottom of the backfill. The average pressure, equal to the applied load divided by the total cross-sectional area (5.8 m x 3.8 m) of the pier, is nearly the same as the measured earth pressure increments. Furthermore, the earth pressures at P1 and P2 are almost the same as each other, while showing a highly linear relationship with the tie rod tension. These results show

that the stress distribution was nearly uniform at the bottom of the backfill and that the bottom reaction block made by in-situ cement-mixing functioned as a nearly rigid mass.

### 3.5 Long-term Behavior under Static Load Condition

After the preloading stage, the full-height rigid concrete facings were cast-in-place, and then two steel girders, each

Figure 3. Long-term behavior during and after preloading and in service; tie rod tension; vertical compression of the pier and the abutment; tensile strain of the grid.

Figure 4. Relationship between the tie rod tension and the settlement of the pier (Tatsuoka et al. 1996b).

weighing 211 kN, were installed on the pier and the abutments. The instantaneous compression of the pier by a girder weight of 211 kN was only 0.04 mm, while that of the abutment by a girder weight of 105 kN was ten times larger, equal to 0.4 mm. Then, the behavior of the pier and the abutment was observed for ten months (Figure 3).

The tie rod tension and the compression of the pier P1 appear to have changed slightly for this long period, but this is likely to be annual change due to temperature effects. The tensile strain in the reinforcement kept almost constant without showing any creep extension.

On the other hand, the abutment A2 showed noticeable creep compression by the self weight and the girder weight. Although the measurement of the abutment compression started just before the girder installing, the total compression has reached 3.1 mm by the summer of 1997.

The difference shows the first advantage of preloading and prestressing that makes long-term creep deformation of the backfill under static load condition very small.

### 3.6 Short-term Behavior at Train Passing

On 19 July 1997, a diesel locomotive of 637 kN in weight passed 6 times over the bridge for inspection. The residual compression of the pier P1 was 0.02 mm, while that of the abutment A2 was 0.52 mm.

Since 3 August 1997, the bridge has been opened to

service. Figure 6 shows the behavior of the pier P1 and the abutment A2 at the first train passing in service; the train consisted of 2 coaches, each weighing 353 kN without passengers.

The amplitude of compression of the pier was 0.02 mm, which was equivalent to a vertical strain of 0.001 percent; this very small strain also suggests nearly elastic behavior of the pier. The tie rod tension responded to the pier compression. The change in tensile strain in the

Figure 5. Relationships between the earth pressure P1 and P2 and the tie rod tension.

Figure 6. Behavior of the pier and abutment at train passing.

reinforcement was very small and elastic, which was due to very small compression of the pier. Apparently, the train road was not supported by the corresponding very small increase in the tensile force in the reinforcement alone, but the backfill having highly elastic properties with high stiffness actually supported the train load; these backfill properties could be achieved by sufficiently large preloading and prestressing, which was possible only with a help of reinforcement.

On the other hand, the amplitude of the compression of the abutment was 0.2 mm; this is not a harmful quantity, but 10 times larger than that of the pier.

The difference shows the second advantage of preloading and prestressing that makes the amplitude of compression by dynamic loading very small.

### 3.7 Long Term Behavior in Service

The behavior of pier and abutment in service has been observed for 2 months (Figure 3). On average, 125 trains, each consisting of two to four coaches, each weighing 30 to 40 tons without passengers, pass over the bridge every day.

The residual compression of the pier was 0.08 mm. Corresponding to that, the tie rod tension decreased by 17.3kN. The tensile strains in the reinforcement did not change largely; as a whole, they have been constant. On the other hand, the abutment showed a residual compression of 5.1 mm. It is still compressing rapidly, even though the compression rate is decreasing. Some maintenance will be necessary. This difference shows the third advantage of preloading and prestressing that makes the residual compression by many times of cyclic loading very small.

## 4 BEHAVIOR AGAINST CYCLIC LOAD

The comparison of the behavior between the pier and the abutment subjected to many times of train passing showed several advantages of preloading and prestressing, by which temporary and residual compression of the backfill against cyclic loading was very effectively restrained. In order to understand these effects of the PLPS method, cyclic triaxial compression tests were performed at a constant confining pressure ( $\sigma_h = 49$  kPa) on a large square prismatic unreinforced specimen (23 cm x 23 cm x 60 cm high) of the backfill gravel ( $\rho_d = 1.95$  g/cm<sup>3</sup> and  $w = 3.3$  percent) (Figure 7). Axial and lateral strains were measured by a set of LDTs, a device to measure small local strains on the surface of the specimen. An LDT consists of a phosphor bronze strip with strain gages attached at the center, supported at the both ends with two hinges glued to the specimen surface. Figure 8a shows the time history of the deviator stress  $q = \sigma_v - \sigma_h$ . The primary loading (PL) was conducted at a stress rate of  $dq/dt = 49$  kPa/min. C1 and C2 mean creep loading stages for 6 hours at a constant

$q = 98$  and  $196$  kPa, respectively. CYC1 to CYC5 mean cyclic loading stages of 500 cycles, in which  $q$  changed between 98 and 196 kPa for CYC4 and between 0 and 98 kPa for the others. PL simulated a short-time preloading without creep compression, while C2 simulated a long-time preloading with creep compression at the peak load.

Figures 8b and 9 show the test results. Even after some creep (C1), the vertical compressive strain  $\epsilon_v$  increased noticeably (by 0.013 percent) during the first cyclic loading stage CYC1. During CYC2 after PL, the increase in  $\epsilon_v$  by cyclic loading was nearly zero. On the other hand, during CYC3 after C2 and CYC5 after CYC4,  $\epsilon_v$  decreased during cyclic loading (by 0.006 percent and 0.007 percent respectively). During CYC4,  $\epsilon_v$  increased noticeably (by 0.023 percent) by cyclic loading, but the double amplitude stiffness  $\Delta q / \Delta \epsilon_v$  is about 2.5 times larger than those during CYC1 to CYC5 at the lower  $q$  level.

The test results suggest the following:

1. If the backfill is not preloaded, it may be compressed largely by cyclic loading (CYC1). This trend of behavior was actually observed with the abutment A2.
2. For the same amplitude of cyclic stress and number of loading cycles, the settlement of the backfill becomes very small after preloading; this trend becomes more obvious after the occurrence of the creep deformation or cyclic loading during the preloading stage. This trend of behavior was actually observed with the pier P1.
3. The higher prestress on the backfill causes higher stiffness of the backfill during cyclic loading. But if the stress level is near the maximum stress during preloading, residual compression becomes larger.
4. To make both of the amplitude and residual value of compression by cyclic loading very small, the backfill should be preloaded at sufficiently high stress level, and the prestress should be some non-zero level; otherwise it leads

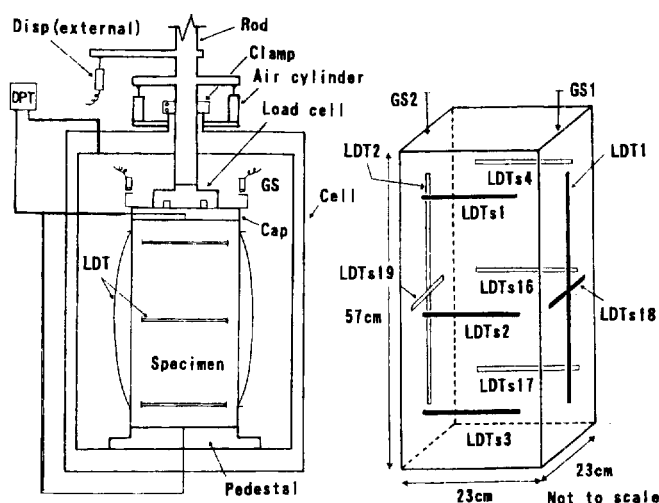

Figure 7. Schematic diagram of the large scale triaxial test (Uchimura et al. 1996).

to a large amplitude of compression during cyclic loading. On the other hand, the prestress should not be very high so that the maximum stress during cyclic loading does not approach the maximum stress during preloading. Some intermediate prestress level is appropriate.

## 5 CONCLUSIONS

The behavior of the first prototype PLPS geogrid-reinforced soil bridge pier was observed during and after construction and in service. Compared to a bridge abutment of geogrid-reinforced soil constructed without preloading and prestressing in the adjacent place at the same time, the pier showed very small transient and long-term deformation. The different performances demonstrated significant effects of the preloading and prestressing procedures in restraining creep compression under long-term static compressive load; the amplitude of compression by dynamic loading; and residual compression by many times of cyclic loading. The results of triaxial cyclic loading tests on a specimen of the backfill gravel also showed a high efficiency of preloading and prestressing, particularly preloading with creep compression or cyclic loading, to restrain temporary and residual compression of the backfill. Both field and laboratory observations showed that it is not preferable to unload the prestress to zero because it leads to a large amplitude of compression during cyclic loading. On the other hand, to make the residual compression very small, prestress should not be very high so that the maximum stress during cyclic loadings does not approach the maximum stress during preloading.

**ABSTRACT:** The problem of void development under bridge approach slabs has been correlated to the use of integral abutment bridges (Schaefer and Koch, 1992). The observation of the occurrence of voids under approach slabs, even in cases where no traffic had yet occurred led to a hypothesis of thermally-induced movements of bridge beams/abutment walls as the mechanism causing the void development. As a result of identification of the mechanism of void development, changes to the approach system needed to be made to accommodate this mechanism. A method used by the Wyoming Department of Transportation, and subsequently by the South Dakota Department of Transportation, uses a fabric reinforced soil wall behind the abutment to build a vertical, self contained wall capable of holding a vertical shape and forming a void behind the abutment. This paper will detail the design concept used by the South Dakota Department of Transportation, present data obtained from instrumented bridges currently being monitored, and show how this system alleviated the integral bridge abutment approach problems.

**KEYWORDS:** Geotextile, Temperature Effects, Retaining Walls, Integral Abutment, Pavements

## 1 INTRODUCTION

The problem of void development under bridge approach slabs has been correlated to the use of integral abutment bridges (Schaefer and Koch, 1992). The observation of the occurrence of voids under approach slabs, even in cases where no traffic had yet occurred, led to a hypothesis of thermally-induced movements of bridge beams/abutment walls as the mechanism causing the void development. As a result of identification of the mechanism of void development, changes to the approach system needed to be made to accommodate this mechanism. For this project the approach system design consisted of a geotextile reinforced soil wall behind the abutment resulting in a vertical, self-contained wall capable of holding a vertical shape and forming an air gap between the abutment and retained backfill. This design was based on a system used by the Wyoming Department of Transportation (WYDOT). It was hypothesized that the gap behind the abutment would allow for the thermally-induced movement of the abutment without affecting the backfill. Three bridges were constructed in South Dakota using this design. The field portion of this study consisted of monitoring the variations in gap width between the abutment and geotextile wall and development of voids under the approach slab. This paper will review the design of the bridge systems and geotextile soil wall, data collection and measurement, preliminary analysis and conclusions.

## 2 PREVIOUS RESEARCH

Although numerous factors contribute to the differential movements between bridge abutments and the approach areas to the bridge, previous research has shown that void development under approach slabs to integral abutment bridges occurs due to the elongation and contraction of the bridge beams due to temperature variations. As the bridge beams expand and contract they alternately push into and pull away from the backfill behind the abutment wall, leading to the development of a void near the abutment wall under the approach slab. The observation of such voids in the field has been reported by Jorgenson (1983), Kramer and Sajer (1991), and Schaefer and Koch (1992). The size of the void varies markedly, with Schaefer and Koch (1992), who surveyed 140 bridges in South Dakota, reporting measured voids from 13 to 360 mm (1/2 to 14 in.) in depth and extending as much as 3 m (10 ft.) away from the abutment wall. The study concluded that the development of the voids under the approach slab to integral abutment structures was an inherent problem in the use of integral abutment systems. The void development was not considered to be isolated to one mechanism resulting from abutment movement, but rather to be the result of the cumulative effects of embankment bulging as the backfill deforms, approach slab uplift, backfill densification as particle breakage occurs, and backfill deformation as passive failure occurs in the backfill. The relative contribution of each of these mechanisms

has not been discerned to date. It was suggested that the largest increases in void size occurred when passive failure likely occurred and this mechanism was probably the most important one.

Edgar, et al. (1989) investigated the use of a reinforced soil wall as a means to prevent void development under the approach slab in highway embankments. This research determined that retaining the backfill with a geotextile wall, thereby creating a gap between the retained fill and bridge abutment, reduced the applied stresses to the soil to near zero. The reduction of the passive stress to near zero eliminates the passive failure mechanism in void development. Consequently, this system was adopted for use in the construction of three bridges in South Dakota based on the hypothesis that the presence of a gap between the abutment and retained fill would prevent or greatly reduce void development under the approach slabs.

### 3 BRIDGE BACKFILL DESIGN

The backfill design used by the WYDOT was adapted by the South Dakota Department of Transportation (SDDOT) for replacement of a single concrete bridge, 134 m (440 ft) in length, on Highway 73 across the White River near Kadoka, SD in the spring of 1996. This design was also used on two concrete bridges, 122 m (400 ft) in length, on Interstate 29 across the Big Sioux River south of Brookings, SD. The southbound bridge was constructed in the fall of 1996 and the northbound bridge in the summer of 1997. These three bridges are being monitored to measure seasonal variations in the gap spacing and for the development of voids under the approach slab. This design has been adopted for all new bridge construction in South Dakota.

Design of the backfill system followed current SDDOT bridge design and construction practices except for the presence of the woven geotextile wall. Prior to the implementation of this design methodology, backfill material consisted entirely of select granular material. This expensive backfill was used since it had been shown to reduce void development because of its greater passive resistance. This backfill contained material with less than five percent passing the #200 sieves and extended the depth of the abutment and back at typically a 1:2 slope. A design developed by the WYDOT incorporated the use of a gap between a reinforced soil wall and the abutment wall. During construction of the three bridges monitored in this project, a 15.4 cm (6 in) cardboard spacer was placed against the concrete abutment. The wrapped face geotextile wall was then constructed against the cardboard, which acted to maintain the gap and control the alignment of the wall face. The first three layers of the reinforced soil wall were 30.5 cm (1 ft) thick and the top layer thickness

varied with respect to grade specifications. A fabric overlap of 1.2 m (4 ft) was used on all layers of the wall. Upon completion of the wall, the cardboard spacer was saturated with water and removed. The backfill material was the same select backfill used in previous SDDOT designs. Based on the results of this project, the state may specify less expensive backfill materials in the future. The drainage pipe was installed in the bottom most layer of the geotextile wall. A general illustration of this backfill design is shown in figure 1.

Figure 1. Typical geotextile reinforced soil wall behind the bridge abutment.

### 4 DATA COLLECTION

Over the course of this three-year project (1996-1999) physical measurements of the gap width, bridge length, and void development were obtained. More detailed instrumentation of these bridges was not feasible due to limited funding.

The gap width between the reinforced soil wall and the bridge abutment was monitored to determine if the abutment came in contact with the reinforced soil wall, thereby creating a passive pressure condition on the backfill. Also, if the abutment and wall do not come in contact, this data would be used to determine if a smaller gap width would be appropriate. To monitor gap width on the White River abutments, four vertical rows of four holes each were drilled through each abutment between the bridge beams. In each row, the approximately 5 cm (2 in) diameter hole locations were evenly spaced on the vertical profile of the wall. Initial measurements of the gap width at each hole location were recorded after the supporting cardboard had been removed. For the I-29 bridges, four vertical rows of three holes each were installed in each abutment

between the bridge beams.

A second series of holes were formed into the approach slab to monitor the formation of voids beneath the slab. These holes were installed with removable caps to cover the hole but allow access for measurement. Void measurement locations measuring 5 cm (2 in) in diameter are located at 0.46 m (1.5 ft), 0.76 m (2.5 ft), 1.68 m (5.5 ft), and 4.72 m (15.5 ft) back from the face of the abutment. These measurements can be made along the centerline, along the centers of the driving lanes, and at the edges of the approach slab.

Physical measurements were also taken to monitor the thermal expansion and contraction of the bridge deck. Nails driven into the bridge deck served as bench marks for measurements of bridge deck movement. Three benchmarks were installed at 0.6 m (2 ft) from the guardrails at the midpoint of the span of the bridge and on the north and south ends of the bridge. Additional benchmarks were placed on the centerline of the bridge at the midpoint and on both ends.

In addition, air temperatures were recorded each time field measurements were made.

## 5 DATA

The gap width of the White River Bridge has been monitored for a full one-year temperature cycle. Gap width measurements are being taken on two Interstate 29 bridges. The southbound lane has been monitored since completion in November of 1996 and at the time of writing is going through its first high temperature cycles. The northbound lane is near completion and initial gap width readings have been recorded. Figure 2 shows the approximate gap measurement hole locations in between the bridge beams. Due to the space limitations of this paper, only the results from the south abutment of the White River Bridge are shown, see figure 3.

Due to the distance from Brookings this bridge is located, readings on the gap width for the White River bridge were made about every three months, with readings scheduled to ensure readings were taken in the high temperature and low temperature periods in a one-year cycle.

Monitoring of the void development under the approach slab on the White River Bridge will start after the summer of 1997. The thermal expansion and contraction of the bridge system relative to the backfill system is currently being evaluated. No significant findings can be presented on these subjects until two full years of data have been recorded.

Figure 2. White River Bridge south abutment hole configuration.

Figure 3. White River Bridge south abutment gap width for a one-year temperature cycle.

Gap width measurements taken from the White River Bridge and the one completed I-29 Bridge show changes in the gap width due to seasonal variations in temperature. The south abutment of the White River Bridge was constructed first. Based upon the limited number of readings taken thus far, the gap widths on this bridge are somewhat more scattered than the others. This has been attributed to the construction of the wall, which was visually observed and noted to be less than ideal. The south abutment was the first reinforced soil wall built by that particular construction company and was the first wall to be constructed by the State of South Dakota in a bridge end backfill application. Construction techniques were refined considerably following construction of the south abutment, which lead to a higher quality of construction for the north abutment. Due to improved construction practices, the north abutment displayed a larger initial gap measurement. Thus, it is essential to ensure all the layers of the wrapped faced reinforced soil wall are pulled very tight to reduce deformations after the cardboard is removed. The results show that experience in construction improved the performance of the north abutment backfill system.

The top of the abutment, which is integral to the bridge deck, undergoes the most movement. In most cases, the gap width for the upper two-thirds of the abutment changes more than the lower third. This suggests that a point of rotation exists in the foundation piling system below the bridge abutment. It can be observed in figure 3 that the minimum measured gap corresponds to the warmest temperatures, 100°F (38°C). Even measurements corresponding to the coldest temperature, 0°F (-18°C), are smaller than the initial gap, indicating a closure of the gap as the abutment cyclically moves. However, the data also shows that the initial gap has not fully closed in even the warmest temperatures, indicating the geotextile wall is functioning as intended. In all cases, the gap has remained open and prevented the abutment from pushing against the backfill and void development has not occurred.

## 7 CONCLUSIONS

At this early stage of the project conclusions as to the effectiveness of this design methodology in preventing void development will not be made. The data must be recorded over a longer time period to establish the repeatability of the data. Additional monitoring is necessary to distinguish how much of the gap closure is due to the initial movement of the wrapped face geotextile wall or is due to temperature induced abutment movement. The quality of construction of the backfill wall may also affect closure of the gap.

Therefore, quality control measures must be taken during construction. However, from one year's data it appears that the 15.2 cm (6 in) gap will provide sufficient space to allow for both movement of the abutment, movement of the soil wall related to inadequate construction, and movement due to creep of the geotextile soil wall.

## 8 ADDITIONAL WORK

Additional research, not discussed in this paper, is also being performed as part of this project. Alternative backfill materials and designs are being studied and tested in a SDDOT model bridge facility and will be the subject of future papers.

# Field Performance Test of a Geosynthetic-Reinforced Soil Wall with Rigid Facing

Y. Tsukada, Y. Ochiai and H. Miyatake

Public Works Research Institute, Ministry of Construction, Tsukuba, Japan

N. Tajiri

Fukken Co., Ltd., Consulting Engineers, Hiroshima, Japan

**ABSTRACT:** Geosynthetic-reinforced soil walls have gained wide acceptance in the world as retaining walls of roads and so on. The functions of their facings and reinforcing materials laid in them vary, and different design methods have been proposed to date. The present paper describes the experimental results of an outdoor, full-scale, reinforced soil wall and the evaluation of the results, the experiment being a part of a series of experimental studies to elucidate the reinforcing mechanism of geosynthetic-reinforced soil walls with concrete facings and establish a design method which takes account of the effect of such wall facings.

The test wall of 8 m-high was constructed on a soft ground, and its facing was of concrete blocks. Its behavior has been observed during the construction and for two years thereafter. During the time period, it was exposed to heavy rains and not so large earthquakes. The focus of this paper is the evaluation of the stability of reinforced soil walls based on the experimental results.

**KEYWORDS:** Geosynthetic-reinforced wall, Field test, Design, Long-term observation, Stability analysis

## 1 INTRODUCTION

Various approaches have been taken to the design and construction of geosynthetic-reinforced soil walls. In particular, researchers have proposed a number of design methods, maintaining that wall facings contribute to the reinforcing effect of the walls (Tatsuoka 1992, Leshchinsky 1993, NCMA 1993, and Gotteland et al. 1992). Regarding roads of which less severe constraint of deformation is required, the Public Works Research Institute (PWRI) of the Ministry of Construction has been pursuing experimental studies on the reinforcing effect of various types of wall facings (Tajiri et al. 1996, Nakajima et al. 1996, and Ochiai & Fukuda 1996). As shown in Figure 1, a full-scale vertical reinforced soil wall of 8 m-high with concrete-block facings (under an overloaded embankment of 9.8 kN/m<sup>2</sup>) was constructed, and its behavior has been observed during the construction and for two years thereafter. The present paper compares and contrasts the observed behavior with the

behavior assumed and predicted by the current design method, and discusses subjects which require due consideration in the design of reinforced soil walls in future.

## 2 SPECIFICATIONS OF TEST WALL

To design the test wall shown in Figure 1, its design conditions were set based on the previous test results and so on. The banking material was sandy soil, and its internal friction angle  $\phi_s'$ , cohesion  $c'$ , and unit weight  $\gamma_s$  were 29°, 0 kN/m<sup>2</sup>, and 18.6 kN/m<sup>3</sup>, respectively. The dimensions of the concrete blocks to be used were 50 cm in height, 100 cm in width, and 35 cm in depth, and their hollows were to be filled with crushed stone. Their unit weight was 21.1 kN/m<sup>3</sup>. A zone of crushed stone about 30 cm thick was to be provided at the back of the concrete-block facing as a drainage, and its internal friction angle  $\phi_g'$  and unit weight  $\gamma_g$  were 45° and 19.6 kN/m<sup>3</sup>.

The internal friction angles between materials were set as follows:  $\delta_1=(2/3)\phi=19^\circ$  between banking soil and blocks,  $\delta_2=0$  between reinforced soil mass and banked soil behind,  $\delta_3=(2/3)\phi_g=30^\circ$  and  $\delta_3=(1/2)\phi_g=22^\circ$  (two cases) between blocks,  $\delta_{bf}=\delta_3$  between blocks and concrete foundation, and  $\delta_{sg}=\phi_s'=29^\circ$  between banking soil and reinforcements. Reinforcing geosynthetic to be used was geogrid (Tensar SR-55), of which the design tensile strength  $T_d$  was 29.4 kN/m.

To determine the arrangement of the reinforcements, comparative design was performed by using the following design methods: PWRI method (Onodera et al. 1992), Geogrid Research Board (GRB) method (Yamanouchi & Fukuda 1993), Leshchinsky method (1993), and monolithic wall method which assumes that short reinforcements and a facing unite with each other to exert the soil retaining effect. Figure 2 shows the stability analysis mode by the PWRI method. For the stability analysis under the seismic condition, the horizontal seismic coefficient  $k_h$  of 0.10 was assumed.

Figure 3 summarizes the specifications of reinforcements found by the comparative calculation. The focus of this study was put on the verification of the reinforcing mechanism by

Figure 1. Cross-section and reinforcement pattern of test wall.

Figure 2. Failure mode of PWRI's design method.

Figure 3. Required reinforcement length and steps.

constructing the test wall into a critical state, the calculation results taken into account. Namely, the test wall was based on the ordinary condition, the number of reinforcement layers was set at 11 on reference to the results by the Leshchinsky method, and the length of reinforcements  $L$  was set at 6.0 m (see Figure 1). To prevent the blocks not connected to main reinforcements from coming out of the wall surface, short reinforcements of 1.0 m-long were connected to them. The wall given these conditions and specifications, its stability was calculated by the PWRI's method as shown in Table 1. The overall stability  $F_s$  by the slip circular method was found to be 1.055, a state near the critical condition. Under the seismic condition of  $k_h=0.10$ , it ( $F_s$ ) was found to be 0.917, an unstable state.

Table 1. Stabilities of test wall calculated by PWRI method.

Analysis mode	Ordinary condition	Seismic condition ( $k_h=0.10$ )
Overall stability (Circular slip)	$F_s=1.055 < 1.2^*$ NO	$F_s=0.917 < 1.0^*$ NO
Direct sliding	$F_{sd}=2.142 > 1.5^*$ OK	$F_{sd}=1.844 > 1.2^*$ OK
Overturning (Eccentricity)	$ e =0.690 < L/6^*$ OK	$ e =0.566 < L/3^*$ OK
Bearing capacity	$q_{max}=252 < q_a^*$ NO	$q_{max}=264 < q_a^*$ NO

$L$ : length of main reinforcement, (=6.0m).

$q_a$ : allowable bearing capacity, (=49kN/m<sup>2</sup>) estimated from  $N$ -value (6) after Nakajima et al. 1996.

\*: design criteria.

Photo 1. Overview of test wall (June 1997).

### 3 FIELD MEASUREMENT OF TEST WALL

The long-term observation of the test wall has been conducted with the measuring instruments shown in Figure 1 for about 800 days including the construction period. The wall experienced the heavy rainfall of 81.5 mm/d ( $t=189$  d) and the of 191.5 mm/d ( $t=559$  d). The wall was also exposed to three small to medium earthquakes, but maintained its stability as Photo. 1.

#### 3.1 Horizontal Displacements of Test Wall

Figure 4 shows the displacements of the wall surface measured during the observation period. The maximum horizontal displacement was approximately 100 mm, and the wall surface took a bulgy shape, the center portion in height most prominent. The displacements immediately after the construction were small enough.

Since the overhanging of wall surfaces mars their scenes and offends our sense of security, it would be preferable to give the wall surfaces small backward leans in their construction. The deformation of the wall slowed down considerably and settled after some 800 days passed in the observation.

Figure 4. Horizontal displacement of test wall.

### 3.2 Earth Pressure on Wall Facing and Subgrade Reaction

Figure 5 shows the distribution of earth pressure on the back of the facing during and after the construction of the wall. The measured values were larger in the upper zone and smaller in the lower zone than the values calculated on the basis of Coulomb's earth-pressure theory.

As shown in Figure 6, the subgrade reactions were equal to or smaller than the overburden pressure in the area distant from the facing, and exceeded largely the pressure by the dead weight of the concrete blocks at the bottom of the facing. This does not

Figure 5. Earth pressure distribution on back of facing.

Figure 6. Distribution of subgrade reaction at bottom.

agree with the assumption, made in the design manual of the PWRI regarding the external stability analysis for the bearing capacity of foundation grounds, that the reinforced zone of an embankment behaves as a rigid body and the distribution of the subgrade reaction takes a trapezoidal shape, the reaction decreasing linearly from the facing toward the rear.

### 3.3 Strain of Reinforcements

Figure 7 shows the distribution of the strain of the reinforcements measured by foil strain gauges bonded on them. The maximum strain of each reinforcement was observed in the immediate vicinity of the facing. This distribution pattern is typical of walls with high-rigidity facings. At the completion of the test wall, the maximum strains were approximately 1%, 8.8 kN/m in terms of tensile force, which were smaller than the design strength of 29.4 kN/m. The maximum strains of the additional short reinforcements were at the same level as those of the main reinforcements.

Figure 7. Distribution of strain of reinforcements.

## 4 DISCUSSION ON STABILITY OF TEST WALL

### 4.1 External Stability Analysis

In the PWRI design method, its external stability for the bearing capacity of the foundation ground is examined by checking whether the subgrade reaction is contained within the bearing capacity or not. The top layer of the foundation ground of the test wall was a filled Kanto-loam layer 2.15 m thick. As its  $N$ -value was about 6, its bearing capacity was estimated at 49 kN/m<sup>2</sup> or so. On the other hand, the maximum subgrade reaction was estimated at 252 kN/m<sup>2</sup> under the ordinary condition and 264 kN/m<sup>2</sup> under the seismic condition ( $k_s=0.10$ ), suggesting the instability of the test wall. Besides, the subgrade reactions observed were about 261 kN/m<sup>2</sup> under the facing and about 117 kN/m<sup>2</sup> under the embankment. Thus, it can not be explained why the test wall has maintained its stability.

On the other hand, since almost the whole test wall consisted of soil and it could basically be regarded as an embankment, another stability analysis was performed by using a circular slip surface which runs into the foundation ground. The soil-filling history of the ground taken into account, its strength parameters in the original state and in the state immediately before the construction of the test wall were estimated. With the safety factor  $F$ , of 1.027 thus found, the stability of the test wall could be explained (Nakajima et al., 1996).

Thus, it was suggested that the external stability analysis for the bearing capacity of foundation grounds can basically and advantageously be replaced by the circular slip stability analysis using slip surfaces which run into the foundation grounds.

#### 4.2 Stability Analysis under Seismic Conditions

The test wall underwent three small to medium earthquakes so far in 1996: the first was of  $M=4.7$  and estimated acceleration at Tsukuba 14 gals on August 16; the second,  $M=6.2$  and 26gals on September 11; and the third,  $M=5.4$  and 45 gals on December 21. The stability analyses of the wall under the third earthquakes (45 gals,  $k_s=0.05$ ) turned out as follows: the safety factors against slip circle  $F_s=0.989<1.0$ ; the safety factors against direct sliding  $F_{sd}=2.326>1.2$ ; and the stabilities against overturning  $e=0.373<L/3$ , indicating the instability against slip circle in particular. Nevertheless, the wall maintained its stability during the earthquakes. Accordingly, it would also be necessary to review the seismic-stability analysis method of the PWRI design method.

## 5 CONCLUSIONS

Based on the long-term observation results of the full-scale reinforced test wall 8-meter high, the behavior of the test wall was compared and contrasted with that assumed and predicted by the PWRI's design method, to identify future subjects toward the establishment of a more rational design method. Main findings are as follows:

1. The arrangement of the reinforcements of the test wall was determined to construct the wall into a critical state under the ordinary condition, critical when evaluated by the PWRI design method. During the some 800 days observation, the test wall was exposed to heavy rains and small to medium earthquakes. Although the test wall, given such specifications, was supposed to lose its stability, it maintained its stability. Accordingly, it is necessary to establish a more

rational design method in future.

2. The PWRI design method is built on the concept of limit equilibrium. However, the following inconsistencies were observed: (i) the measured earth pressures on the back of the test wall's facing in the lower zone were smaller than the active earth pressures estimated by the Coulomb's earth-pressure theory, (ii) the measured values of the tensile force on the reinforcements were smaller than the values estimated in designing the test wall, and (iii) the distribution of the subgrade reaction did not take the trapezoidal shape which is assumed of concrete retaining walls, and the design and measured values of the subgrade reaction exceeded the bearing capacity of the foundation ground.
3. The bearing capacity, one factor in analyzing the external stability of walls, need not be examined, if their external stability is examined by the circular slip stability analysis using slip surfaces which run into their foundation grounds.

# Multi-Anchored Soil Retaining Walls with Geosynthetic Loop Anchors.

H. Brandl

Professor, Institute for Geotechnical Engineering, Technical University, Vienna Austria

**ABSTRACT:** The paper deals with reinforced modular block walls using loop anchors. The bearing behavior of such structures is the deadman principle, but there exists simultaneously a composite effect between modular units, straps, and soil. Accordingly, several hypotheses of calculation are presented, based on model tests and comprehensive in-situ measurements on construction sites since the year 1977. Recommendations for on-site installation, filling, and backfilling of the structure are also given.

**KEYWORDS:** Retaining walls, Slope stabilization, Geo „Others“, Design by Function

## 1 SCHEME OF LOOP ANCHORED WALL SYSTEMS

Figure 1. illustrates the scheme of a loop anchored wall system. Generally, the front side of the wall consists of L-shaped elements (modular prefabricated reinforced concrete units) arranged in displaced position to each other and connected by tension straps (loop anchors) to anchor elements (e.g. half tubes) on the back of the wall. Similarly, for embankments both facings can be constructed of L-shaped elements (e.g. Figure 3).

The core of the wall consists of soil being placed in layers and compacted. The prefabricated elements and the loop anchors prevent the soil from giving way. Thus the fill material increases the bearing capacity, and the whole structure acts as a composite body - similar to crib walls but more flexible. Accordingly, the effect of the loops is primarily not a soil reinforcement, and friction is merely of secondary importance.

In order to avoid long term corrosion problems and to provide a flexible behavior of the retaining wall, geosynthetics have been preferred since about 15 years as tie-elements: High modulus polyester has proved especially suitable. Aramid is relatively expensive but exhibits less strain and creep. Consequently, a combination of polyester and aramid yarns is especially useful in critical cases. Special loops consist of geocomposites comprising a polyester tie element with a strip drain, and this core being wrapped by a non-woven geotextile. These composite loops have proved suitable for low-permeable fill material of a high water content.

The retaining structure with anchor loops is not only used for retaining walls but also for

- Noise protection walls.
- Bridge abutments.
- Protective structures against avalanches, mud flows.
- Quay walls and bank protection.
- Increase of the height of embankment dams.

## 2 MODEL TESTS AND FIELD MEASUREMENTS

Small scale tests (1:20) in the laboratory were combined with 1:1 - field measurements on several construction sites. The maximum wall height was 21 m.

From Figure 2 it can be seen that overturning is the dominating mode of the global wall displacement. But in detail the structure does not tilt like an ideal monolith: There are differential movements among the layers, thus indicating internal shear deformations. The layers are pushed outside in steps, remaining rather horizontal. With

Figure 2. Laboratory test No.2. Scale 1:20, hence wall height  $H = 21,8\text{m}$  in nature.  $1\text{ N/cm}^2 = 10\text{ kPa}$

increasing surcharge load, structural failure begins on top of the wall where the composite behavior of the wall is not yet as strong as in greater depth. The bond effect among backfill, loops and modular elements increases with the overburden pressure. This could be proven especially clearly by cutting some of the loops. In this case a rearrangement of internal forces took place, thus avoiding failure to a high extent. Collapse of the wall is announced by large movements and does not occur suddenly.

This bearing deformation behavior is characteristic of multi-anchored soil retaining walls with geosynthetic loop anchors. It could be found not only in model tests but also

on numerous construction sites. Figure 3 shows a loop anchored retaining wall as a catch-system for avalanches and mud flows which threatened a highway and railroad on toe of a steeply inclined slope. Figure 4 illustrates the base pressure during the construction period and its long-term behavior. The stress distribution exhibits a maximum near the inner pressure cell which is caused by the embankment-like cross section of the retaining system. This differs widely from the behavior of gravity walls.

The tensile forces in the loops are plotted in Figure 5 showing a typical long-term decrease within the first years after wall completion. Four strain gauges were mounted on

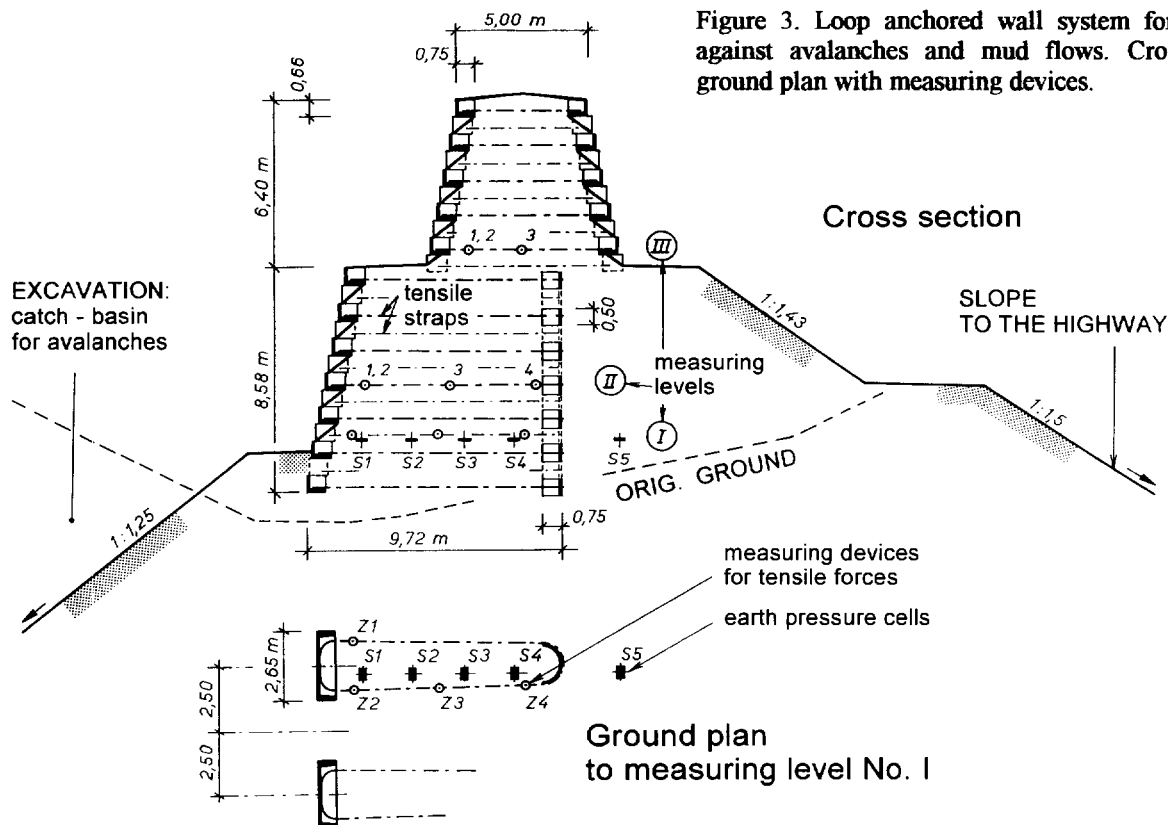

Figure 3. Loop anchored wall system for a catch-basin against avalanches and mud flows. Cross section and ground plan with measuring devices.

Figure 4. Measured base pressures versus wall height and long-term behavior (to Figure 3).

Figure 5. Measured tensile forces versus wall height and long-term behavior (to Figure 3).

each loop. The measured tensile forces are smaller than calculated, especially in the lower part of the retaining system. After reaching a certain overburden, additional wall heights cause less increase in tensile force than could be expected by the dead weight of  $\gamma \cdot z$  and  $\sigma_h = K \cdot \gamma \cdot z$ . This is caused by a variable coefficient of lateral earth pressure. Similar to reinforced soil,  $K$  varies with depth from  $K_0$  at the top, to  $K_a$  below several meters depth. Furthermore, low tensile forces can be explained by arching or silo pressure conditions in the fill and by an increasing modulus of the fill. A gradual increase of the bond effect between soil, loops, and anchor elements plays an additional role. Loops generally experience stress reduction, as the soil progressively takes over a higher portion of load. Creeping of the loops could be widely excluded, because some sections of the retaining system had loops of coated steel - and the results were fairly

similar. The difference between theoretical and actual tensile forces represents an additional safety factor compared to conventional calculation.

### 3 DESIGN AND CALCULATION

In order to develop a practicable design method, several hypotheses and theoretical assumptions were compared. Their accuracy and limits of application had to be verified on the basis of small scale tests, field experiments, in-situ measurements and site experience.

For design, external, internal, and local stability analyses have to be performed. The external stability comprises base sliding, overturning, and ground failure. It is calculated similarly to conventional retaining walls, the structure being considered a „quasi-monolith“, but with a statically

Figure 6. Internal failure mechanisms of loop anchored walls. Left: Block theory (assuming three slices). Right: Cofferdam scheme.

reduced, fictive width of the wall. According to the deformability of the wall, the active earth pressure can be assumed at the back of the wall and an angle of wall friction,  $\delta = \phi$ . The resultant of all acting forces should run generally within the core of the cross section. Commonly, block-like overturning is not a relevant failure mechanism.

The internal stability comprises three failure mechanisms: pull-out, tensile overstress, internal sliding (including possible slope failure). Furthermore, the local stability of the segmental wall units has to be proven: facing connection and bulging (shear transfer failure). The calculation can, above all, be performed similarly to that of cellular cofferdams, assuming a lateral earth pressure between the active limit value and the earth pressure at rest, depending on the stretchability of the loops.

For assessing the tensile forces,  $T$ , in the loops two boundary analyses have proved suitable:

$$T = K_{ah} \cdot \sigma_1 \cdot \Delta A \quad \text{.....for } \delta = \phi$$

$$T = K_a \cdot \gamma_f \cdot z \cdot \Delta A \quad \text{.....for } \delta = 0$$

whereby

$K_a$  = active earth pressure coefficient

$z$  = depth of the loop beneath top of wall

$\gamma_f$  = unit weight of the fill material

$\sigma_1$  = front edge pressure (fictious value of „quasi-monolith“)

$\Delta A$  = portion of the wall area referring to one loop

$\delta$  = angle of wall friction

$\phi$  = friction angle of fill material.

The maximum calculated  $T$  should be considered the design value.

The influence of surcharge loads on the back or directly on the crown of the wall can be assessed by conventional calculation methods. Traffic loads are idealized by static replacement loads. Contrary to reinforced soil, a friction loss along the tie elements caused by dynamic loads is not relevant.

Site observations have disclosed that the internal stability of loop anchored walls is actually higher than assessed by conventional calculation. This refers especially to internal

Figure 7. Idealization of soil (fill material) and structural members of a loop anchor wall system as a truss like retaining structure.

E = earth pressure

C = soil in compression

T = anchor loops acting in tension

sliding of slender structures. For a slenderness of  $B/H \geq 0.6$ , Janbu's block method has proved suitable. The methods of Kranz and others provide by far too small safety factors. Sliding analyses based on block theories (e.g. Figure 6/left) underestimate the actual safety factor of very slender structures. Numerous site observations have shown that in such cases values of only  $FS_{calc.} = 0.4$  to  $0.8$  are calculated, whereas the walls have been exhibiting a fully stable behavior since 10 years and more (checked by long term monitoring). Consequently, such slender structures should be designed similar to cofferdams with multiple anchorage (Figure 6/right).

Another calculation method idealizes the loop anchor wall system as a truss-like structure. According to Figure 7, the loops are the truss members acting in tension, and the soil between the loops and modular units represents the truss members in compression. This truss-like behavior increases with compaction degree of the fill material. A high compressive strength and dilatant properties of the soil enable it to interact with the loops and the anchor elements on the front and back side of the retaining structure. Vertical, possibly prestressed anchors through the prefabricated anchor elements at the back of the wall would provide further improvement.

Experience has shown that loop anchored walls hardly fail on a plane passing through the toe. Commonly, the critical failure plane runs through the face of the structure at a point  $1/4 H$  to  $1/3 H$  above the toe ( $H$  = wall height). In case of high surcharge loads, failure may occur at even higher points.

If inextensible (metallic) loops are used, the failure of the wall can occur rather rapidly according to potential overstress of adjacent loops - like a zip effect. Contrary to

Figure 8. Forces on the facing element of a loop anchor wall system and force polygon for the soil fill on the concrete element.

$T_{\text{exist}}$  = existing tension force  
 $G, G_G$  = dead weights of soil and concrete element

that, overstressing of extensible loops (polymeric anchors) first of all leads to creep and only limited load shedding. The deformation increases, thus indicating in time the necessity of strengthening the structure.

The connection between the tie elements and the facing of a permanent soil reinforcement wall is a critical part of the design. Contrary to that, anchor loops allow a full strength solution without requiring special starter elements embedded in the modular facing. Figure 8 illustrates the load transfer in a typical modular structure. Vertical wall friction can be assumed  $\delta_v = \emptyset$ , and horizontal friction  $\delta_h = 0.75 \emptyset$ .

Loop anchored walls require smaller widths than conventional reinforced soil structures. This reduces the slope cut, which is especially important if the retaining structure has to be placed into unstable terrain. No special footing is necessary except on soft soil.

The structure allows adaptation to various site conditions, geometries, and varying loads, and it behaves fairly insensitive to differential settlement, to dynamic loads, and to earthquakes. Furthermore, full-face draining and intensive greenery planting are possible.

#### 4 LONG TERM BEHAVIOR

Regarding the long term behavior of loop anchored wall systems, two factors have to be considered before all: Creeping and effect of hydrolysis on polyester.

Monitoring of loop anchored wall systems has disclosed that creeping can be widely neglected. Figure 9 shows the tensile strength-extension characteristics of various loops. At a working stress level of about  $\leq 30\%$  for the initial ultimate tensile strength of geosynthetic straps, long term creep elongation could be expected less than 1% occurring

Figure 9. Tensile strength - elongation characteristics of various loops. Draplamat is a coated steel strap.

after construction. The (allowable design) extension is likely to be  $< 5\%$  in total for polyester and  $< 1\%$  for aramid and draplamat.

There is a significant difference between the load-deflection characteristics of a loop and a reinforcing strip. Contrary to laboratory tests on free tie elements, creeping gradually decreases on the site where the loops are embedded in soil. This effect increases with composite effect, hence with compaction degree and friction/adhesion. Changes in ambient operating temperature between 10 to 40 ° C practically do not alter the creep characteristics.

Draplamat consists of coated steel tendons and is cheaper than aramid. Polyaramid loops can exhibit even greater shear strength and lower extension than steel straps (Figure 9). Such tie elements are sometimes preferred for very high retaining structures and high loads. Mostly, the ultimate tensile strength of draplamat is similar to that of aramid, i.e.  $\sigma_T = 2600 \text{ N/mm}^2$ . The strain at failure is  $\epsilon_f = 3\%$  and 2 to 4% respectively. Commonly used polyester straps exhibit  $\sigma_T = 1050 \text{ to } 1250 \text{ N/mm}^2$  and  $\epsilon_f = 10 \text{ to } 14\%$ .

Composite loops consisting of aramid and polyester have proved suitable for structures in unstable slopes and seismic areas. Overstressing is indicated by a period of great deformation which is succeeded by strain hardening. This ductile behavior enables a timely strengthening of the structure before failure might occur. Consequently, such retaining systems are especially suitable for designing by the observational method.

When polyester fibres are directly exposed over longer periods of time at  $\text{pH} > 11$ , the presence of water (exactly OH ions) can have a detrimental and destructive effect, resulting in chain scission, reduced molecular weight and strength loss. Consequently, a coating of polyester loops is

Figure 10. Loop anchored wall to reconstruct a road in a steep slope after landslide had occurred.

sometimes required. Generally, hydrolysis is not relevant if well engineered materials are used for loop anchored wall systems.

## 5 CONSTRUCTION PRINCIPLES

Commonly, indigenous and waste fill materials can be used for loop anchored wall systems. This provides significant savings in construction costs. The maximum grain size of the fill should not exceed 2/3 of the thickness of a layer. Cohesive or cohesive-frictional material provides more stable structures than purely frictional fill. On the other hand, sufficient drainage is essential if the retaining structure supports a slope. In such cases the grains finer than 0,06 mm should be limited to 15%. Furthermore, this value avoids frost damages within the composite structure. Sandwich filling, with alternating cohesive and non-cohesive layers has also proved suitable.

Usually, the fill material and the backfill of the structure should be compacted to  $D_{pr} = 97$  to 100% of standard Proctor density. The higher value is for widely grained fill material and a distance of more than 1 m behind the back of the wall. Near the front face, a lower compaction is preferred (about  $D_{pr} = 92\%$ ) to avoid local damage and to facilitate the planting of greenery. Compaction should begin about 1 m behind the face elements and proceed toward the backside of the wall. Thus, a slight prestressing of the loops is obtained, and the front blocks remain in their position. The back members of the deadman anchorage have to be well embedded in densely compacted soil. The front zone shall be compacted as last part.

During wall construction, the anchor loops must be protected from local overstress (e.g. passing of heavy vehicles or site equipment). This can be performed by a cover of sand, by a stable coating, or by excavating small trenches where the loops are placed. Polyester loops should be isolated from direct contact with concrete facing elements. Accordingly, a coating is recommended if polyester loops are installed. Commonly, robust loop coatings of polyethylene or PVC are used. Coating of the modular concrete elements has also proved suitable.

The concrete elements do not require a special interlock, e.g. by slotting dowels into preformed locating holes. Experience has shown that an accurate positioning of successive layers of blocks can be fully obtained simply by a precise installation of the elements. But bituminous soft-fibrous boards should be placed between the concrete elements to avoid local overstressing and edge cracking. Furthermore, such interlayers improve the flexible behavior of the structure, and they may compensate possible installation deficiencies. Flexible interlayers, covering the whole contact zone, have proved more suitable than small boards.

Commonly, loop anchored wall systems are stepped back at 5 to 15 cm per layer to provide an attractive face inclination and to improve planting conditions. Furthermore, facing elements can be colored to give specific aesthetic effects. Small unit sizes allow an adaption to various geometry, including stepped foundations and wall heights and varying length of anchor loops (e.g. Figure 10).

The main advantages of the loop anchor wall system are:

- Modular standards of the pre-fabricated elements.
- The assembling of the wall requires only a light crane; no special technical knowledge is required.
- Short construction period.
- The excavated soil can be used as fill material in most cases.
- No footings (except on soft subsoil).
- Well adaptable to locally differing conditions (geometry, soil, loads, etc.).
- Rather insensitive to differential settlements, to dynamic and cyclic loads, and to earthquakes.
- No sudden rupture in case of overloading, but gradually increasing failure indications, due to the great plastic reserves.
- Excellent drainage of the fill and backfill.
- Sufficient place for plant growth (hence also „green walls“).

**ABSTRACT:** Design of mechanically stabilized earth (MSE) walls includes internal and external stability analyses. External stability, which includes sliding, overturning, bearing capacity, global stability, and compound stability analyses, generally governs the required length of reinforcement and the wall embedment depth. This paper discusses the components of external stability design of MSE walls, the focus being on bearing capacity and the impact of non-generalized site conditions on reinforcement lengths and embedment depths required to satisfy bearing capacity and sliding design criteria. Results indicate that the minimum L/H ratios of 0.6 or 0.7 taken for granted by many designers are not satisfactory for non-generalized site conditions. This paper is directed towards members of the geosynthetics community who design and construct MSE walls.

**KEYWORDS:** Bearing capacity, Segmental retaining walls, Geosynthetic reinforcement, Foundations, Embedment depth.

## 1 INTRODUCTION

Design and construction of mechanically stabilized earth (MSE) walls has dramatically increased with the advent of segmental retaining wall (SRW), or modular block, units. Design of MSE walls is routinely completed by many engineers (e.g., civil, structural, geotechnical) with varying technical expertise. The need to fully understand the concepts of MSE wall design appears to have diminished with the widespread availability of computer software and design charts provided by manufacturers, suppliers of geosynthetic reinforcement and SRW units, and others.

Design of MSE walls includes internal and external stability analyses. Most designers find that completing the internal stability design, which tends to focus on the economic placement of the geosynthetic reinforcement, is straightforward. For very generalized site conditions, such as a wall with horizontal backslopes and front slopes, general design rules-of-thumb may be satisfactory for determining the reinforcement length. For non-generalized site conditions, however, such as a wall with a front slope and/or backslope, external stability is likely to govern the design of the wall, especially with respect to required reinforcement lengths and wall embedment depth.

External stability includes: sliding, overturning, bearing capacity, global stability, and compound stability. Many designers do not have all of the tools required to complete all of the components of the external stability analysis for non-generalized site conditions. Most current MSE wall design software products do not address all of the components of external stability design for non-generalized site conditions.

This paper discusses the components of external stability design of MSE walls. The focus of the paper is on bearing capacity and the impact of non-generalized site conditions on required reinforcement lengths and wall embedment depths.

The purpose of the paper is threefold: (i) to rekindle a classical geotechnical engineering oriented approach to the design of MSE walls with respect to external stability; (ii) to highlight the significance of non-generalized site conditions on bearing capacities for MSE wall system foundations; and (iii) to disseminate findings regarding the ultimate bearing capacity of MSE wall system foundations, for both generalized and non-generalized site conditions.

## 2 CURRENT DESIGN PRACTICE

### 2.1 Design Methodology

Several design guides for MSE wall systems are available. This discussion will focus on two of the generic design guides which are available: the National Concrete Masonry Association (NCMA) design manual (1996); and the Federal Highway Administration (FHWA) design guidelines (Elias and Christopher 1997). The general design approach for both methods consists of two interrelated but separate procedures: design for internal stability; and design for external stability. A generic MSE wall cross-section is presented in Figure 1.

Figure 1. Typical geosynthetic-reinforced MSE wall cross-section (after NCMA, 1997).

### 2.1.1 Internal Stability

Internal stability refers to the interactions between the soil, facing units, and geosynthetic reinforcement in the reinforced soil zone. The spacing and tensile strength of the reinforcing layers are determined in this analysis, along with a check of the connection strength between the facing units and the reinforcement.

### 2.1.2 External Stability

The reinforced soil zone is considered to act as a composite gravity mass for the purposes of external stability analyses other than composite stability analyses. Forces acting on this mass include: the weights of the soil and facing units; the lateral earth pressure of the retained backfill; and any surcharge loads. Sliding, bearing capacity, overturning, settlement, compound stability, and global stability are possible failure modes that must be considered.

### 2.1.3 Empirical Design Criteria

The base width,  $L$ , of the reinforced soil zone is usually established from external stability analyses. In addition, certain minimum values for  $L$  have been established from experience. The NCMA guidelines recommend that  $L$  shall not be less than  $0.6H$  regardless of the results of stability calculations. FHWA guidelines recommend a minimum  $L$  of  $0.7H$ .

To insure a safe allowable bearing capacity is achieved, minimum wall embedment depths,  $H_{emb}$ , have been established for the bottom of the wall below finished grade. These values vary from  $H/20$  for walls with a horizontal slope in front of the wall to  $H/5$  for slopes of 3 horizontal to 2 vertical (3H:2V). A minimum wall embedment depth of 0.5 m, except for structures founded on rock, where no

embedment of the wall is required, is stated in the FHWA guidelines. NCMA guidelines require a minimum wall embedment of 0.15 m.

## 2.2 Lateral Earth Pressures

Lateral earth pressures are calculated differently in the two design procedures. With the NCMA guidelines, lateral earth pressures for both internal and external analyses are based on Coulomb earth pressure theory, which can account for the inclination of the wall facing units, the backslope angle, wall friction, and MSE mass-retained backfill friction. The vertical component of earth pressure is neglected in NCMA internal and external stability calculations.

Using the FHWA guidelines, lateral earth pressures are based on Coulomb theory for external stability and Rankine theory for internal stability. Face batters are ignored for batters less than or equal to 10 degrees from the vertical. The earth pressure direction is considered to be parallel to the backslope angle for external stability. A horizontal earth pressure direction is used for internal stability, with and without sloping backfills.

## 2.3 Bearing Capacity

As this paper is primarily concerned with bearing capacity determinations, the analysis methods for sliding, overturning, settlement, compound stability, and global stability are not discussed herein; a complete discussion of these analyses is contained in the literature (Elias and Christopher 1997; Holtz et al. 1997; Simac et al. 1993; and Berg et al. 1989).

Conventional bearing capacity analyses are carried out assuming that the reinforced soil mass acts as a continuous strip footing of width,  $L$ . The vertical stress on the base of the footing should be less than the allowable bearing capacity of the foundation soil. The vertical stress is assumed to act uniformly over a footing of effective width,  $B'$ , which is determined from

$$B' = L - 2e \quad (1)$$

where  $e$  is the eccentricity of the resultant vertical force on the base. The ultimate bearing capacity,  $q_{ult}$ , may be determined from the Terzaghi bearing capacity equation using the Vesic bearing capacity factors:

$$q_{ult} = c N_c + q N_q + 0.5 \gamma B' N_\gamma \quad (2)$$

Allowable bearing capacity,  $q_{all}$ , is determined by dividing the ultimate bearing capacity by an appropriate factor of safety, which is typically 2.0 for MSE wall systems (NCMA, 1997; U.S. Army Corps of Engineers, 1989 and 1990) to 2.5 (Elias and Christopher, 1997):

$$q_{all} = q_{ult} / FS \quad (3)$$

Design procedures in the FHWA guidelines require that the eccentricity,  $e$ , not exceed  $L/6$ , and if it does, the reinforcement length must be increased. A limitation on eccentricity is not required in the NCMA procedures.

Both the NCMA and FHWA design procedures consider only the vertical components of foundation loads in ultimate bearing capacity calculations. Thus, effects of the inclination of the resultant foundation load, which typically reduce the ultimate bearing capacity of a foundation, are neglected.

The NCMA and FHWA design procedures do not address the presence of a ground slope in front of the wall, except with respect to general guidance and recommendations of minimum embedment depths for typical ground slopes in front of the wall. The ultimate bearing capacity of a wall with a front slope is reduced by an amount proportional to the angle  $\beta$  of the front slope, assuming no bench in front of the wall. A ground slope bearing capacity factor is included in the bearing capacity equation (Bowles, 1996). Equation (2), with  $\beta$  measured counterclockwise in degrees from the horizontal, is modified to:

$$q_{ult} = c N_c g_c + q N_q g_q + 0.5 \gamma B' N_\gamma g_\gamma \quad (4)$$

where:

$$g_c = 1.0 - \beta/147 \quad (5)$$

and

$$g_q = g_\gamma = (1 - 0.5 \tan \beta)^5 \quad (6)$$

Assuming a cohesionless soil and all other conditions equal, a 3H:1V front slope reduces the ultimate bearing capacity by approximately 60 percent; a 2.5H:1V front slope reduces the ultimate bearing capacity by approximately 68 percent; and a 2H:1V front slope reduces the ultimate bearing capacity by approximately 76 percent. These are staggering reductions in ultimate bearing capacity values, which are typically not directly accounted for in most MSE wall design software.

Bowles (1996) also presents a procedure for determining the ultimate bearing capacity of foundations on slopes, with and without a bench in front of the foundation, independent of the application of a ground slope bearing capacity factor to the general bearing capacity equation.

A goal of this paper is to verify the NCMA and FHWA minimum embedment depth and reinforcement length guidelines and to enlighten the reader as to a more thorough understanding of the impacts of various front slope and backslope combinations on the ultimate bearing capacity of MSE wall systems.

### 3 GEOTECHNICAL SITE CONDITIONS

#### 3.1 Generalized Site Conditions

MSE wall systems are often designed for generalized sites conditions, such as: a horizontal front slope; a nominal surcharge loading; adequate foundation soil shear strengths; and a depth to groundwater which does impact the bearing capacity of the foundation soils. For these generalized site conditions, the guidance and recommendations regarding embedment depths and L/H ratios may well be applicable. In many instances however, especially of late, many MSE wall systems are being carried to extreme heights in locations where the generalized site conditions discussed above do not exist. Such conditions are referred to in this paper as non-generalized site conditions.

#### 3.2 Non-Generalized Site Conditions

Many MSE walls are being designed and constructed with backslopes and ground slopes in front of the wall which can vary from 3H:1V to 1.5H:1V. In addition, foundation soil shear strengths may be lower than is typically assumed for generalized site conditions (Meyers et al. 1997). These non-generalized site conditions obviously result in lower ultimate bearing capacities than would be determined for the generalized site conditions. In addition, compound stability may govern the design in some instances. As such, the general guidance and recommendations regarding embedment depths and L/H ratios may not provide sufficient safety factors against failure.

## 4 METHODOLOGY

### 4.1 General

A spreadsheet was developed to analyze the sliding stability and ultimate bearing capacity of MSE wall foundations for the generalized and non-generalized site condition combinations presented in Table 1. A cohesionless soil with an angle of internal friction equal to 30 degrees and having a unit weight of 19.6 kN/m<sup>3</sup> for the wall fill, retained backfill, and foundation soil were assumed for these analyses. Only the NCMA methodology was used for the analyses. The NCMA bearing capacity equations were modified to include a ground slope factor, assuming no bench in front of the wall. Analyses include determination of bearing capacity factors of safety and L/H ratios.

### 4.2 L/H Ratio Determinations

The minimum length of geosynthetic reinforcement required to just meet a factor of safety equal to 1.5 against sliding failure was determined for various wall height, surcharge,

**Table 1. Combinations Analyzed For Ultimate Bearing Capacity of MSE Walls.**

Case	Front Slope	Back Slope	Surcharge (kN/m <sup>2</sup> )	Embedment Ratio Denominator <sup>a</sup>
1	0	0	0	20, 10, 7, 5
2	0	3H:1V	0	20, 10, 7, 5
3	0	2H:1V	0	20, 10, 7, 5
4	0	0	12	20, 10, 7, 5
5	3H:1V	0	0	20, 10, 7, 5
6	3H:1V	3H:1V	0	20, 10, 7, 5
7	3H:1V	2H:1V	0	20, 10, 7, 5
8	3H:1V	0	12	20, 10, 7, 5
9	2H:1V	0	0	20, 10, 7, 5
10	2H:1V	3H:1V	0	20, 10, 7, 5
11	2H:1V	2H:1V	0	20, 10, 7, 5
12	2H:1V	0	12	20, 10, 7, 5

<sup>a</sup>Wall embedment depth equal to H/Embedment Ratio Denominator (e.g.  $H_{emb} = H/5$ ).

and backslope combinations. The critical sliding plane was taken as the reinforced fill-foundation soil interface (i.e., at depth equal to H). This required reinforcement length, or a minimum reinforcement length of 0.6H, whichever was greater, was then used in the bearing capacity computations to determine the factor of safety against bearing capacity failure for various wall heights, backslope, front slope, surcharge, and wall embedment depths. A minimum embedment depth of 0.15 m was used. A bench in front of the wall was not included in the analyses.

Minimum length of geosynthetic reinforcement required to just meet a factor of safety equal to 2.0 against bearing capacity failure were determined for various wall heights, backslope, front slope, surcharge, and wall embedment depths. The minimum L/H ratio for the various backslope, front slope, embedment depth, and surcharge combinations was, thus, defined as the longer of the lengths required to: (i) meet a factor of safety of 2.0 against bearing capacity failure; (ii) meet a factor of safety of 1.5 against sliding failure; and (iii) meet a minimum L/H ratio of 0.6.

## 5 RESULTS

### 5.1 Bearing Capacity Factors of Safety Determinations

Typical bearing capacity factor of safety results are presented in Figure 2, which plots the bearing capacity factor of safety against the foundation embedment depth (as a ratio of the wall height) for several different front slopes of a typical MSE wall condition assuming a horizontal backslope and a surcharge of 12 kN/m<sup>2</sup>. As is to be expected, for a horizontal front slope, the factors of safety are well above 2.0 and indicate that a minimum embedment ratio of H/20 or 0.15 m, which ever is greater, should be satisfactory with respect to the sliding and bearing capacity components of external stability, for walls varying in height from 1.5 to 12 m.

The bearing capacity factors of safety are reduced dramatically when the only variable modified is the front slope, which was increased from horizontal to 3H:1V. A minimum embedment ratio of H/20 or 0.15 m is still satisfactory for the wall height and embedment ratio combinations analyzed. However, with the factor of safety approaching 2.0 for the shorter embedment depths, the designer should have a higher degree of confidence in the definition of the design parameters used in the sliding and bearing capacity analyses.

For a 2H:1V front slope, a factor of safety of 2.0 is not attained for most wall height and embedment depth ratio combinations. Either a greater geosynthetic reinforcement length is required or an increased embedment depth ratio is required. Since an embedment depth ratio of H/7.5, which results in a bearing capacity factor of safety of just 2.0 for a wall height of 12 m, corresponds to an embedment depth of 1.8 m, it may be more economical to increase the effective width of the footing by increasing the length of geosynthetic reinforcement.

### 5.2 Minimum L/H Ratios

Typical minimum L/H ratio results are presented in Figure 3, which is a bar graph plot of the range of L/H ratios required to satisfy both sliding and bearing capacity design requirements against the various combinations of front slopes, backslopes, and surcharges for wall heights which vary from 1.5 m to 12 m, assuming an embedment depth ratio of H/20 and no bench in front of the wall. A thick horizontal line is drawn across the bar graphs at an L/H ratio equal to 0.6, the minimum L/H ratio recommended by the NCMA Manual.

An L/H ratio greater than 0.6 is required to satisfy the sliding and bearing capacity requirements for many of the design cases. The following conditions require a L/H ratio greater than 0.6:

1. A backslope of 2H:1V, regardless of the front slope.
2. A front slope of 2H:1V, regardless of the backslope.
3. A front slope of 3H:1V, if a backslope other than horizontal is used.

Figure 2. Typical bearing capacity factors of safety for various wall embedment ratios.

Figure 3. Minimum L/H Ratios for the combinations listed in Table 1.

Since the embedment ratio of  $H/20$  represents the shortest embedment depth investigated, the required  $L/H$  ratios for increased wall embedment depths are not quite as large. However, the same design cases (No. 1, 2, and 3 noted above) require  $L/H$  ratios greater than 0.6 for wall embedment depth ratios of  $H/10$ ,  $H/7$ , and  $H/5$ .

## 6 CONCLUSIONS

This paper has presented a basic review of the determination of the ultimate bearing capacity of MSE wall systems. The impact of various combinations of front slopes, back slopes, surcharges, embedment depths, and wall heights on ultimate bearing capacity is presented and discussed.

Conclusions, based on the assumptions previously listed, are:

1. The ground slope in front of a MSE wall system can significantly impact the ultimate bearing capacity beneath an MSE wall.
2. The magnitude of the angle of the ground slope in front of an MSE wall is proportional to the reduction in ultimate bearing capacity for the wall.
3. A backslope of 2H:1V requires an  $L/H$  ratio greater than 0.6, regardless of the front slope and wall embedment depth used.
4. A front slope of 2H:1V requires an  $L/H$  ratio greater than 0.6, regardless of the backslope and wall embedment depth used.
5. A front slope of 3H:1V requires an  $L/H$  ratio greater than 0.6, if a backslope other than horizontal is used, regardless of the wall embedment depth used.
6. A  $L/H$  ratio of 0.6, with a wall embedment depth ratio of  $H/20$ , is most likely satisfactory for generalized site conditions limited to horizontal front slopes and backslopes and a surcharge of  $12 \text{ kN/m}^2$  or less.

## 7 RECOMMENDATIONS

The intent of this paper was to investigate the impact of non-generalized site conditions on the bearing capacity of MSE wall systems. The authors note that performance of comprehensive sliding, bearing capacity, and compound stability analyses are particularly important for all projects with non-generalized site conditions, especially where a front slope or backslope of any magnitude is to be used. The site conditions will dictate the minimum reinforcement length,  $L$ , and wall embedment depth ratio for the MSE wall structure.

## 8 DISCLAIMER

The opinions and recommendations included in this paper are solely those of the authors and do not represent the views of the US Army Corps of Engineers or the University of Wisconsin-Platteville.

**ABSTRACT:** The paper presents a study on the behaviour of brick-faced retaining walls reinforced with geosynthetics. This new method of construction for low height retaining walls combines the reinforced earth techniques with a conventional brick wall. While the walls are being built reinforcement sheets are anchored to the wall by the bed joints of the brickwork. After cure, backfilling is done in layers and a surcharge load is applied.

The influence of the reinforcement configuration's length and spacing is studied by using a numerical model based on the finite elements method. The reliability of the model is checked by comparing the numerical results with those obtained from laboratory studies on small scale models. A brief description of the bidimensional model used is presented and followed by the definition of the geometry of the analysed structure. The backfill, reinforcement and face materials of the retaining wall are characterized.

**KEY WORDS:** Geosynthetic reinforcement, Retaining walls, Finite element analysis, Nonwoven Fabrics.

## 1 INTRODUCTION

Nowadays retaining walls reinforced with geosynthetics are being constructed frequently throughout the world. Therefore the establishment of reliable criteria of behaviour for each type of these structures is of the utmost importance.

This paper presents a study carried out on brick faced retaining walls reinforced with geosynthetics, built on rigid foundations. The effect of varying the reinforcement configuration both its length and spacing was investigated by using a two dimensional numerical model based on the finite elements method. The validity of the model is checked by comparing the results with those obtained from laboratory studies on small model walls.

This study follows an experimental test program (Pinto 1992, Pinto and Cousens 1996) on this type of wall and the development of a numerical model for reinforced retaining walls (Lopes 1992, Lopes et al 1994).

## 2 EXPERIMENTAL STUDY

The method of construction is similar to that proposed by Dalton (1977) for low height retaining walls and combines the reinforced earth technique with a conventional brick wall.

The walls were built "in situ" in a test tank near its free end. The internal dimensions of the tank are 240 mm wide x 490 mm high x 630 mm long. It is made mainly of steel in order to ensure minimum deformations so that plane strain conditions could be considered. The walls were 300 mm high x 240 mm wide and half a brick thick (20.5 mm).

The reinforcement material was a non-woven fabric used as interfacing in dressmaking, with a deformability modulus of 6.9 kN/m and a thickness of about 0.3 mm.

The walls were built with scale model bricks sawn from full size bricks "class B engineering bricks" as recommended by BS 5628 (1978). While the walls were being built, reinforcement sheets were anchored to the wall by the bed joints of the brickwork. After cure backfilling was done in 30 mm layers (each layer being compacted by a small vibrating plate in order to achieve the required density) while the reinforcement were extended horizontally into the backfill. Finally a surcharge load was applied.

Different reinforcement lengths and spacings were tested. The walls were instrumented in order to measure the wall movement and the horizontal earth pressure acting on the rear face of the wall.

## 3 NUMERICAL MODEL

The numerical model was developed for reinforced retaining walls and simulates the construction process. It is based upon the finite elements method and assume the validity of the plane strain conditions. The soil and the face are simulated by bidimensional elements with 5 nodes (Doherty et al 1969), the soil-face and the soil-reinforcement interfaces by joint elements with 4 nodes (Goodman et al 1968) and the reinforcement by elements with 2 nodes.

The construction process was simulated according to Kulhawy (1977). When a finite element is activated its self weight is divided by the element nodes and applied to the system. The deformability modulus of these elements is very small in order to simulate a material with weight and

without stiffness, however, before the placement of the next layer of backfill (next stage) the deformability modulus returns to its real value. The vertical and the horizontal stresses correspond to the overburden pressure, and to the at rest state respectively. The movement of the nodes of the activated elements is considered to be the same as the top nodes of the previous elements.

## 4 NUMERICAL ANALYSIS

### 4.1 Problem Conditions

In order to carry out the study a total of 5 finite element meshes were created, one for an unreinforced wall, and four for reinforced walls. These include two lengths (8 and 12 cm) and two spacings (3 and 4 brick courses, i. e., 45 and 60 mm respectively) for the reinforcement.

Figure 1 shows a finite element mesh for the wall reinforced every 3 brick courses with 12 cm long reinforcement sheets.

Figure 1. Finite element mesh.

Each mesh starts with only 20 elements, corresponding to the face of the wall. New elements are progressively activated in order to simulate the backfilling process: 300 for the backfilling, 126 for the interfaces and 48 for the reinforcement. Each reinforcement element is activated immediately after the placement of some soil on top of it. At the end of the backfilling stage the full mesh (which is activated in 10 steps) has a total of 494 elements and 495 nodes. The surcharge is then simulated by an equivalent load applied to the upper nodes of the top elements.

The boundary conditions were defined taking into account the geometry of the test tank (left lateral boundary) and the foundation condition (bottom boundary). In the former, the horizontal movement is prevented while in the latter, neither horizontal nor vertical movements are allowed in order to simulate a rigid foundation.

The soil of the backfill is a medium grain size containing about 15% of fine sand, with limiting densities of 14.4

$\text{kN/m}^3$  and  $16.8 \text{ kN/m}^3$ . Other characteristics of the soil are given in Table 1.

Table 1. Soil characteristics.

$\gamma$ ( $\text{kN/m}^3$ )	$K_0$	$\phi$ ( $^\circ$ )	$c$ (kPa)	$\nu$	$E$ (kPa)
16.3	0.36	40	0	0.35	7000

$\gamma$  denotes density,  $K_0$  at rest coefficient,  $\phi$  angle of friction,  $c$  cohesion,  $\nu$  Poisson's ratio and  $E$  deformability modulus.

Table 2 shows the characteristics of the interfaces. The deformability modulus of the wall was assumed to be 25000 kPa after comparative studies on unreinforced walls.

Table 2. Interface characteristics.

	Soil - Reinforcement	Soil - Face
$c_a$ (kPa)	0	0
$\text{tg } \delta$	0.73	0.75
$K_t$ (kPa/m)	2000	750

$c_a$  denotes adhesion,  $\delta$  angle of friction and  $K_t$  stiffness modulus.

### 4.2 Results

#### 4.2.1 Reliability of the numerical model

The reliability of the numerical model was checked by comparing the numerical results with those obtained from the laboratory tests. The comparisons were made both during the backfilling stage and under a surcharge load equivalent to a 270 mm high embankment on top of the backfill. In general a good degree of agreement was found when comparing the movement of the wall and the horizontal pressures acting on the rear face of the brickwall.

The influence of the increase of the backfill on the movement of the wall is shown in Figure 2 for a wall reinforced every 3 brick courses with 8 cm reinforcement length.

Figure 2. Displacements during backfill.

Figure 2 shows the variation of the displacement of the wall at different heights: 40, 115, 200 and 280 mm from the base of the wall, which corresponds to the position of the LVDT's 1, 2, 3 and 4 respectively. This figure shows in general, good agreement between the results obtained from the numerical model and those obtained from the laboratory tests. Small differences are however noticed as the values from the numerical model are lower than those from the laboratory. This is more evident near the end of backfilling stage and was also noticed during surcharging.

Figure 3 shows the displacements along the height of a wall reinforced every 4 brick courses with 8 cm reinforcement length during surcharging. The results from the numerical model and the laboratory test show a similar profile with values close to each other, but again, with the numerical model giving lower values when compared with the laboratory tests.

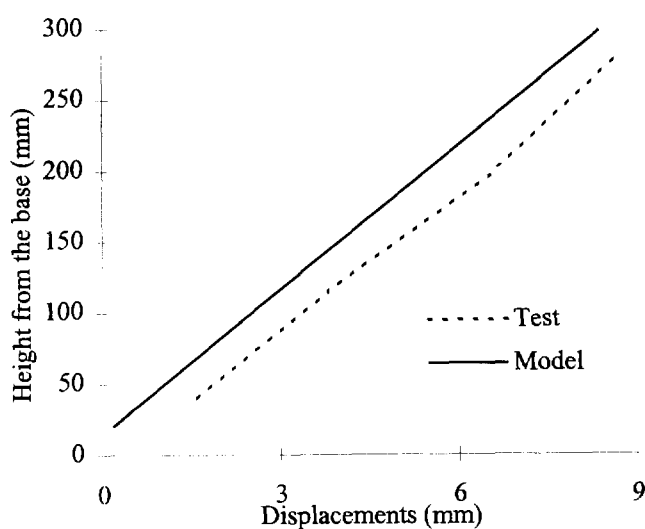

Figure 3. Displacements during surcharging.

The difference observed might be explained by a combination of two effects: the compaction which is not simulated by the numerical model and was found to be important during the laboratory test program (Cousens and Pinto 1996); and the restriction of displacement on the base of the wall imposed by the boundary conditions of the numerical model necessary to simulate the rigid foundation.

#### 4.2.2 Influence of the reinforcement configuration

A study of the influence of the reinforcement length and spacing configuration was carried out. The movement of the face of the wall (Figure 4) and the stresses developed on the reinforcement (Figure 5) were considered.

When comparing the curves plotted in Figure 4, corresponding to the same reinforcement length (i.e. 3b.c.-8 cm with 4b.c.-8 cm and 3b.c.-12 cm with 4b.c.-12 cm), it can be seen that displacements decrease with a decrease of spacing for both reinforcement lengths.

Comparisons between curves corresponding to the same spacing (i.e. 3b.c.-8 cm with 3b.c.-12 cm and 4b.c.-8 cm with 4b.c.-12 cm) reveal a decrease of displacements with

an increase of length for both reinforcement spacings.

Figure 4. Displacements during surcharge for different reinforcement conditions.

The influence of the reinforcement configuration can also be studied comparing curves 3b.c.-8 cm and 4b.c.-12 cm of Figure 4. These curves correspond to walls with the same total amount of reinforcement ( $1152 \text{ m}^2$  for each wall) although differently distributed along the height of the wall. Figure 4 shows smaller displacements for the situation with lower spacing (3b.c.-8 cm) as opposed to that with long reinforcement (4b.c.-12 cm), suggested that the spacing is more important than the length of the reinforcement.

Figure 5 shows the variation of the stresses along the reinforcement length for walls with different reinforcement conditions. The curves plotted correspond to the most solicited layers of each wall which are those positioned at about mid-height. However, similar results were obtained for other layers. All curves show a non-linear behaviour, characteristic of highly deformable materials. The stresses are highest at the connection with the wall, and decrease towards the free end, which is characteristic of rigid walls (Shen et al 1979). Unlike walls with flexible faces, walls with rigid faces do not follow the vertical movement of the soil mass, consequently some bending takes place on the reinforcement, which generates tensile stresses.

The influence of the spacing can be studied comparing curves 3b.c.-8 cm with 4b.c.-8 cm and 3b.c.-12 cm with 4b.c.-12 cm in Figure 5. A decrease of the stresses can be related to a decrease in spacing, for both lengths. The influence seems to be more important on walls with the longest reinforcement.

When comparing curves corresponding to the same spacing (i.e. 3b.c.-8 cm with 3b.c.-12 cm and 4b.c.-8 cm with 4b.c.-12 cm) it can be seen that higher stresses are associated with shorter reinforcement, for both spacings, and specially for lower spacing.

Figure 5. Stresses along the reinforcement length during surcharge for different reinforcement conditions.

Comparing stresses on walls with the same amount of reinforcement (i.e. 3b.c.-8 cm and 4b.c.-12 cm) it can be seen that lower stresses are associated with lower spacing. This is in agreement with the findings relating to the movement of the wall where the most important factor was found to be the spacing as opposed to the length. The difference of stresses between the two reinforcement situations increases towards the top of the wall.

## 5 CONCLUSIONS

A satisfactory degree of agreement was found when comparing the numerical results with those obtained from the laboratory tests.

From the study carried out it can be concluded that both the reinforcement length and spacing are important as far as the behaviour of the structure is concerned.

In fact, small movement and low stresses on the reinforcement are associated with longer reinforcement and lower spacing between reinforcing layers. This might be explained by the relative movement between the soil and the face of the wall which decreases both with the increase of the reinforcement length and with the decrease of the reinforcement spacing. Due to this movement some bending takes place on the reinforcement generating tensile stresses. The lower the movement the lower the generation of these stresses.

The spacing seems more important than the length of the reinforcement for both the movement of the wall and the development of tensile stresses on the reinforcement.

**ABSTRACT:** This paper describes the use of finite element (FE) method in large deformations to predict the behaviour of reinforced soil walls loaded on the top by a concrete slab load. The measured results are compared to the numerical ones for both the simulations done. A parametric study was also carried out to investigate the effect of some important parameters for design, such as the geotextile length, the facing stiffness and the position of top load application considering a geotextile-reinforced retaining wall with a continuous and vertical facing.

**KEYWORDS:** Finite element analysis, Retaining wall, Geotextile reinforcement, Top load.

## 1 INTRODUCTION

This paper outlines the use of the finite element (FE) method for the analysis of two full scale experimentations on segmental walls (4.35 m height by 5 m wide) loaded on the top and constructed with extensible reinforcement : one with non woven geotextile and another with woven geotextile. The reinforcement distribution in the two reinforced walls are not exactly the same as illustrated in Figures 1 and 2, this is justified by the difference in mechanical properties between the two geotextiles. The experimentation was performed and reported by Gourc et al., (1995). The analysis of the reinforced soil walls was performed using a finite element program GOLIATH developed at Lirigm which is appropriate to simulate the great deformations of this kind of structures and the membrane behaviour of the geotextiles in the slinding process.

The comparison between the predicted and the experimental results shows the difficulties to simulate correctly field prototype structures behaviour.

In this study, the effect of some parameters such as reinforcement length, facing stiffness and the position of load application is examined, considering a reinforced-retaining wall with a continuous and a vertical facing.

## 2 NUMERICAL MODELLING

### 2.1 Materials

A plane strain finite element analysis in large deformations was performed using the finite element (FE) program GOLIATH. The finite element mesh adopted for the analysis is shown in Figure 3. The fill is modelled by three

node isoparametric elements. The soil was assumed to be an elastic-perfectly plastic material with a Mohr-Coulomb failure criterion ( $E_s$ ,  $\nu_s$ ,  $c_s$ ,  $\Phi_s$ ) with a non associated flow rule with a dilatancy angle  $\psi_s$ . The unit weight of the soil is  $\gamma_s = 19 \text{ kN/m}^3$ . The foundation of the structure is supposed to have an elastic behaviour ( $E = 60 \text{ MPa}$ ,  $\nu = 0.33$ ).

Figure 1. Non Woven wall (NW) profile and notations

Figure 2. Woven wall (W) profile and notations.

The facing is modelled using four node isoparametric elements and was supposed to be elastic ( $E_f, \nu_f$ ) with a unit weight  $\gamma=22 \text{ kN/m}^3$ . Backfill, foundation, and facing element are modelled in large strain.

The facing is assumed to be continuous and the sheets are assumed to be fully bonded to the soil (no relative displacement).

The geotextile sheets were modelled using linear elastic bar elements in large displacement with negligible compressive strength and no bending stiffness (which allows the simulation of the membrane behaviour).

Figure 3. Finite element mesh adopted.

The geotextile stiffness are respectively  $J_{NW}=95 \text{ kN/m}$  and  $J_W=340 \text{ kN/m}$  for a non woven and woven fabrics.

## 2.2 Construction and loading

The compaction process is not simulated in this analysis. The full height of the wall is initially constructed applying body forces on the structure with ten load increments of 0.1g. Then the concentrated load is applied step by step through a linear elastic slab ( $E = 1500 \text{ MPa}, \nu = 0.2$ ) with 10 kPa increments until 100 kPa, followed by 2.5 kPa increments until failure.

The two reinforced walls have been analysed by Arab et al., 1996 using the set 1 of parameters as summarised in Table 1 which was modified after additional laboratory test (set 2) as indicated in table 1.

Table 1. soil and facing parameters for the modelisation

	$E_s$ (MPa)	$\nu_s$	$\phi_s$ (°)	$\psi_s$ (°)	$E_f$ (MPa)	$\nu_f$
Set 1	20	0.3	36	6	25	0.2
Set 2	35	0.3	36	16	20	0.2

## 3 RESULTS OF ANALYSIS

The predicted slab settlements versus surcharge  $Q$  obtained

with the two sets of parameters, are compared to the experimental one, respectively on Figures 4 and 5 for the two reinforced walls. The large settlement values considered shall be noticed.

For low value of the top load, the predicted settlement of the slab is very close to the measured one. It is worth noting that below the critical surcharge (breakpoint) the deformations and the displacement for the two structures are very small. Above this surcharge value the deformations increase significantly with the top load.

The measured slab settlement curves versus top load shown a breakpoint which corresponds to about 130 kN/m called the "critical surcharge". This is not predicted by the simulations. The breakpoint is very significant for designer because below it, only small deformations and displacements occur.

In the case of the Non Woven wall (NW) the predicted settlement obtained great with the two sets of parameters is lower than the measured one, particularly the solution calculated with the first set. However for the Woven structure (W) the measured settlement curve is enclosed by the numerical ones.

Figure 4. Slab load settlement versus top load (NW wall).

Figure 5. Slab load settlement versus top load (W wall).

The low settlement measured below the "critical surcharge" in the case of the Non Woven wall (NW) is probably due to the compaction effect. Under compaction, the extensibility and the texture of the geotextile combined

to the fine sand used to construct the Non Woven (NW) reinforced wall induce a better improvement of the mechanical characteristics than in the case of the Woven structure (W).

#### 4 PARAMETRIC STUDY

A parametric study was carried out to investigate the effect of mechanical and geometric parameters for gaining an insight into the effects of several of the important design factors, such as the geotextile length, the facing stiffness and the position of top load application considering a geotextile-reinforced retaining wall with a continuous and vertical facing. The structure geometry, the finite element mesh and the material properties of backfill, foundation, facing used are those corresponding to set 2 as summarised in Table 1 unless otherwise stated. The geotextile stiffness adopted corresponds to the non woven fabrics ( $J_{NW}=95$  kN/m).

##### 4.1 Effect of geotextile length (L)

The effect of reinforcement length  $L$  is examined by considering different lengths of reinforcement while the height  $H$  of the wall reinforced by eight sheets with a constant spacing  $\Delta H=0.58$  m is kept the same. The range of  $L/H$  considered varies from 0.36 to 0.8. As shown in Figure 6 the influence of increasing length of the geotextile is no more significative when  $L$  reaches  $0.5H$ . The short reinforcement sheets ( $L/H=0.36$ ) contribute to the increasing of the bearing capacity as demonstrated by comparison with the unreinforced retaining wall (No reinf). This demonstrates that not only the reinforcement tensile beyond the failure surface will be considered in the design methods.

Figure 6. Effect of reinforcement length on the slab settlement under surcharge.

##### 4.2 Effect of wall facing stiffness

The rigidity of the wall facing depends of the construction mode. The effect of facing stiffness on the performance of

geosynthetic-reinforced soil retaining wall is not fully understood and is usually ignored in the design. An analysis is performed considering a retaining wall reinforced by  $N_p=8$  sheets of geotextile. The sheets are equally spaced,  $\Delta H=0.58$  m and are 2.6 m long ( $L/H=0.5$ ). Different facing stiffness were examined ( $E=5, 10$  and  $20$  MPa). A wrapped facing was also analysed ( $E=0$  MPa). The slab settlement versus surcharge and the lateral deflections of the facing induced by a top load of  $Q=60$  kN/m for all the cases considered are illustrated respectively on Figures 7 and 8.

Figure 7. Effect of facing stiffness (E) on the slab load settlement.

Figure 8. Effect of facing stiffness (E) on the wall facing horizontal deflection  $\Delta x$ .

In the absence of a facing or with a facing of low stiffness, the wall deformed greatly, particularly at high top load.

##### 4.3 Effect of the position of top load

To examine the effects of the position of the top load, different distance of slab position from wall face were considered ( $d=1, 1.5$  and  $2.5$  m). The height of the wall, the number of reinforcement layers and their length were the same as previously i.e. ( $H=4.35$  m,  $N_p=8$ ,  $L/H=0.5$ ). The slab settlement curves versus top load are illustrated in Figure 9 for the three cases. When the rear of the geotextile is not horizontally beyond the upstream

corner of the slab, the failure occurs roughly as in the case corresponding to  $d = 2.5$  m. The mean shear strain field ( $\epsilon_1 - \epsilon_3$ ) for the cases  $d = 1.5$  m and  $d = 2.5$  m are shown in Figures 10 and 11. We notice from these patterns that when the reinforcement length does not include horizontally the slab width a shear band develops from downstream side of the slab to the bottom of the facing.

Figure 9. Effect of the point application of the top load on the slab settlement.

## 5 CONCLUSION

A finite element method has been used to model two experimental walls reinforced by extensible reinforcement. Despite the assumption done, the predicted results are quite satisfactory until large deformations. However some physical phenomenon observed are not predicted like the experimental "breakpoint" of the diagram surcharge-settlement. To simulate this phenomenon, it would be necessary to take into account the compaction effect and the construction stages. However lack of experimental data on the compaction mode and effect makes such approach very difficult.

Figure 10. shear strain field ( $\epsilon_1 - \epsilon_3$ ) induced by a top load  $Q=90$  kN/m (scale : 1.5).

Figure 11. shear strain field ( $\epsilon_1 - \epsilon_3$ ) induced by a top load  $Q=90$  kN/m (scale : 1.5)

In addition, numerical simulations have been performed to investigate the effects of some parameters on the behaviour of reinforced soil wall loaded on the top. The parameters considered included the reinforcement length, the facing stiffness and the point of application of the top load. All of these parameters influence the behaviour of the structure. But the most important geometric parameter is the ratio of the reinforcement length to wall height. For a ratio equal or greater than 0.5 there is no significant increasing on the bearing capacity. It is also found that the reinforcement length has to be extended beyond the potential failure surface developing from the upstream side of the slab to cover the width of the slab load.

**ABSTRACT:** The purpose of the paper is to evaluate the effects of deformation of geosynthetic reinforced soil wall backfill on the bearing resistance of the foundation ground using the results of finite element analysis. Here, the reinforced soil wall constructed on relatively soft sloping ground, which is a real construction site in Japan, is taken into consideration and a series of parametric study is conducted, in which the effects of the condition of foundation ground and a backcut angle behind the reinforced backfill are discussed, and also the effectiveness of soil improvement at the toe of the wall is also evaluated. The conclusions drawn from this study are: (1) the effect of the backcut angle behind the reinforced backfill on the bearing resistance of foundation ground is less, so that this effect does not have to be considered on the design calculation of bearing capacity; and (2) when the foundation ground is relatively soft, the deformation property of the reinforced backfill deeply affects to the reaction at the base of the reinforced backfill. The soil improvement technique at the base of the reinforced backfill is one of the effective methods.

## 1 INTRODUCTION

Applications of geosynthetics to the embankment or retaining wall have been most popular technique among all the earth reinforcement practices around the world. This is because the behavior and failure mechanism of these reinforcing structures have been successfully evaluated under the contributions by many researchers. The results of these researches have been presented in recent international conferences and symposia (e.g. Proceedings edited by Yamanouchi et al., 1988, Ochiai et al., 1992, and Ochiai et al., 1996). But recently, such as in Japan, these applications have been applied to more severe conditions such as relatively soft sloping ground or various backcut angle behind the backfill. And those conditions have to be considered on the stability calculation in order to design these structures safely.

In the current design method, the stress distribution at the base of the retaining soil wall has been assumed by the moment equilibrium with assumption of Coulomb earth pressure theory. However, this distribution is affected by the deformation and strength properties of the reinforced backfill and it also depends on the property of foundation ground. These properties have not been considered in the current design method so far and besides, in-situ conditions at the construction site, e.g. the backcut angle, is variously changed.

The purpose of the paper is to evaluate the effects of deformation of geosynthetic reinforced soil wall backfill on the bearing resistance of the foundation ground using the results of finite element analysis. Here, the reinforced soil

Figure 1. Forces on the reinforced backfill in the design.

wall constructed on relatively soft sloping ground, which is a real construction site in Japan, is taken into consideration and a series of parametric study is conducted, in which the effects of the condition of foundation ground and a backcut angle behind the reinforced backfill are discussed. And also the effectiveness of soil improvement at the toe of the wall is also evaluated.

## 2 CALCULATION OF BEARING RESISTANCE ON CURRENT DESIGN METHOD

Current design calculation of the stability concerning bearing capacity of foundation ground at the base of the reinforced backfill is summarized based on the design

manual by Public Works Research Center(PWRC) in Japan. This design calculation is based on the equilibrium of all the loads subjected to the reinforced backfill as shown in Fig.1. As shown in this figure, the ground reaction at the base of the reinforced backfill is always set to be trapezoidal shape and this is based on the assumption that the ground under the backfill is always rigid and the effect of ground settlement is not evaluated in the design method. As described above, the application of these structures is extended to the relatively soft foundation ground nowadays. When the foundation ground is relatively soft or the backcut angle behind the reinforced backfill is changed, this trapezoidal assumption may not be true and has to be examined. This is a key issue here in this paper and is discussed based on the results of finite element analysis.

### 3 FINITE ELEMENT ANALYSIS

#### 3.1 Problem to be solved

The finite element analysis is conducted for the real construction site in Japan and this is shown in Fig.2(a). The geosynthetic reinforced soil wall was constructed on the sloping foundation with its slope angle of  $25^{\circ}$ . The ground conditions are also shown in the figure and these are summarized as follows:

- For natural ground:
  - a) Ground I: clay with gravel (SPT N-value = 2 - 5);
  - b) Ground II: weathered dacite (SPT N-value = 12 - 50);
  - c) Ground III: dacite (SPT N-value is more than 50).
- For artificial ground:
  - d) Reinforced ground: compacted Ground I;
  - e) Improved ground: improved by cement.

It is noted that the Ground I is a sloping soft ground and the application of soil improvement technique at the toe of the wall was taken into consideration. The geogrid type of reinforcing material was used at the site. As shown in Fig.2(a), there are 11 layers of geogrid and three different types were used (Tensar SR55, SR80 and SR110), in which SR110 was used for the first four layers from the bottom, SR80 for fifth to seventh layers and SR55 for top four layers.

#### 3.2 Method of analysis

In order to evaluate not only 1) the effect of backcut angle behind the reinforced backfill but also 2) that of soil improvement in the ground, a series of finite element analysis is conducted. The method used here is elasto-plastic finite element method using Drucker-Prager failure criterion with non-associated flow rule(Otani et al.,1992). The geogrid type of geosynthetics is modeled by beam element in the analysis with perfectly elasto-plastic assumption. The material properties were determined from material tests in laboratory. The interaction between soil and geogrid is ignored. The soil testings for both in-situ and laboratory have been conducted for the soils at this

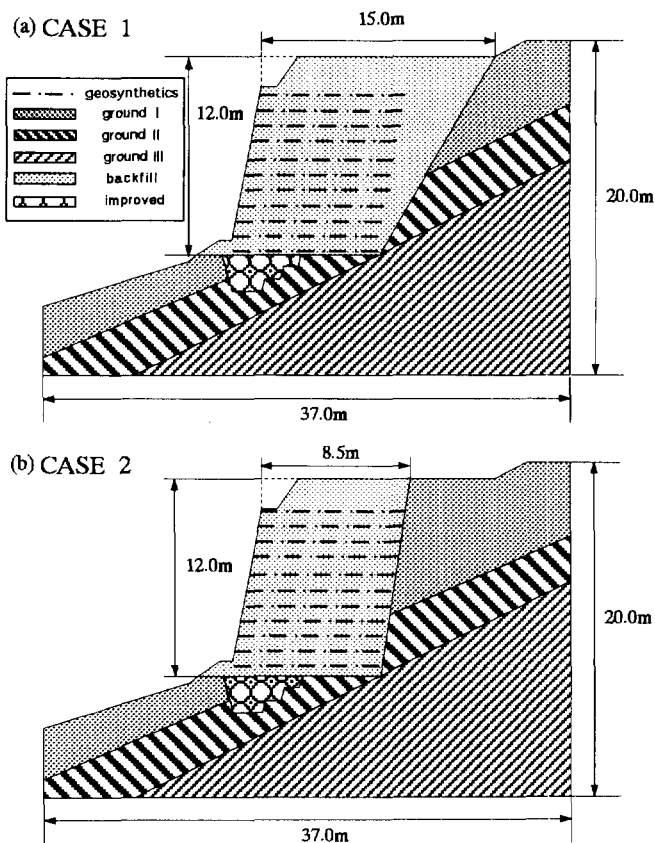

Figure 2. Problems to be analyzed.

construction site, so that the material property of the ground was determined from these testings and is shown in Table 1. In the analysis, the case shown in Fig.2(b) is also analyzed in order to evaluate the effect of backcut angle. The analysis is conducted with loading condition of step-by-step construction of the backfill. It is also noted that the joint element is used between natural slope and the backfill in order to express the discontinuity phenomenon, in which this interaction is modeled as a friction property with setting the shear stiffness of the soil itself in the joint element. The total cases of the analysis are listed as follows:

- CASE 1: ground condition of natural sloping ground as shown in Fig.2(a)
- CASE 1-1: for rigid foundation ground;
  - CASE 1-2: without improvement; and
  - CASE 1-3: with improvement,

- CASE 2: ground condition of natural sloping ground as shown in Fig.2(b)
- CASE 2-1: for rigid foundation ground;
  - CASE 2-2: without improvement; and
  - CASE 2-3: with improvement.

It is noted that the case of rigid foundation is also analyzed for the comparative study and this is conducted by assuming all the natural ground to be Ground III without improvement technique.

Table 1. List of material property of the ground.

	Young's modulus	poisson's ratio	cohesion	friction angle	unit weight
	$E(\text{kN/m}^2)$	$\nu$	$c(\text{kN/m}^2)$	$\phi(^{\circ})$	$\gamma(\text{kN/m}^3)$
ground I	$4.90 \cdot 10^3$	0.30	18.63	29	$1.67 \cdot 10^2$
ground II	$2.94 \cdot 10^4$	0.25	0.00	32	$1.77 \cdot 10^2$
ground III	$2.94 \cdot 10^5$	0.20	0.00	41	$2.62 \cdot 10^2$
backfill	$1.47 \cdot 10^4$	0.40	10.79	23	$1.63 \cdot 10^2$
improved	$5.88 \cdot 10^4$	0.35	95.12	31	$1.73 \cdot 10^2$

4 RESULTS AND DISCUSSION

Figure 3 shows the results of deformation for all the cases, in which CASE 1-1 is shown in Fig.3(a); Fig.3(b) for CASE 1-2; Fig.3(c) for CASE 1-3; Fig.3(d) for CASE 2-1; Fig.3(e) for CASE 2-2; and Fig.3(f) for CASE 2-3. Comparing the results between CASE 1-1 and CASE 1-2 or CASE 2-1 and CASE 2-2, the deformation around the base of the reinforced backfill for the case of rigid foundation is much less than that for the case of without improvement. The lateral deformation is also remarkable for the case of without improvement. But this is improved by the application of soil improvement technique as shown in Fig.3(c) and Fig.3(f). Figure 4 shows the results of both distributions of settlement and vertical pressure beneath the reinforced retaining backfill. Looking at the shape of stress distribution at the base of the

Figure 3. Deformation Property from analysis results.

backfill, it is not always the trapezoidal shape. So that it affects the calculation of overall stability for the reinforced soil wall and this depends on the deformation property of the reinforced backfill. It is also pointed out that not only

the force equilibrium on the reinforced backfill but also the local deformation around the toe of the wall have to be checked for its overall stability. For comparing the effect of slope angle of natural ground behind the reinforced backfill, it is obviously realized that it is not much difference between two cases (CASE 1 and CASE 2).

(a) Effect of rigidity of foundation ground

(b) Effect of soil improvement technique

Figure 4. Distributions of earth pressure and settlement at the base of reinforced backfill.

## 5 CONCLUSIONS

Recently, the earth reinforcement practice has been applied to the cases with more severe conditions such as on relatively soft sloping ground or various backcut angle behind the backfill. These conditions on the bearing capacity of foundation ground were evaluated.

The conclusions drawn from this study are listed as follows:

- (1) The effect of the angle of natural slope behind the reinforced backfill on the bearing resistance of foundation ground is less, so that this effect does not have to be considered on the design calculation of bearing capacity.
- (2) When the foundation ground is relatively soft, the deformation property of the reinforced backfill deeply affects to the reaction at the base of the reinforced backfill. Therefore, this should be considered in the design calculation.
- (3) For overall stability of the reinforced wall on relatively soft sloping ground, not only the force equilibrium on the reinforced backfill but also the local deformation around the toe of the wall should be checked.
- (4) The improvement technique around the toe of retaining wall makes the settlement less and earth pressure equivalent at the base of the reinforced backfill.

The field measurements such as earth pressure and deformation of the reinforced backfill at this site are still on the way at this moment. When the results of this paper is compared with this in-situ measurement, it is promised that the analysis results are quantitatively evaluated.

# PARAMETRIC STUDY FOR GEOSYNTHETIC REINFORCED WALLS UNDER SUSTAINED EARTHQUAKES

**A. Carotti**

Professor, Dept. of Structural Eng., Politecnico di Milano, Milan (Italy)

**P. Rimoldi**

Director, Tenax SpA, Geosynthetics Division, Viganò (Italy)

## Abstract

The Authors propose a newtonian model for the dynamics of geogrid reinforced soil retaining walls, based on a scheme with lumped masses having elastic, viscous and coulombian interactions. The model allows to evaluate the local amplifications by integrating the elasticity and inherent damping with the contribution of the geogrid layers. The aim of the present paper is the drawing, for the different cases analyzed, of design charts which will allow engineers to evaluate the number and characteristics of the geosynthetic reinforcing layers required to satisfy given safety requirements, as a function of the characteristic parameters of the earthquake. A trial-and-error procedure for the seismic analysis of geogrid reinforced walls is outlined.

**Keywords:** Geogrids, Dynamic Mechanical Analysis, Retaining Walls, Seismic Design, Seismic Loads.

## 1. INTRODUCTION

A non-linear multidof newtonian model for the seismic dynamics of slopes and walls on horizontally accelerated bedrock (Carotti and Rimoldi, 1997), is taken as the basic mathematical and computational support for a pseudo-static design procedure for geosynthetic reinforced walls.

From the multidof model, a series of 2-D response spectra and design charts have been obtained; from such plots the following kinematic and mechanical information can be deduced:

- maximum values of the seismic response at the top of the wall;
- spectral values of the active coefficient of earth pressure  $K_{aE}$  under seismic condition.

Based on these charts, a trials-and-errors procedure for checking the seismic feasibility of statically designed reinforcements is presented for various peak accelerations at bedrock and various frequency contents of the accelerogram.

A first major group of parameters are discussed in the present paper; successive developments, which are under way, will take into consideration other characteristics, including the interlayer stiffness and viscous damping.

## 2. NON-LINEAR NEWTONIAN MODEL WITH GEOGRIDS

From laboratory tests (Montanelli and Moraci, 1997), we assume the following mechanical actions between the geogrids and the soil layers on top and bottom, as a consequence of the soil-geogrid interlocking:

1. an increase of the interlayer soil stiffness, proportional to the elastic stiffness of the geogrids. From monotonic tensile tests on geogrids (Fig. 1) the load-strain curve has been reduced to a tri-linear curve and the stiffness value in each linear segment have been identified. We have focused the attention on the 1<sup>st</sup> stage, with strain threshold  $\epsilon_1 = 0.03$ . If  $L_g$  is the geogrid length in the direction of the seismic acceleration,  $F$  is the tensile force applied to the geogrid and  $\Delta l$  its elongation, we postulate that, in condition of interlocking between the geogrids and the soil layers, the contributed inter-layer stiffness is:

$$K_{gi} = \frac{F}{\Delta l} = \frac{F}{\epsilon_1 \cdot L_g} \quad (1)$$

2. An increase of the interlayer viscous damping force, equal to the inherent viscous damping of the geogrid. From sinusoidal cyclic tests (Montanelli and Moraci, 1997) with frequency  $f = 1.0$  Hz (see Fig. 2) and from the examination of an average elliptical cycle, the average viscous force  $F_{vinc}$  (force in counterphase

to the velocity, when the displacement is nil) has been obtained, together with the value of the peak velocity (product of the peak displacement, obtained from the test plot, and of the circular frequency  $\omega = 2\pi f$  of the test). From the ratio force/velocity the damping coefficient is immediately obtained. In details :

$$C_{gi} = \frac{F_{visc}}{\Delta l \cdot \omega} = \frac{F_{visc}}{\epsilon \cdot L_g \cdot \omega} \quad (2)$$

where  $\Delta l$  is the differential interlayer displacement ( $x_i - x_{i-1}$ ), when perfect interlocking between soil and geogrid has been assumed.

3. An increase of the interlayer damping due to the friction between the geogrid and the soil layers, under the weight of the soil. The frictional damping due to the i-th geogrid (where N is the number of geogrid layers) is:

$$F_{Ci} = -tg \phi_{sg} \cdot g \cdot \sum_{k=i}^n M_k \cdot sign(\dot{x}_k) \quad (3)$$

where the signum function  $sign(\dot{x}_k)$  introduces the non linearity in the model. The direction of the frictional force is determined by the sign of  $\dot{x}_k$ . In Eq. (3)  $\phi_{sg}$  is the soil-geogrid interface friction angle; g is the gravity acceleration.

The Newtonian equations of motion for the N-DOF non-linear model with geogrids (N soil layers with N geogrid layers) can be obtained taking into account the elastic stiffness  $K_{gi}$ , the viscous damping  $C_{gi}$  and the Coulomb-type friction force  $F_{Ci}$  induced by the geogrids, defined in Eq.s (1)÷(3).

Indicating with  $\hat{M}$  the distributed load on top of the wall, the Newtonian equation of motion for the i-th layer is:

$$M_i \cdot \ddot{x}_i = -K_i(x_{i-1} - x_i) - C_i(\dot{x}_{i-1} - \dot{x}_i) + K_{i+1}(x_i - x_{i+1}) + C_{i+1}(\dot{x}_i - \dot{x}_{i+1}) - K_i(x_{i+1} - x_i) - C_i(\dot{x}_{i+1} - \dot{x}_i) + K_{i+1}(x_i - x_{i+1}) + C_{i+1}(\dot{x}_i - \dot{x}_{i+1}) + tg \phi_{sg} \cdot g \cdot \left( \sum_{k=i}^n M_k + \hat{M} \right) sign \dot{x}_i - tg \phi_{sg} \cdot g \cdot \left( \sum_{k=i+1}^n M_k + \hat{M} \right) \cdot sign \dot{x}_{i+1} = -M_i \cdot \ddot{x}_i \quad (4)$$

where  $g \cdot \left( \sum_{k=1}^n M_k + \hat{M} \right)$  represents the total gravity load acting on the i-th geogrid layer.

### 3. CONTROL OF DYNAMIC EQUILIBRIUM FOR GEOGRID REINFORCED WALLS

The steady dynamic equilibrium for a 1-DOF (one Degree Of Freedom) linear oscillator under sinusoidal resonant excitation is described in Fig. 3, where the inertia force is balanced - at maximum displacement

- by the elastic recalls.

In this non-linear model (see Carotti and Rimoldi, 1997), the contribution of the friction force to the equilibrium (at maximum displacement) of the i-th reinforced layer of the wall must be taken into consideration.

In the present research, a geogrid reinforced earth wall is assumed, with a cohesionless backfill and possible permanent surcharge loads on the top surface; the vertical spacing  $S_v$  of the geogrids and the overall length L are taken as constant.

Here the following hypotheses are introduced:

- the static earth pressure  $P_{st}$  is balanced even in seismic conditions by the friction  $F_{C_i}$  and by the tensile strength  $T_{g_i}$  of the geogrids;
- in seismic conditions, the forces  $F_{C_i}$  furtherly provide an increase of damping, the forces  $T_{g_i}$  provide an increase in terms of damping and stiffness;
- the dynamic earth pressure  $Pa_d$  can be obtained through the superposition of effects of the static earth pressure  $Pa_s$  and the seismic earth pressure  $Pa_{ge}$  (suffix "G" for geogrids and "E" for earthquake):

$$Pa_d = Pa_s + Pa_{GE} \quad (5)$$

- The earth pressures can be described with the Rankine type equations:

$$Pa_d = \frac{1}{2} Ka_d \gamma H^2 \quad (6)$$

$$Pa_s = \frac{1}{2} Ka_s \gamma H^2 \quad (7)$$

$$Pa_{GE} = \frac{1}{2} Ka_{GE} \gamma H^2 \quad (8)$$

Therefore :

$$Pa_d = \frac{1}{2} (Ka_s + Ka_{GE}) \gamma H^2 \quad (9)$$

and :

$$Kad = Ka_s + Ka_{GE} \quad (10)$$

- due to the previous hypothesis, the dynamic forces can be studied independently from the static ones; therefore now on only the equilibrium of the dynamic forces will be considered.

The conditions of dynamic equilibrium and the mechanical interaction between the two adjacent layer, (i-1)-th and i-th, are described in Fig. 3, which gives an imagine at maximum displacement (zero velocity) of the wall. Being in conditions of zero velocity, at this point of time the viscous damping force  $F_v$  is zero.

As said above, only the dynamic forces are

considered here, without the static earth pressure  $P_{a_i}$ .  
 Let  $F_{IN_i}$ ;  $F_{e_{(i-1)}}$ ;  $F_{e_i}$  represent, respectively, the overall inertia force and the elastic recalls above and under the  $i$ -th layer; and let  $F_{c_{(i-1)}}$ ;  $F_{c_i}$ ;  $P_{agE_i}$  represent the upper and lower Coulomb friction force, and the active earth pressure due to the  $i$ -th layer.

With the assumption that the 1<sup>st</sup> modal shape is dominating (Carotti and Rimoldi, 1997), then all the displacements of the single layers are in phase. Hence we can assume that there is a balance between the elastic recall forces of the soil itself: therefore  $F_{e_i}$  is almost equal to  $F_{e_{(i-1)}}$  and computationally they can be neglected.

Under these hypotheses, in condition of dynamic equilibrium we have (see Fig. 3):

$$P_{axE_i} = F_{IN_i} + T_{g_i} \quad (11)$$

$$F_{IN_i} = -M_i \cdot \ddot{x}_{v2}$$

where  $T_{g_i}$  is the tensile strength in the geogrid under the  $i$ -th soil layer (see Fig. 3):

$$T_{g_i} = F_{c_i} \quad (12)$$

When the expression of Eq. 8 is introduced, a pseudo-static expression for the coefficient of active earth pressure  $K_{agE}$  under seismic excitation can be obtained:

$$K_{agE} = \frac{2 \cdot P_{agE}}{\gamma \cdot H^2} \quad (13)$$

#### 4. PRELIMINARY PARAMETRIC DISCUSSION

The following design parameters has been taken into consideration for discussing the effects of geosynthetic reinforcement on the seismic response of the wall.

##### a) Soil:

$$\gamma = 18 \text{ kN/m}^3 ; \phi = 25^\circ - 40^\circ ; c = 0$$

$$\text{shear modulus } G = 10^4 \text{ kN/m}^2 ;$$

$$H = 3 \text{ m} - 6 \text{ m} - 9 \text{ m}.$$

The first three natural frequencies and damping ratios for the 3 m and 6 m high walls, without reinforcements, are given in Table 1.

Tab. 1 - Natural frequency  $f$  and damping ratio  $\xi$  for some of the walls considered in the parametric study.

	H = 3 m.		H = 6 m.	
	f (Hz)	$\xi$ (%)	f (Hz)	$\xi$ (%)
1st mode	5.63	4.9	2.95	1.3
2nd mode	14.43	14.3	8.8	3.8
3rd mode	25.89	22.6	14.45	6.3

##### b) Geogrids:

We have considered the geometrical and mechanical characteristics of the TENAX TT401 Samp mono-oriented geogrid, which have the following properties:

$$\text{Unit weight: } w = 0.77 \text{ Kg/m}^2$$

$$\text{Polymer density: } \rho = 0.950$$

$$\text{Tensile strength: } T = 80 \text{ kN/m}$$

$$\text{Elongation at peak: } \varepsilon_{peak} = 13\%$$

$$\text{Strength at 2\% strain: } T_{2\%} = 26 \text{ kN/m}$$

$$\text{" " 5\% " : } T_{5\%} = 48 \text{ kN/m}$$

Taking into consideration the cross sectional area of the longitudinal stretched rib of the geogrids:  $A_r = 1.6 \text{ mm} \times 6.5 \text{ mm} = 10.4 \text{ mm}^2$ , and a number of 50 ribs/m, the resistant section is:  $Ar = 5.2 \times 10^{-4} \text{ m}^2/\text{m}$ :

And therefore,

$$\sigma_{peak} = T/Ar = 154 \text{ MPa}$$

$$E_{peak} = \sigma_{peak} / \varepsilon_{peak} = 1185 \text{ MPa}$$

$$\sigma_{2\%} = T_{2\%} / Ar = 50 \text{ MPa}$$

$$E_{2\%} = \sigma_{2\%} / 0.02 = 2500 \text{ MPa}$$

Other data used in the model are:

- soil-geogrid interface friction angle:

$$\phi_{sg} = \arctan(\tan \phi / f_{ds})$$

where the direct shear factor  $f_{ds}$  has been assumed equal to 0.80;

- constant vertical spacing:  $S_v = 0.6 \text{ m}$ ;

- geogrid length:  $L = 0.5 H - 1.0 H$

where  $H$  is the wall height.

##### c) bedrock excitation:

the following classes of acceleration time histories have been implemented:

c1) a stationary gaussian zero-means white noise, low-pass filtered with fixed bandwidth (0,5 Hz) and variable peak acceleration, varying between 0.1 g to 1.1 g.

c2) as above but with parametrically fixed peak acceleration  $a_g = 5 \text{ ms}^{-2}$  and variable bandwidth: all the bandwidths considered have the same left cut-off frequency (zero Hz) and different right cut-

off frequencies, ranging from 1 Hz to 10. By this way the effects of many historic earthquakes can be modelled and simulated: from very low frequency “near-fault” earthquakes, to earthquakes with increasingly wider bandwidths as the San Salvador (1986), Mexico City (1985) and El Centro (1940) records.

Using these types of bedrock excitation it is possible to obtain the following spectra:

**1. spectra under excitation c1:** spectra of top relative displacement and top absolute acceleration of active earth pressure coefficient  $K_{agE}$  and the overall active earth pressure  $P_{agE}$  for two different geogrid lengths, are given in Figg. 4, 5, 6. Such spectra are obtained by plotting the maximum value of the response quantity (extracted from the time history) vs the peak acceleration of the bedrock.

The family of parabolic curves are monotonically increasing with the base peak acceleration. Both  $K_{agE}$  and  $P_{agE}$  decrease with increasing geogrid length  $L$ .

**2. spectra under excitation c2:** spectra as above vs variable bandwidth of the bedrock acceleration, are given as well in Fig. 4, 5, 6, respectively for the 3 m, 6m, 9m high walls. The amplification effect when the seismic bandwidth includes the natural frequencies of the wall (see Tab. 1) is evident: spectra show the possibility of controlling such amplifications by means of geogrid reinforcements of variable lengths.

Note 1: the 1<sup>st</sup> mode of vibration is dominating in reinforced soil structures. Hence resonance occurs around the frequency of the 1st mode (compare Figg. 4, 5 with Tab.1).

Note 2: For soil without geogrids, in order to stress the influence of geogrids, the model has taken into account only the viscous damping and not the Coulombian one (which has been accounted for in the model with geogrids). As a consequence the model for soil alone is not sensitive to the parameter  $\phi$  (in favour of safety); hence in the charts all the curves without geogrids are the same. This limitation will be eliminated in the future developments of the model.

## 5. DESIGN CHARTS FOR GEOGRID REINFORCED WALLS IN SEISMIC CONDITIONS

The analysis has been extended to the ranges of practical interest of the main soil and geogrid parameters. Design charts are given in Figures 4, 5 and 6. The following procedure can be used for the seismic analysis of geogrid reinforced walls:

**STEP 1:** design the reinforced block in static conditions. Adopting, as example, the “tie-back wedge” method, the following three parameters shall be determined :

- minimum length of geogrids  $L_{min}$ ,
- vertical spacing  $S_v$ ,
- overall number of geogrids:  $n_{grid}$ .

**STEP 2:** the seismic input is established. At first, a standard 0 - 5 Hz bandwidth and variable peak acceleration are assumed (characteristic statistical parameters of the time record, including RMS, crest-factor and variance, can be imposed),

**STEP 3:** the design charts in Figg. 4 - 6 are then entered and the seismic active pressure coefficient  $K_{agE}$  is obtained.

**STEP 4:** the dynamic earth pressure coefficient  $K_{ad}$  is determined with Eq. 10; then the stability analysis of Step 1 is re-calculated with reference to  $K_{ad}$  and allowing for a reduction of the safety factor FS according to each National Code (usually a 20% reduction of FS is envisaged in the seismic Codes for earthworks, e.g.: a reduction from 1.3 to 1.06 of the  $FS_{\text{overturning}}$ ; a  $FS_{\text{pullout}}$  reduction from 1.5 to 1.2 etc.)

**STEP 5:** if any of the before mentioned checks at Step 4 are not satisfied, then by a trials-and-errors procedure the following corrections may be introduced:

- increase the number of geogrids and/or the geogrids length  $L$ ,
- with these new values, the design procedure starting from Step 3 is repeated,
- as long as all the checkouts are satisfied.

**STEP 6:** the sequence from Step 2 to Step 5 can be repeated for a different choice of the seismic input.

If the effects of variable bandwidths and fixed peak-acceleration must be investigated, spectra at the bottom in Figures 4 -6 will be considered.

# Influence of Reinforcement Stiffness, Length and Base Condition on Seismic Response of Geosynthetic Reinforced Retaining Walls

R.J. Bathurst

Professor, Department of Civil Engineering, Royal Military College of Canada, Kingston, Ontario, Canada

K. Hatami

Research Associate, Department of Civil Engineering, Royal Military College of Canada, Kingston, Ontario, Canada

**ABSTRACT:** The paper reports selected results from a set of numerical experiments that were carried out to investigate the influence of reinforcement stiffness, length and base boundary condition on the seismic response of a geosynthetic reinforced full-height panel wall. The two-dimensional explicit finite difference program FLAC was used to carry out the numerical experiments. The paper illustrates how program FLAC may be a useful research tool to corroborate current empirical guidelines for the pseudo-static analysis and design of geosynthetic reinforced wall structures or to propose new guidelines. For example, the numerical results illustrate that the dynamic response of the simulated walls is very sensitive to base foundation condition.

**KEYWORDS:** Retaining walls, Geosynthetic reinforcement, Seismic analysis, Finite difference, Parametric study.

## 1 INTRODUCTION

In North America, geosynthetic reinforced soil walls are routinely designed using pseudo-static limit-equilibrium methods for sites with peak horizontal ground accelerations  $\leq 0.29g$ . A limitation of pseudo-static methods is that they cannot consider the effect of duration of seismic loading, acceleration amplification through the backfill soil, and foundation condition on the development of reinforcement loads and structure deformations (Bathurst and Alfaro 1996; Bathurst and Cai 1995). The results presented in this paper are part of an ongoing project directed at understanding the dynamic response of geosynthetic reinforced wall structures due to earthquake. The results presented in this paper show that the two-dimensional explicit finite difference program FLAC may be a useful tool to investigate the seismic performance of reinforced wall structures. Ultimately, numerical simulation results of the type demonstrated here may be used to verify or modify currently accepted pseudo-static design methods.

## 2 MODEL

The example walls were chosen to have the same height and number of uniformly spaced reinforcement layers as the base case example reported by Rowe and Ho (1992) (Figure 1). A preliminary set of static analyses were carried out using the same geometry, material properties and reinforcement layout as that reported by Rowe and Ho to confirm that FLAC (version 3.30) analyses for the end of construction loading case give similar results to their finite element analyses. However, boundary conditions were then modified for the current study to accommodate the need for a larger mesh and other details related to the two different foundation conditions investigated.

Each wall was modeled as a continuous panel with a height of 6.0 m and a width of 0.14 m. The bulk and shear moduli of the wall were  $K_w = 20,000$  MPa and  $G_w = 10,000$  MPa, respectively. The wall was hinged at its toe using beam elements. The soil was modeled as a purely frictional elastic-

Figure 1. Numerical grid for example problem with fixed base condition.

Figure 2. Base acceleration-time history.

plastic material with a Mohr-Coulomb failure criterion and non-associated flow rule. The friction angle of the soil was  $\phi = 35^\circ$ , dilatancy angle  $\psi = 6^\circ$  and unit weight  $\gamma = 20$  kN/m<sup>3</sup>. The bulk and shear moduli of the soil were  $K_s = 27.5$  MPa and  $G_s = 12.7$  MPa, respectively.

A uniformly spaced reinforcement was considered in the model. The reinforcement was modeled using linear elastic cable elements with negligible compressive strength and an equivalent cross-sectional area of  $0.002 \text{ m}^2$ . The stiffness of the reinforcement ( $J$ ) was a variable in this set of parametric analyses. The tensile yield strength of the reinforcement was  $T_{\text{yield}} = 200 \text{ kN/m}$  to ensure that reinforcement rupture was not a failure mechanism.

The interface between the reinforcement (cable elements) and the soil was modeled by a grout material of negligible thickness with interface friction angle  $\delta_g = 35^\circ$ . The bond stiffness and bond strength of the grout model were taken as  $k_{\text{bond}} = 2 \times 10^6 \text{ MN/m/m}$  and  $s_{\text{bond}} = 10^3 \text{ kN/m}$ , respectively. The interface and grout properties were selected to simulate a perfect bond between the soil and reinforcement layers. The soil-wall and soil-foundation interfaces (for the sliding wall cases) were modeled using a thin soil layer of  $0.05 \text{ m}$  thick. However, the friction angle of the interface layer between the reinforced soil and the panel wall was set to  $\phi_{\text{int}} = 20^\circ$  and the dilatancy angle to  $\psi_{\text{int}} = 0^\circ$ .

The numerical grid was selected to represent an infinitely wide region. To achieve this condition the soil region was extended to  $40 \text{ m}$  beyond the back of the wall and a *free field* boundary condition was applied at the truncated boundaries at the left and right edges of the grid to allow for the radiation of elastic waves to the far field.

The soil and reinforcement elements were constructed in layers while the panel wall was braced horizontally. The propped panel supports were then released in sequence from the top of the structure as reported by Rowe and Ho. After static equilibrium was achieved, the full width of the foundation was subjected to the acceleration history illustrated in Figure 2.

Table 1. Numerical simulation configurations.

Test	Base condition	L/H	J (kN/m)
1	fixed	0.7	500
2	fixed	0.7	1000
3	fixed	0.7	2000
4	sliding	0.7	500
5	sliding	0.7	1000
6	sliding	0.7	2000
7	fixed	1.0	500
8	fixed	1.0	1000
9	fixed	1.0	2000
10	sliding	1.0	500
11	sliding	1.0	1000
12	sliding	1.0	2000

### 3 PARAMETRIC ANALYSES

The test configurations considered in the current investigation are summarized in Table 1. The base foundation condi-

tion was either fixed (i.e. the toe of the wall was slaved to the foundation but was free to rotate) or free to slide horizontally along a thin  $0.05 \text{ m}$  thick layer of soil and rotate about the toe. The stiffness ( $J$ ) and length ( $L$ ) of the reinforcement were also varied as shown in the table. The synthetic horizontal acceleration record shown in Figure 2 was applied to nodes along the entire base of the numerical grid at equal time intervals of  $\Delta t = 0.05 \text{ s}$ . The accelerogram simulates a ground motion with both increasing and decaying peak acceleration portions. The peak amplitude of the input acceleration was  $0.2g$  with a dominant frequency of  $3 \text{ Hz}$  which is typical of medium to high-frequency content earthquakes. A mass proportional damping of  $\zeta = 0.05$  was assumed for the model. The total duration of the input excitation was limited to  $6 \text{ seconds}$  in order to minimize computational time.

## 4 RESULTS

### 4.1 Wall Displacements

Wall displacements predicted at the end of the excitation period are shown in Figure 3. For the same base condition, the *total* wall deflections diminish with increasing reinforcement stiffness. Similarly, for the same base condition and reinforcement stiffness, there is less total wall displacement for  $L/H=1.0$  compared to configurations with  $L/H=0.7$ . However, the plots show that for the range of reinforcement stiffness values used, the base condition (fixed or sliding) has a greater influence on wall deflection than the magnitude of reinforcement stiffness. In addition, the *relative* wall deflections taken with respect to the wall toe are less for the sliding foundation case than for the fixed toe case.

### 4.2 Reinforcement Forces

In general, reinforcement forces were observed to accumulate with duration of seismic shaking. Figure 4 shows the relative distribution of axial forces in the reinforcement layers at the end of the  $6 \text{ second}$  acceleration record. The reinforcement forces at the connections were almost always greater than the internal reinforcement forces at all stages of the numerical experiments including end of construction. This trend can be attributed to the relative downward movement of the reinforced soil zone relative to the continuous wall panel.

Figures 5a and 5b show the distribution of maximum *total* reinforcement force (typically at the end of the shaking duration when ground accelerations have returned to static conditions) and the distribution of forces at the end of construction for each experiment (initial). The largest reinforcement forces at the end of construction and after dynamic loading were predicted for the sliding foundation case. The distributions of maximum total reinforcement forces are very different for sliding and fixed foundation cases. The influence of toe fixity and the structural panel member on reinforcement forces is clear in the two figures. The maximum reinforcement force occurs at the bottom layer for the sliding cases while the peak reinforcement layer occurs at the second from bottom layer for the fixed toe condition. The maximum total

a) sliding base ( $L/H=0.7$ )

b) sliding base ( $L/H=1.0$ )

c) fixed base ( $L/H=0.7$ )

d) fixed base ( $L/H=1.0$ )

Figure 3. Wall displacements predicted at end of seismic record (time = 6 s).

Figure 4. Reinforcement forces at  $t = 6$  s for fixed base condition with  $L/H=0.7$  and  $J=2000$  kN/m.

reinforcement force distributions are relatively insensitive to reinforcement ratio ( $L/H$ ) for the two values investigated but relatively sensitive to the reinforcement stiffness value under dynamic loading. Reinforcement loads increase with reinforcement stiffness. Superimposed on these two figures are predicted reinforcement forces using Rankine earth pressure theory and Coulomb earth pressure theory. These curves do not capture the trend in reinforcement loads at the end of construction for both foundation conditions and are generally very much lower in magnitude than the peak reinforcement forces generated as a result of shaking.

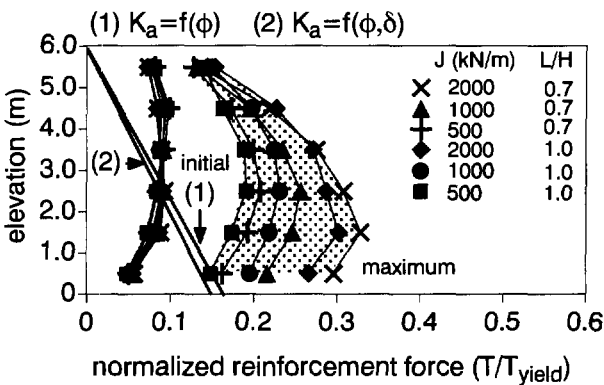

Figures 6a and 6b show the peak dynamic increment force recorded in all simulations. These values are calculated by subtracting the total dynamic load curves in Figure 5 from the corresponding initial static values. Superimposed on the figures are the predicted dynamic increment forces using the current AASHTO (1996) method with a peak ground acceleration of 0.2g. In general, the empirical AASHTO method underestimates the magnitude of additional reinforcement forces. In addition, the trend in additional reinforcement load cannot be captured by the empirical AASHTO curves for the fixed toe condition.

#### 4.3 Other

Figure 7 shows a plot of shear zones in the failed volume of soil within the reinforced zone and in the retained fill. This figure is typical of all numerical simulations reported in this paper. There was no evidence of a well-defined Rankine type failure surface contained within the reinforced soil zone. Rather, the reinforced soil zone acted as a parallel sided monolithic mass. Large shear strains were recorded at the wall-soil interface and at the reinforced soil-retained soil interface. The failure volume can be approximated by a bilinear wedge with the orientation of the linear segment in the retained soil approximately  $31^\circ$  from the horizontal. This failure surface orientation is consistent with Mononobe-Okabe earth pressure theory when ground acceleration amplification is considered (i.e. peak accelerations in the soil were as great as 2 to 3 times the 0.2g peak input value at the base of the structure).

## 5 CONCLUSIONS

Program FLAC holds promise as a numerical simulation tool to investigate the seismic response of geosynthetic reinforced soil walls. In particular, the numerical results may be used to corroborate current empirical guidelines for the pseudo-static analysis and design of geosynthetic reinforced wall structures or to propose new guidelines. More work remains to investigate a wider range of wall geometries and facing types before predictions based on program FLAC can be used as an aid to the development of simplified seismic design guidelines. However, it is important to note that the seismic response values reported in this paper have not been verified against laboratory models of any scale. The writers are currently carrying out reduced-scale shaking table tests of geosynthetic reinforced soil walls that will be used to calibrate numerical simulations and to verify simulation results.

# The Verrand High Reinforced-Soil Structure

G. Sembenelli

Geotechnical Consultant, SC Sembenelli Consulting, Milan, Italy

P. Sembenelli

Geotechnical Consultant and Managing Director, SC Sembenelli Consulting, Milan, Italy

**ABSTRACT:** The Verrand Embankment is a 27.5 m High Reinforced Soil Structure topped by a 10 m high unreinforced embankment, located at the bottom of a steep V-shaped valley, in the Italian Alps. Scope of the structure, which was completed by the end of 1996, was threefold: providing a stabilising weight to the natural slope, providing a disposal for material from tunnel excavation and providing access beyond the embankment. The reinforced portion mainly consists of three 9 m high blocks, with face angle about 60° from the horizontal. The reinforcements are non-woven geotextiles. The Paper describes the project geometry, fill and reinforcing materials as well as the construction sequence. Monitoring data, collected since the early construction phases, are also presented and discussed.

**KEYWORDS:** Reinforced slope, Geotextiles, Case study, Construction, Deformations

## 1 INTRODUCTION

A new highway connecting the Monte Bianco Tunnel with the city of Aosta, in the Italian Alps, requires the construction of a bridge, some 600 m long, parallel to a very steep slope, about 35 to 40° from the horizontal. The slope forms the left side of a V-shaped valley, created by the Dora Baltea River.

The geology of the site is quite complex. Originally, the valley was filled by a very large earth and rock slide. During the latest glaciation the slide materials were overconsolidated by the action of a thick layer of ice. Locally, concretions of carbonate-rich waters had also formed. By the end of Würmian glaciation the increased erosive potential of the river deeply cut the overconsolidated deposits. The slope material, which is observed today, can be described as a silty sand matrix containing gravel and large boulders, slightly cemented. The surficial part of the mass is often decompressed. The natural water table daylight in the bottom half of the slope.

Presently the slope is close to limit conditions and repeated slides of limited extent occur, whenever the river cuts into the toe of the slope. A particularly large slide took place, in the early years of the century, near the village of Verrand.

Pier #4 of the bridge is located within the perimeter of this slide. It was thus decided that the slope had to be stabilised with a high buttressing embankment.

The steepness of the valley sides imposed the use of reinforced soil technologies, so that the volume of fill and thus the stabilising weight could be maximised. As a side result of this solution, a large volume of muck from nearby tunnel jobsites could be disposed in an environmentally acceptable way.

## 2 PROJECT DESCRIPTION

The Verrand Embankment, shown in plan on Fig. 1, is a 27.5 m High Reinforced Soil Structure overlaid by 10 m of unreinforced, 1.5H to 1V embankment. The structure is some 150 m long for a total volume of about 120 000 m<sup>3</sup>, out of which 50 000 m<sup>3</sup> are reinforced fill.

The reinforced portion mainly consists of three 9 m high blocks, with face angle of 60° from the horizontal. The blocks are stepped to create 5 m wide sloping berms, almost parallel to the riverbed grade. A 5 m wide service ramp runs on the lower berm and cuts the second and third blocks. A ramp was necessary for construction and to provide access beyond the buttress.

The area where the lower block is founded was cleaned and excavated to reach a competent foundation. Also the natural slope was cleaned and stepped in order to get a better interlocking with the new fill. This operation was carried out as filling progressed.

The toe of the HRSS had to be protected from river action by a cyclopean wall, about 4 m high. Additional riverbed training and erosion preventive works are presently underway.

A deep drainage was located at the contact between fill and natural slope, in order to keep water away from the reinforced fill. The drainage system consisted of two sloping collectors along the sides and one collector at the toe. All collectors were created backfilling a trench with selected gravel, wrapped in a geotextile separator. The drainage system also included geonet bands placed on the slope at 10 m spacings, across the collectors. Drainage in form of bands instead of a continuous sheet was selected in order to avoid creating a low friction contact between the new fill and existing slope. In addition, a number of nearly horizontal drain holes heading in the main drainage collector were drilled to depress the piezometric level as far as possible inside the slope. The main collector discharges to the river, on both sides of the embankment.

A surface drainage system was also foreseen. Rain water is collected and carried to the river by a system of ditches and collectors, running along the berms and along the slopes. Collectors along the slopes are included in the facing system and consist of trapezoidal channels on galvanised steel.

## 3 THE REINFORCED SOIL

The first step in designing a reinforced soil structure is selecting the facing technology, on account that it strongly

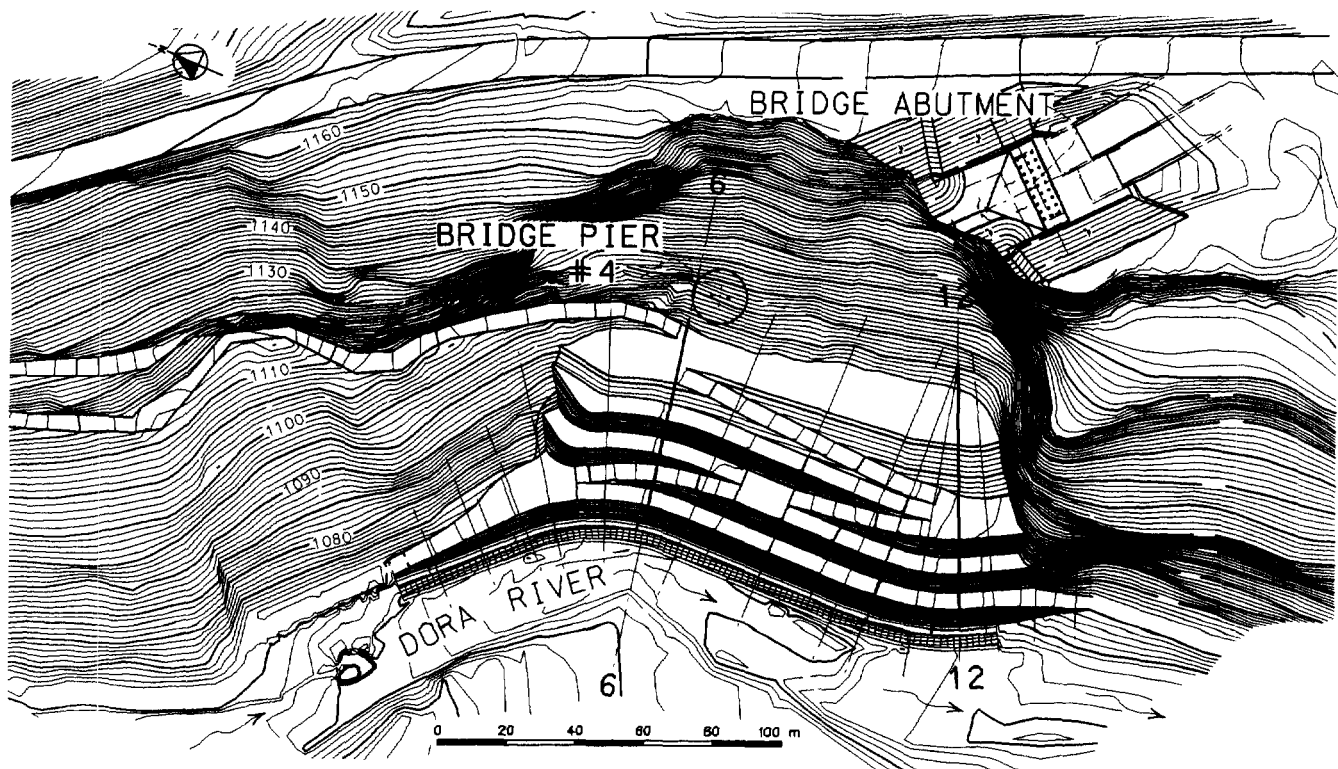

Figure 1. Plan of the Verrand High Reinforced Soil Structure

influences the construction process and the overall structural behaviour. Due to environmental constraints, it was chosen one patented facing systems, resulting in a completely grassed surface, once construction completed.

The basic element of the selected facing technology are 0.5 or 0.6 m high, L-shaped forms made by a welded wire steel mesh, left in place. Each form element is to be bent to an angle which is the one selected for the slope. Short steel tendons holding the two arms of the forms keep the section undeformed during lift compaction. A light woven geotextile is placed inside the form to retain the soil. The fill material is usually spread and compacted in half form high lifts, stopped 0.4 m short from the form. A band of topsoil is placed between the woven geotextile and the lift edge, in order to create a support for vegetation growth. The surface is finally hydroseeded so that it becomes completely and permanently grassed in a short time.

The appearance of the grassed surface at Verrand HRSS before and after hydroseeding is shown in Fig. 2.

An heavy vibrating roller is normally used to provide the necessary compaction effort. The roller actually used at Verrand was a DYNAPAC CA35 Class (7 static tons on drum), instead of the specified CA 25 class (5 static tons on drum). The roller moves parallel to the slope, covering the whole spread of both fill and topsoil placed over the geotextiles, up to the forms.

#### 4 MATERIALS FOR CONSTRUCTION

The fill material placed within the reinforced section was

well graded crushed rock with a relatively large sand and silt fractions, obtained by processing tunnel muck. This material mainly came from tunnelling in schists. The tunnel muck was first crushed in order to reduce its maximum grain size to 150-200 mm and then mixed with material obtained from open air excavations. The latter material was added considering that a relatively high content in sand and silt fines could reduce the potential for damaging the reinforcements.

The specifications for fill materials could not be excessively tight, on account of the fact that random tunnel muck from different excavations fronts were used to supply the needed volume.

The backfill was basically the same material with maximum size in the order of 500 mm. No processing was required for the backfill.

The reinforcements used at Verrand were anisotropic nonwoven geotextiles, continuous filament, needle-punched, Polyester (PET) fibre of three grades, manufactured by Fritz Landolt A.G., Switzerland. The nominal tensile strengths of the geotextiles were 40, 100 and 120 kN/m and their main characteristics are summarised in Table 1.

The reinforcements of grade 1000 and 1200 are quite thick and sometimes the unrolled sheets were undulated. This required special care during placement, in order to avoid wrinkles under the lifts, which might reduce the overall stiffness of the reinforcements. The above deformation were mainly considered to be a consequence of the production process.

Figure 2. View of the Verrand High Reinforced Soil Structure after completion. Vegetation is not yet fully developed in the upper part.

Table 1. Main characteristics of geotextiles FLN-TEXA used as reinforcement at Verrand HRSS

Type	Mass	Machine direction		Transverse direction	
		Strength	Elongation at failure	Strength	Elongation at failure
[-]	[g/m <sup>2</sup> ]	[kN/m]	[%]	[kN/m]	[%]
350	350	48.5	36.8	21.8	37.6
1000	900	115.5	38.3	47.8	36.2
1200	1050	132.7	40.1	55.4	39.6

Geotextiles survivability was checked by full scale tests, under the worst expected condition, i.e. with the coarsest fill compacted in 0.3 m thick lifts. After placing the geotextiles sheets on a compacted layer of fill, 3 additional fill lifts were spread and compacted with the same roller used in construction. The reinforcements were then carefully dug out. Exhuming operations are very difficult and

some additional damage is inevitably produced.

The most damaged zones of the unearthed sheets were thoroughly mapped. From those zones, specimens were taken, described and tested according to UNI-8639 (Italian) Standard. This testing procedure requires 100 mm wide and 200 mm long tubular (folded) specimens (Cazuffi et al., 1986).

Damages were not uniformly distributed over the geotextiles, but rather concentrated in patches. This is probably related to coarse particles segregation processes in the fill, as shown in Fig. 3. The tendency for damages to concentrate close to the outer slope was observed. Apparently segregation tends to increase along the edge of a given lift. Special attention should be devoted to avoid excessive segregation and hence excessive damages near the face, considering that here tensile stresses are the greatest. The extent of the damaged areas was about 50% of the reinforcements width.

Damage was classified under three main types: tears, through-going punctures and partial punctures. Tears were large damages probably related to the unearthing operations and were not considered in the analyses. Through-

going punctures are the most significant damages on account that they produce an appreciable loss of strength. They are small cuts, either rounded or linear, randomly oriented, 10 to 30 mm long. Partial punctures are small indentations, where the filaments are displaced and not necessarily cut.

Within the most damaged zones, the number of observed through-going punctures ranged from a minimum of 40 per square meter (30 per sq. yard) to a maximum of 100 to 120 per square meter (80 to 100 per sq. yard). The corresponding average strength loss was in the order of 50 to 60%. The above results could be observed on all the reinforcement examined and are in good agreement with previously published works (Sembenelli, 1995).

On account that the most damaged zones spread over about half the width of each reinforcement, it may be concluded that the actual strength retained by the whole reinforcement is 70 to 75% of that of the undamaged material. Correspondingly, the appropriate Factor of Safety to account for installation damage is  $F_d = 1.35$  to 1.45.

Our observations suggest that the maximum particle size has more influence on the width of the damaged areas than on the level of damage itself.

Figure 3. Compacted fill material surface under a reinforcement. Segregation of coarse particles in foreground is clearly visible

## 5 DESIGN OF THE REINFORCEMENT DISTRIBUTION AND LENGTH

The selection of the reinforcement requirements (force and length) was based on the limit equilibrium. In the Writers' opinion, when dealing with complex High Reinforced Soil Structures, this is still the most suitable design tool available.

The total horizontal force necessary for equilibrium was determined on a homogeneous unreinforced cross section. The required tensile force to be taken by the reinforcements was then computed as the force required for obtaining a minimum Factor of Safety  $F_s = 1.3$  against sliding. The computations were carried out with the Simplified Janbu Method, working directly on horizontal forces.

The assumed geotechnical characteristics of the fill material were: total unit weight  $TUW = 21 \text{ kN/m}^3$ , cohesion  $c = 0 \text{ kPa}$  and angle of friction  $\phi = 35^\circ$ . Tri-axial CD strength values, obtained from 100 mm diameter, compacted specimens, were larger than the assumed ones. However, a conservative value of the friction angle was selected to take into account the reduction of friction at high confining pressures and high strain levels. With this, the conditions of the lower block and situations of excess of silty fines were covered.

Several design sections were analysed, in order to cover all typical configurations. On each section a number of potential sliding surfaces were selected, so that part of a single block as well as one or more blocks were cut. The computed maximum horizontal force needed for equilibrium at each potential sliding surface was hence distributed over its height. Finally, the minimum required reinforcement was computed as the envelope of the above values.

The geotextiles tensile strength values were reduced to account for installation damage, long term durability and creep. The Design Strength was finally assumed to be 27% of the Wide-Width (500 mm) strength determined according with CNR-UNI (Italian) standards (Cazzuffi et al., 1986).

The length of the reinforcements was selected so that the computed minimum factor of safety for surfaces passing just beyond the reinforcements would be  $F_s = 1.3$ .

Detailed drawings of each reinforcement level were provided to the Contractor to ensure a proper distribution of the overall strength and to minimise wastage. This required a large number of construction drawings including plans, front views and cross sections. The curved contours of the reinforced embankment surface required detailed drawings to show the exact location in plan of both the reinforcement sheets and their overlaps.

The heaviest reinforcements were located within the lower blocks, not only to fulfil strength requirements but also to provide greater stiffness. Grade 350 reinforcements were used only locally in the very upper portion of the upper block. Additional reinforcements at the base of the top unreinforced fill were introduced to reduce the earth pressure on the reinforced blocks.

A typical reinforcement distribution is shown in Fig. 4. It is worth noting that the inner side profile of the reinforcements is stepped in order to meet the overall stability requirement.

Figure 4. Design cross section 12 with blocks numbering, reinforcements and instrumentation

## 6 CONSTRUCTION

Construction started in summer 1994. The lower block and about 3 m of the mid block were completed by November 1994. From winter 1994 through April 1996, construction was stopped, due to non-technical reasons. Fill could not be placed between late November and early April anyway, on account of the cold climate.

After resuming construction, the reinforced portion was completed early in September 1996 and the unreinforced fill was hence added to final grade. Actual construction took about 9 months.

The flow of material from neighbourhood excavations was slow so that a standard production, say 300 to 500 m<sup>3</sup>/day for a crew of 3 men, could not be sustained.

Hydroseeding was carried out early in 1996 for the lower part, already completed at that time, and at the end of 1996, for the upper blocks. Some delay between completion of construction and seeding is usually tolerated, though not beneficial for the facing which remains unprotected.

A large flood, in the order of 600 m<sup>3</sup>/s, occurred in the summer of 1996. The estimated return period of such flood was 50 years. The water level rose to the top of the toe wall, but no effects were noted on the reinforced embankment, though a scour, up to 2 m deep, produced in the riverbed.

## 7 BEHAVIOUR

Since early construction, vertical and horizontal displacements were monitored, with topographic surveys of reference points at cross sections 6 and 12. On the same cross

sections, long-base extensometers were placed to measure horizontal average strains. Due to installation problems, however, no one of the bases gave reliable readings.

The selected reference points were special plates and the heads of the extensometers. Horizontal displacements were measured from stations located on the opposite bank of the river, so that the distance between station and measuring points was in the order of 100 m. The location of the reference points on cross section 12 are shown in Fig. 4. Plates and extensometers are similarly located in section 6. It should be noted that the extensometer 2E in section 6 is below the service road.

The main data recorded are summarised in the time histories of Fig. 5 and 6. The shape of all displacement

Figure 5. Horizontal and vertical displacements measured on section 6. See Figure 3 for key

curves is hyperbolic and a horizontal asymptote appears to be reached after 9 months, from completion.

At Section 6, the maximum horizontal displacements is in the order of 70 mm, on the lower plate of the lowest block. The upper blocks exhibited lesser horizontal displacements, in the order of 50 mm. Vertical displacements range between 30 and 45 mm.

At Section 12, the measured horizontal displacements of the lower block are somehow larger, with maximum in the order of 100 mm. The horizontal displacements of the upper blocks were approximately 50 mm. Vertical displacements are about 70 mm, in the lower block, and 40 mm, above.

The normalised Horizontal Displacements with respect to the relevant height vary over a wide range, between

Figure 6. Horizontal and vertical displacements measured on section 12. See Figure 3 for key

$ds/H = 0.25\%$  to  $ds/H = 0.56\%$ . A good correlation between the normalised height and the average slope above the reference point, to which displacements are referred, seems to exist as shown in Fig. 7. Data from Champagne HRSS, a similar structure built according with the same facing technology, are also included for reference (Semenelli, 1995). The experimental points from Verrand HRSS fit to a logarithmic curve, with a satisfactory correlation. Only one point from Champagne HRSS lays close to the above fitting curve while the other ones lay on an almost parallel curve. This latter points actually refer to a different condition, which included an arched facing and geogrids reinforcements (Semenelli, 1994).

All points, which fall close to the fitting curve, are related to structures built with well graded (silty) sand and gravels, reinforced with non-woven geotextiles.

Casagrande Standpipe Piezometers will also be installed in order to monitor the water table in the long term.

# GEOGRID REINFORCEMENT OF SLOPES FOR EARTHQUAKE RESISTANCE AT THE NEW U.S. EMBASSY IN CARACAS, VENEZUELA

J.R. Lambrechts

Vice President, Haley & Aldrich, Inc., Cambridge, Massachusetts

**ABSTRACT:** Construction of a new U.S. Embassy building in Caracas, Venezuela posed a number of site stabilization challenges that were overcome with extensive use of geosynthetics. The new site contained several deep, steep sided valleys that had been previously filled in an uncontrolled manner. These 15 to 30 m thick fills were stabilized by installing more than 200,000 sq.m. of geogrid to provide necessary seismic stability in what was the largest application of geogrids in South America, and ranks high in worldwide use at a single building site. Two large walls supported with geo-mechanical stabilization were incorporated into slope stabilization design. This paper reviews the site conditions, design requirements that prompted the use of geogrid stabilization, and the unique application for stabilizing long sloping valley fills placed on bedrock.

**KEYWORDS:** Geogrids, Slope stabilization, Reinforcement, Seismic design.

The construction of the new U.S. Embassy building in Caracas, Venezuela required extensive site stabilization with geogrid to make the long, steep slopes on the site resistant to the local severe earthquake design conditions. Stability considerations that were incorporated into slope reinforcement designs required special construction to provide resistance to interface sliding of reinforced fill along the surface of underlying sloping bedrock. Other applications of geosynthetics included support of retaining walls and surface slope stabilization using cellular confinement systems in landscape areas of steep final ground surface.

## 1 SITE CONDITIONS

### 1.1 Local Geology

The site of the new embassy is in the Alameda area of southeastern Caracas, near the top of a high ridge that rises more than 150 m above a major southern trending valley corridor in this city of 5 + million people. At the edge of the Caribbean tectonic plate, the region is seismically active, and mountains and hilly terrain are present throughout. The bedrock in the area of the embassy is a dark gray micaceous, calcareous schist, which is a member of the Las Mercedes Formation.

The local hilly topography results from erosion of the bedrock. The tropical environs has produced deep weathering of the bedrock. A mantle of residual soils that has developed over the weathered bedrock is typical for such environs, with gradual transition from weathered bedrock upward through decomposed bedrock, which becomes residual soils, and finally topsoil.

### 1.2 Original Site Preparation for Development

An area of several square miles south and east of the embassy site was developed in the early 1980's, with level

building lots being formed on previously steep sloping hillsides. The initial site development in the early 1980's involved considerable earthwork to make level building lots in the originally hilly terrain. This involved bulldozing off topographic high ridges to fill in the deep intervening, incised valleys.

Several building lots were combined to make a site large enough to accommodate the security needs of a U.S. Embassy. Most of the embassy site had been transformed from hilly terrain, to a series of relatively level plateaus by extensive cutting and filling. Figures 1.a and 1.b present the pre- and post-development site topographic conditions, with the major fill areas labeled. The principal building and land uses of the new embassy are also indicated.

Figure 1.a Pre-Development Site Topography

## 2 DESIGN CONSIDERATIONS

Site use requirements for the proposed embassy necessitated adding fill on the slopes of Fills 2 and 3, and changes in grading on Fill 4. Also, in certain areas adjacent to the new building, filling was necessary for landscaping, with slopes as steep as 45 deg. However, the calculated stability of the Fill slopes existing before construction was marginal for even static conditions. Conditions for Fill 2 are shown on Figure 2, indicating new fill necessary for required final site grading and critical stability surfaces. Similar Factors of Safety were found for Fill 3. Factors of Safety were calculated using the program GEOSLOPE for the Janbu procedure to study irregular sliding models. The constraining effects of the buried valleys were considered, and applied by increasing the calculated Factors of Safety by 10 %, per findings of Baligh and Azzouz (1975).

Figure 1.b Conditions After Development Grading

Ground surface across the majority of the developed site area varies El. 945 m to El. 990, but lower levels to El. 915 occur at the bottom (east end) of Fill 2. Bedrock was exposed at ground surface after site development in the flat areas and on slopes between the Fills. Only about half of the Fill 4 area, at the southwest side of the site, is within the site limit, with the remainder continuing across the road and onto the sites on the other side of the street. Similarly, Fill 3 continues downhill beyond the site limit and road, and beneath the lot across the street. The design of stabilization for each Fill area had to account for these conditions.

The Fills were found to be 20 m to 35 m thick, with density being generally loose to compact. The fill was a mixture of the topsoil, the residual soils, and the decomposed and weathered bedrock. Gradation of fill generally varied from silty coarse to fine sand, to medium to fine sandy silt, all with trace clay and rock fragments. Some organic matter was also randomly present. Since there had been little clearing and grubbing prior to valley filling, in many borings topsoil and residual soil were found below fill. Also, as a result of the bulldozing of ridges, vegetation was sometimes found buried in bottoms of fills. Based on results of test boring Standard Penetration Test N-values, the following strengths were assigned to the various strata:

Stratum	Friction Angle (deg)	Unit Weight (kN/m <sup>3</sup> )
Uncompacted Fill	30	19.6
Residual Soil (& Topsoil)	25	20.4 (18.8)
Decomposed Rock	35	21.2
Schist Bedrock	40	22.0
Compacted Backfill	33	20.4

Figure 2. Stability Conditions of Original Fill 2

Primary geotechnical design considerations stem from the severe regional seismicity, which requires design for Richter magnitude 7.0. From earlier site specific seismicity study, the design earthquake was determined to produce bedrock horizontal acceleration of 0.30g. This was used in seismic slope stability analyses, which lowered calculated factors of safety to considerably below 1. Major reconstruction of the large site fills was therefore imperative.

Design for developed site required static Factor of Safety of 1.5, and for seismic conditions a FS of at least 1.0, plus the requirement that toe of slope not move beyond the property line as result of earthquake shaking. To satisfy these requirements, it was found necessary to remove and replace considerable amount of the existing fill in the three major Fills.

## 3 DESIGN OF SLOPES USING GEOGRID

In designing the stabilized fills for surface slopes as steep as 2 hor. to 1 vert., extensive use of geogrid reinforcement was essential to meet design criteria. Slope stability Factors of Safety were calculated using friction angle of reinforced fill judged to be at least 5 deg. more

than compacted backfill; i.e., 38 deg. Generalized profile through Fill 2 in Figure 3 shows the extent of reinforced fill necessary to meet design requirements for both the resist deep seated and shallow instability. As indicated, the dynamic conditions were the more severe, and thus necessitated more geogrid than would have only static considerations.

Figure 3 Calculated Stability for Reinforced Fill Buttress in Fill 2

However, design consideration was necessary to prevent a possible sliding surface from occurring on the interface between reinforced fill and bedrock, which would have been at the lower strength of the unreinforced fill. A means was devised to anchor the geogrid reinforced fill into the bedrock using "step cuts" into the weathered rock (below the decomposed rock). The need to "tie" the reinforced fill into the bedrock illustrated in Figure 4; the  $T_g$  force would have to be developed to bolster base friction is to prevent sliding along the bedrock surface.

Figure 4 Sliding Block Model for Slope Stabilization

The necessary tension force from the geogrid was determined from the slope stability calculations as increments of load applied to bottoms of slope slices to hold the slice in place, thus supplementing base friction. The geogrid force,  $T_g$ , provides the increase in frictional

resistance to make up the 5 deg. difference in friction angle between the compacted unreinforced fill and the reinforced fill. This force was then converted into equivalent length of geogrid using reasonable grid spacings and applying the equation shown in Figure 5. The equation parameters were derived from FHWA (1989).

Figure 5 Model for Determining Embedment Length

The key feature to make the geogrid reinforcement effective was the use of "step cuts" into the top of bedrock, as shown in Figure 5. The width of the step cuts had to be long enough to engage the  $L_e$  of the geogrid. This was generally accomplished by limiting the height of cut to 2 m. since the slope of bedrock was relatively gentle, see Figure 3. The upper layers of geogrid in each step cut were less than fully effective, but this was taken into account in the overall stabilization design.

Further, the effectiveness of the engagement zone was enhanced by use of coarse to medium sand as a 1 m minimum thickness "slope drain" layer between the reinforced fill and bedrock. The slope drain contained less than 5% fines and is used to keep piezometric pressures from building up in the base of the reinforced fill. Although bedrock was not found to freely yield groundwater, infiltration over the life of the project from surface irrigation, rainfall, or the surface drainage system were considered possible sources which the slope drain would protect against. Leaks in drain pipe lines are considered possible given the seismic potential of the area.

The non-uniformity of the valley fills led to intricate zoning of the reinforced fills in design drawings. Typical sections of the fills are shown on Figures 6.a, 6.b and 6.c. In the Fill 3, the stability of the on-site fill was provided for with the arrangement shown in Figure 6.a. The Fill 3 section proceeded further downslope beyond the property limit, so the deeper overall stability of the valley fill could not be fully improved. However, the reinforcement provided makes the slope within the site secure against earthquake loadings.

At the sides of the Fill 3 valley, the soil fill was joined to the bedrock as shown in Figure 6.b, with a series of step cuts. Also of importance in the design of the geogrid

was the retained fill wall at the top of the slope which was designed as a geogrid supported precast concrete wall. Spacing of geogrid layers is shown on the cross-sections. At both locations above Fill 3, a retaining wall was constructed to achieve area needed for parking lots. The wall was designed to use pre-cast concrete panels supported by geogrids extended back sufficient distance for seismic loading conditions.

Figure 6.a Fill 3 Deep Buttress

Figure 6.b Fill 3 Provisions for Fill over Rock Slope

Figure 6.c Fill 2 Cross Section of Reinforcement

Fill 2 profile shown on Figure 6.c provides heavy reinforcement at the toe to create a buttress, with geogrids anchored in the step cuts. Further up the slope, reinforcement was provided only to provide stability of the

"surficial" slope, since the overall stability was sufficient with the large buttress formed in the bottom part of the slope. At the bottom of the Fill 2 slope, another retaining wall was provided for grade separation at the property line. It also will act as buttress in the event adjacent ground support is removed (by earthquake or excavation).

The contract documents set the following requirements for geogrid material:

Weight, per square m.	644 g/sq.m
Minimum Opening Size, in.	15.2 mm
Long-Term Allowable Design Load determined per GRI GG4 (1991)	14.6 kN/m

Material chosen by the Contractor was Mirafi 10 T. In limited areas around the building where small slopes were reinforced to provide 45 deg. inclinations, Mirafi 7 T was used, since the LTADL was less. To maintain landscape slopes adjacent to the building that were at 45 deg. inclinations stable against surface runoff, Geoweb cellular confinement system was installed and interconnected with the layers of geogrid.

Stabilization of the three large fills to provide site slopes, roads and parking areas that would be stable under the design earthquake conditions involved removal of deep fill, and reconstruction with geogrid reinforced backfill. At the time of installation in 1992-3, the more than 200,000 sq.m of geogrid used was the largest installation in South America. About 8,500 sq. m of cellular confinement was also installed.

#### ACKNOWLEDGMENTS

The Foreign Buildings Office of the U.S. Department of State supervised the design and construction of the Caracas embassy project, and their permission to publish this paper is gratefully appreciated. Project Architect was Gunnar Birkerts Associates of Birmingham, MI. Ammann and Whitney of New York City was the site civil engineer. General Contractor for the construction was Perini International, of Framingham, MA. Haley & Aldrich served as the geotechnical consultant for the project, including design of the geogrid system, and provided on-site geotechnical consultation during building foundation and geogrid installation during earthwork construction.

# The Construction of Steep Reinforced Slopes in Hilly Terrain

C.R. Lawson  
CEO, TC Nicolon Asia, Malaysia

T.W. Yee  
Manager, TC Nicolon Asia, Malaysia

**ABSTRACT:** The flexibility of reinforced soil makes it an ideal solution for the construction of steep reinforced slopes in hilly terrain. However, due to the nature of hilly terrain, four major construction constraints can arise. These are the lack of a firm foundation on which to construct the reinforced slope; excavation instability or the occurrence of bedrock that limits the width of the base of the reinforced zone; the presence of groundwater emanating into the excavation from behind the reinforced zone; and the overall instability of the hilly terrain that limits the geometry of the reinforced slope. A parametric study was performed to evaluate the effect of these constraints on reinforced slope stability. Guidelines for maximising reinforced slope geometry, the role of drainage, and the modular approach to design are given for reinforced slopes constructed in hilly terrain.

**KEYWORDS:** Reinforced slopes, Hilly terrain, Construction constraints, Slope geometry, Drainage, Instability

## 1 INTRODUCTION

The use of reinforced soil as a technique to construct steep, stable slopes is a common practice. Today, much is known of the performance of reinforced soil slopes designed and constructed to "standard" geometries. Standard geometries include the presence of a flat, firm foundation beneath the reinforced slope; no limitations on the width of the reinforced zone for stability purposes; and no unusual loading regimes above the reinforced zone.

Reinforced soil is also an ideal technique for the construction of steep slopes in hilly, or mountainous, terrain. The technique results in a retaining structure that is flexible (i.e. it can undergo deformation without exhibiting structural distress) and highly cost-effective. This is important because the topography of hilly terrain dictates the adoption of significant earthworks structures, in some cases founded on suspect and unstable foundation materials. In addition, groundwater is normally present in this type of topography. This is particularly so in tropical climates where heavy rainfall can result in severe groundwater conditions. In this environment the construction of stiff, brittle structures is to be avoided.

In South East Asia, development effort is spreading from the coastal areas into the hinterland of many countries. For the majority of these countries, large areas of the hinterland consist of hilly and mountainous terrain. The overall topographical and geomorphological geometry of this terrain coupled with the need to maximise stable earthworks platforms for infrastructure and other development purposes results in reinforced slopes of significant magnitude. Slope heights over 20 m and slope angles greater than 60 degrees are not uncommon.

An example of such a reinforced slope, whose final height will be over 40 m, is shown in Figure 1 (it is currently at a height of 30 m). It should be emphasised that slopes of this magnitude require good construction quality. Two examples of good construction quality shown in this

example is the use of grass-impregnated soil bags for the slope facing and the use of tiered catchment drains for the collection of surface and subsurface water run-off. The use of grass-impregnated soil bags enables a stable slope face to be developed while at the same time promotes quick vegetation growth. The use of tiered catchment drains enables the quick removal of surface water run-off as well as being the exit drains for the subsurface drainage galleries within the reinforced slope.

Figure 1. Example of a high, reinforced slope constructed in hilly terrain.

## 2 REINFORCED SLOPE CONSTRAINTS IN HILLY TERRAIN

The geomorphological and topographical nature of hilly, or mountainous, terrain poses considerable constraints on the design and construction of steep reinforced slopes. The general geomorphology is similar to that shown in Figure 2a where the terrain consists of a soil-filled slope overlying a dipping bedrock stratum. The soil-filled slope either has formed naturally or is the result of the dumping of earthfill

Figure 2. Constraints on construction of reinforced slopes in hilly terrain.

from nearby construction sites. In South East Asia these soils are normally saprolytic, residual or colluvial deposits. In many instances these soils are not compacted and

consequently exhibit relatively high hydraulic conductivities enabling easy penetration by groundwater.

When a reinforced slope of standard geometry is proposed for construction in this type of terrain (Figure 2b) a number of constraints may exist that considerably affects the final design geometry. These are (Figure 2c):

- The ability to excavate the soil-filled slope in order to provide an adequate base width for the reinforced slope. Slope instability at the rear of the excavation may limit the base width possible.
- The foundation at the base of the reinforced slope may be uncompacted and soft. This may constrain the geometry of the reinforced slope.
- The presence of groundwater during excavation of the soil-filled slope can promote slope instability at the rear of the excavation and can prevent the formation of a firm foundation beneath the proposed reinforced slope.

While each of the above constraints has a marked effect on the design geometry of the final reinforced slope it is impossible to foresee these events with any degree of certainty until construction is in progress. Consequently, in many instances it is necessary to carry out a revised reinforced slope design once the construction constraints are known. To accommodate these construction constraints the final design geometry of the reinforced slope may resemble that shown in Figure 2d.

The revised reinforced slope geometry shown in Figure 2d is not what one would consider a "standard" reinforced slope geometry inasmuch as:

- The foundation surface dips down from the toe of the reinforced slope and is not horizontal.
- The foundation may not be firm but may be soft and compressible.
- Instability at the back of the excavation limits the width of the reinforced zone at the base of the reinforced slope.
- The presence of the bedrock stratum may limit the extent of the reinforced zone and may concentrate shear stresses behind the reinforced zone.

Because of the above features, the use of design procedures based on "standard" geometries is only of limited use. When establishing an appropriate, safe geometry for the required reinforced slope all of the above features need to be considered. Because of some of the unusual topographical and geomorphological features involved in hilly terrain it is important to have an understanding of their effect on the resulting geometry of the reinforced slope. This is especially the case where required reinforced slope heights are to be maximised.

Table 1. Geotechnical parameters used in the parametric study.

	Reinforced soil	Foundation soil			Backfill soil	Bedrock
		Firm	Moderate	Soft		
Bulk density ( $\text{kN/m}^3$ )	18	18	16	15	18	22
Friction angle ( $^\circ$ )	35	35	32	30	35	45
Cohesion (kPa)	150	150	20	10	10	5,000
Bulk modulus (MPa)	115	115	65	15	85	20,000
Shear modulus (MPa)	70	70	40	10	50	15,000

### 3 PARAMETRIC STUDY

To evaluate the effect of various geometric and material parameters on the stability of reinforced slopes in hilly terrain a parametric study was performed. It was considered that the boundaries of external stability were important aspects that required assessment for reinforced slopes constructed in hilly terrain. In addition, stresses and deformations were also considered important parameters for investigation. Because of the specific nature of this type of terrain and the need to evaluate the effect of foundation compressibility as one of the aspects of reinforced slope stability, it was concluded that a sophisticated modelling procedure would be required. Consequently, the parametric study was performed using a continuum method approach (FLAC 1995).

#### 3.1 Slope Geometry Analysed

A slope geometry indicative of that encountered in hilly, or mountainous, terrain was used as a basis for the parametric study. This is shown in Figure 3. The reinforced zone has variables  $H$ ,  $L$  and  $\beta$ .

Figure 3. Reinforced slope geometry used in the parametric study.

A bedrock stratum, on a 1:1 dipping plane, is present near the heel of the reinforced zone. The presence of this bedrock stratum concentrates shear stresses within the backfill zone behind the reinforced zone, thus accelerating a potential global failure mode. The location of the bedrock stratum also restricts large vertical deformations at the heel

of the reinforced zone. This condition is considered common in hilly terrain.

The reinforced zone is seated on a soil foundation with a surface slope of 3:2 ( $34^\circ$  to the horizontal). This slope angle is close to the natural angle of repose for various soil types and is considered common in hilly terrain.

#### 3.2 Material Parameters Used

The various geotechnical parameters used in the study are listed in Table 1. The soil in the reinforced zone was assumed a compacted cohesive-frictional fill indicative of the saprolytic, residual and colluvial soils found in South East Asia. In the reinforced zone, the reinforcement was modelled by means of an additional apparent cohesion within the compacted soil. To ensure the maintenance of internal stability within the reinforced zone the layers of reinforcement would have to impart an apparent cohesion of 130 to 140 kPa according to the method proposed by Hausmann (1976). Consequently, a total cohesion of 150 kPa was assumed for the reinforced zone.

Three different foundation soil conditions were adopted for the parametric study – firm, moderate and soft (see Table 1). Standard design methods for reinforced slopes always assume a firm foundation beneath the reinforced slope. While never specifically stated, a firm foundation can be assumed to be one where it is impossible for a bearing failure to occur, or where another type of external instability occurs before the onset of bearing failure. For the parametric study, the firm foundation has been given the same properties as the reinforced zone. This was done to ensure that foundation failures beneath the reinforced zone could not occur, given the specific geometry of the problem. With a foundation having these properties the only external failure modes are global, sliding, compound or overturning instability.

The soft foundation soil parameters listed in Table 1 may be considered indicative of loosely placed soil or fill. While not implicit, groundwater may be also present within the loose fill.

The moderate foundation soil parameters are considered indicative of naturally deposited soil without any form of densification carried out. This is considered to be the most prevalent type of foundation condition encountered in hilly terrain in South East Asia.

It has been assumed that the soil backfill consists of compacted local soil taken from the excavation of the

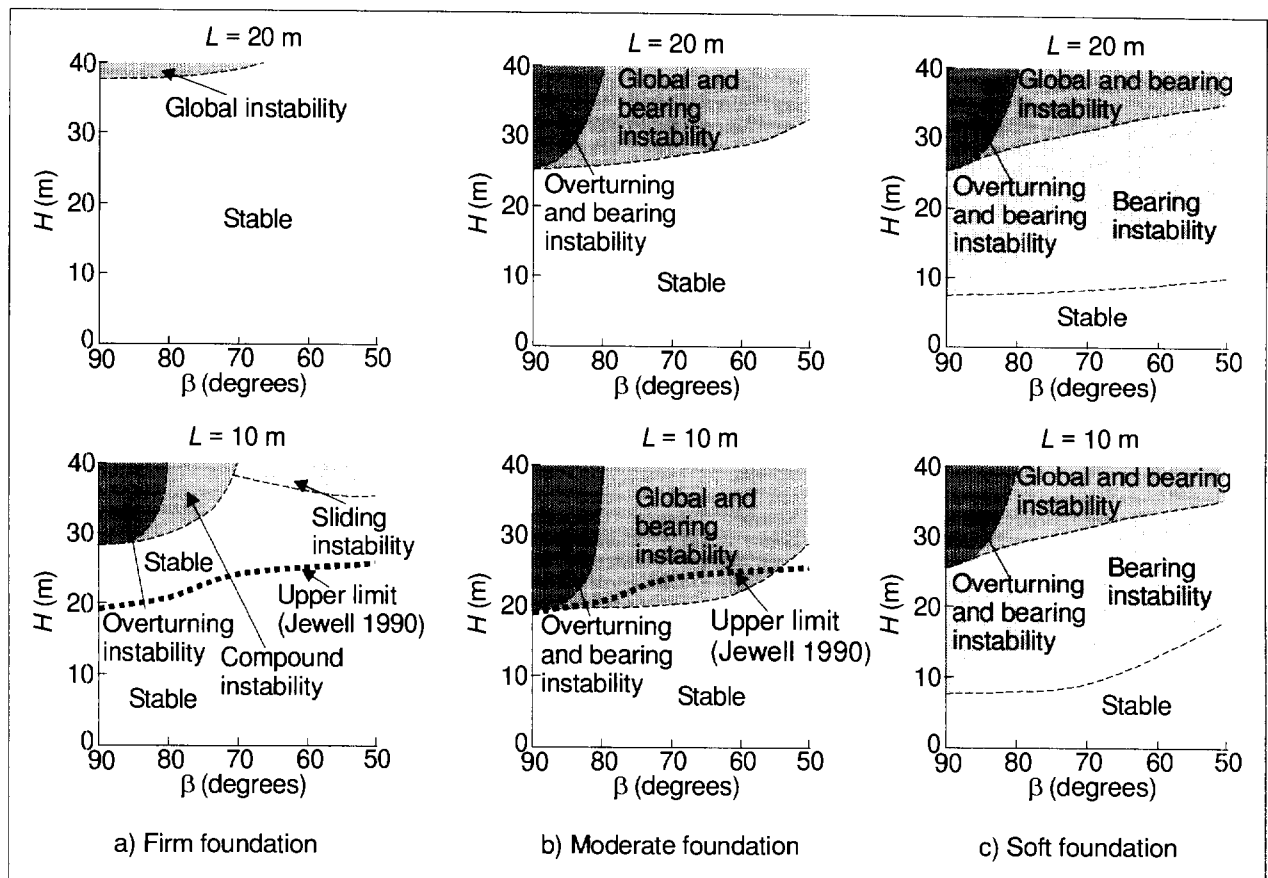

Figure 4. External stability boundaries for reinforced slopes constructed according to the geometry shown in Figure 3.

reinforced slope. The bedrock is an incompressible stratum that cannot fail internally.

For the parametric study, a reinforcement layer was included at the base of the reinforced slope. The inclusion of this layer was not to enhance the internal stability of the reinforced zone but to determine what additional tensile loads are exerted on the base reinforcement layer, given the different foundation conditions and potential failure modes occurring. In addition to the base reinforcement layer a horizontal interface was included between the reinforcement layer and the surface of the soil foundation. This interface layer was given a bond coefficient  $a' = 0.7$  which, while being lower than expected for modern geosynthetic reinforcements, would be considered to provide conservative (i.e. safe) stability solutions.

A second interface was included between the compacted backfill and the rear of the reinforced zone. For this interface a bond coefficient of  $a' = 1.0$  was used for all cases.

### 3.3 External Stability Boundaries for Reinforced Slopes

From the parametric study it was possible to determine the boundaries of acceptable external stability for reinforced slopes analysed according to the geometry shown in Figure 3. Figure 4 contains plots of regions depicting stable and unstable behaviour for the cases of reinforcement length  $L$

$= 10$  m and  $L = 20$  m and for firm, moderate and soft foundation conditions.

For the firm foundation case, Figure 4a, and for reinforcement length  $L = 20$  m global instability begins at around 40 m height for the reinforced slope. Global instability occurs along the boundary of the bedrock stratum (see Figure 3). "Standard" design methods such as the chart method proposed by Jewell (1990) would indicate that significantly higher slopes were possible for  $L = 20$  m, however, these methods cannot take into account the geomorphological features shown in Figure 3. For the reinforcement length  $L = 10$  m case shown in Figure 4a external instability can be induced by overturning, compound or sliding depending on the reinforced zone geometry. The calculated upper limit according to Jewell (1990) has also been plotted. The results show that an additional slope height of 8 to 10 m can be adopted compared to that calculated using "standard" design methods.

For the moderate foundation case, Figure 4b, and for reinforcement length  $L = 20$  m the onset of external instability occurs around 25 to 30 m in height depending on the slope angle. The onset of global and bearing instability occurs before other forms of instability, e.g. sliding, etc. Comparison with the firm foundation case shown in Figure 4a shows the effect of the change in foundation properties on the achievable reinforced slope geometry. For the

reinforcement length  $L = 10$  m case shown in Figure 4b external instability is also induced by global and bearing but (as expected) at a lower slope height than for  $L = 20$  m. The calculated upper limit according to the design charts of Jewell (1990) has also been plotted. The results show that there is fair agreement, however, this is considered to be by chance as “standard” design methods cannot account for bearing instability, which is the major mode of instability in this case.

For the soft foundation case, Figure 4c, and for reinforcement length  $L = 20$  m the onset of external instability occurs around 8 to 10 m in height depending on the slope angle. As to be expected the dominant mode of instability is bearing failure. For the reinforcement length  $L = 10$  m case shown in Figure 4c external instability is also induced by bearing failure at comparable slope heights to the  $L = 20$  m case.

### 3.4 Vertical Stress at Base of Reinforced Slope

The vertical stress acting across the base of the reinforced slope was also recorded from the parametric study. This stress was derived in the form of a vertical stress ratio (VSR), being:

$$VSR = \frac{\sigma'_{vb}}{\gamma H} \quad (1)$$

where:  $\sigma'_{vb}$  = vertical stress along the base of the reinforced slope;  $\gamma$  = bulk density of the soil in the reinforced slope; and  $H$  = height of the reinforced slope.

While the vertical stress at the base of the reinforced slope varies across the width of the reinforced zone, for simplicity, the vertical stress ratio at the toe of the slope ( $VSR_{toe}$ ) and at the heel of the slope ( $VSR_{heel}$ ) were the only two locations recorded.

Figure 5 shows the results obtained for the firm foundation case. At the toe of the reinforced slope (Figure 5a)  $VSR_{toe}$  ranges from 1.2 to 0.35 according to slope angle and  $H/L$  ratio. For slope angles greater than  $75^\circ$   $VSR_{toe} \geq 1.0$ . This is consistent with retaining wall theory. For slope angles less than  $75^\circ$   $VSR_{toe} < 1.0$ , the value reducing as the slope angle reduces. At  $\beta = 75^\circ$ ,  $VSR_{toe} = 1.0$ .

At the heel of the reinforced slope (Figure 5b) the magnitude of  $VSR_{heel}$  is greatly dependent on the  $H/L$  ratio of the slope. Relatively high values of  $VSR_{heel}$  are obtained for  $H/L = 0.5$ . The reason for this is the effect of the development of full friction between the reinforced zone and the soil backfill. This effect reduces as the slope angle reduces. For  $H/L = 1.0$  there is still some effect of backfill friction giving  $VSR_{heel} > 1.0$  for slope angles greater than  $55^\circ$ . For  $H/L \geq 1.5$  the effect of backfill friction is negligible and consequently,  $VSR_{heel} = 1.0$  for slope angles greater than  $65^\circ$ .

Figure 6 shows the results obtained for the moderate foundation case. In general, the results are similar to those

Figure 5. Vertical stress ratio at the base of the reinforced slope for the firm foundation case.

presented in Figure 5 for the firm foundation case. However, the moderate foundation, being more compressible than the firm foundation, enables a more uniform stress distribution to develop across the base of the reinforced zone than is the case with the firm foundation. Consequently, the curves plotted in Figure 6 show more agreement between the  $VSR_{toe}$  and  $VSR_{heel}$  values than is the case for the firm foundation.

### 3.5 Additional Load in Reinforcement at Base of Reinforced Slope

Standard design methods that assume the presence of a firm foundation calculate reinforcement loads according to

Figure 6. Vertical stress ratio at the base of the reinforced slope for the moderate foundation case.

internal stability requirements only. However, in situations where the foundation is compressible additional tensile loads may be imparted to the reinforcements as the reinforced slope deforms. These additional tensile loads would be a maximum at the base of the reinforced slope. The parametric study was also used to calculate the magnitude of these additional tensile loads imparted to the reinforcement layer at the base of the reinforced slope.

Table 2 contains a summary of the results obtained. It is noted that for stable conditions the additional loads imparted to the base reinforcement layer are relatively small and may be neglected for all cases except the soft foundation case. For the soft foundation case the additional loads are greatest, at around 10 kN/m. For most reinforced

slope applications the design loads carried by the reinforcements are between 30 and 60 kN/m. Thus, only for soft foundation conditions would the additional reinforcement load be significant.

Table 2. Additional reinforcement load at base of reinforced slope due to different foundation conditions.

Foundation	Additional reinforcement load	
	Stable conditions	Onset of instability
Firm	$\approx 1$ kN/m	$\geq 20$ kN/m
Moderate	$\approx 3$ kN/m	$\geq 30$ kN/m
Soft	$\approx 10$ kN/m	$\geq 40$ kN/m

However, at the onset of instability the additional load applied to the base layer reinforcement increases significantly, even for the firm foundation case. This increase in reinforcement load should provide added incentive to ensure that reinforced soil slopes do not approach external instability as the additional loads applied to the base layer reinforcements could lead to their premature rupture with subsequent collapse of the structure.

#### 4 THE ROLE OF DRAINAGE

The influence of good drainage on the performance of reinforced slopes constructed in hilly terrain should not be underestimated. This is especially the case in wet, tropical climates where significant flows of surface and subsurface water can occur. In these environments well- designed and constructed drainage systems are essential and should be considered an integral part of reinforced slope design and construction.

Water may penetrate the constructed slopes in two ways – as groundwater flow from the existing undisturbed deposits behind the slopes, and as surface water run-off due to rainfall. To accommodate these events a recommended drainage layout is shown in Figure 7.

Figure 7. Recommended layout of drainage system within high, reinforced slopes.

Figure 8. Modular approach to the design of steep reinforced slopes.

To ensure the effective removal of groundwater from behind the constructed slope subsurface drainage galleries should be constructed within the fill zone, preferably at every tier level in the reinforced slope. Since the compacted backfill material is normally the same material as that excavated at site, when replaced and compacted it exhibits significantly less hydraulic conductivity than the adjacent undisturbed deposits. Consequently, to remove the groundwater effectively it is essential that the subsurface drainage galleries be extended beyond the compacted backfill zone to interface with the existing undisturbed deposits. The subsurface drainage galleries can be of the form of drainage blankets or feeder drains. The materials used for the drains are normally small aggregates (for drainage) with geotextile filters. The outlets of the subsurface drainage galleries extend beneath the reinforced soil zones and exit within the surface catchment drains at the toes of the reinforced slope tiers.

If the excavated soil is suitable it is normally used with the geosynthetic reinforcement to construct the reinforced soil zones. This is common practice in South East Asia where the saprolitic, residual and colluvial soils exhibit good shear resistance when combined with geosynthetic reinforcement. The use of the locally available soil also provides the most economical solution. When these soils are compacted to form the reinforced zones it is difficult for surface water to penetrate these fills especially when one considers the nature of the surface geometry of steep slopes. Consequently, surface water damage is normally confined to surface erosion. To protect against surface erosion, open catchment drains should be constructed at the toe of each reinforced zone tier to prevent excess surface

run-off, Figure 7. To prevent surface soil loss it is normal practice either to use an erosion control mat on the surface of the slope or to use grass-filled soil bags. Grass-filled soil bags are normally used for the steeper reinforced soil slopes.

## 5 MODULAR APPROACH TO DESIGN

The design of steep reinforced slopes in hilly, or mountainous, terrain lends itself to a modular approach inasmuch as the reinforced slope can be divided into similar regions, or modules, within the height of the reinforced slope. Each module can be assessed for internal stability as well as sized appropriately to ensure external stability of the whole reinforced slope. A modular approach to design also enables added flexibility in the sizing of the individual modules, standardisation and simplification of the reinforced soil components within each module, and the ability to readily re-size specific modules if construction conditions are not the same as assumed during the design phase.

Figure 8 shows the general basis for the modular design approach. The reinforced slope is designed as a series of reinforced soil modules. Each module consists of its reinforced soil zone along with its associated integral drainage system. Each reinforced soil module can be 6 to 10 m in height, but is more commonly 6 to 8 m. During construction, it is common practice to step-back the face of each succeeding module between 1 to 1.5 m. This enables enough space for the construction of the surface catchment drain.

The length of each module,  $L_n$  in Figure 8, needs to be assessed with regard to the maintenance of internal and external stability. The results shown in Figure 4 may be used as a basis for the assessment of external stability.

The internal stability of each module is assessed by plotting the horizontal stress distribution through the module and ensuring that there is adequate reinforcement capacity to resist the horizontal stresses. The procedure used to determine the horizontal stress distribution through each module is shown in Figure 8. First, the vertical stress distribution at the top and the base of each module is determined, e.g. by using the results in Figures 5 and 6. Second, the vertical stress distribution through each module can then be determined using the vertical stress at the toe of each module as the basis. Third, the horizontal stress distribution can then be determined by adopting an appropriate value of  $K$ , the ratio of horizontal to vertical stress. Values of  $K$  as proposed by Jewell (1990) may be used. Checks for adequate reinforcement bond capacity can be performed by deriving a vertical stress distribution through each module based on the vertical stress at the toe and the heel of each module.

## 6 CONCLUSIONS

The paper has concentrated on a specific, but important, aspect of reinforced slopes – that of their construction in hilly, or mountainous, terrain.

While the use of “standard” design methods may be appropriate for assessing the internal stability of reinforced slopes constructed in this type of terrain, their use for assessing the overall dimensions of the reinforced zone for external stability purposes is not appropriate. Specific aspects such as local topography and geomorphology, as well as foundation conditions need to be considered, and these can result in significantly different solutions compared with those solutions provided using standard design methods and charts.

Good drainage should form an integral part of any reinforced slope design in hilly terrain, especially in tropical climates where high rainfall is prevalent. Attention to the controlled removal of both surface and subsurface water is crucial for good performance.

A modular approach to the design of steep reinforced slopes offers a number of advantages over the conventional approach of considering the reinforced zone as one single mass. Its major benefit lies in the flexibility of being able to consider the reinforced slope as separate regions (modules) that can be sized according to their location in the slope, and reinforced according to the magnitude of the vertical stresses acting at the top and the bottom of each module. The modular approach enables a number of the components of reinforced slope design to be standardised, and allows the slope geometry to be easily adjusted according to local construction conditions.

# Case Study. Bluewater Retail & Leisure Destination - Major reinforced soil slopes to form steep sided new lakes.

J.H. Dixon

Tensar International Ltd, New Wellington Street, Blackburn, UK

**ABSTRACT:** Bluewater is a new £360M (\$580M) retail and leisure destination located in a former chalk quarry in England. Enabling Works involved bulk filling and the formation of a number of lakes. Two of these lakes were formed with slopes at  $70^{\circ}$  to the horizontal, about 10m high, and which in places were surcharged with highway embankments. Lakes 1 and 2 were constructed with several hundred linear metres of reinforced soil slopes, incorporating high density polyethylene uni-axially oriented geogrids. Lake 1 was also lined with a geomembrane which, to avoid damage could not be placed on or near the slope face. The geomembrane was therefore located underneath and behind the rear face of the reinforced soil block. This detail posed unusual design considerations involving sliding stability and the analysis of a number of load cases for different combinations of water level. The design and construction of these lakes including three innovative facing details are discussed.

**KEYWORDS:** Geogrid, Steep slope, Reinforced embankment, Geomembrane lake liner.

## 1 INTRODUCTION

Bluewater, developed by Lend Lease is located approximately 30km east of London. On completion, in March 1999, it is intended to be the largest and most prestigious retail development in Europe, containing 140,000m<sup>2</sup> of retail space, 13,000 car parking spaces, nearly 12,000m<sup>2</sup> of leisure space and with a million trees and shrubs landscaping the area.

The site is located in a former deep chalk quarry. The construction of several lakes was included within an Enabling Works contract which principally involved bulk filling with approximately 3M m<sup>3</sup> of a local silty sand. Two of the lakes, Lakes 1 and 2, were formed with steep sides in order to maximise their water volume and depth for environmental reasons.

Lake sides sloping at  $70^{\circ}$  to the horizontal and approximately 10m high were selected. In places these slopes were to be surcharged by highway embankments and landscaping fill under a later contract. The Client's Consulting Engineer, Waterman Partnership, recognised at an early stage the economic and practical advantages of reinforced soil techniques.

As the ground water level was known to vary significantly it was decided to line Lake 1 with a geomembrane in order to retain a constant lake water level. There were concerns about the long-term durability of the geomembrane and in particular its vulnerability to potential damage from burrowing wildlife or boat impact if it were placed on, or close to, the slope surface. It was therefore decided to locate it underneath and up the rear face of the reinforced soil block.

## 2 REINFORCED SOIL DESIGN

### 2.1 Outline Design Brief

The Engineer invited Tensar International Ltd to assist with specialist design support in developing the reinforced soil design beyond the concept stage.

Lake 1, with the geomembrane lining located below the reinforced soil block, presented two unusual reinforced soil design challenges:

- The potential for sliding of the reinforced soil block over the geomembrane.
- The combination of the large number of possible water levels (within both the lake and the external ground) and various imposed loadings conditions, phased with the subsequent highway and landscaping contracts.

Furthermore, the design brief called for a low-cost durable face with a 120 year life and high security against wash out of the fill.

#### 2.1.2 Basic Design Parameters

The fill which was to be sourced from an adjacent quarry was a silty fine sand (Thanet Sand). Its design parameters were:

$$\phi'_{cv} = 31^{\circ}, c' = 0, \gamma_{opt} = 19.3\text{kN/m}^3 \text{ and } \gamma_{sat} = 20.2\text{kN/m}^3$$

A series of 30cm x 30cm laboratory shear box tests was commissioned to measure the frictional shearing resistance between the various specified geosynthetic materials and this fill.

The selected lining system was 1mm thick modified low density polyethylene (LDPE) geomembrane protected by a 700g/m<sup>2</sup> polypropylene needle punched geotextile. The critical interface shearing angle ( $\phi_{is}$ ) for this combination was measured at  $20^{\circ}$ .

Two strengths of high density polyethylene (HDPE) geogrid reinforcement were selected; Tensar 40RE (Type 1) and Tensar 80RE (Type 2). These are manufactured from extruded sheets and orientated (stretched) in the machine direction. Their Index QC strength in the longitudinal direction is 40kN/m and 80kN/m respectively and rib thicknesses ( $t_f$ ) 0.7mm and 1.3mm and ( $t_b$ ) 1.9mm and 3.6mm respectively (Figure 1). Shear tests on these two grid types with the chosen fill material indicated friction angles in excess of  $26^\circ$  (i.e. a coefficient of soil interaction  $\mu > 0.8$ ).

Figure 1 Geometry of the grid reinforcement

## 2.2 External Stability

The shear box testing confirmed that a critical potential failure mechanism for Lake 1 was sliding over the geomembrane lining system. It was therefore decided to incline the lining at an angle  $\alpha$  of approximately  $5^\circ$  below the reinforced soil block (This equated to a fall of 1.5m from toe to heel over the width of the block).

The basal reinforcement layer remained horizontal and was positioned a minimum distance of 100mm above the lining system at the face. This ensured that the critical interface frictional value would not be further reduced.

The factor of safety against sliding over the inclined geomembrane was calculated by resolving forces about the geomembrane (Figure 2).

Figure 2 Force resolution on reinforced soil block.

Note: the net mobilising force ( $P$ ) is assumed to act on an angle to the rear of the reinforced soil wall =  $\frac{1}{2} \times \phi'_{ls}$ .  $W$  = weight of the reinforced soil block and  $F$  and  $N$  are the frictional and normal forces acting on the inclined geomembrane.

By resolving forces perpendicular to the geomembrane:

$$W \cos \alpha + P \sin (10^\circ + \alpha) = N \quad (1)$$

By resolving forces parallel with the geomembrane:

$$F = N \tan 20^\circ \quad (2)$$

$$FoS = \frac{F + W \sin \alpha}{P \cos (10^\circ + \alpha)} \quad (3)$$

$$FoS = \frac{[W \cos \alpha + P \sin (10^\circ + \alpha)] \tan 20^\circ + W \sin \alpha}{P \cos (10^\circ + \alpha)} \quad (4)$$

Where FoS = Factor of Safety against sliding over the lining system. (i.e. the resisting force divided by the sliding force).

FoS for design was specified as 1.5 for the temporary condition and 2.0 for the completed works. Figure 3 shows the cross section through the north side of Lake 1 and the particular loading condition which was found to be critical for sliding stability i.e. the condition prior to the placement of landscaping fill and with the lake water level lower than its final design level.

The width of the reinforced soil block is dimensioned to provide sufficient weight ( $W$ ) to satisfy FoS.

Lakes 1 and 2 were also checked for other external stability conditions, including sliding over the reinforcement.

## 2.3 Internal Stability

The specialist designer's experience of other reinforced soil structures with a similar geometry was that design principles based on the German Institut für Bautechnik (DIBt) would produce a stable and economical solution. Internal stability calculations take the form of a two-part wedge analysis through the reinforced soil block. A series of two-part wedges are examined with the lower part of the wedge originating at the structure face and passing through the block, and the upper part of the wedge passing up the back face of the reinforced soil block. The active pressure, above that point where the lower part of the wedge cuts the back face of the reinforced soil block, is added to the disturbing forces acting on the two-part wedge to give the total disturbing force. In the case of internal stability, the resultant active

force is taken to act on angle equal to the friction angle of the soil block rear face.

Figure 3

Reinforcement must be provided to resist the disturbing force on each two-part wedge by intercepting the wedge being considered. The two-part wedge stability calculation should be carried out from the toe of the structure, the bottom grid layer, at all levels where the grid spacing alters and at every level where the grid type alters.

The reinforcement design strength is obtained from the creep-limited strength appropriate to the design life and in-soil temperature. Specific partial factors are then applied to take account of such factors as installation damage. Finally, an overall FoS = 1.75 is applied to the strength.

The reinforcement layout was derived by analysis with lower part wedge angles ( $\theta$ ) set at  $3^\circ$  intervals (Figure 4) using the specialist designer's computer program - Winwall. (Tensar International, 1995)

Figure 4 Two-part wedge analysis.

For Lake 1, the critical condition for internal stability was identified as the completed structure fully landscaped under the rapid 'draw-down' condition with the lake empty (perhaps during a future maintenance operation) and the backfill behind the reinforced soil block fully saturated. A typical reinforcement layout for the north side of Lake 1 is shown in Figure 5. The maximum vertical reinforcement spacing was set at 60cm.

Figure 5 Typical reinforcement layout.

Note: The road embankment (part of a later contract) was constructed using reinforced soil.

#### 2.4 Face Detail

The face of the reinforced slopes had to be relatively inexpensive while possessing high durability and damage resistance. The Engineer ruled out a proprietary segmental concrete block face on the grounds of cost, and instead selected a geogrid wrap-around face. With this detail, the horizontal reinforcement layers are extended up the temporarily supported face of the fill and then returned back horizontally and connected with a full-strength joint to the next layer of reinforcement. There was sufficient information on the durability of the specified grids to satisfy long-term serviceability questions (Wrigley, 1987).

The face also had to remain permeable and retain the silty sand fill. Attention was therefore focused on the selection of a geotextile filter to line the wrap-around face. It was recognised that any damage or malfunction of this geotextile could lead to a steady wash out of fines and ultimately to collapse.

Netlon 1004R geotextile was specified. It has independent certification from the German Federal Waterways Authority (BAW) based on rigorous performance testing with a range of soils including silty sand. These tests assess:

- filter performance by filtering a real soil in turbulent conditions and also examining the resultant permeability after impregnation with soil particles.
- residual tensile strength following exposure to abrasion (16 x 5000 revolutions of a rotating drum containing gravel and water).
- puncture resistance in a test replicating rock armour units being dropped on a soil supported sample.

This non-woven geotextile is manufactured by needle punching two separate geotextiles, one containing staple (short) fibres of polypropylene and the other, a polyester, to create an integrated 800g/m<sup>2</sup> duplex material. This efficient double layer arrangement provides a coarse fibre pre-filter which, additionally, interacts with the soil to achieve a degree of mechanical stabilisation of soil particles which may otherwise be prone to migration.

Despite this certified evidence of the geotextile's robustness and field experience with similar products under extremely severe test conditions (Dixon et. al, 1990), the Engineer was concerned about its vulnerability to damage e.g. from accidental impact, burrowing animals, nesting birds and long term exposure to ultra violet (UV) radiation.

The Engineer, therefore, specified an outer grid wrap-around face retaining a 15cm wide layer of 5 - 10cm sized hard durable fill as cover protection to a geotextile wrap-around local to the face of the silty sand fill (Figure 6).

With the specified grids it is possible to create a full-strength connection between adjacent lengths using an HDPE bodkin (Figure 7). In a wrap-around detail this bodkin provides a more positive joint than simply relying on a frictional anchorage. Furthermore, when the higher grid length is tensioned during installation this helps pull the lower wrap-around face tight.

Figure 6 Cross-section showing face detail.

Figure 7

### 3 CONSTRUCTION

#### 3.1 Contract Award

The Enabling Works contract was let by Bluewater Construction Management Team (BCMT) to O'Rourke Civil Engineering Limited in early 1996 following a competitive tendering process. O'Rourke chose to use the specified geosynthetics. They appointed a specialist sub-contractor to supply and install the lining system for Lake 1 and opted to construct the reinforced soil slopes themselves.

#### 3.2 Lake 1

Lake 1 is oval in plan with a perimeter slope length of approximately 500m. Reinforced soil installation began in April 1996. The Contractor selected a 2.4m high timber formwork system, supported by scaffold tube and fittings, for temporary support to the grid wraparound face (Figures 8 & 9). A 60cm high inner plywood former with lifting holes, tapering in cross section from 20cm at the top to 15cm at the bottom, was used to form the inner geotextile wrap-around.

The grids were cut to design length on site. Bodkin joints were used to avoid wastage from end of roll off-cuts. These lengths were abutted against the inside face of the shutter and nominally joined by cable ties to avoid any gaps opening during installation. The internal former was then placed against the grid face and the geotextile was wrapped around the internal face of the former. A geotextile overlap of 50cm was specified. The silty sand fill was placed and compacted in lifts to a depth of 60cm. This fill was found to have sufficient short-term cohesion that the former could be carefully raised and the resulting void filled, by hand, with coarse material without any slumping of the geotextile face.

Figures 8 & 9

The grid wrap-around face was next returned over the coarse fill and connected to the next grid layer using a bodkin. The free end of the upper grid was then hand tensioned using a steel beam.

The face of Lake 1 was slightly reprofiled by local steepening to accommodate 20cm horizontal ledges at the top of each 2.4m lift on which the shutter could be seated. The overall slope remained at 70°. (The geomembrane which extended up the rear of the reinforced soil block also required its own temporary shuttering).

These details resulted in relatively slow outputs of around 40 - 50m<sup>2</sup> of completed face area per day using two gangs. In order to improve this, the Contractor developed a face detail which replaced the shutter and plywood former with an internal steel mesh former. This was produced by site cutting 5mm diameter steel mesh sheets and bending them into 'U' shaped units 60cm high x 28cm wide. These units were positioned to act as a permanent face former (Figure 10) and then filled with the coarse fill. Since the steel mesh aperture was 20cm x 20cm, the vertical face of the unit was lined with geogrid Type 1 before filling. The top of the unit was cross braced using steel tie wire.

Figure 10

The geotextile was then wrapped up the rear face of the filled unit and the bulk fill placed behind. The main grid length was then wrapped up the front face of the unit and bodkined and tensioned as normal.

This alternative method proved a little quicker, particularly for the higher levels, although the alignment, while acceptable, was less consistent.

The reinforced soil slopes of the Lake are constructed with approximately 60,000m<sup>2</sup> and 80,000m<sup>2</sup> of geogrids Types 1 and 2 respectively supplied in 50m x 1.3m rolls. They were constructed in approximately 3 months.

### 3.3 Lake 2

The water level of Lake 2 was designed to fluctuate with that of the surrounding chalk aquifer and so no geomembrane lining was necessary. About half of the slope length of Lake 2 was formed from the existing chalk quarry face.

Reinforced soil construction took place in the Winter and Spring of 1997. In order to simplify and accelerate installation the Contractor, with assistance from the grid manufacturer, proposed a radically different face comprising site-cast, ordinary-Portland-cement concrete blocks (with 50MPa 28 day compressive strength). These blocks were 2.7m long, 0.6m high and 0.3m wide and contained either one or two layers of 'starter' lengths of cast in Type 2 geogrid (Figure 11). The deeply embedded thick transverse bar of the grid has been shown to provide an anchorage in excess of the design strength of the reinforcement.

HDPE grids have been shown to be unaffected by the highly alkaline environment associated with concrete embedment. (Wrigley, 1987)

This solution was attractive to the Contractor who had already established a batching plant on site and estimated

that he could produce blocks at about a third the cost of typical proprietary segmental units.

For simplicity, the blocks were produced with a stepped vertical face and so the slope profile was amended (Figure 12).

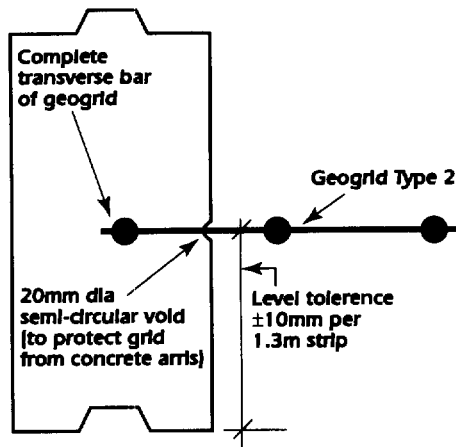

Figure 11 Cross-section of typical block.

These blocks overcame the need for both the shuttering and the coarse fill. The main grid lengths were connected to the starters using bodkins and the geotextile was used to prevent wash out of fines through any small gaps between blocks.

The blocks were cast at a rate of up to 36 per day. Over 1,000 blocks each weighing approximately 1 tonne were required. Installation was much less labour intensive when compared to Lake 1.

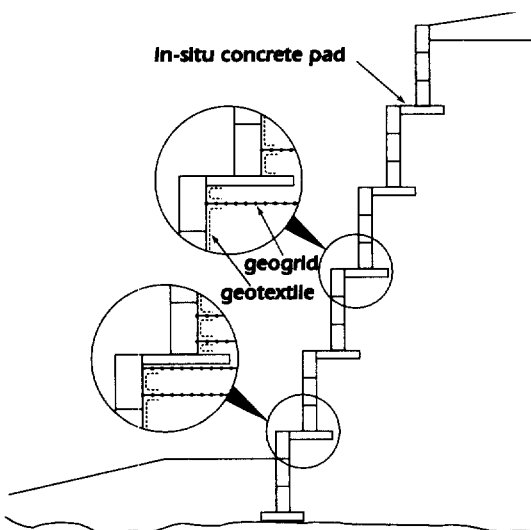

Figure 12

#### 4 CONCLUSIONS

This paper explains the design approach used to address the unusual situation of a reinforced soil lake slope overlying a geomembrane lining system.

The construction details of the three reinforced steep slope facings on this major UK project are also described.

Although the retail park is not scheduled to open until early 1999, Lake 1 (lined) had been substantially completed by the end of 1996 and Lake 2 by the Spring of 1997. There has been no sign of any movement or instability in the reinforced soil structures.

#### ACKNOWLEDGEMENTS

The writer is indebted to Lend Lease, BCMT, Waterman Partnership and O'Rourke Civil Engineering Limited for permission to produce this paper and to J Cannon who carried out much of the original reinforced soil design.

# Soil Bioengineering\Biotechnical Stabilization Of A Slope Failure

Robbin B. Sotir

Principal, Robbin B. Sotir & Associates, Marietta, Georgia

John T. Difini

Engineer, Haley & Aldrich, Inc., Cambridge, Massachusetts

Andrew F. McKown

Vice President, Haley & Aldrich, Inc. Cambridge, Massachusetts

**ABSTRACT:** This paper describes the basic principles of steep slope stabilization using soil bioengineering to reconstruct and stabilize a section of slope along Massachusetts Turnpike at Mile 79.3 E.B. Discussions will focus on the principles of soil bioengineering and reinforced soil slope (RSS) designs, benefits of this interdisciplinary environmentally sound approach, and case study details: vegetation harvesting and storage, design, installation and project status as of October 1997. Design of a fill material, satisfying both agronomic needs of vegetative components and engineering requirements for slope stability, is described. Meeting environmental and aesthetic goals was paramount.

Use of tensile inclusions made from live branches and polymeric geogrids made it possible to construct a highly steepened 4V:1H vegetated earthen buttress slope.

RSS is useful in constructing steepened slopes, improving stability and reducing required fill volumes. Soil bioengineering uses woody vegetation installed perpendicular to the slope face on constructed fill terraces. The installed branches offer immediate reinforcement as supplemental tensile inclusions.

**KEYWORDS:** Soil Bioengineering, Biotechnical, Slope, Stabilization, Vegetation.

## 1 INTRODUCTION

Mechanically stabilized earth (MSE), or reinforced soil slope (RSS) embankment systems are commonly used for the widening and reconstruction of existing roads and highways. This paper focuses on the benefits achieved by combining the principles of soil bioengineering and reinforced soil slope design to reconstruct a failed slope on the Massachusetts Turnpike.

## 2 SYSTEM OVERVIEW

### 2.1 Soil Bioengineering and Biotechnical Slope Stabilization Techniques

Soil bioengineering techniques have been used around the world for centuries and were used in the United States by the Department of Agriculture's Soil Conservation Service in the 1930s. They have since been incorporated into the USDA's National Resources Conservation Service Engineering Field Handbook as Chapter 18, "Soil Bioengineering for Upland Slope and Erosion Control." Soil bioengineering uses mechanical, hydrological, biological, and ecological principles to develop living structures for the stabilization and revegetation of cut and fill slopes. Living woody plant material forms the main structural component. Soil bioengineering is typically used in conjunction with sound engineering data and design, a fact that is especially evident on this project.

In this case, live cuttings from woody plants were installed in the ground in specific configurations and served immedi-

ately as soil reinforcements, horizontal drains, barriers to earth movement and hydraulic pumps or wicks. Much the same as with geogrids, additional stabilization occurs when the roots develop along the length of the embedded stems. Woody vegetation, when properly designed and installed in these specific configurations, can create stable, composite earth masses. Its functional value has been well established. These cuttings can be used alone or in combination with geosynthetic materials.

When living vegetation is combined with inert components such as geogrids, the approach is referred to as biotechnical stabilization. Essentially the vegetated geogrid is a composite of soil bioengineering and an RSS system in which the slope will always be dependent upon the RSS structural measures for stability. This case study project represents an excellent example of how to combine technologies.

### 2.2 Engineering a Reinforced Soil Slope

The design approach to engineering an RSS is a generic process that is typical from slope to slope.

### 2.3 Anticipated Benefits

The combination of RSS and soil bioengineering systems typically provides the following benefits:

- Immediate slope stabilization and erosion control
- Elimination of the need to purchase additional rights-of-way since slopes can be reconstructed at very steep angles
- Reduction of maintenance costs, as there is no need to return to the site to add soil or gravel, or to hydroseed
- Modification of soil moisture regimes using backslope

drainage systems and/or the brushlayer branches which act as wick drains

- Enhancement of opportunities for wildlife habitat and ecological diversity
- Improved aesthetic quality and scenic beauty through revegetation and naturalization of the slope.

### 3 CASE STUDY

#### 3.1 Project Site

The project site is located immediately adjacent to the eastbound lane of the Massachusetts Turnpike at Mile 79.3 in Charlton, Massachusetts. The slope was approximately 144.87 meters (475 feet) in length, ranged from 3.05 meters (10 feet) to 15.25 meters (50 feet) in height and had a slope angle of approximately 1V:1.5H. Stabilization was needed to remediate ongoing surficial sloughing failures. These failures ultimately formed a large exposed, unvegetated area that was increasingly vulnerable to progressive surface erosion and further failure. Groundwater seepage, saturated surficial soils, and seasonal freeze-thaw cycles exacerbated the instability of this north-facing slope. On both sides of the failed area, the slope was well vegetated and appeared stable; however, it was apparent that the failure was expanding on both sides, as shown in Figure 1.

Subsurface conditions at the site include widely graded, slightly cohesive, dense to very dense glacial till overlain by shallow surficial topsoil and forest mat. Bedrock is typically located within 3.05 meters (10 feet) of the base elevation of the slope. However, during construction an outcrop of poor rock was discovered along a 7.62 meter-long (25 feet) section of slope. The rock sloped unfavorably toward the roadway and required controlled blasting to cut it to a stable surface on which the slope could be reconstructed.

#### 3.2 Project Background

Due to the nature and extent of the failure conditions, the Massachusetts Turnpike Authority (MTA) decided it was imperative to correct this situation by reconstructing the slope. See Figure 1. If not treated, these conditions would inevitably lead to further slope failures, additional maintenance costs and an expanding, unsightly, unvegetated slope along a scenic

Figure 1. Overall view of the project from the west-bound lane (Sept. 1994), prior to slope excavation and slope reconstruction

stretch of the Turnpike. A concrete barrier was installed along the base of the slope to contain the failed soil mass and prevent it from moving onto the roadway.

The aim of the project was to design and construct a 4V:1H earthen buttress immediately in front of the cut slope to provide internal, external, and compound stability. The soil bio-engineering approach was adopted to meet the requirement of an aesthetically pleasing and environmentally sound reconstruction, and to assist in controlling internal drainage. This combined approach uses vegetated geogrids to provide the much-needed surficial stability and to support long-term vegetative growth with almost no maintenance requirements. The geogrid is a hybrid design that incorporates brushlayers in the frontal, wrapped portion of the RSS. Over time the live branches take root and increase the internal stability of the reinforced slope.

#### 3.3 Remedial Design

The remedial design called for excavating the failed slope back approximately 6.1 meters (20 feet) to the same slope angle (4V:1H) as the proposed slope and constructing a steepened, biotechnically stabilized earthen buttress. The slope was stabilized with layers of primary and secondary geogrids, burlap, vegetated geogrids at the face, and live fascines over the top of the finished slope. Figure 2 shows a cross section depicting the existing slope (dashed line) and the remedial design.

Figure 2. Cross section of remedial slope design

The primary geogrid was designed to provide global, internal, and compound stability to the slope. This grid extends approximately 6.1 meters (20 feet) from the face to the back of the slope. The vertical spacing of the primary geogrid is .61 meter (2 feet) over the lower half of the slope and 1.22 meters (4 feet) over the upper.

As shown in Figure 3, the secondary geogrid, burlap, and brushlayers (which together constitute the vegetated geogrid) were primarily designed to provide facial stability to the slope. As shown in Figure 2, the secondary geogrid and burlap "wrap" the face of each vertical lift between each row of brushlayer branches. The burlap temporarily prevents soil from sloughing out of the face through the grid openings until the plant materials produce leaves and roots. The face wrap extends .91 meters (3 feet) into the slope at the bottom of each vertical lift and five feet at the top. All lifts were constructed using a continuous batter board to control the slope of the face. A front view of the vertical and lateral limits of the vegetated geogrid lifts and brushlayers is provided in Figure 4.

Brushlayers consisting of 2.44 to 3.05 meter (8 to 10 feet) long willow (*salix* sp.) and dogwood (*cornus* sp.) branches were placed on the constructed earthen terraces between each .91 meter (3 feet) vertical lift. These brush-layers, which are installed in layers with the growing ends exposed, extend from the face approximately 3.05 meters (10 feet) back to the mid-point of the slope. During the growing season, these brushlayers will root and produce leaves, stabilizing the face of

the slope. They will also provide some measure of internal stability initially and over the long term. The alternating sequence of constructed earthen terraces and live branch brushlayers is shown in Figure 5.

Drainage panels (1.52 meters (5 feet) wide, spaced 4.57 meters (15 feet) on center) that extend vertically along the back side of the slope were designed to accommodate the migration of groundwater into the reinforced portion of the slope, preventing the buildup of hydrostatic pressures in that area. These panels connect

into a .305 meter (1-foot) thick crushed-stone drainage layer at the base of the slope, which extends the full length and width of the slope.

As shown on Figure 1, four types of backfill were used to reconstruct the slope in addition to the crushed-stone drainage layer at the base. These backfills are granular borrow, ordinary borrow, 50/50 mix, and specified fill. The first three constitute the structurally competent "core" while the specified fill at the face provides a media amenable to plant growth. The specified fill used in the front 3.05 meters (10 feet) of each lift is a blended material consisting of four parts ordinary borrow to one part organic loam by volume. It should be noted that the lifts were constructed to slope away from the face (~20°)

Figure 3. Close-up view of the vegetated geogrid along the front face.

For design of

the slope, stability analyses were conducted to determine: (1) the width of the reinforced zone required to provide a minimum safety factor of 1.5 for deep-seated failure surfaces, and (2) the vertical spacing and design strength of soil reinforcement elements required to provide a minimum factor of safety of 1.3 for both internal

Figure 4. Front view of as-built slope illustrating limits of slope remediation activities.

and that fertilizers were added to each lift to further optimize the growing conditions for the installed brushlayers.

A 1V:3H cut was made above the steep slope and live fascine bundles were installed to prevent surface erosion and to rapidly revegetate the slope with woody plant materials. As illustrated in Figure 6, a live fascine is a collection of live cut branches grouped together in a bundle and secured with twine. The bundle was placed in trenches and anchored with dead stout stakes and live stakes. These structures provide immediate mechanical stabilization and erosion control and will eventually grow and reinforce the surface soil mantle. In this particular application, they also act as a drain, collecting water and transporting it laterally to both ends of the site.

### 3.4 Stability Analyses

A series of slope stability analyses were conducted to design the RSS and assess the stability of the slope under temporary construction conditions (i.e., the cut slope condition). These analyses were conducted using the University of

and compound failure surfaces. For temporary construction conditions, stability analyses were conducted to configure the cut so that a minimum factor of safety of 1.2 was maintained during the construction process. The computer output for the global stability analysis used to determine the lateral extent of the reinforced zone is provided in Figure 7. The failure surface yielding a minimum factor of safety of 1.5 generally defines the extent of the reinforced zone.

### 3.5 Agronomic and Geotechnical Considerations

The design and construction of this slope presented several

Figure 5. The alternating sequence of constructed earthen terraces and live branch layer

Figure 6. Establishing live fascine.

challenges involving the need to balance agronomic and geotechnical requirements. The factors to be balanced were these: (1) the need for water and nutrients in the slope to sustain and promote vegetative growth versus the desire to remove water so as to eliminate hydrostatic pressures; (2) the need to use organic matter in the slope to provide nourishment for plant growth and development versus the desire to construct the slope with free-draining, inorganic, granular soils; and (3) the need to construct the slope during the fall and winter months while the vegetative plant materials were in a dormant state versus the desire to construct the slope during warmer weather to prevent soil freezing problems and weather delays. A final agronomic consideration was that the plant materials needed to be properly stored following harvesting to protect them from shock. A brief discussion of each of these topics follows.

• **Drainage** - The original design called

for a continuous backslope drainage system to intercept groundwater before it enters the reinforced portion of the slope and divert it to the gravel subbase and drainage system beneath the slope. The backslope drainage system was originally designed to consist of free-draining crushed stone, with filter fabric against the naturally deposited gla-

cial soils. However, since it was desirable to allow some water to migrate to the willow and dogwood branches in the slope, the design was modified to utilize 1.52 meter (5 feet) wide prefabricated drainage strips spaced 4.57 meters (15 feet) on center in place of the continuous crushed-stone backslope layer. That allows some groundwater to migrate into the reinforced zone without permitting hydrostatic pressures to develop on the back side of this zone. The brushlayers also function as horizontal drains, reducing the possibility of hydrostatic pressures.

• **Organic material** - To provide favorable conditions for plant growth, it was desirable from an agronomic standpoint to incorporate organic material in the backfill. To accommodate this, the outer 3.05 meters (10 feet) of slope, starting approximately 1.52 meters (5 feet) up from the base of the slope, was backfilled with a blended material consisting of four parts of ordinary borrow to one part loam by volume. By carefully selecting the mixture and the location within the slope and checking the global stability and location of failure planes, it was possible to satisfy both the agronomic and geotechnical design requirements.

• **Construction time frame** - The freezing of subgrade soils that contain high organic material and water was a daily concern, since the construction was done mostly during the winter

since the construction was done mostly during the winter

Figure 7. Factor of safety for deep-seated global failure surface.

Figure 8. The condition of the project site, July 1996.

months. To minimize the impact of freezing, the lifts were adequately compacted at the end of each workday, and were inspected the following day for the occurrence of heave or formation of ice lenses; in addition, unsuitable frozen subgrade soils were removed when needed. Furthermore, frequent snow-storms limited the number of workdays on the project's already tight schedule. Accumulating snow, which had to be plowed from the previously constructed lifts before work could continue, shrunk staging and storage areas significantly. It should be noted that a near record snowfall in excess of 254 centimeters (100 inches) occurred during the winter this slope was constructed, following an unseasonably warm fall.

• Harvesting, handling and storage of cuttings - The harvesting of suitable, biotechnically capable plant material and installation of the soil bioengineering systems needed were carefully planned, coordinated and maintained. Numerous potential harvest sites were located before the project started. Sites were then selected based on the quality of material, site accessibility, and proximity to the project site. These harvesting sites contained large stands of willow (*Salix* sp.), a species well-suited for soil bioengineering construction. Refrigerated trucks were used to transport and store the live cut branches, which allowed the cuttings to be stored for long periods of time, such as a month or more. Proper temperature and humidity controls were maintained to keep the branches in dormancy and prevent the cuttings from dying out. The use of refrigerated trailers allowed the contractor to transport larger quantities of material to the site, providing installation crews with immediate access to live cuttings when needed and improving overall operations and efficiency.

#### 4 CONCLUSIONS

The face of the major slope reconstruction, the vegetated geogrid, looks very good. As shown in Figure 8, the slope is stable and the vegetation is well developed. The cut slope above is also well vegetated and appears stable.

This biotechnical installation should continue to root and grow, thus providing for increased surface protection, soil reinforcement, and an aesthetically pleasing revegetated slope. Over time, natural invasion from the surrounding plant community is expected to occur, causing the system to blend into the naturally wooded scenic setting of the area. Thus the long-term mechanical and ecological goals of the project will be satisfied.

# Finite Element Analysis of instrumented geogrid reinforced slope

A. Ghinelli

Professor, Department of Civil Engineering, Florence University, Italy

M. Sacchetti

Researcher, Department of Civil Engineering, Florence University, Italy

**ABSTRACT :** A 15 m high green faced reinforced slope was built in 1996 to consolidate a landslide situated on the Montone hill in the province of Perugia (Italy). The reinforced slope was built using as fill material locally available soils and as reinforcement HDPE mono-oriented extruded geogrids. A section of the slope has been fully instrumented in order to verify its long term behavior. To evaluate the field stress and deformation behavior of the Montone reinforced slope a finite element analysis has been carried out. The paper describe the model technique developed to evaluate the filed stress and deformation of steep reinforced slope using special interface elements. The results of finite element analysis are in good agreement with the field measured results.

**KEYWORDS:** Steep slope, Geogrids, Field test, Finite Element analysis

## 1 INTRODUCTION

The Montone hill located in the province of Perugia (Italy), was interested in the past by several instability and erosive phenomena along its slopes, which caused great damage at historical buildings and at road network.

During the last decades important landslides concerned the North-East slope of Montone hill, particularly along the Montone-Pietralunga main road. These phenomena that involved an area of about 15.0 m high and 200.0 m long, produced in proximity of the Fosso Fornaci a road interruption.

In one of the sub-project for the consolidation of the Montone hill, near the Fosso Fornaci, was foreseen to restore the interrupted main road and to stabilize the natural slope by rebuilding it with the local soils reinforced with HDPE geogrids. The reinforced slope presents a maximum height of 15.5 m and a length of about 53.0 m (see Figure 1). Due to the importance of the project, a section of the slope has been instrumented in order to verify its long-term behavior.

The paper deals with the stress and deformation analysis of the Montone reinforced slope by finite element analysis. A procedure to model the fill soil, the reinforcements and the soil-reinforcement interaction using discrete finite elements are described. The properties of the soil fill and of the reinforcement geogrids are also presented.

Field measurement taken over two months period after construction are reported and compared with numerical analysis results.

The paper shows a good agreement between compared results. This fact highlights the possibility to use element finite methods to predict filed behavior of reinforced slopes without rigid face and with a complex geometry.

Figure 1. Reinforced slope location

## 2 REINFORCED SLOPE DESCRIPTION

In the last decades the North-East slope of Montone hill was interested by important landslides and erosive phenomena that produced in proximity of the Fosso Fornaci an interruption of the Montone-Pietralunga main road.

For better understanding the reasons of slope instability an intensive geophysical and geotechnical test campaign and a back-analysis study on the old landslide bodies were carried out (Coluzzi et al., 1997).

To restore the interrupted main road and to stabilize the natural slope a green faced reinforced slope was built. The

construction commenced in the summer of 1996 after the landslide body has completely been removed from the main road and after the existing ground surface has been remodeled.

The reinforced slope shows a running length of 53.0 m and a maximum height of 15.5 m, split up in three bodies respectively of 5.3, 5.6 and 4.6 m of height, with 1:1.73 side slope, separated by two horizontal berms of 4.1 m and 3.1 m length (see Figure 2).

As above mentioned the reinforced slope was built using as fill material locally available soils and as reinforcement HDPE mono-oriented extruded geogrids. In particular the entire slope was supplied of 23 reinforcement layers, 0.65 m vertically spaced, with length variable between 4.5 m and 3.15 m.

The green faced reinforced slope was built using the TENAX RIVEL system (Rimoldi et al., 1996), which consist in the use of sacrificial steel mesh form-works that help in the face construction and permit to obtain a very uniform geometry of the slope. A thick drainage system was placed beneath the reinforced bodies.

The Jewell method (Jewell, 1990) was used to design the reinforced slope, whereas global stability analysis was carried out using the STABGM, a code based on the Bishop's modified method (Coluzzi et al., 1997).

The main geotechnical properties of the fill soil and mechanical properties of the reinforcement geogrids

adopted to design are reported in Table 1.

Table 1. Geotechnical properties of the fill soil and mechanical properties of the reinforcement geogrids adopted to limit equilibrium design

## 2 INSTRUMENTATION

Due to the importance of the project, a section of the was provided with extensive instrumentation.

The main purpose of the instruments installed is to

Figure 2. Cross section of the instrumented geogrid reinforced slope

check the overall deformation of the slope and to indicate the long-term behavior of the reinforcements under field stress conditions. Moreover, field measurements are very valuable input data for subsequent numerical analysis with finite element method.

The instrumented section was equipped with 40 strain gauges (electrical wire resistance type) positioned on geogrid ribs of the first and second reinforced block; 3 total vertical pressure cells positioned at the bottom of the first reinforced block; 2 vertical inclinometers installed on the first block and on the top of the third block; 1 pore pressure cell and 1 acquisition system installed on the first block (see Figure 2). Descriptions of instrumentation types and installation procedure are detailed in Coluzzi et al. (1997).

The strain gauges and total pressure cells has been activated after construction, whereas inclinometers and pore pressure cell are not yet active. After about one month measurements 9 strain gauges are "dead".

### 3 FINITE ELEMENT ANALYSIS

For reinforced slopes, deformation and stability are the two main concerns. Nevertheless an accurate assessment of deformations in field condition can only be achieved through a stress-deformation analysis, such as a finite element analysis.

To evaluate the field stress and deformation behavior of the Montone reinforced slope a finite element model of the entire structure has been developed. The numerical simulation has been performed using the CRISP90 computer code (Britto et al., 1990), developed at Cambridge University in the eighties, which uses many soil constitutive models, and capable to simulate drained and undrained geotechnical problems with static load conditions. In particular to simulate the field behavior of steep reinforced slope, without rigid facing, a modeling technique has specifically been developed. This technique foresees to use the following elements:

- "BAR" elements, with linear-elastic or linear elasto-plastic behavior, for reinforcements.
- "LSQ" (Linear Strain Quadrilateral) and "LST" (Linear Strain Triangle) elements, with linear elastic-plastic behavior, for fill soil.
- "SLIP" elements, with behavior based on the Goodman & Taylor (1968), for soil-reinforcement interface.
- "LSQ" and "LST" elements, with linear-elastic behavior, for foundation soil.

To obtain a true and correct forecast of the stress and deformation behavior of reinforced slope by numerical finite element analysis it is necessary to define and subsequently to simulate the very complex interaction mechanisms establishing between the fill soil and the

reinforcement geogrids. In this pattern the use of "SLIP" elements with frictional and adhesive behavior, which permits relative displacements, seems to be able to simulate the above mentioned interaction mechanics.

The finite element model created consist of 2107 nodes and 872 elements (161 reinforcement elements, 322 interface elements and 389 soil elements) (see Figure 3). Computational problems connected with the dimension of the overall stiffness matrix imposed heavy limitations on the elements number of soil foundations. Therefore we decided upon to model a little portion of natural slope with very simple linear-elastic elements having adequate resistance and stiffness to support the reinforced body.

Figure 3. Finite element model

### 4 MATERIAL PROPERTIES

With the final purpose to obtain a more realistic numerical simulation a series of field tests on the reinforced slope and laboratory tests on materials taken from reinforced bodies were carried out. From these tests were assessed the most important mechanical parameters to introduce into numerical model. The tests undertaken are:

- Field density tests, carried out on all three reinforced bodies, that supplied the unit weight of the fill soil.
- Field pull-out tests, performed on geogrid layers, about 0.50 m wide with different anchorage length, purposely embedded into the bottom reinforced body, that given the pull-out factor of reinforcement.
- Rigid plate load tests, carried out on the first reinforced body using circular plates with 300 mm and 600 mm diameter, that supplied the principal deformation parameters of the fill soil.
- Classification tests, performed on several samples of

fill soil taken from reinforced slope, that supplied the limit indexes and the particle size distributions.

- Direct shear tests with standard box of 60x60 mm, performed on samples of fill taken from reinforced slope, that given the shear resistance of fill with particle size finer than ASTM10 sieve.
- Tensile creep tests, carried out on geogrids samples, using different tensile loads and temperatures (Cazzuffi et al., 1997), taken from the reinforced slope after end construction, that given the long-term tensile stiffness of reinforcement.

The most important test results achieved are summarized in Table 2.

Table 2. Geotechnical properties of fill soil and mechanical properties of reinforcement geogrids adopted to finite element analysis

## 5 FINITE ELEMENT ANALISYS RESULTS

The state of deformation at end construction of the Monotone reinforced slope, achieved with numerical analysis, is showed in Figure 4.

Figure 5 shows the comparison between the distribution of reinforcement strains achieved with numerical analysis (light dots and dashes) and achieved from field measurement (dark dots) after two months of the end construction, relating to the first reinforced body (layers A to H). Figure 6 shows the same comparison relating to the second reinforced body (layers I to R).

With reference to numerical analysis results, all layers presents the same shape strain distributions, excepting the

Figure 4. Deformation state of entire reinforced slope

layers G and H on the first body and Q and R on the second body. In particular the second layer of each body (respectively B and L) has the largest strain whereas the top layer (respectively F and P) has the smallest. The peak reinforcement strains occurred in the bottom layers closer to the slope surface than the top layers. The very particular strain profiles of layers G and H on the bottom body and Q and R on the second body are mainly related to their specific border conditions.

From Figures 5 and 6 it is also possible to highlight a close affinity between measured values and calculated values, excepting the at layers A and G. The reasons of this disagreement may be attributable to specific border conditions. In fact for layer A the distribution of strains along its length depends also from foundation soil-geogrid interface characteristics, while for layer G the distribution of strains is influenced by different confinement pressure conditions and different support soils along its length. The presence of a second peak in the strains profile in proximity of different contour condition confirm the above mentioned consideration.

At the last Figure 7 shows a very good agreement between numerical and measured distribution of total vertical pressure at the bottom of the first reinforced body. In the same figure the total vertical pressure has been compared also with "static" pressure due at the weight of reinforced slope. The different envelope is obviously due to thrust of backfill.

## 6 CONCLUSION

To evaluate the field stress and deformation behavior of the Montone green faced reinforced slope a finite element model of the entire structure has been carried out. A modeling technique has specifically been developed to simulate the field behavior of reinforced slope without

Figure 5. Strain distributions on the reinforcement geogrids of the first reinforced block

Figure 6. Strain distributions on reinforcement geogrids of the second reinforced block

Figure 7. Total vertical pressure at the bottom of the first reinforced block

rigid facing which foresee the use of “SLIP” elements with frictional and adhesive behavior, which permits relative displacements, to simulate the complex interaction mechanisms establishing between the soil fill and the reinforcement geogrids.

A series of field and laboratory tests was carried out to assess the most important mechanical parameters to introduce into numerical model.

The performance of the Montone reinforced slope was monitored by a specific instrumentation installed in a section of the slope during its construction. Field measurement showed the mobilization of tensile resistance on the geogrids and the distribution of total vertical pressure at the base.

The strain distribution results of finite element analysis are in good agreement with field measurement results taken after two months of the end construction. Nevertheless the border conditions have a remarkable influence on the base reinforcement layer and on the layers disposed between each reinforced body. This influence is negligible in the others reinforcement layers.

The good agreement achieved confirm the validity of modeling technique developed and highlights the concrete possibility to use of element finite methods to obtain detailed information about stress and deformations under field condition.

## ACKNOWLEDGMENT

The field measurement is a co-operative project in association with the Department of Civil Engineering of Florence University, TENAX SpA, Viganò, Italy, and R.P.A., Perugia, Italy. The contribution of these organization is acknowledged.

A particular acknowledgment to the SEAS SpA, Perugia, Italy, for precious assistance given during the execution of all the field tests.

# The Assurance Of Durability

John H Greenwood

ERA Technology Ltd, Cleeve Road, Leatherhead KT22 7SA, UK

**ABSTRACT:** The design engineer requires assurance that the geosynthetics he uses will function over a particular service lifetime. This paper introduces the CEN Guide to Durability which provides guidance to the user of geotextiles for non-reinforcing and, to a limited extent, reinforcing applications on the resistance to weathering, chemical and biological effects. "Normal service conditions" are defined for which testing is restricted to a minimum and there is exemption for materials where there is sufficient field experience. The designer of reinforced soil will require in addition information on potential reductions in strength, expressed as partial safety factors, and methods are described for deriving these factors expressed as in BS 8006.

**KEYWORDS:** Degradation, Polymeric ageing, Predictions, Reinforcement, Safety factors

## 1 INTRODUCTION

The design engineer requires assurance that the geosynthetics he uses will function over a particular service lifetime. In the absence of long-term experience, it is necessary to make predictions, which of necessity are based on changes in properties measured over shorter periods, or under more severe or accelerated conditions. For most applications an assurance of a minimum level durability is sufficient, and standards committees on both sides of the Atlantic have defined practical tests intended to assure a minimum durability.

Reinforced soil design requires additional calculation of the reduction in strength due to environmental or other factors and the calculation of a corresponding partial factor for use in design.

## 2 NON-REINFORCING APPLICATIONS

### 2.1 "Normal Service Conditions" and When to Test

The CEN Guide to Durability of Geotextiles and Geotextile-Related Products (CEN 1998) has been written by members of Working Group 5 (Durability) of CEN Technical Committee TC189, Geotextiles, to guide the user and to provide the background to the recommendations it makes. Starting with definitions of durability, "required" and "available" properties, design life and end of life, it then describes the polymer structure, polymer types and manufacturing processes relating to the principal types of geotextile. The environments above and below ground are noted, with particular reference to the temperature, humidity, organic and chemical content of soils and of their potential effects on the polymer. In addition mechanical

load will cause creep or rupture, particularly of soil reinforcements, while transverse load in coarse soils can lead to mechanical damage and to compressive creep of drainage composites. Under some circumstances mechanical load can accelerate chemical attack (or vice versa), although this is not seen as a major problem in the highly oriented polymers used in fibres and geogrids.

The final chapter of the Guide provides guidance on what testing is necessary and when, introducing the concept of a window of "normal service conditions" for which only very limited testing is necessary. Recognising that the geotextiles have been used for upwards of 25 years after which, with few exceptions, the only significant degradation found has been that caused by mechanical damage, the normal service conditions are defined as:

- functional design lifetime less than 25 years
- pH value between 4 and 9
- soil temperature not greater than 25°C
- natural soil, excluding landfills and contaminated land.

It is recognised that the soil may be dry, partially or fully saturated, aerobic or anaerobic, and may contain common transition metals in ionic form such as  $\text{Fe}^{2+}$  and  $\text{Fe}^{3+}$ .

For non-reinforcing applications in natural soil where the geotextile has a functional design life of less than five years, even when the soil structure itself has a longer lifetime, the only tests required are for mechanical damage and weathering. For all other applications with design lives of up to 25 years, screening tests for the hydrolysis of polyester and for the oxidation resistance of polypropylene and polyethylene will be required in addition. A soil burial

test for biological resistance is not required for these polymers, but should be performed on new materials, vegetable based products, geocomposites, coated materials and any others of doubtful quality (such as materials recycled after consumer use). Other polymers require separate assessment, including polyamides which can be subject to both hydrolysis and oxidation.

An important feature of the Guide is the inclusion of a clause allowing manufacturers to use a demonstration of satisfactory long-term service as an alternative to screening tests. The user will decide whether the site conditions experienced were sufficiently similar to the new design conditions for the field evidence of good durability to be accepted, and whether the new product is sufficiently similar to the old. So far, most studies on exhumed samples have shown little evidence of degradation other than mechanical damage due to compaction in coarse fills on installation. The assessment of field experience is mentioned further in Section 3.8.

## 2.2 Mechanical Damage

A simulated site test for mechanical damage has been described by Watts and Brady (1990) and a database of measurements has been compiled by Allen and Bathurst (1994). The results are generally expressed as a reduction in tensile strength (see below, Section 3.4), but for visual observation holes and tears may be more significant for applications in filtration and separation.

## 2.3 Weathering Tests

The screening test for weathering test, ENV 12224, will be a fluorescent tube test based on current practice in artificial weathering and is described further in Greenwood et al. (1996). Drawing on the results of intercomparison tests on a range of stabilised and specially prepared unstabilised geotextiles, the Guide recommends that, unless they are to be covered on the day of installation, all materials should be subjected to accelerated weathering for a UV radiant exposure (total ultraviolet light below 400 nm wavelength received per unit area) of 50 MJ/m<sup>2</sup>. This corresponds to approximately 250 hours in a weatherometer and to one summer month's exposure on site in southern Europe. As with mechanical damage, loss of strength is taken as the indicator of degradation for all applications, since it can be measured quantitatively and more accurately than, for example, hydraulic permeability.

For applications in soil reinforcement or otherwise dependent on long-term strength, geotextiles which retain over 80% of their strength in the weathering test should be covered within one to four months, while those which retain 60% to 80 % of their strength should be covered within 2 weeks. For non-reinforcing applications the acceptable bands of retained strength are over 60% and 20% to 60% respectively. The time to cover depends on the season and location in Europe, it being unreasonable to apply the same

rule on a hot summer's day by the Mediterranean as on a short winter's day in Scandinavia. If the material fails the test it has to be covered on the day of installation.

Correlation between the reduction in strength and the time to cover on site is believed to be a useful and practical concept. Extended artificial weathering tests using similar methods are required for materials which are to be exposed for longer durations.

## 2.4 Hydrolysis and oxidation

Apart from the soil burial test for biological resistance (ENV 12225), which was described by Greenwood et al (1996), the only tests required for non-reinforcing applications with service lives from 5 to 25 years are the screening of polyester geotextiles for resistance to internal hydrolysis and of polypropylene, polyethylene and polyamide for resistance to oxidation. It is well established that normal textile grade polyester degrades slowly under moist conditions, and high tenacity polyesters even more slowly. Based on current quality control practice in polyester manufacture, ENV 12447 proposes immersing the geosynthetic in water at 95°C for 8 weeks and determining the percentage reduction in strength. This is a simple and directly relevant screening test that avoids the problems of determining carboxyl end-group count and molecular weight. The screening test for oxidation of polyethylene and polypropylene is an oven ageing test at 110°C for polypropylene and at 100°C for polyethylene. The passmark is 50% of tensile strength and the durations are longer for reinforcing than for non-reinforcing applications.

## 2.5 Beyond Normal Service Conditions

Outside the "window" of normal service conditions the Guide recommends the designer to consider further tests. For example, for pH values below 4 and above 9, screening tests in concentrated alkali and in acid under aerobic conditions have been developed. For landfill sites, contaminated land, or for very long durations under hydrolysing or oxidising conditions, Arrhenius type accelerated testing should be considered.

# 3 REINFORCING APPLICATIONS

## 3.1 General

The design of reinforced soil is not covered in detail by the CEN Guide to Durability but is governed by codes such as BS 8006 which specify a safety factor  $f_m$  for the durability of the material which is applied to the design strength. Design lives are long, typically 50 to 120 years. Definition of  $f_m$  requires a numerical estimate of the reduction in strength that will occur by the end of the design life.  $f_m$  is the product of several partial safety factors (>1) as listed in Table 1 but for only some of them does the code specify the

means of calculation. Methods for deriving these factors from the properties of the reinforcement are not included in the Guide, but some have been drafted elsewhere (for example WSDOT 1997). The following Sections are intended to point out some of the items which should be addressed.

Table 1. Partial safety factors as defined by BS 8006: 1995.

$f_{m11}$	applied where the base tensile strength is not the characteristic strength	statistical*
$f_{m112}$	= 1.0 for polymers	
$f_{m21}$	statistical scatter of long-term data	statistical
$f_{m22}$	uncertainty of extrapolation	uncertainty
$f_{m211}$	mechanical damage	reduction
$f_{m212}$	long-term effect of mechanical damage	uncertainty
$f_{m22}$	chemical effect of the soil environment	reduction/ uncertainty

\*For the use of these definitions see Section 3.9

### 3.2 Specifications

The general service environment including the soil types, temperatures and gradations, the expected loads and the design life must first be defined. The information required includes:

- tensile properties including characteristic strength
- creep and rupture tests
- damage tests
- chemical description of the material
- chemical durability tests
- field experience (if any)
- quality assurance statement.

The range of loads, temperatures, times and soil gradations used, in particular those for the creep and rupture tests, must correspond to the service environment. Without a complete set of data it is necessary to resort to default and uncertainty factors which too often turn out to be controversial. The ultimate goal must be to define a procedure which is independent of the operator and excludes all uncertainty factors.

### 3.3 Separation of Long-Term Strength from Long-Term Strain

Until there is an integrated theory of creep and stress-rupture the calculation of partial safety factors for strength and strain should be kept separate. While strength is sensitive to mechanical damage and to environmental influences such as weathering and possible long-term

chemical degradation, creep strain at lower loads is affected by little except load and temperature.

### 3.4 Mechanical Damage

As mentioned in Section 2.2, the effect of mechanical damage is generally expressed as the ratio in strengths of a damaged material compared with the undamaged material and expressed as a percentage. The partial safety factor  $f_{m211}$  will then be the inverse of the ratio. Methods are being developed for performing damage tests in the laboratory using standard fills. The reduction in strength for the fills on the site being considered can be interpolated by plotting the reductions in strength against a soil parameter such as  $d_{50}$  (WSDOT 1997).

Very little information exists on the effect of mechanical damage on long-term strength, if any, and in this situation the method of Allen and Bathurst (1996) could be used to define  $f_{m212}$ .

### 3.5 Environmental effects

The principal potential degradation mechanisms for commonly available geotextiles are those which are the subject of screening tests (Section 2.1). Internal hydrolysis, the slow degradation of polyester fibres in water irrespective of pH, has been studied by a number of authors and the reduction in strength of high tenacity fibres has been predicted. From measurements of both retained strength and molecular weight after immersion in water (pH7) at elevated temperatures the rate of bond breakage can be derived as a function of temperature. The strength of the polyester at long times and lower temperatures can then be derived by extrapolation using Arrhenius' formula. The predictions in Table 2 use the calculations of Burgoyne and Merii (1993) for the two fibres they used, PET1 and PET2, while the results of Schmidt et al (1994) for tests at 50 to 70°C have been extrapolated assuming that the rate of loss of strength is linearly proportional to the rate constant. All refer to high tenacity fibres with number-average molecular weight  $M_n > 25000$ . A similar calculation has been made by Salman et al (1997) for a polyester with  $M_n = 18200$ .

Table 2. Percentage retained strength following internal hydrolysis.

	50 years		120 years	
	20°C	30°C	20°C	30°C
Burgoyne (PET1)	98	92	96	87
Burgoyne (PET2)	96	85	92	74
Schmidt et al.	95	89	85	64
Salman et al.	84	54	62	0

These predicted reductions in strength can be used to derive the reduction factor  $f_{m22}$ . It should be noted that the data

refer to saturated conditions and that internal hydrolysis will take place more slowly in unsaturated soils. Alkaline hydrolysis, which reduces the strength due to surface attack, should be considered in addition for soils with a pH of 9-10 or above.

There is no generally accepted method for predicting the reduction in strength of polyolefins due to oxidation, but that of Salman et al (1997) provides an example.

Extrapolations based on logarithmic scales as in Arrhenius' method can have wide confidence limits and an estimate should be made of the sensitivity of any prediction to changes in the input data. It may therefore be necessary to set an additional factor to account for the uncertainty of the extrapolation, but this factor should be handled separately as described in Section 3.9.

Weathering is discussed in Section 2.3. If a reduction in strength is anticipated due to weathering during installation, then this must be included in the calculation of  $f_{m22}$ .

### 3.6 Stress-Rupture

As with all extrapolations, stress-rupture results must be examined for any evidence of a change of behaviour, whether in the shape of the curve, the elongation at break or the appearance of the broken specimen. Any change in the mechanism of failure will invalidate the extrapolation.

Long-term design strength is currently predicted by fitting a curve to the stress-rupture data, conventionally plotted as in Fig. 1, and extrapolating it from shorter times at high loads to longer times at lower loads. The most commonly used fit is:

$$T = T_0 - b \log t \quad (1)$$

where  $T$  is applied tension (load) expressed as a percentage of the tensile strength of the same batch of material,  $t$  is time and  $T_0$  and  $b$  are constants. With  $x = \log t$ ,  $y = \sigma$ , and the subscript  $av$  indicating a mean,

$$S_{xx} = \sum (x_i - x_{av})^2 \quad (2)$$

$$S_{yy} = \sum (y_i - y_{av})^2 \quad (3)$$

$$S_{xy} = \sum (x_i - x_{av})(y_i - y_{av}) \quad (4)$$

$$b = S_{xy} / S_{yy} \quad (5)$$

and the straight line fit is:

$$T_0 = y_{av} - x_{av} / b \quad (6)$$

The regression line is then extrapolated to the design lifetime to give the unfactored design strength  $T_{CR}$ , again as a percentage of the batch tensile strength. The regression line is expected to cross the line  $T = 100\%$  at a time comparable with the duration of a tensile test.

Table 3: Example of stress-rupture results (fictitious).

load as % tensile strength		time to rupture (h)	
85		1.2	
85		7	
85		21	
80		19	
80		61	
80		225	
75		345	
75		716	
75		2,014	
70		3,970	
70		9,836	
70		>18340	
$x_{av}$	2.351	$b$	-0.214
$y_{av}$	77.5	$n$	12
$S_{xx}$	19.06	$K$	0.0442
$S_{yy}$	375	$t$	1.812
$S_{xy}$	-80.27	$s$	0.4340
predicted stress rupture load for 1000000 h			60.5%
lower confidence limit for 1000000 h			54.7%
$f_{m121}$ based on statistical procedure			1.11

Fig. 1 Stress-rupture diagram

Statistically, the lower confidence limit is given by a formula which combines the variance of the data with the variance of the gradient of the line:

$$y = y_{av} + b(x - x_{av})/K - (ts/K)[K(1 + 1/n) + (x - x_{av})^2/S_{yy}]^{1/2} \quad (7)$$

where  $n$  is the number of measurements,  $t$  is the value of Student's  $t$  corresponding to  $(n - 2)$  and the appropriate (one-sided) probability level, and

$$s = [(S_{xx} - S_{xy}^2/S_{yy})/(n - 2)]^{1/2}; \quad K = b^2 - t^2 s^2/S_{yy} \quad (8)$$

This curve forms the lower branch of a hyperbola that draws away from the stress-rupture line on extrapolation and meets the design life at  $T_D$  such that  $T_{CR} / T_D = f_{m121}$  (see example with numerical data in Table 3 and stress-rupture diagram in Fig. 1). WSDOT (1997) defines the reduction factor as equalling  $100/T_{CR}$  and applying it to the MARV strength, which in the BS 8006 system is equivalent of applying  $f_{m111}$  and then setting  $f_{m121} = 1$ . In either case it is important not to double-count the variability due to scatter. The question of whether design should more correctly be based on residual strength has been raised elsewhere (Greenwood 1997).

Methods for defining  $f_{m122}$ , the uncertainty factor which reflects the considerable step of predicting 50 to 120 year performance from rupture data over much shorter periods, are based on the duration of the longest test result. The methods allow extrapolation up to ten times without further penalty and then increase  $f_{m122}$  progressively to reach values of 2 for extrapolation by a factor of 100 based on  $T_d$  (BS 8006), or 1.2 or 1.4, depending on the likelihood of a knee, based on the confidence limit as defined by WSDOT (1997). Following current practice in the calculation of stress-rupture characteristics, it is proposed that the duration of an incomplete rupture test should be acceptable for this procedure provided that it lies to the right of the curve as in Fig. 1.

Any such procedure should include measurements made at different temperatures, firstly to allow design strengths to be defined for different design temperatures and secondly to accommodate predictions made by time-temperature shifting. If this is done, the longest duration used to define  $f_{m122}$  may be redefined as the longest test after time-temperature shifting (WSDOT 1997). A maximum temperature shift of 20°C below the lowest test temperature is proposed.

Measurement of stress-rupture data is laborious, expensive and can give similar results on similar products. Small and Greenwood (1991) combined results from a range of polyethylene geogrids to produce a general stress-rupture curve for the range. Such measurements on products from the same range of products are generally acceptable but the rules for acceptance require definition (WSDOT 1997).

### 3.7 Combination of Partial Safety Factors

Following Greenwood and Yeo (1996) partial safety factors should correctly be classified and combined as follows:

reduction factors	multiply
statistical factors	combine statistically to give the correct final probability level
uncertainty factors	choose an appropriate overall factor not less than the largest partial factor

The resultant factors defined by the three classes should then be multiplied.

### 3.8 Creep Strain

In the absence of a satisfactory method for predicting the creep of the soil-reinforcement composite, current practice is to measure the unrestrained creep of geosynthetics for soil reinforcement in air. This yields maximum and thus conservative values for strain.

The comments made at the start of Section 3.6 concerning the extrapolation of stress-rupture apply equally well to creep. Again, there is no fundamental materials based equation for curve fitting. The equation

$$\varepsilon = \varepsilon_0 + \varepsilon_1 \log t \quad (9)$$

is normally sufficient for polyester and a power law

$$\varepsilon = \varepsilon_0 + \varepsilon_1 t^n \quad (10)$$

is a useful model for the primary creep of polyethylene with  $\varepsilon =$  strain.  $\varepsilon_0, \varepsilon_1$  and  $\varepsilon_2$  (below) are all functions of applied load, the shape of which is reflected in the isochronous curves. For polyethylene it is necessary to predict the onset of secondary (constant strain rate) creep. This can be done by adding a constant strain rate term  $\varepsilon_2 t$  and curve fitting to tests at higher values of load which exhibit secondary creep. If a relation is established between  $\varepsilon_2, T$  and applied load, for example by using Sherby-Dorn diagrams, then the onset of secondary creep can be predicted at lower values of  $T$ .

As for stress-rupture, creep strain curves can be time-temperature shifted, offering the possibility of abbreviated testing (see for example Thornton et al 1997). It should be noted, however, that since the elongation at break is itself a function of time and temperature the shift factor for creep strain may differ from that for stress-rupture of the same material.

The accuracy of the prediction of creep strain has been examined by Müller-Rochholz and Koslowski (1996) and found to lie within 0.7% strain for polyesters and polyethylene at 7% strain, predicted from 24 h to 24000 h. These levels of accuracy are comparable with the variability in short term creep modulus, suggesting that a partial safety factor for uncertainty of strain extrapolation is superfluous. As 10 year creep strain measurements on polyester based products are become available, the only partial safety factor

required for creep strain extrapolated to 100 years, given that temperature has already been taken into account, should be to reflect the variability in the initial strain or modulus of the material. This argument will not apply to creep rupture data until corresponding 10 year data are available.

### 3.9 Field Experience

The above predictions will increasingly be complemented, and eventually replaced, by experience from site. Statements that no degradation took place should always be accompanied by an estimate of what degradation might have been predicted given the site conditions. A conclusion that "no degradation occurred, and none was expected" serves only as a demonstration that no unexpected phenomena are present.

## 4 CONCLUSIONS

A document on the durability of geotextiles is in place for the guidance of civil engineers. Further details are necessary to cover the definition of partial safety factors used in the design of reinforced soil.

### ACKNOWLEDGEMENTS

I acknowledge the many contributions made by members of CEN TC189/WG5 toward the first part of this publication. The second part is based partly on work supported by the Geotechnical Engineering Office, Hong Kong, and is published with the permission of the Director of Civil Engineering of the Hong Kong Government. The views expressed are those of the author. The Directors of ERA Technology Ltd are thanked for permission to publish.

# Long-Term Experience with Reinforced Embankments on Soft Subsoil: Mechanical Behavior and Durability

K.-H. Blume

Dipl.-Ing., Federal Highway Research Institute, Bergisch-Gladbach, Germany

D. Alexiew

Dr.-Ing., HUESKER Synthetic GmbH & Co., Gescher, Germany

**ABSTRACT:** Two projects of embankments on soft ground with high-strength basement reinforcement are shortly described. Started in 1981 and 1986, respectively they belong to the first one's using preloading plus reinforcement for autobahns and highways in Germany. Site conditions, construction stages, measurement data and evaluation are presented, including long-term reinforcement strain measurements. The geotextiles are still under tension. In 1995 high-tenacity polyester woven was exhumed from underneath the first embankment and analyzed for evaluation of durability. Important preliminary results are reported, showing negligible loss of strength in 14 years. In conclusion, findings and recommendations for focal points of design, long-term reinforcement behavior and durability are summarized.

**KEYWORDS:** Embankments, Reinforcement, Long-term-measurements, Soft soils, Durability

## 1 INTRODUCTION

In Germany, in the construction of highways on soft saturated subsoils, increased use is being made of the preloading method. The advantages compared to soil replacement are not only the high cost savings but also countryside, environmental and ground water protection. The development of the preloading method is closely connected with the development of geosynthetics. The reinforcement function is of particular importance as it can be required not only to ensure the short-term stability during construction, but also the final long-term stability.

Since around 1970, the Federal Highway Research Institute (Bundesanstalt für Straßenwesen -BASt) has been involved in such projects on federal highways and autobahns. Investigation and measuring programs have been performed on large-scale test embankments. The aim was to ascertain the behavior of the soft subsoil and the long-term behavior of high-strength geosynthetic reinforcement. Some of the experimental embankments were just loaded up to ground failure to verify the assumptions and results of the stability calculations.

For the Federal autobahn project BAB A 26, connecting the cities of Hamburg and Stade, a test embankment was built near the town of Rübke (designated as 'Rübke-embankment' here) by the BASt in 1981, simulating a real autobahn-section on saturated peat with high-strength basement reinforcement. The project, materials used and deformation behavior until now are reported below.

Based on this experience the entire highway B 211 at the town of Grossemeer was built in 1986 under similar conditions using a reinforcement of even higher strength (designated as 'Grossemeer-embankment' here). The measurements in this case were extended by direct strain measurements on the high-strength woven used, which are continued up to now. The project, materials and most important measurement results including the long-term strains are shortly described.

In autumn 1995, after a 14-years-service period, parts of the high-tenacity polyester woven from underneath the 'Rübke-embankment' were exhumed. Tests and analyses were carried out for evaluation of durability. The most important findings are also presented.

## 2 TEST EMBANKMENT AT RÜBKE

### 2.1 Description Of The Full-Scale Test

The dimensions of the embankment were in compliance with the standard cross section RQ 26 planned for the autobahn. Geometry and essential characteristic values of the peat subsoil are shown in Figure 1. The consolidation calculations resulted in a required preloading height of 3.6 m. A part of preloading had to be removed after consolidation. The stability calculations were performed according to DIN 4084 (Bishop's method) modified by reinforcement retaining force. Only low short- and long-term strains were allowed. The calculations resulted in a reinforcement mobilizing at least 90 kN/m at maximum 5% short-term strain, with an ultimate tensile strength (UTS) of at least 200 kN/m and ultimate strain  $\leq 10\%$ . Only 1% creep strain in two years was allowed under 90 kN/m tension force. A high-strength polyester woven geotextile (Stabilenka® 200) was selected. The test comprises preloading with a subsequent consolidation period of just under two years, removal of preload, a reloading and the long-term measurements of the deformation behavior.

The test embankment was constructed directly on the terrain without any soil replacement. First of all the woven was laid on the grass in July 1981.

Loads, heights and settlements to date are shown in Figure 2.

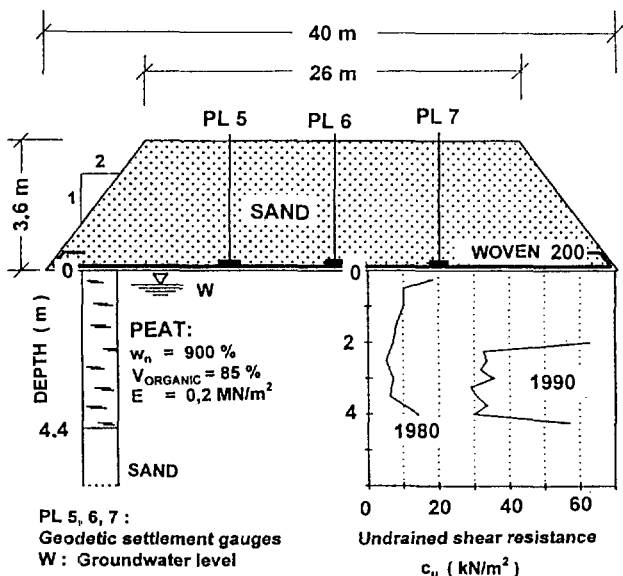

Figure 1. Full-scale test embankment at Rübke (not to scale).

## 2.2 Course Of The Test And Measurement Results

Measurements of settlement, pore water pressure, base pressure, inclination and groundwater level were performed.

In this test, it was not possible to perform strain measurements directly on the fabric. Because, at this time, a measuring system with robust, precise and water-proof strain gauges was not available. Four years later, long-term resistant strain gauges were developed and applied for the 'Grossenmeer-embankment' (see section 3).

The development of the settlement shows a significant drop in the settlement rate, which was below 1 cm/year in the first year after the reloading. Nowadays the settlement rate is less than 0.5 cm/year with a decreasing tendency. The BAST is continuing the measurements.

Figure 2. Load and settlement at Rübke from July 1981 until July 1997.

The high permeability of the peat in the unconsolidated state has made a rapid consolidation settlement easier.

For an embankment thickness of 2.3 m, the degree of consolidation was already 80% after two-months. Very high primary settlements of around 1.1 m were measured. The

transition primary / secondary settlements at a degree of consolidation of 90% occurred after 5.5 months. The total settlement of the peat mounted to around 1.6 m. The peat was compressed by around 40%.

The average strain of reinforcement derived from the settlement profiles (not shown) amounted up to 3%. Maxima and minima could not be registered due to absence of strain gauges (compare with section 3, 'Grossenmeer').

During filling and consolidation relatively low horizontal displacements occurred at the toe of embankment: maximum 18 cm in the peat and 12 cm on the ground surface. In a distance of 10 m from the toe of the embankment horizontal displacements of 1 cm to 3 cm were registered. The increase of undrained shear strength is shown in Figure 1.

## 2.3 Assessment Of The Measurement Results

The measurement results confirmed the feasibility of controlled construction of reinforced embankments on very weak subsoil (peat) by preloading, removing of preload and partial reloading to justify the final gradient. Due to the controlled preloading and the reinforcement, no failure-type deformations occurred, neither in the embankment nor in the foundation soil. The high-modulus geotextile (see section 2.1) allowed only small lateral spreading/squeezing deformations. Based on the average strain only the reinforcement looked understressed compared to design assumptions and calculations. But note, that strain (and tensile force) could had been higher e.g. in the usually critical zone (from the point of view of stability) under the slope and near the toe (see section 3.3). Summarizing: the simplified design calculations according to DIN 4084 agreed well enough for engineering purposes with the measured behavior. Nevertheless, continuous measurements are an important tool to control the construction progress.

The measurement results and the collected experience from July 1981 until March 1985 were adequate to recommend the preloading method with high-strength reinforcement for the entire new autobahn route BAB A 26.

## 3 HIGHWAY EMBANKMENT AT GROSSENMEER: TEST AND REFERENCE SECTIONS

### 3.1 Description Of The Project

Due to the positive results from the 'Rübke-embankment', the BAST recommended the preloading method with geotextile reinforcement for the construction of the new federal interstate highway B 211 at the town of Grossenmeer.

The BAST performed measurements on two sections. The first one with steeper slopes, called here 'test embankment', had to be integrated later after reshaping in the standard highway embankment. The second one, called here 'reference section', was already from the beginning a standard highway embankment. The test program was extended here by direct short- and long-term strain measurements of

the high-strength basement reinforcement.

The highway embankment at Grossenmeer has a length of around 2 km. The weak subsoil consists of layers of peat and organic silts in all 3 m to 5 m thick, underlayered by dense sand. According to pre-design calculations, typically an embankment thickness of 4.5 m height was selected for the stage of consolidation (preloading). The consolidation period was expected to be about two years. After that layers of different adequate thickness had to be removed to fit the planned final gradient.

The following design soil parameters were assumed for the stability calculations according to DIN 4084:

Soft subsoil: Undrained shear strength  $c_u = 8 \text{ kN/m}^2$   
Unit weight  $\gamma_n = 11 \text{ to } 13 \text{ kN/m}^3$   
Sand: Angle of internal friction  $\phi' = 32.5^\circ$   
Unit weight  $\gamma_n = 18 \text{ kN/m}^3$

The calculation resulted in an allowable embankment height of only 2.6 m without reinforcement. To achieve the aimed preloading height of 4.5 m and the required FOS = 1.2 (global stability, temporary stage) according to DIN 4084, a reinforcement tensile force of about 200 kN/m was required (Blume 1995, Blume 1996). For reasons of deformation compatibility the corresponding short-term strain was limited to 5%, and the total strain (short-term plus creep) was not allowed to exceed 6% for several years. Based on the stress-strain and creep curves a high-tenacity polyester woven with an UTS = 400 kN/m and 10% ultimate strain was selected (Stabilenka® 400).

The earthwork for the entire 2 km-stretch was carried out from June 1986 until June 1987, followed by a consolidation period of 15 months. After then in some sections the embankment thickness had to be increased additionally from 4.5 m up to 6.5 m (including the 'reference section', see below) to compensate the unexpected high settlements. After a new consolidation period of 17 months, parts of the preloading thickness were removed in March 1990 for fitting the final gradient. The highway was opened to traffic in October 1990.

Since October 1990, after the end of the measurements directly accompanying construction, measurements have been and are being performed on the long-term deformation behavior of the subsoil, of the completed highway and on the strain behavior of the basal reinforcement.

### 3.2 Description Of The Tests

The main aim of both the 'test embankment' and the 'reference section' was to provoke the highest possible stress in the woven, selecting sections of the highway having particularly unfavorable subsoil conditions. Knowledge was to be gained of the long-term behavior of the reinforcement.

Under the 'test embankment', which was planned as a 'crash test', extremely high reinforcement stress had to be generated by rapid construction (4.5 m in four days), and by a steep slope of 1 V : 2 H. Nevertheless, ground failure had to be avoided because of the later integration in the stan-

dard highway embankment, after reshaping. Around 40 m away, in the 'reference section' with a standard (flatter) slope of 1 V : 3 H, the loading process lasted around a year.

For the direct geotextile strain measurements, the BAST developed a suitable strain measuring system which does not influence the strain of the fabric. Robustness, precision and water-resistance were proved in advance in contact with soil and under water also.

Settlements, pore water pressure, inclination and groundwater level of the subsoil were measured. The strain measurements were performed on, in total three cross sections, two of them in the 'test embankment' and one in the 'reference section'. In each case 9 strain gauges were installed at 2 m space. Additionally, settlement gauges were placed near the strain gauges (Figure 3 a, d).

### 3.3 Measurement Results And Assessment

The most important results are depicted in Figure 3 a, b, c for the 'test embankment' and in Figure 3 d, e, f for the 'reference section'. Note, that embankment material, single layer thickness, height (4.5 m) and reinforcement are the same.

The construction periods and slope inclinations are quite different, as mentioned above.

In Figure 3 b, c the graphs show the development only within the first 4 days (height from zero to 4.5 m). After that the increase in strain became less and, after 2 months, came almost to a halt (not shown). In the subsequent 25 months the strains asymptotically came up to a maximum final strain of about 7% below the slope and 6% below the center of the embankment (not shown).

In Figure 3 e, f the graphs show the processes within around one year (height from zero to 4.5 m stepwise). The line with the number 1 corresponds to the 4<sup>th</sup> day (1.5 m sand), and with the numbers 2 to 5 to the 30<sup>th</sup> day after placing of the respective sand layer, at nearly constant time intervals.

Although the distance between the 'test embankment' and the 'reference section' is only around 40 m, the subsoil conditions seem to be considerably different, resulting in unexpected high settlements of the latter. In both cases a weak zone below the slopes was identified. Nevertheless, slope failure was not observed in the embankment body itself, neither for the 'test embankment', nor for the 'reference section'. On the contrary, the horizontal displacement of the subsoil near the toes became large, for the 'test embankment' up to 40 cm, destroying the inclinometer tubes. The ground tended to a 'squeezing-out', but a real failure did not occur. Note, that the typical subsoil-squeezing-mode cannot be checked by Bishop's method (DIN 4084) used for design calculations. Nowadays this mode should be checked e.g. according to Michalowski and Lei Shi (1993).

The reasons for the surprisingly high reinforcement-strains (and corresponding stresses) below the slopes in both cases are apparently both the weak zones and the squeezing-out tendency.

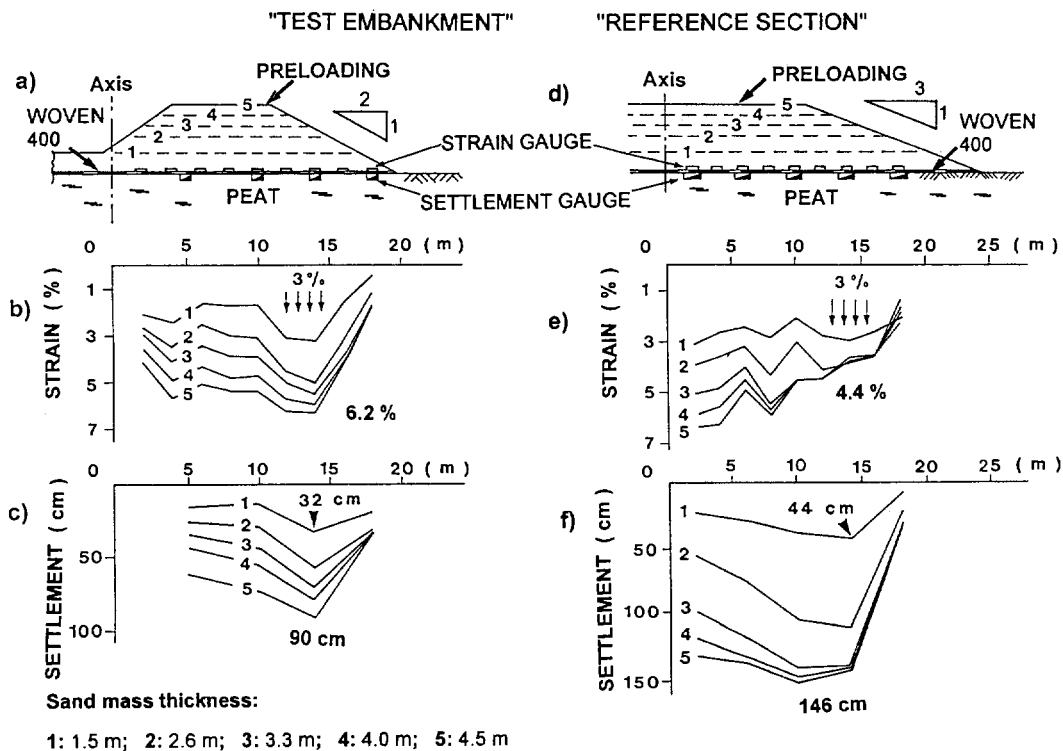

Figure 3. Grossemeer: construction stages, settlements and strains

The strain increase and the horizontal deformations came to a halt shortly after completion of the construction. Based on the observation, it can be concluded that the reinforcement prevented both slope failure of the embankment and ground failure due to squeezing of the soft layers.

The reinforcement strains exceeded at some locations the values of 5% (short-term) and 6% (long-term) assumed in design. The real mobilized tensile forces were higher than expected according to the stability calculations (DIN 4084, Bishop's method). The stress ratio (tensile force/UTS) exceeded 50% clearly.

In 1993, the strain measurements in the 'test embankment' were terminated due to adjacent building activities. Only the results of the continued long-term measurements from the 'reference section' are reported below.

Note, that in Figure 3 d, e, f only the period from June 1987 to June 1988 is depicted. After that in Autumn 1988 the height of the 'reference section' was increased to 6.5 m to compensate the high settlements, and was reduced again just in Spring 1990 (Figure 4).

So far, at the center of the embankment, maximum strains between 6.8% and 7.6% and maximum settlements of the soft subsoil of between 190 cm and 205 cm have been measured. The strains presented in Figure 4 from commencement of construction in July 1986 until July 1997 remained practically unchanged after removal of the preloading height and opening of the highway to traffic in October 1990.

Figure 4. Variation of load, strain and settlement in the Grossemeer 'reference section' (1986 to 1997).

The constant strain level indicates that the reinforcement is still under tension after 10 years. It is difficult to evaluate the effective tensile forces from the registered strains with high precision now. In comparison with the short-term behavior a reduction in the effective tensile stress could be expected theoretically due to some factors. Relaxation could

play a (negligible) role; for the high-tenacity polyester used relaxation due to creep is very low. Furthermore, installation/compaction damage and environmental effects could have reduced the really available mobilized tensile force.

For the evaluation of relaxation the isochrones could be used, and the percentage of installation damage in sands is known in good confidence, being in the range of 5% to 10% for the reinforcement used. For evaluation of environmental effects the best way is to exhume and analyze an analogous reinforcement material, which has been embedded under similar conditions for a long time. For this purpose the Rübke-embankment offered a good possibility (see section 2).

#### 4. INVESTIGATION OF A HIGH-STRENGTH POLYESTER WOVEN AFTER 14 YEARS EMBEDDED IN SOIL

##### 4.1 Description Of Exhumation And Tests

In 1995, the BAST initiated the investigation of exhumed fabric samples. Since it is not possible to take samples from Grossemeer, the BAST proposed, samples to be taken at Rübke (see section 2).

In September 1995, around 120 m<sup>2</sup> of the high-strength woven were exhumed from the embankment base after 14 years in use. The entire geotextile was lying below the terrain in the peat and groundwater due to settlements. By an excavator, embankment parts were removed down to the woven, from the slope to the center of embankment. At the beginning, it was possible to remove the remaining sand by hand. Due to the rapid rising of water, it was unavoidable to pull out and up most of the woven directly by the excavator. Thus, abrasion and damage of the fabric could not be fully avoided.

It was observed during uncovering, that the woven was still under tension before cutting. A considerable effort was necessary to lift up the edge of the woven by a shovel (Figure 5). This observation corresponds to the strains under the Grossemeer 'reference section', which indicate considerable tensile forces until today also (Figure 4). Discoloration of the fabric due to contact with the rotted grass and the peat were clearly visible. In some places, grains of sand had penetrated its structure.

Samples for the testing institutes, participating in the investigations, were taken from four different geotextile areas after exhumation, corresponding to defined different positions in the base.

For each of the four areas the following tests were performed:

- (1) Yarn tensile tests according to DIN 53834, T 1 with 15 individual tests per each area
- (2) Analyses for determination of the carboxyl end groups (CEG) and of the molecular weights of the high-tenacity polyester
- (3) Scanning electron microscopy (SEM) of filaments
- (4) Chemical analysis of the groundwater (pH-values).

##### 4.2 Evaluation Of The Results Available To Date

The evaluation of the investigations regarding durability are almost completed. The most important results to date are presented here. The final evaluation and details will be reported separately.

The results of yarn tensile tests form a better criterion for evaluation of strength loss due to environmental effects than the wide-width strip tests. Damage caused by installation, compaction and (in this case) removal and exhumation, and sand-grain inclusions in the woven structure has a less pronounced influence on the cleaned single yarn (although it can not be eliminated). The graphs in Figure 6 show the stress-strain behavior of the exhumed yarns. Each curve represents the average of 15 tests per area.

Figure 5. Rübke: the woven being still under tension after 14 years.

The specific yarn strength of the 'virgin' (brand new) high-tenacity polyester used (Diolen<sup>®</sup>: CEG < 27 meq/kg; number average molecular weight  $M_n > 25000$ ; further exact data are known also) is shown in Figure 6, too. To perform a durability evaluation on the safer side, an increased possible average value of 'virgin' strength of 86 cN/tex (instead of 84.6 cN/tex) could be assumed. Thus, the residual strength is around 83% of the 'virgin' strength. The ultimate strain is practically unchanged. Note, that the yarn-strength-loss of around 17% includes (in chronological order) the effects of weaving of the yarns producing the fabric, of installation and compaction damage, of biological and chemical degradation (chemical attack plus hydrolysis) and of exhumation process.

Figure 6. Specific yarn strength after 14 years in soil under groundwater level for the four different sampled areas according to DIN 53834, T 1.

The loss of yarn-strength due to the manufacturing process is 7% to 12%, on the average 9% (HUESKER Synthetic 1996). Further, for the woven mentioned loss of strength during compaction in sands of 5% to 10% has been observed. The loss of strength due to exhumation process is hardly to be identified exactly, but it can be set to 1% to 5% in this case. (Note, that a gentle exhumation was not possible, as mentioned above.)

The comparison of the percentage terms described above (weaving, compaction and exhumation) with the registered total loss of yarn-strength of about 17% results in 0% to 3% loss of strength due to environmental effects in this case.

Further, the SEM-photomicrographs performed indicate no chemical damage of the filament surface; it is completely smooth.

The comparison of molecular weights and number of CEG of 'virgin' and exhumed material leads so far to the conclusion, that 1% to 2% of strength-loss could be caused by changes in the polymer itself.

These latter evaluations of the microscopic and chemical investigations correspond well to the evaluation of loss in strength based on mechanical yarn-tests as mentioned earlier.

The pH-value of the groundwater is 6.6 on the average. This fact together with the SEM leads to the conclusion, that no chemical attack ('external' hydrolysis) has taken place.

The loss of strength of about 1.5% per 10 years, evaluated by different methods in this case, may be explained by 'internal' hydrolysis ('aging') in the groundwater and (unlikely) by biological effects (rotted grass, peat).

## 5 SUMMARY AND CONCLUSIONS

Two projects of embankments on soft subsoil with high-strength basement reinforcement have been started in Germany in 1981 ('Rübke') and 1986 ('Grossenmeer')

respectively.

The 'Rübke-embankment' is a pure test-embankment for the autobahn BAB A 26. The 'Grossenmeer-embankment' is an integral part of the federal highway B 211. In both cases high-modulus polyester woven is used with 200 kN/m and 400 kN/m UTS, respectively, and 10% ultimate strain. For stability calculations DIN 4084 (Bishop's method) has been used, modified by reinforcement force. Measurement programs are performed up to now, including direct strain measurements at 'Grossenmeer'.

Woven from 'Rübke' was exhumed after 14 years under tension below groundwater to evaluate durability.

1. Stability calculations according to DIN 4084 are correct enough to prevent failure of embankment and/or subsoil, at least when high tensile force at low strain is mobilized to restrain deformations.
2. High-moduli for a long period (low creep) are important, because the reinforcement works after consolidation also. In the projects described it is still under tension after 15 and 11 years, respectively.
3. The high-strength reinforcement used proved to resist overstressing successfully for a long period.
4. Local weaker subsoil zones can easily result in reinforcement overstressing and/or failure tendency; it should be kept in mind when selecting safety factors.
5. Subsoil squeezing-out is recommended to be checked additionally to DIN 4084-calculations by other methods.
6. The analyses of durability and operation conditions indicate in this case, that (internal) hydrolysis under stress in groundwater is the main reason for the registered negligible loss of strength.
7. The loss of strength due to 'aging' (environmental effects) is 1.5% to 2% in 14 years for the high-tenacity polyester woven used.

# Durability of Polyester and Polypropylene Geotextiles Buried in a Tropical Environment for 14 Years

J.W. Cowland

ERA Technology, United Kingdom

**ABSTRACT:** The demolition of a 14 year old embankment on soft clay provided the opportunity to exhume samples of the geotextiles that had been used to reinforce the base. Specimens of these woven polyester and woven polypropylene geotextiles were then tested to assess their durability. From tensile and hydrolysis tests it was found that the polypropylene geotextile largely retained its strength, and the polyester geotextile lost about 15% of its strength. A portion of the polyester strength loss was attributed to hydrolysis.

**KEYWORDS:** Durability, Polyester, Polypropylene, Geotextiles, Tropical Environment.

## 1. INTRODUCTION

In 1982, a 3.5 km long coastal road embankment was constructed on soft clays in a tidal area of Hong Kong. The base of this embankment was reinforced with woven polyester and woven polypropylene geotextiles. Figure 1 shows a typical cross-section of the embankment.

In 1996, part of this embankment was demolished to make way for a river improvement scheme, which provided the opportunity to exhume some of these materials. Large pieces of both the polyester and the polypropylene geotextiles were carefully removed from the embankment by hand, and tests were carried out to determine their durability.

Tensile tests were carried out to determine the strengths of the recovered geotextiles, and they were also examined under a scanning electron microscope to determine the extent of site damage. Carboxyl end group counts, and molecular weight determinations, were performed on the polyester geotextile to evaluate the extent of hydrolysis. This paper presents the results of these durability tests.

## 2. GEOTEXTILES

A single layer of reinforcing geotextile was used beneath the embankment. Rolls 5 m wide were placed on the intertidal mud flats and stitched together. The project commenced with a polyester geotextile, which was substituted in places by a polypropylene geotextile. The exhumation encountered areas of both materials.

### 2.1 Polyester

The woven polyester geotextile was a multifilament material, with a weight of 450 g/m<sup>2</sup>. Quality control tests at the time of construction demonstrated a characteristic tensile strength of 200 kN/m in the warp. The maximum tensile strength was often 220 kN/m, at a strain of 8%, with a 10% strain at break. In the weft the characteristic tensile strength was 45 kN/m, with a 20% strain at break.

Ten strain gauges were attached to one roll of the polyester geotextile during laying, and a 9% extension was recorded after the placing of the fill material.

### 2.2 Polypropylene

The woven polypropylene geotextile was a fibrillated tape material, with a weight of 570 g/m<sup>2</sup>. Quality control tests demonstrated a characteristic tensile strength of 200 kN/m in the warp, with a strain of 12% at the maximum tensile strength, and 40 kN/m in the weft.

## 3. ENVIRONMENT

The coastal road embankment was constructed in the intertidal zone of a mangrove swamp. The geotextiles were placed by hand directly onto the very soft dark grey organic silty clay, which contained a large number of shells. The fill material, essentially a brown gravelly silty sand of granitic origin, was mechanically placed on top in 0.5 m layers.

Figure 1. Cross-Section of the Embankment

During exhumation, pieces of pH indicator paper were placed in the water surrounding each geotextile, and they all indicated a pH of 7. It should be noted, though, that the portion of the exhumed embankment where the polyester geotextile was located was adjacent to the estuary of the Shan Pui River, which flows through the Yuen Long Industrial Estate, and is polluted.

The Hong Kong Observatory has been measuring soil temperature, for agricultural purposes, for over 25 years. At a depth of 3 m below ground level, the average soil temperature has consistently been found to be 26°C.

#### 4. EXHUMATION AND SAMPLE SELECTION

The polypropylene geotextile was encountered during the initial stage of demolition of the embankment. With the full cooperation of the site staff, careful hand excavations were then made to recover large pieces of both the polyester and the polypropylene geotextiles. These large pieces were then washed with a hose of water to remove some of the adhering soil, their appearance carefully observed and recorded, before being transported to the laboratory.

The appearance of the black polypropylene geotextile was relatively uniform, and appropriate samples were taken for tensile testing, and examination for site damage.

The white polyester geotextile had more marked differences in appearance, especially in colour. One area was greyish white, and showed some signs of installation damage, whilst another area was stained brown and grey. Samples for testing were selected from areas that were visually undamaged (to the human eye), although stained.

#### 5. DURABILITY TESTING

##### 5.1 Tensile Tests

Ten specimens of the polyester geotextile, and ten specimens of the polypropylene geotextile, were subjected to wide width tensile tests, in accordance with BS 6906: Part 1 (1987), except that individual specimens were tested at different rates of strain. Two specimens of each geotextile were tested in the warp direction at 100, 10, 1, 0.1 and 0.01 per cent/minute strain. The specimens were gripped with roller clamps, and their extensions measured using a non-contacting video extensometer.

The results are shown in Table 1. Examples of the load strain curves for both the polyester and the polypropylene geotextiles, at a constant strain rate of 10%/min, are shown in Figure 2. None of the polyester specimens showed any visible signs of damage before testing, although some staining was evident on all specimens. Specimen F of the polypropylene material showed visible fraying of some of the warp fibres, and this probably accounts for the low value of tensile strength.

The results are summarised in Figure 3.

##### 5.2 Scanning Electron Microscope Examination

Three specimens of the polypropylene geotextile were examined in a scanning electron microscope, one on both sides. Their appearance, as shown in Plate 1, was typical of a fibrillated tape geotextile. Most of the damage was confined to the surface. Both warp and weft were damaged equally. Soil residue had penetrated the textile.

Table 1. Tensile Test Results

Rate of strain (%/minute)	Polypropylene Geotextile			Polyester Geotextile

Table 2. Hydrolysis Test Results

Specimen	Staining	Intrinsic viscosity	Viscosity molecular weight	Carboxyl end group (CEG) (meq./ $\mu$ g)			Mean CEG (meq./ $\mu$ g)
1	Greyish white	1.08	38,200	28.9	25.9	29.8	28.2
2	Grey / brown	0.61	19,200	30.4	30.1	29.8	30.1
3	Grey / brown	0.64	20,300	29.6	30.2	29.4	29.7

Two specimens of the polyester geotextile, one from the area stained brown and grey, and the other from the area stained greyish white, were examined in the scanning electron microscope. There was no damage visible to the unaided eye in either specimen. Examples of the micrographs are shown in Plates 2, 3 & 4; in which the warp direction is horizontal.

Locally there was damage to the fibres in the form of splits, indentations or openings in the fibre surface parallel to the axis. In places the surface of the fibres appeared flaky. This was sometimes, but not always accompanied by local distortion, as shown in Plate 3. Individual soil particles and smeared areas were present, primarily attached to the warp fibres.

X-ray analysis of an area stained brown and grey showed that the smeared areas contained aluminium, silicon and some iron, and were therefore likely to be from an iron containing clay. Analysis of the discrete particles showed that some were clay, but others consisted mostly of sulphur. Analysis of an area stained greyish white found similar distributions of sulphur containing particles. The clay was found to contain silicon and aluminium as before, but no iron.

### 5.3 Hydrolysis Tests

Nine carboxyl end group tests were carried out on the polyester geotextile, using the non-aqueous titration method of Pohl (1954), but with bromocresol green as the indicator. Three tests were performed on a specimen of the material stained greyish white and six were performed on two specimens of the material stained brown and grey. The results are shown in Table 2.

Three intrinsic viscosity measurements were made, in accordance with ISO 1628-1 (1984), using o-chlorophenol as the solution medium; from which the viscosity molecular weight, which approximates to the weight average molecular weight, was then calculated. These results are also shown in Table 2.

## 6. DISCUSSION OF RESULTS

### 6.1 Polypropylene

The loss of strength of the polypropylene geotextile after burial for 14 years was relatively insignificant. Also, as shown by comparison of a test at 10%/minute strain (Figure 2) and the original properties, there was little change to the strain characteristics.

In addition, examination in the scanning electron microscope found only surficial surface damage to the material. Thus, it is concluded that this woven polypropylene geotextile has survived installation, and burial in the ground for 14 years at 26°C., with little change.

### 6.2 Polyester

The polyester geotextile lost about 15% of its strength after installation and burial for 14 years in a saturated ground at 26°C.

From Table 1 it can be seen the strain at maximum strength was less than that measured before installation. Figure 2 shows that the strain at break was also less. The relatively flat gradient of the polyester change of strength with strain rate plot, shown in Figure 3, indicates that it is not particularly strain rate sensitive.

The carboxyl end group test results ranged from 26 to 30 equivalent ends/microgram, which when compared with the range of 25 to 50 normally required for the production of high tenacity polyester fibres, indicates little hydrolytic degradation. The results for the material stained brown and grey were slightly higher than for the greyish white material.

The weight and number average molecular weights of the original geotextile are believed to have been at least 33,000 and 12,400 respectively. The intrinsic viscosity measurements and molecular weight determinations showed that material from the areas stained brown and grey was only two thirds of the original molecular weight.

Taking all these measurements into account, especially the loss of molecular weight, it is concluded that a portion of the 15% loss of strength of this woven polyester geotextile was due to hydrolysis. The rest may be due to installation damage (Brady et al, 1994).

The analysis of Burgoyne and Merii (1993) and the Arrhenius diagram of Schmidt et al (1994) both predict a loss of less than 5% due to hydrolysis after 14 years in saturated soil at 26°C. Salman et al (1997) predict a larger loss, and Schmidt et al indicate that a 30% loss of molecular weight would be associated with a 14% loss of strength.

The relationship between a change of carboxyl end group count and the change in the molecular weight depends on the distribution of molecular weights. Local hydrolysis may be associated with the presence of metal ions in the degraded areas.

This loss of strength does not preclude the use of similar polyester geotextiles for the basal reinforcement of embankments on soft clay, as the strength of the reinforcement is only required for a few months, until the clay has consolidated. It is suggested, though, that similar durability studies be carried out on polyester geotextiles and geogrids exhumed from permanent reinforced fill.

**ABSTRACT:** The behaviour under creep of polymeric materials used to reinforce soil structures is an essential criterion in the study of the durability of structures. The report presents the results of full-scale tests carried out to study the behaviour under creep of polyester tendons. Loading tests to rupture were performed on tendons for assumed life periods of 2, 10, 30, 100, 300 and 1000 days. Samples taken before rupture at different ages allow determination of the residual strength characteristics of the tendons. The results obtained confirm the law of the linear behaviour of creep rupture versus the logarithm of time. It also shows that the residual strength of tendons subjected to creep tests remains greater than that calculated from the stress rupture curve and very close to the initial test strength of polymeric materials.

**KEYWORDS:** Polyester, creep rupture, residual strength, creep.

## 1 INTRODUCTION

The results of creep rupture tests on polyester fibres are generally expressed in the form of creep rupture curves of the type: load in relation to log (time) as shown in Figure 1. The admissible tension load at time "t" is determined by extrapolation of the tensile strength data obtained from creep tests at time  $t_0$ . Safety coefficients are applied to the tensile strength to allow for uncertainty due to extrapolation. Knowing the true strength of the material under the effect of creep related to time is of major interest when defining these safety coefficients.

It is important, therefore, to establish the residual strength of tendons used i.e. what is their actual breaking load  $Tf_1$  at time " $t_1$ ", under a given load applied  $Tf_2$ , when off loading takes place some time before creep rupture, as per the creep rupture line at time " $t_2$ " (Figure 2).

Figure 1. Creep rupture curve.

The report presents the results of a study carried out in order to establish the characteristics of creep rupture of polyester cables used as tendons in reinforced fill and to evaluate their residual strength before rupture (Linear Composites Ltd 1995).

Figure 2. Residual strength.

## 2 TESTS

The loading test was performed to full scale in a covered test pit under ambient atmospheric conditions. A device allowed maintenance and monitoring of the temperature in the pit at about 18°C. Tendon test pieces were loaded to a constant value calculated for different rupture times. For each series, the tests were continued on the one hand up to creep rupture of the test pieces, and on the other hand by

taking samples at different times before rupture for determination of their residual strength in a laboratory tensile test.

## 2.1 Tested Material

For this study and for experimental purposes, the tests were performed on Parafil polyester tendons of the same nature as polyester reinforced strips used in the reinforced fill. These were composed of polyester fibres covered with a polyethylene sheath. The test pieces, prepared specially for these tests, were 550 mm long and comprised two termination devices at their extremities.

## 2.2 Loading Weights

These tendons are characterised by:

- their Nominal Breaking Load "N.B.L." defined as 10 kN,
- their actual breaking load i.e. the mean of 20 samples tested as initial reference. However, this value can vary between various series of samples tested due to termination dimension as pre-tensioning conditions during samples preparation.

The weights consist of concrete blocks which are adjusted by adding additional weights before loading the samples.

## 2.3 Table 1

This table gives the plan of the experiments carried out. The set of samples was prepared successively for the tests. In general, 16 samples were loaded for each creep rupture point and 6 samples for each strength retention point.

Table 1. Plan of experiments performed.

Phase	Reference	Loading for		Test performed		Type	
	Sample	Test pieces	Rupture at (days)	Test pieces	Time (day)	Test pieces	
0		2	5	2	5	Creep	
1	1	20	2	12	2	12	Creep
			10	16	10	16	Creep
			30	14	30	14	Creep
2	2	20	100	40	2.10	4x6=2	Resi. strength
					30.60	4	
					100	16	Creep
					30	6	Resid. strength
					300	34	100
3	3	5	1000	24	200	6	
					300	16	Creep
					30	6	
					100	6	Resid. strength
					200	6	Resid. strength
			300	6			

## 2.4 Determination of Creep Rupture Loads

The calculation of the creep rupture loads for each phase of the tests was determined from the experimental results obtained during a previous study and readjusted by a series of rupture tests under creep. This relationship subsequently recalculated after each test phase, was used for calculating the weights for the following phase. The weights were calculated with reference to the tensile strength of the test samples.

## 2.5 Determination of the Reference Tensile Strength

Characterisation of the 550 mm long tendons due to be tested was established using tensile tests at a strain rate of 100 mm/min. Table 2 gives the results for the tendons for the three series of samples tested.

Table 2. Reference tensile strength.

Series	1		2		3	
Samples	20		20		5	
	Loads kN	Extension at rupture (%)	Loads kN	Extension at rupture (%)	Load kN	Extension at rupture
Mean	15.85	10.09	14.72	9.7	15.57	10.3
S.D. <sup>1</sup>	20	0.31	56	0.5	71	0.7
V.C. <sup>2</sup> %	1.3	2.9	3.8	4.8	4.5	7.0

<sup>1</sup>Standard Deviation - <sup>2</sup>Variation Coefficient

All tendons tested came from the same batch of cable. However, slight changes were introduced in the termination conditions (dimension and pre-stressing rate during preparation stage). This can explain the slight changes observed for reference tensile strength measurement between phases.

## 3 TEST RESULTS

Table 3 gives the creep test results. The graph in Figure 2 shows an adjustment by linear regression of the relation load - f(log(time)) with very good correlation.

The creep rupture equation line obtained is:

$$Tf(\%) = 88.8 - 2.38 \log(t_{\min}) \quad (1)$$

where: Tf(%) = actual breaking load (in % of original breaking load) at time t ; and t = time in minutes.

This equation has been established using creep rupture results at 2, 10, 30 and 100 days. It will be confirmed by 300 days tests which are still on going.

**Table 3. Rupture time under creep.**

Phase	Weight values (kN)	Rupture time under calculated creep (day)	Rupture under observed creep (day)		
			Mean	S.D. <sup>1</sup>	V.C. <sup>2</sup> %
0	13.40	2	0.05	0.05	100
	12.62	2	1.21	0.91	74.9
1	12.41	10	10.34	7.47	72.2
	12.20	30	15.51	10.81	69.7
2	11.95	100	81.87	62.61	76.5
3	11.75	300	*	*	*

\* Test under way

<sup>1</sup> Standard Deviation - <sup>2</sup> Variation Coefficient

Table 4 gives the results of the determination of residual strength for tendons subjected to creep tests. These show that, for different loads and before termination of their foreseeable life span, the residual strength is not affected by the load (Cf. Figure 3).

**Figure 3. Creep rupture curve and residual strength.**

**Table 4. Residual strength of tendons subjected to creep test.**

Phase	Refe. <sup>3</sup> (kN)	Time of rupture calculated creep <sup>4</sup> (day)	Age of the test (day)	Measure residual strength % of the reference tension		
				Mean	S.D. <sup>1</sup>	V.C. <sup>2</sup> %
2	14.72	100 (81,2%)	2	95.2	4.6	4.9
			10	92.5	3.5	3.7
			30	99.0	4.8	4.8
			60	90.4	1.7	1.9
			300	102.8	3.1	3.0
3	15.57 (75,5%)	100 (74,2%)	100	100.8	5.3	5.2
			200	99.5	1.9	1.9
			30	100.9	8.8	8.7
			1000	100.7	6.2	6.2
			200	101.4	2.3	2.3
		300	94.5	7.1	7.5	

<sup>1</sup> Standard Deviation - <sup>2</sup> Variation Coefficients - <sup>3</sup> Reference

<sup>4</sup> Rate of loading in relation to reference

For phase 2, the variations observed, as well as the fall in measured residual strength, may result from problems related to the termination devices on the tendons, which were improved for phase 3.

#### 4 DISCUSSION

The objective of this project was to firmly establish the long-term tensile behaviour of Paraweb soil reinforcing products. However, the creep and creep rupture behaviour of webbing is difficult to study because slip-free methods of holding the web are complex and expensive and preclude the multi-sample approach. Polyester cable was used in this work to simulate webbing because it performs in an identical manner to the equivalent web and is easier to hold in standard terminations. The breaking load of the cable was limited to about 15 kN so that the concrete weights could be restricted to a maximum of 14 kN.

The test results for creep rupture and strength retention are shown in Tables 3 and 4 and graphically in Figure 3. The anticipated creep rupture performance was confirmed and the regression equation established.

Evidence of retention of strength under load approaching 100% is clearly demonstrated for three different loads (it is clear that the phase 2 results were slightly lower than anticipated. This was due to minor termination difficulties which were resolved for phase 3).

Evidence is also presented confirming the retention of initial strength until close to the creep rupture point.

This strength retention phenomenon brings into question the current techniques (based on creep rupture) used to establish safety factors for design loads. The following example demonstrates the anomaly:

- taking the Characteristic Breaking Load (CBL mean - 1.64 SD) of series 2 as 13.8 kN,
- assume a typical factor of safety (which includes the effects of creep rupture) of 3 on CBL,
- the design load for the tendons becomes:

$$DL = \frac{CBL}{3} = \frac{13.8}{3} = 4.6 \text{ kN}$$

- using the creep rupture equation, if we calculated the time to rupture for a load of 4.6 kN from:

$$\log(t_{\min}) = \frac{88.8 - 31.25}{2.38}$$

this results in  $t = 2.3 \times 10^{18}$  years.

The evidence presented in this paper suggests that if this tendon was off-loaded after "only" 120 years its breaking load would still be close to 100%.

It is believed, therefore, that the phenomenon of strength retention should be a major consideration when calculating design loads. Clearly, providing the final design load is below the predicted creep rupture load for 120 years, safety factors should be applied to the retained load i.e. the initial strength of the geotextile. In addition any factors for transient load increases during the life of the structure should be based on the retained, i.e. initial strength.

## 5. CONCLUSION

1. This work has confirmed the linear nature of the creep rupture performance of polyester tendons on a load versus log time basis.
2. The residual strength of the tendons when subjected to the creep tests remains far above the creep rupture curve and is unaffected by time under load until close to the creep rupture life.
3. A new approach to design load safety factors should be considered which take into account residual strength (as opposed to the current BNSR 1991).

**ABSTRACT:** The load/deformation behavior of geogrids is the dominant characteristic for the bearing behaviour of the composite soil-geogrid. As deformations of soil shall be small during implementation of geogrid and very small after construction high modulus at low deformations and low creep are the aims. As polyester normally has a orientation phase at low deformations the attempt was made to use other polyester yarns for geogrids. Short-time and creep tests show significantly better behavior in initial load bearing capacity and creep behavior.

**KEYWORDS:** Creep, Design deformation, Polyester, Geogrid

## 1 INTRODUCTION

The coaction of reinforcing geosynthetic and soil is the basis of design methods. Examples are given by OECD Expert Group I8 (1991). The following figures are taken from the OECD report.

Figure 1 a. Calculation of slope stability and compatibility of soil and geotextile reinforcement

(A) General principles of calculation of the internal stability  
(B) Two part wedge method  
(C) Displacement method

Figure 1 b. Calculation of slope stability and compatibility of soil and geotextile reinforcement

The curves show load/extension curves for the geosynthetic („isochronous stress-strain curves) and the soil curve. Independent from the design approach, it is to be seen that a steeper curve for  $t = t_1$  (for example  $t_1 = 10^6$  h = 114 years) leads to structures with low movement. A big difference between  $t = 0$  and  $t = t_1$  leads to movement in a post construction phase i.e. service period. For the post construction deformation values are given between .5 % for rigid structures and 1 % for not sensitive structures by the OECD Expert Group I8 (1991).

So a reinforcing material should have a curve with low deformation in the design-relevant area

(deformations of  $\leq 3\%$ ) and the smallest difference possible between  $t = 0$  and  $t = t_1$ .

As some polymers have orientation phases of the macro molecules at relativ low deformation, this orientation should be eliminated by stretching during production or other thermo-mechanical pretreatment.

This investigation deals with two types of polyester (PES-) yarns and grids woven from these yarns.

## 2 GENERAL DEFORMATION BEHAVIOR

Geosynthetics deformation behavior is influenced by

- deformation in the textile structure
- polymer type
- thermo-mechanical treatment of tapes, yarns, fibres etc.

The deformation in the textile structure of woven materials may be influenced by kind of weaving and warp tension. Knitwear may have straight load bearing elements, thus having no construction deformation. The same is valid for extruded and stretched grids.

Polyester materials are characterized by a orientation phase between 20 and 30 % of short-time strength. The phenomenon is visualized in Figure 2 (C. Koslowski, 1996) versus time, as this orientation occurs under sustained load at lower stresses.

- $\epsilon_T$  = tertiary creep deformation
- $\epsilon_s$  = secondary creep deformation
- $\epsilon_p$  = primary creep deformation
- $\epsilon_0$  = initial deformation

Figure 2. Creep deformation and creep rate

## 3 TARGET OF THE INVESTIGATION

The tests reported here should show, whether a different yarn [called New Technology (NT) in this report] gives better performance at low deformation values than a

standard PES-yarn. Short-time tensile, tensile creep and creep rupture tests were conducted, this report deals with short-time tensile and creep tests.

### 3.1 Short-time Tests

The short-time tests were carried out with two grids of identical nominal maximum force. All tests were performed on identical equipment by same staff according to ISO 10319 i. e. 1 % preload, 20 %/min strain rate, videoextensometer. Figure 3 shows the stress-strain curves, which (best to be seen for the product with 150 kN/m) miss the typical orientation phase, characterized by a degressive gradient from about 1 % strain up to 4 %. Also the ultimate deformation is about 9 % for the NT-materials compared with about 12 % for the standard material.

Figure 3. Stress-strain curves - woven polyester-geogrid

### 3.2 Creep Tests

For the creep comparison we took old values for the standard materials [published by J. Müller-Rochholz and R. Kirschner at the 4<sup>th</sup> International Conference on Geotextiles, Geomembranes and Related Products, The Hague, Netherlands (1990)], therefore sometimes stress/strength values and temperatures are close but not identical.

Creep curves for yarn and geogrids of different strength woven of this yarn are shown in Figures 4 a and b. The problem in testing is to be seen by the remark „clamp failure“. If stress level is very close to the bearable load, any lateral stress may cause rupture.

Figure 4 a. Creep curves - woven polyester-geogrid „new technology“ (35 kN/m)

Figure 4 b. Creep curves - woven polyester-geogrid „new technology“ (150 kN/m)

Figure 5 shows 1 year NT-values at 30 % stress level and 3 years lines of standard PES of lower (= 25 %) stress level, showing ca. 1 % higher strains for the lower stress level of standard yarns.

Figure 5. Creep curves - woven polyester-geogrid

In Figure 6 identical stress levels (50 %) of products are compared at differing temperatures showing the low influence of temperature for PES and ca. 2 % less strain for the NT-materials. In this figure results of yarn creep tests supplied by the producer are plotted additionally. There is a different stress level for the standard yarn. The coincidence of yarn and product strains shows low construction influence.

Figure 6. Creep curves – woven polyester-geogrid (80 kN/m)

Figure 7. Isochronous curves – woven polyester-geogrid „new technology“

From these creep curves isochronous stress-strain curves were derived, showing in Figure 7 the close lines for 1 h up to 10000 hrs. Two lines of Figure 7 are transferred to Figure 8 to see the difference between the products with different yarns; which leads to strain differences f. e. at 20 % stress-level of > 3,5 % strain at 10000 hrs for standard to < 1,5 % for NT-products or at strain level of 2 % to stress levels from 5 % (standard) to 15 % (NT).

Figure 8. Isochronous curves – woven polyester-geogrid

#### 4 CONCLUSION

It can be shown that the thermo-mechanical treatment of yarns (here: Polyester) may lead to significant changes in the load deformation behavior especially in the application relevant area of admissible deformations/stresses. So the load bearing capacity at 2 % strain is tripled.

**ABSTRACT:** To qualify geosynthetics for in ground reinforcement use, it becomes mandatory to assess their durability within a short time with respect to environmental parameters to which they will likely be subjected for 75 to 100 years. This requires the development of accelerated tests permitting prediction of potential degradation under actual use conditions. It is known that polyolefin may oxidize resulting in polymeric molecular chain breaks directly resulting in strength loss of the material. The available studies of polyolefins oxidation indicate that rates of oxidation are very low at ambient temperatures, however in the context of the lifetime of civil engineering applications, may not be negligible. Comprehensive studies of polyolefin oxidation indicated that the rate of reaction among other factors, depends on the oxygen partial pressure in the system as well as on temperature. Complex antioxidant mixtures are commonly used to reduce the rate of oxidation for commercial polyolefin products during processing and in end use.

**KEY WORDS:** Geosynthetics, durability testing, oxidation, life prediction, antioxidant consumption

## 1. RESEARCH OBJECTIVES

This study was focused on considering the prime factors affecting the rate of degradation which are temperature, oxygen partial pressure, manufacturing process and effectiveness of antioxidants.

The scope of this reported research was limited to the laboratory investigation of thermooxidative degradation of a few typical commercial products selected to represent geosynthetic materials potentially used in highway applications. It is only a part of a larger FHWA study to develop durability testing protocols for geosynthetics.

The scope of the study is limited in that:

- a small number of commercial geosynthetic products are considered;
- only "severe" conditions of treatment, as compared to the in-service conditions, are used to accelerate degradation to achieve measurable chemical and mechanical changes during 2 to 3 years of laboratory incubation time.

## 2. LABORATORY ASSESSMENT PROCEDURES

The basic principles of thermooxidative degradation of polyolefin polymers indicate that environmental conditions such as oxygen partial pressure may have a significant impact on the rate of mechanical deterioration caused by oxidation. In order to assess the influence of oxygen partial pressure on the rate of mechanical degradation for

polyolefin geosynthetics, the following initial conditions have been selected for accelerated laboratory testing:

1. Oven aging in circulating air (21% O<sub>2</sub>) to represent surface and near surface conditions
2. Oven aging in stagnant atmosphere containing 8% O<sub>2</sub> balanced by N<sub>2</sub> to represent reduced oxygen found in reinforced fills (Yanful, 1993).

The overall effect of antioxidant additives is assessed by testing a specially manufactured polypropylene textile P-3a. This material is identical to the commercial products P-3 in terms of polymeric composition and manufacturing, except that it was manufactured with a minimum amount of additives required for production purposes.

## 3. GEOSYNTHETIC MATERIALS TESTED

Results from 2 commercial and 1 research grade geotextiles are reported in this study. The materials are differentiated by manufacturing process, composition and antioxidant additives. The main characteristics are shown in Table 1.

### 3.1 Testing procedures

The testing procedure consists of: (i) sample preparation; (ii) oven aging of prepared samples at different levels of oxygen concentration (iii) mechanical testing to determine tensile strength using a Wide Width Strip Test (ASTM D-4595); (iv) chemical testing to determine Oxygen Induction Time (OIT) by Differential Scanning Calorimetry

Table 1. Major characteristics of selected commercial polyolefin geosynthetic products.

(DSC) at 175°C; and (v) analysis of surface morphology by SEM and/or optical microscopy. The major features of the testing procedure are outlined below.

To perform accelerated thermodegradation of polyolefin geosynthetics in air (21% O<sub>2</sub>), forced-draft ovens with a temperature uniformity of ±1% and substantial fresh air intake are used in a compliance with ASTM D-3045, "Heat aging of plastics without load". To conduct aging in a stagnant atmosphere containing 8% O<sub>2</sub>, a special chamber was designed and manufactured. This apparatus provides a temperature uniformity of ±1°C, and allows control of oxygen concentration in the chamber. The specimens are suspended in the oven or in the chamber without pretension and without touching each other.

The temperature of exposure varied from 50° to 90°C. At least 5 consecutive retrievals were made over the period of aging at each specific condition with each retrieval represented by a minimum of 5 specimens.

The study further indicated that Oxidative Induction Time (OIT) measurements for these geotextiles appeared to be ineffective in monitoring strength degradation for the products tested.

Measurements of remaining OIT for the geotextiles reported did not correlate with remaining strength or antioxidant consumption as measured by induction time.

#### 4. LABORATORY ACCELERATED DEGRADATION RESULTS

Each of the selected geosynthetic products tested exhibits a unique pattern of degradation under the tested environmental conditions. Surface morphology studies are discussed in the context of measurable deterioration of mechanical properties observed for the aged geosynthetics.

##### 4.1 Nonwoven continuous filament geotextiles, P-3 and P-3a

The monitoring of weight changes during exposure to elevated temperatures in different atmospheres, indicated

no statistically significant variation of weight for the P-3 and P-3a geotextiles.

SEM study of the fiber surface morphology indicated that there are no apparent changes on the fiber surface on a microlevel, for either geotextile, aged in different atmospheric environments and at temperatures varying from 50° to 90°C.

The progressive strength loss versus time for the P-3 and P-3a geotextiles, are shown on Figure 1, indicates a non linear strength loss and the presence of an induction period. The induction period is defined as the initial period of oven aging, when no statistically significant changes of a tensile strength is observed. The P-3a geotextile exhibits no induction period for the same range of test temperatures.

One of the properties which affects the rate of thermooxidation processes is the composition and concentration of antioxidant additives in commercial products. The effect of antioxidant additives on the rate of mechanical degradation of polyolefin geosynthetic products is clearly illustrated by the relative performance of two products, P-3 and P-3a. The P-3 product contains a HALS type of antioxidant additive, and P-3a is a specially manufactured textile with only a minimum amount of antioxidants required for production purposes. The beneficial effect of antioxidants is clearly demonstrated by the summarized comparisons between degradation rates for these two products which is shown in Figure 1. There is an indication that at the lowest temperature tested of 50°C, the effect of the antioxidants is more pronounced than at the highest temperature of exposure of 80°C which is closer to the upper limit of effectiveness of about 135°C, for HALS type antioxidants (Fay, King, 1994).

Samples of the P-3 commercial geotextile were exposed to elevated temperatures of 70°, 80° and 90°C in a stagnant atmosphere of 8% oxygen balanced by nitrogen. The summary of results is shown on Figure 2.

Results indicate that the rate of mechanical degradation in stagnant diluted air is much slower than the rate of degradation in circulating air ovens. It can be observed that in stagnant diluted air (8% O<sub>2</sub>) P-3 exhibits an initial

Figure 1. Effect of antioxidant additives on the rate of thermooxidation for the P-3 commercial product and P-3a research grade textile.

Figure 2. Tensile strength for continuous filament geotextile P-3 during oven aging in stagnant diluted air at 8% O<sub>2</sub> and in circulating air at 21% O<sub>2</sub>.

tensile strength increase when tested at 70°C. However, tensile strength decreases with exposure time.

#### 4.2 P-4, nonwoven staple geotextile

Commercial geosynthetic P-4 does not exhibit shrinkage or swelling over the period of aging in circulating air and stagnant diluted air ovens.

Analysis for microscopic changes on fiber surface morphology has been conducted by SEM of fibers "as received" and fibers taken from the specimens aged in circulating air oven at 50°C. The virgin fibers appear to

be smooth and clean, however, there are traces of initial cracks on the surface of virgin fibers transverse to the fiber length. The SEM study further indicates a progressive development of circumferential cracks on the fiber surface during exposure to elevated temperatures in circulating air.

The SEM study of fiber surface morphology for this geotextile aged in stagnant diluted air (8% O<sub>2</sub>) at 70 °C, indicated no development of circumferential cracks on the surface of fibers after the 473-day thermal treatment. No changes of the fiber diameters have been observed.

Weight changes for P-4 measured over the period of exposure to elevated temperatures in different atmospheric conditions are minimal. The weight changes measured vary within the range of 0 to 2 percent.

The observed development of fiber cracking explains the rapid loss of tensile strength during thermooxidation in intense circulating air. It appears that this material loses 50% or more of its initial strength during the first 50 days of exposure in temperatures varying from 50° to 80°C as shown on Figure 3.

The results of mechanical testing for P-4 aged in a stagnant atmosphere of diluted air (8% O<sub>2</sub>, 92% N<sub>2</sub>) are at first quite unexpected. The specimens aged at 70° and 80°C in stagnant diluted air exhibit a strength increase by factor of 1.8 after first 80 days of exposure followed by statistically insignificant changes of tensile strength. However, no tensile strength increase is observed at 90°C. The summarized experimental results for mechanical degradation in these conditions are also shown on Figure 3.

#### 4.3 Summary of laboratory data on the rate of mechanical deterioration caused by thermooxidation

Results of tensile strength monitoring for these two polypropylene geosynthetics, indicate that each of the products studied, exhibits a unique pattern of tensile strength changes during exposure to elevated temperatures under differing environment conditions (oxygen partial pressure). However, the common features are as follows:

1. Oven aging in stagnant diluted air at 8 percent oxygen results in the decrease of the rate of tensile

Figure 3. Tensile strength loss for geotextile P-4, aged in circulating air at 21% O<sub>2</sub> (solid line) and at 8% O<sub>2</sub> (dashed line).

- strength loss as compared to the rate observed in circulating air (21% O<sub>2</sub>) at the same temperature.
2. The two commercial products tested, exhibit a different morphology in their virgin state. SEM microphotographs at a magnification of 3000x reveal the presence of initial crazes/cracks on the surface of virgin fibers for nonwoven staple geotextile P-4. There is no indication of surface imperfections under the same magnification, for the virgin fibers of the nonwoven continuous filament product, P-3. This difference in fiber morphology is one of the causes for the differences in degradation patterns for P-3 and P-4 product.
  3. Staple product P-4 exhibits very low resistance to oxidation in circulating air (21% O<sub>2</sub>) at elevated temperatures which results from intensive surface cracks growth over the period of aging. By contrast, the continuous filament product P-3 exhibits no fiber surface crack development during oxidation under the same conditions, and a much lower rate of mechanical deterioration.
  4. Aging in stagnant diluted air (8% O<sub>2</sub>) results in the healing of the initial crazes on the fiber surface of the P-4 product. This may explain the tensile strength increases by a factor of about 1.5-1.6, observed in stagnant diluted air. Product P-3 exhibits the increase of tensile strength by a factor of 1.2-1.3, under the same conditions of aging.
  5. It appears that the effectiveness of antioxidant package can be measured by the developed induction time for products with no cracks or crazes in their as manufactured state.

Intensive surface crack growth in circulating air as well as crack healing in stagnant diluted air, indicate that there may be other or additional mechanisms to ther-

mooxidation, which contribute to mechanical degradation for staple product P-4 under accelerated temperature testing. The crack disappearance phenomena may occur due to an increase of molecular diffusion rate in the polymer leading to crack healing, analogous to the cold welding of metals. When the rate of diffusion and crack healing prevails over the rate of oxidation, a strength gain effect is observed. This adds to the complexity of the degradation process at high temperatures and brings to question the validity of oven aging as the appropriate accelerator for thermooxidative degradation studies especially for products which exhibit initial cracks/crazes in their as manufactured state.

The nonwoven continuous filament product, P-3, exhibits a more classic behavior and the temperature accelerated data lends itself to analysis within a framework of polymer chemistry.

## 5. A NUMERICAL MODEL FOR DEGRADATION RATE AND LIFE EXPECTANCY

The main objective of durability studies for commercial geosynthetic products is to estimate a degradation rate and corresponding life expectancy for in-service conditions.

The results of tensile strength losses for P-3 during oven aging in circulating air (21% O<sub>2</sub>) at elevated temperatures up to 70°C exhibit a substantial period of time with no changes of mechanical strength followed by a nonlinear decay of strength. Experimental data obtained in stagnant diluted air (8% O<sub>2</sub>), show a significant decrease in the rate of mechanical degradation as compared to the rate in circulating air (Figure 1). These patterns of degradation indicate that conventional "Arrhenius modeling" as suggested in the literature (Wisse and Berkenfield, 1982; Koerner, Lord and Hsuan, 1992) may be too simplistic to describe the degradation behavior of geosynthetic products. Therefore, the basic principles of kinetics of chemical reactions in general, and kinetics of thermooxidation in particular, such as the Basic Autoxidation Scheme (BAS) (Bolland, 1948; Kelen, 1982) must be considered in formulating an appropriate numerical model for materials which in their virgin state are completely intact and exhibit no cracks/crazes.

An interpretation procedure using BAS has been recently developed by the authors (Salman, Elias et al., 1997) and is used to interpret the laboratory results for P-3, which exhibits a more classic behavior.

## 5.1 Interpretation Procedure

In chemical kinetics (Adamson, 1973) the rate  $R$  of a reaction  $A+B+C+\dots \rightarrow \text{Products}$  at constant temperature is expressed as a function of composition of the system, according to mass action law as:

$$-\frac{d[P]}{dt} = R = k[A]^x[B]^y[C]^z \quad (1)$$

where  $[A]$ ,  $[B]$ , and  $[C]$  are the concentrations of reactants, and  $k$  is the rate constant being independent of the concentration of the reactants but dependent on temperature.

The order of the rate law is the sum of the exponents ( $x+y+\dots$ ). The important cases are zero, first and second-order reactions. The rate should be determined experimentally (Atkins, 1986).

The rates  $k$  of most reactions increase with temperature according to the Arrhenius law as:

$$k = Ae^{-E_a/RT} \quad (2)$$

with  $A$  - the pre-exponential factor, usually considered as a constant which is independent of temperature;  $E_a$  - the activation energy;  $R$  - the ideal gas constant; and  $T$  - the temperature in  $^{\circ}\text{K}$ .

The kinetics of autoxidation for the general case of antioxidant presence, consist of two phases. The first phase (induction period) describes the consumption of antioxidants, with the reaction constant for consumption defined by an Arrhenius-type dependency. During the second phase, the oxidation and corresponding mechanical degradation is described by the kinetics of the BAS.

The data usually obtained in the laboratory, does not provide sufficient information on the kinetics of antioxidant depletion during aging. Therefore, the order of reaction for antioxidant consumption cannot be determined directly from experimental data. Analysis of integrated rate laws for kinetics of chemical reactions (Adamson, 1973) yield a general expression for induction time versus temperature at any given level of antioxidant depletion  $[A]/[A_0]=c$ . Assuming that the reaction constant for antioxidant consumption obeys the Arrhenius law, the following relationship is indicated:

$$\ln \frac{1}{t_{ind}} = C_1 + C_2 \frac{E_a}{RT} \quad (3)$$

where  $C_1$  and  $C_2$  are the constants for a particular antioxidant and given level of depletion  $c$ .

This relationship (3) suggests a procedure for estimating induction time at a given temperature  $T_0$   $^{\circ}\text{K}$  as follows:

1. The induction period  $t_{ind}$  is determined at each temperature of exposure, defined as the period of no statistically

significant changes in mechanical strength. It is determined by extending a tangent line to the slope of the post induction degradation curve until it intersects the no strength loss line. With limited data it requires some judgment.

2. A linear regression analysis is conducted for the function  $\ln(1/t_{ind})$  versus the reciprocal temperature ( $1/T$   $^{\circ}\text{K}$ ). The obtained linear equation  $\ln(1/t_{ind}) = a(1/T)+b$  is used to find the value of the induction period at any given temperature,  $T_0$   $^{\circ}\text{K}$  as follows:

$$t_{ind} = 1/\{ \exp[a(1/T_0)+b] \} \quad (4)$$

The determination of induction period at elevated temperatures is shown in Figure 4 for P-3 commercial geosynthetic, aged in circulating air at 21 percent oxygen and reduced oxygen at 8 percent.

Figure 4. Induction period for P-3 aged in circulating air at 21% (solid line) and 8% (dashed line)  $\text{O}_2$ .

3. The solution of the equation for linear regression of  $\ln(1/t_{ind})$  versus reciprocal temperature at  $20^{\circ}\text{C}$  (Figure 5), yields a value for P-3 of anticipated induction period  $t_{ind} = 51$  years at 21%  $\text{O}_2$  and 240 years at 8%  $\text{O}_2$ . For P-3a which does not exhibit an induction period at the temperature tested, no prediction at ambient temperature can be made from the data.

Interpretation of data for mechanical degradation observed in the post induction period, requires the determination of the order of reaction for the product tested, with a subsequent estimate of anticipated rate of degradation (strength loss per 100 years) or time to 50 percent strength loss at any given temperature. In this study zero-, first- and second-order reactions are considered. The procedure of determining the order of reaction and degradation rate estimates are as follows:

1. Functions representing the kinetics of zero-, first- and second-order are used to fit the experimental data for the measured mechanical degradation, after the induction period for each temperature of aging.

Figure 5. Linear regression analysis of  $\ln(1/t_{ind})$  versus  $1/T^\circ K$  for P-3.

2. The obtained values of the logarithm of reaction constant  $\ln(k)$  for the chosen type of kinetics, are plotted versus reciprocal temperature of aging (Arrhenius plot).
3. A linear regression analysis is used to find the equation for  $\ln(k)$  as a function of reciprocal temperature  $1/T$ ,  $\ln(k) = a(1/T) + b$ . This equation yields the value of  $k$  for the temperature of interest,  $T_0$ ;  $k(T_0) = \exp[a(1/T_0) + b]$ .
4. The obtained  $k(T_0)$  value of the rate constant is used to calculate a normalized retained strength at a given time  $x(t) = F(t)/F_0$  or to calculate time  $t_i$  to reach certain level of retained strength  $c = F/F_0$  at a given temperature  $T_0$  K for a specific reaction:

$$x(t) = 1 - k(T_0)t; t_i = \frac{1 - c}{k(T_0)} \text{ - for zero-order reactions; } \quad (5)$$

$$x(t) = \exp(-k(T_0)t); t_i = \ln(1/c)/k(T_0) \quad (6)$$

- for first-order reactions; and

$$x(t) = \frac{1}{1 + k_1(T_0)t}; t_i = \frac{1 - c}{k_1(T_0)c} \quad (7)$$

- for second order reactions law.

The results of exponential curve fitting corresponding to a first-order reaction which has the greatest likelihood ( $R^2$ ) for approximating the experimental data, are shown in Figure 6.

A first-order reaction is predicted by the BAS model for kinetics of mechanical degradation of polyolefins without antioxidants at a constant oxygen pressure. Therefore, the priority in the selection of the reaction order, is given to the exponential law (first-order).

Figure 6 summarizes the result of a linear regression analysis for the reaction constant  $k$  corresponding to a first-order reaction for mechanical degradation for P-3 in circulating air at 21 percent oxygen.

Figure 6. Exponential curve fitting corresponding to a first-order reaction, after an induction period, for P-3 at 21%  $O_2$ .

The solution of a linear regression line equation and sequential substitution of the obtained value of the reaction constant  $k$  into a first-order reaction, yields an estimate of 50 percent strength loss at 20°C of 38 years after the induction period of 51 years at 21%  $O_2$  and 240 years at 8%  $O_2$ . The obtained estimates of anticipated strength is valid only for the conditions of testing, e.g. circulating air at 21%  $O_2$  and in stagnant diluted air at 8%  $O_2$ .

It appears, that the estimate for the induction period of 51 to 240 years with no strength loss, suggests that antioxidant consumption rate and ambient regime primarily determine the practical durability of this commercial product.

For the research grade textile P-3a, the interpretation of data in circulating air at 21%  $O_2$ , yields an estimate of anticipated time to 50 percent strength loss at 20°C as of 29 years. This result is in a good agreement with the estimate of degradation rate after the depletion of antioxidants, for the P-3 geotextile. The interpretation of data in stagnant diluted air at 8%  $O_2$  yields an estimate of anticipated time to 50% strength loss at 20°C as of 47 years for the P-3a textile which is a decrease by a factor of 1.6 when compared to the degradation rate in air at 21%  $O_2$  (FHWA, 1997). This result is in general agreement with an estimate of the reduction of the degradation rate in diluted air at 8%  $O_2$  based on the integrated law of chemical kinetics (Equation 1).

Arrhenius equation for reaction rate constant could be rewritten as:  $\ln(k) = C - U/RT$ , where  $U$  is apparent activation energy, and  $R = 8.31$  J/mol. Solving this equation with respect to  $U$ , one obtains value of  $U = 61$  kJ/mol, which is in a reasonable agreement with the value of 65 kJ/mol, reported by Wisse and Birkenfeld (1982) for PP geosynthetic with extracted antioxidants tested at 21%  $O_2$ .

Tests for P-4 in stagnant diluted air indicate that some process other than oxidation, controls the behavior of this

material at elevated temperatures. Therefore, both elevated temperature aging results and the numerical model developed within the framework of BAS, cannot be directly applied to laboratory data obtained for the P-4 product or other products with initial cracks or circumferential cracks developed during aging at elevated temperatures. For these geosynthetics, alternate testing methods at ambient temperature and elevated oxygen pressure (50 to 100 atm) as indicated by the BAS, result in mechanical degradation rates in for shorter time and may be more applicable.

## 6. ALTERNATE TESTING PROTOCOL AT ELEVATED OXYGEN PRESSURE

In a simplified process of polyolefin oxidation, it is assumed that the rate of reaction at constant temperature depends on the concentration of original polymer [A] and the concentration of oxygen [B], in equation (1). Data reported in the literature (Kelen, 1982) indicate that the rate of oxidation may be proportional to the concentration of oxygen in the system, which corresponds to a first order reaction. Therefore, an increase in oxygen pressure should result in the proportional increase of the rate of mechanical degradation for polyolefins. For example, the exposure of polyolefin based geosynthetics to an atmosphere of pure oxygen may result in the acceleration of the degradation rate by a factor of 5 as compared to the rate anticipated in air (21% oxygen) at ambient temperature. The further increase of oxygen pressure to 50 atm should result in an acceleration of the reaction by a factor of 250, as compared to the rate of oxidation under ambient conditions.

### 6.1 Testing conditions and experimental results

An atmosphere of pure oxygen at a pressure of 50 and 100 atm has been selected for an initial feasibility assessment of high oxygen pressure accelerated degradation for polyolefin geosynthetics. It is anticipated that this condition may accelerate the degradation rate by a factor of 250 in 50 atm and by a factor of 500 in 100 atm as compared to the rate under ambient (1 atm, 21% O<sub>2</sub>, 20°C) conditions. Strip size specimens of three geosynthetics previously tested (P-3, P-3a and P-4), were placed in high pressure chamber filled with pure oxygen at 50 and 100 atm at 20°-22°C. The chamber was ventilated and refilled with oxygen once a day.

Tensile strength tests were conducted on strip-size specimens for materials as received and after the incubation. Relative changes of tensile strength are presented in Table 2.

### 6.2 Interpretation of test results

The simplified and preliminary kinetics for oxidation under oxygen pressure yields an acceleration factor of 250 for oxygen pressure of 50 atm and factor of 500 for oxygen pressure of 100 atm. Strength losses from oven aging in circulating air at 21% oxygen and under high pressure oxygen incubation at ambient temperature were calculated within the framework of the Basic Autoxidation Scheme and are shown on Table 3. The comparison is based on strength losses in equivalent periods of time.

Table 2. Tensile strength loss for geosynthetics aged in pure oxygen at 50 and 100 atm and 20°C.

Condition	Equivalent time at ambient condition*, years	Strength loss, %			
		Material			
Oxygen pressure, atm	Incubation time, days		P-3	P-3a	P-4
50	60	40	0	42	10
100	30	40	0	N/A	N/A
100	90	120	16	N/A	N/A

\* 21% O<sub>2</sub>, 20°-22°C

Table 3. Comparison between oven aging and high oxygen pressure strength loss estimates.

Equivalent time at ambient conditions, years	High pressure oxygen strength loss, % (oven aging strength loss estimate, %)		
Material ⇒	P-3	P-3a	P-4
40	0/(0)	42/(63)	10/(100)
80	N/A/(50)	N/A	N/A
120	16/(100)	N/A	N/A

N/A - not available

Results of this limited study indicate that oxygen pressure can be used as an accelerator and that a preliminary acceleration factor can be predicted by the simplified kinetics of oxidation for polyolefins. The estimates of strength loss over 40 years based on data developed under high oxygen pressure conditions are within the range of estimates obtained in oven aging in circulating air for some products or yield more reasonable results as indicated by actual performance. As expected, the P-3 product with an estimated 50 years induction period, exhibits no tensile strength loss over a period equivalent to 40 years. The research grade textile P-3a yields a strength loss of 42% tested under high oxygen pressure condition which is in reasonable agreement with the 63% strength loss over 40 years, obtained for oven aging in circulating air. The difference may be attributed to the

intrinsic variability of mechanical properties for the P-3a product, nonuniformity of the degradation process at different temperatures and in high oxygen pressure etc.

Furthermore and of significant importance is the preliminary finding that the estimated strength loss in 40 years measured for the P-4 nonwoven staple fiber geotextile is more consistent with the anticipated and reported performance for this geosynthetic. Interpretation of P-4 losses from oven aging protocols suggests a 50% strength loss in 6.5 years, which is unreasonable in light of the actual performance of this material over 10 years as measured from retrieved sites. Examination of P-4 samples incubated under high oxygen pressure indicates no changes in surface morphology.

## 7. SUMMARY

Interpretation of experimental data suggests the following:

1. Kinetic models developed within the framework of the Basic Autoxidation Scheme (BAS) appear to provide a satisfactory analysis of the experimental data and permit conservative estimates of time against strength loss at ambient temperature to be made for products which exhibit no cracking/crazes in their as produced state.
2. The rate of antioxidant depletion and the rate of mechanical degradation in stagnant diluted air appears to be lower than in circulating air and may provide better model of in-ground conditions.
3. Products with effective antioxidants may exhibit induction times well in excess of their useful life in civil engineering applications. Oven aging temperatures must be low enough to permit measurements of induction time, which is a method to quantify the effectiveness of the antioxidant package.
4. High oxygen pressure appears to be a viable accelerator for oxidative strength loss measurements and appears to be a viable testing protocol for products where high temperature changes the surface morphology. However more development is necessary to establish more exact relationships.
5. Estimates of strength loss versus time under ambient conditions based on high oxygen pressure degradation are in a satisfactory agreement with estimates obtained from oven aging in circulating air for the monofilament product tested.

**ABSTRACT:** Conventional methods of time-temperature superposition (TTS) are compared to a new procedure for time-temperature superposition called the stepped isothermal method (SIM). Creep and creep rupture properties of two polyester geogrid products are investigated. The conventional TTS approaches studied consumed a total of 18,000 hours of test time. In addition with both polyester products it was found difficult to separate temperature dependence of creep strain response from specimen to specimen variation in elastic strain response to loading events. Using the new SIM method, over 15 load specific master creep modulus curves were generated, some of which extended to over 100 year design lifetimes, each from a single specimen in a test that was completed in less than 18 hours. The results of the conventional and SIM procedures were found to be equivalent for the polyester products examined.

**KEYWORDS:** Time-temperature superposition, shift factors, unconfined creep tests, creep strain, creep modulus, creep rupture, polyester fibers, geogrid, accelerated testing.

## 1 INTRODUCTION

The Stepped Isothermal Method (SIM) for time-temperature superposition (TTS) has been formally introduced at this symposium in a companion paper [Thornton, et. al. (1998)] emphasizing the theoretical aspects of the procedure development and giving examples selected from tests on a polyester (PET) yarn. Thornton, et.al (1997) described SIM for a single temperature step on a wide width PET geogrid sample.

The present paper introduces the application of SIM to two PET fiber based geogrid products designated Product A and Product B from two different geosynthetic material manufacturers in the USA.

Utilization of TTS principles have been applied often to polypropylene and polyethylene products. However, extensive use of TTS for polyester products has been inhibited by three factors. First the creep rates for PET, which are generally linear (or nearly so) in semilog plots, are relatively low, in the range of 0.1 to 0.2% strain per time decade. Secondly, the specimen to specimen variation in the load vs. strain relationship is relatively high, given the small resultant creep strains. A 1% uncertainty in strain level for a given load is not atypical. The third factor is that the temperature dependence of creep curves under the same applied load is comparatively small. Differences in exposure temperatures of 20°C cause less than 1% difference in creep strain at the same exposure time. The above factors conspire to make the TTS process for PET so uncertain that many replicate samples are needed to establish the shift factors and the proper strain level locations for shifted creep curves.

SIM overcomes these difficulties because a master curve is

generated on a single sample which is maintained under load as it is exposed to a series of isothermal dwells separated by increasing temperature steps. Because recovery is prevented by this procedure, the master curve is made up of juxtaposed segments in contrast to the overlapped segments that comprise a conventional master curve. When specimens are taken to rupture, the shifted times to rupture obtained from the SIM procedure can be used to construct creep rupture curves. The experimental efficiencies that result from SIM lead to large cost and time savings.

## 2 OBJECTIVE

The objective of this paper is to introduce the application of the SIM to the characterization of long term creep and creep-rupture of two PET based geogrid products. The results of conventional time-temperature superposition are provided for comparison purposes.

## 3 MATERIALS AND METHODS

Products A and B are from two different manufacturers in the U.S.A. The methods of construction differ significantly, Product A is manufactured by the weft insertion weaving process and Product B is manufactured by a knitting process. Both products are coated to protect the fibers from abrasion. Comparative load vs. strain and secant modulus vs. strain curves for the two materials are given in Figure 1. Both products are made from high tenacity, high molecular weight (>25,000), alkali tolerant (max. 30 carboxyl end group) fibers. The double hump in both load vs. strain curves is

Figure 1. Load and secant modulus vs. strain curves for Products A and B.

characteristic of drawn PET fibers. The initial modulus of Product A is higher than that of Product B due to construction differences. Both products exhibit gradual peaks in secant modulus at strains corresponding to about 75% of the ultimate tensile strength (UTS).

The stepped isothermal creep and creep rupture tests were performed by TRI/Environmental, Inc. of the U.S.A. These tests were all performed in a Model 3111 Instron environmental chamber modified with a Watlow Series 982 temperature controller at a series of temperatures 14°C apart beginning at 26 ± 0.5°C. The 26°C starting temperature was sufficiently above laboratory ambient temperature that adequate temperature control could be achieved by heating only. The tests were performed in an Instron 4505 Load Frame under computer control. Strain was monitored using an extensometer (typically Instron 2620-T24) with a nominal gage length of 2 in. The load cell used was Instron with a rated load capacity of 2248 pounds.

The conventional creep tests on Product A and creep-rupture tests on Product B were performed by ERA Technology, Ltd. of the U.K. Test conditions were 20 ± 2°C/65 ± 2% RH, 40 ± 2°C and 60 ± 2°C for both test programs. Two ribs were utilized in the creep tests and a single rib in the creep rupture tests. The gage lengths were 60mm and 75mm. Roller grips and dead weight loading frames were used in both tests and the strain transducers used were LVDTs.

The Product A and B materials used in SIM tests by TRI and conventional tests by ERA were from different manufacturing lots.

## 4 RESULTS AND DISCUSSION

### 4.1 Creep of Product A

#### 4.1.1 Conventional Time-Temperature Superposition

Figure 2 shows the results of eleven long term creep tests of Product A. The tests were conducted at 21, 31 and 56% of

Figure 2. Creep strain vs. log time for Product A at 21%, 31% and 56% of UTS and 20°C, 30°C and 40°C.

the ultimate tensile load of the material and at 20, 40 and 60 degrees Celsius. Two of the tests at 20°C were of 8000 hour duration (one at 21% UTS and one at 56% UTS) and the balance of the tests were 1000 hour duration. Replicate tests were performed at 56% UTS at 20, 40 and 60°C.

These data illustrate one of the major problems with conventional time-temperature superposition of PET products: specimen-to-specimen variation tends to mask the effect of temperature on test results. In Figure 2 at 21% of UTS, the creep strain curve for 60°C lies on top of the creep strain curve for 40°C. At 56% of UTS, one creep strain curve at 20°C lies over another at 40°C. Also at 56% of UTS, the separation between the two 40°C curves is nearly as great as between the higher 20°C curve and the lower 60°C curve. Clearly, it can be concluded from Figure 2 that the specimen-to-specimen variation exhibited is of the same magnitude as a 20°C change in test temperature.

Figure 3 presents the averages of the two creep strain results at each temperature for 56% of UTS. The average curves display reasonable separation despite variability of the individual curves.

Figure 4 shows the creep data of Figure 3 in terms of creep modulus, which is the quotient of the creep stress by the creep strain. As discussed in the companion paper [Thornton, et.al (1998)] creep modulus, as a more fundamental quantity, is preferred over creep strain when comparing the properties of different materials or even different lots of the same material.

Conventional time-temperature superposition was applied to the creep modulus data of Figure 4 to obtain the master curve of Figure 5. The 40°C and 60°C curves were shifted horizontally to the right (representing an acceleration) until they overlapped the 20°C curve in a reasonable fashion. The horizontal shift of creep strain vs. log time data on a semi log plot is equivalent to multiplying the time for each data point of the curve by the same shift factor. The logarithm of the shift factor is the horizontal distance along the log time scale that the curve is moved. The logarithm of the shift factor used on the 40°C data was about 2.5 and that for the 60°C data was about 5. This means that the 40°C curve was shifted

Figure 3. Creep strain vs. log time for Product A at 56% of UTS and 20°C, 30°C and 40°C. Results to 1000 hr. are the average of 2 specimens; results beyond 1000 hr. (20C) are from one specimen shifted vertically to continue the trend established up to 1000 hr.

Figure 4. Creep modulus vs. log time for Product A at 56% of UTS and 20°C, 30°C and 40°C.

Figure 5. Master creep modulus vs. log time for Product A at 56% UTS for a reference temperature of 20°C.

To the right by two and one-half decades and the 60°C curve was shifted to the right by five decades to achieve the master curve. Since the 20°C curve was fixed in this procedure, 20°C became the reference temperature.

#### 4.1.2 Stepped Isothermal Method (Product A)

Four tests which represent replicate specimens tested at 40% and 56% of UTS were completed on Product A. Since the SIM procedure is described in some detail in the companion paper, only a brief description of the procedure as applied to one of the 40% UTS tests (1801) is given here. The stepped temperature profile for test 1801 is shown in Figure 6, where thermocouple readings representative of the temperatures of the specimen and the grips are displayed. Note that there is a brief exposure to 99°C, which is well above the glass transition temperature (often quoted as 82°C) of PET.

Figure 6. Stepped temperature profile for SIM test 1801 (40% UTS).

The first four isothermal steps are each about 10,800 sec. long, the fifth step about 7000 sec. long and the final step is about 1700 sec. in length. The creep response under the influence of the constant applied load and the temperature profile is presented in Figure 7. The first strain response at 26°C is a normal and complete creep curve, while the subsequent responses at 42°C, 57°C and so on, appear normal, only lacking the initial ramp up portions. Thus, each new temperature exposure sets off a fresh creep response under the constant applied load. Additional interesting features of this graph are the thermal contractions that accompany the increases in temperature. A negative coefficient of expansion is a characteristic of PET fibers. The one shown here is about 35 parts per million per degree Celsius. The load and strain data of this figure were converted to creep modulus and plotted in Figure 8.

Figure 9 contains the creep modulus information of Figure 8 plotted against log time. In addition, the creep modulus responses for the second through the sixth temperature steps

Figure 7. Creep strain response and applied load vs. time for SIM test 1801 (40% UTS).

Figure 10. Creep modulus vs. log time for SIM test 1801 (40% of UTS) showing effect of vertical shifts to eliminate thermal contractions between steps.

Figure 8. Creep modulus and applied load vs. time for SIM test 1801 (40% UTS).

Figure 11. Master creep modulus vs. log time for SIM test 1801 (40% of UTS).

Figure 9. Creep modulus vs. log time for SIM test 1801 (40% UTS) with effect of rescaled start times.

are rescaled to new starting times between 100 and 300 seconds, increasing 2 to 2.5 on the log scale. The next figure, Figure 10 shows the intermediate result of vertical shifts to remove the thermal contractions from the creep data.

Finally, the master creep modulus curve is obtained by horizontal shifts of the segments stacked up in Figure 10 to achieve the result shown in Figure 11 for the reference temperature given by the first step, 26°C. The duration depicted by this master curve is 9.596665 log seconds which converts to over 100 years. Without the 99°C segment of 1700 sec. The shifted time would have been about 32 years.

Master creep modulus curves for the other three tests were created using the method just described.

#### 4.1.3 Comparison of Conventional and SIM Results

Master creep modulus curves for the tests described in the previous two sections are shown in Figure 12. The agreement

Figure 12. Master creep modulus vs. log time curves by conventional and SIM for Product A at 56% and 40% of UTS.

is quite good especially considering the data were generated several years apart on two different lots of material at separate laboratories.

The separation between the two 56% and the two 40% SIM curves are indicative of specimen to specimen variation. Since data from six specimens were combined to give the conventional (56%) curve, the individual effect of specimen-to-specimen variation is somewhat suppressed, but the overall scatter in the data for the conventional curve reflects uncertainty in both specimen-to-specimen variations and selections of the factors used for the time-temperature shifts. A set of creep strain curves, were computed from the master creep modulus curves and are presented in Figure 13.

Figure 13. Strain response to long term loading at 40% and 56% of UTS for Product A.

Figure 14 consists of curves relating the cumulative shift factors used in the time-temperature superposition procedures to create the master curves. The single curve of the factors used to generate the conventional master curve is the one on the left of this figure. A family of four curves to the right define the shift factors for the four SIM master curves. The

SIM shift factor curves are essentially the same, appearing not to depend on load level. The slopes of the conventional and SIM curves differ somewhat as do the origins of the curves. The difference in the origins is arbitrary, depending only on the selection of reference temperature. The difference in slopes is not so arbitrary, but given the sample to sample variation problems inherent in the conventional master curves may not be significant. Note that the shift factor curve that extends to 99°C maintains linearity and constant slope beyond the reach of the other curves.

Figure 14. Shift factors used to construct the Product A master creep modulus curves.

## 4.2 Creep-Rupture of Product B

### 4.2.1 Conventional Time-Temperature Superposition

There are several ways to do conventional TTS for creep rupture data. The first starts with separate linear regression plots of the rupture strengths vs. log times to rupture for each test temperature. The regression lines for each plot are then shifted horizontally along the log time axis to achieve the optimum fit of a combined regression line through all the data. If, in addition to the rupture strength and time-to-rupture data there are creep strain measurements available, as in the present case, then it is possible to obtain additional estimates of the shift factors using the creep modulus curves at the different test temperatures, in a manner similar to that illustrated in Section 4.1.1. The two ways just described should give similar creep rupture regression lines. However, if at the same rupture stress the creep strains at rupture vary with temperature then the factors for shifting rupture regression lines will differ from those for shifting creep modulus curves.

Figure 15 presents the separate linear regression plots of rupture load as % of UTS vs. log time to rupture for tests performed at 20°C, 40°C and 60°C. The regression lines are not parallel, which makes the TTS uncertain. Horizontal shifts to make the regression lines colinear resulted in several visually acceptable curves, using shift factors between 1.91 and 2.3 for the 40°C to 20°C shift and 3.8 and 4.6 for the 60°C to 20°C shift.

Figure 15. Conventional Load vs. time to rupture data with regression Lines for Product B at exposure temperature of 20°C, 40°C and 60°C.

Creep strain data taken during the creep rupture tests are presented in Figure 16, and the creep modulus curves derived therefrom are shown in Figure 17. Notice that the creep modulus data tend to be separated by test temperature, more so than the creep strain data. The natural groupings of the creep modulus data suggest they can be shifted en masse, despite the slightly different load levels applied at the three test temperatures. This is a consequence of the fact that as a quotient, modulus does not change as much as load with strain in the 65 to 80% load range (see Figure 1). More exact estimates of the log shift factors might be obtained by examining smaller groups of individual curves arranged by applied load. However, this would work only to the extent that sample to sample variation effects were controlled by testing numerous replicates. Figure 18 presents the modulus data of Figure 17 shifted by factors of 1.95 (40°C to 20°C) and 3.90 (60°C to 20°C). Using these factors, the data of Figure 15 are shifted to give the master curve of Figure 19.

Figure 16. Creep strain vs. log time curves for the conventional Product B rupture tests.

Figure 17. Creep modulus vs. log time curves for the conventional Product B rupture tests.

Figure 18. Shifted creep modulus curves for the conventional Product B rupture tests.

Figure 19. Conventional master load vs. log time to rupture data and regression line at a 20°C reference temperature.

#### 4.2.2 Stepped Isothermal Method (Product B)

Creep modulus master curves for each specimen were generated using the same procedure described in Section 4.1.2. These are displayed in Figure 20. Note that 5 of the curves terminated in rupture, and the balance did not. We use the term runout to describe the result of a test where rupture did not occur before the test was terminated. Runouts that are close to the loads resulting in rupture can be used in the statistical analysis to help locate the regression line.

Figure 21 presents the creep strain curves derived from the creep modulus master curves.

An expanded set of creep-rupture loads vs. log times to rupture for the SIM tests are shown in Figure 22. The runout loads and log times, included for information, were not included in the regression calculation. The 75 year rupture load at a reference temperature of 26°C is 65.6% of UTS. Less than one decade of extrapolation beyond the temperature shifted results was needed to return this result.

Figure 20. Master creep modulus vs. log time curves for SIM tests on Product B. Load levels and rupture events are noted.

Table 1 provides a guide to the shifted rupture times of Figures 20 - 22. The log shift factors used to construct this table are based on 0.093 decades per °C. Thus a 14°C temperature step creates a time shift of about 1.3 decades.

Table 1. Logarithm of the shifted times at the reference temperature (26°C) corresponding to the unshifted times at the exposure temperatures.

Range Shifted time Log $A_T(t-t')$	Maximum value	
	Exposure Temperature, °C	Unshifted cumulative time, sec
0.0-4.0	26	$1 \times 10^4$
4.0-5.3	40	$1 \times 10^4$
5.3-6.7	54	$1 \times 10^4$
6.7-8.0	68	$1 \times 10^4$
8.0-9.3	82	$1 \times 10^4$

Figure 21. Creep strain curves computed from the data of Figure 20.

Figure 22. SIM master load vs. log time-to-rupture data and regression line for Product B.

#### 4.2.3 Comparisons

Regression lines for the conventional and SIM creep rupture results are compared in Figure 23, and shift factors used to accomplish TTS, in Figure 24. Rupture loads at 75 years for a reference temperature of 20°C are 67.7% for conventional and 66.5% for SIM TTS. Despite an apparent small difference in shift factors for the conventional and SIM approaches, results for the regression lines and the projected rupture loads at 75 years are very close. Figure 25 compares all shift factors for Products A and B.

### 5 CONCLUSIONS

- The use of SIM as a special application of TTS for polyester geogrids appears to be validated by the results presented herein. Differences, if any, in the shift factors obtained in SIM and conventional approaches are not large.

Figure 23. Comparison of conventional and SIM regression lines for Product B.

Figure 24. Comparison of log shift factors for Conventional and SIM rupture master curves.

Figure 25. Comparison of all shift factors for creep and creep rupture for Products A and B.

- An advantage of SIM in this regard is that it reduces the uncertainty of shift factors used to construct master curves.
- Since a SIM master curve is generated from a single specimen, the precise location of the completed curve is uncertain, due to specimen-to-specimen variation. This is not a great disadvantage if several SIM tests are to be done, as in developing a creep rupture curve. Alternatively, if only a single SIM test is done and its location is important, the location can be determined from the results of a few very short term conventional creep experiments.
- The apparent insensitivity of SIM master curves to abrupt transition behavior for tests at 40% of ultimate and higher at and above the glass transition temperature is consistent with a creep mechanism associated with they crystalline regions of the polymer.
- The slopes of SIM generated creep strain curves increase significantly with increase in applied load, but the shift factors are not greatly sensitive to applied load for the range of loads studied here. Thus the increases in slopes are not caused by decreases in shift factors.
- The shift factors for Products A and B (Figure 25) are similar despite differences in construction and load vs. strain behavior confirming the notion that the shift functions are manifestations of basic material properties.
- Obtaining creep strain data in conjunction with performing creep rupture tests is recommended where TTS is to be done. If rupture times at elevated temperatures are shifted based on the basis of achieving superposition of creep strain or modulus curves then the shift factors for creep and those fro rupture will be the same. Rupture times from SIM tests can be obtained no other way.

#### ACKNOWLEDGMENTS

The authors are indebted to Dr. John H. Greenwood for helpful suggestions and experimental efforts at ERA Technology, Ltd., for both products A and B over several years, Shawn L. Arnett of TRI/Environmental, Inc. and J.M. Palmer of ERA are acknowledged for conducting the experimental program. Funding from Texas Research International, Inc., Strata Systems, Inc., and T.C. Mirafi, Inc. is greatly appreciated. T.C. Mirafi, Inc. is also acknowledged for providing seed funding for SIM development.

**ABSTRACT:** The stepped isothermal method (SIM) is a new procedure for assessing the long term viscoelastic behavior of polymeric materials. SIM is a special case of time-temperature superposition (TTS) that is convenient for characterizing viscoelastic materials. It utilizes a single specimen which is loaded continuously through a sequence of timed isothermal exposures at increasing temperature in stair step fashion. Generating master curves involves rescaling the times for the elevated temperature and utilizing horizontal shifts in such a way that smooth curves are achieved. Relationships between the rescaling times and the resulting horizontal shift factors as well as the relative magnitudes of the temperature and time steps are investigated to demonstrate that the SIM can tolerate reasonable variations in these parameters and provide master curves and shift factors comparable to those obtained by conventional time temperature superposition. Conventional and SIM results are obtained on a 3 ply, 1000 denier poly(ethylene terephthalate) yarn. PET is an ideal object for study because its creep properties are well behaved. Also, as the basic ingredient for a number of commercially viable geosynthetic fabrics and grids, the properties of PET yarn are of special interest on their own.

**KEYWORDS:** Stepped isothermal method, time-temperature superposition, shift factors, unconfined creep tests, creep strain, creep modulus, creep rupture, polyester yarn, accelerated testing.

## 1 INTRODUCTION

Polymer scientists have been using time-temperature superposition techniques for at least 4 decades to describe long term viscous or viscoelastic properties of polymers [see, for example, Ferry (1980)]. The fundamental notion is that elevating temperature accelerates the response to mechanical load. Deformations, such as creep strain, occur relatively rapidly when load is first applied, but the rate of increase decreases with time. Consequently, graphs produced with log time as the abscissa are indispensable for describing viscoelastic behavior.

The precise way that increasing temperature accelerates these physical processes, governs how creep response can be "shifted" along a log time scale. Ferry (1980) refers to TTS as the method of reduced variables for corresponding states. A temperature dependent time factor,  $a_T$ , relates the ratio of the time,  $t_T$ , for a viscoelastic process to proceed a given amount at an arbitrary temperature to the time,  $t_R$ , for the same process at a reference temperature.

$$a_T = \frac{(t_T)}{(t_R)}$$

At temperatures greater than the reference temperature  $a_T$  is less than 1. For this reason, some in the accelerated testing business refer to  $a_T$ , as an attenuation factor and  $A_T$ , defined as its reciprocal, as an acceleration factor. Both, collectively, are referred to as shift factors.

Early master creep (or relaxation) curves using TTS were specialized to small strain linear viscoelastic situations. Single specimens were used (to reduce specimen to specimen variation) and these were permitted to recover between creep exposures by removing the load (without removing the specimen from the apparatus to avoid problems of repeatable clamping stress transfers) for a time period that was long compared to the loading time between creep tests (10 times the loading time would generally effect 99+% recovery of the creep strain of the prior creep test).

Most engineering applications that engage time-dependent behavior of polymeric materials deal with non-linear viscoelastic behavior. For such situations, creep master curves are generated using several specimens to reduce the uncertainties of non-identical specimens, and each is only tested one time because recovery is generally too complex to consider doing. Hence, the corresponding states must come from averaging a range of states from the several specimens tested at each exposure temperature. Despite the preoccu-

pation of this paper with large strain nonlinear viscoelastic effects we believe it will be helpful preparation to review the Boltzman Superposition Principle, which is the first mathematical statement of linear viscoelasticity.

From this brief review we will see that tracking the creep response to a series of loading steps includes starting a new clock with each new step. Boltzman (1876) proposed that, a) the creep response of a material is a function of the entire loading history, and b) each loading step is treated as an independent event, and c) the total creep response is the sum of the individual responses to those independent events. In mathematical notation the time dependent strain  $e(t)$  is

$$e(t) = \int_{-\infty}^t D(t-t') \frac{d\sigma(t')}{dt'} dt'$$

The integral is over all time to the present hence the limits are from  $-\infty$  to  $t$ . The first factor  $D(t-t')$  is the compliance function where  $t'$  symbolizes the times at which increments of stress  $d\sigma$  are applied; so that  $t-t'$  starts a new clock that activates the compliance function at the application of each stress increment. The second factor  $d\sigma(t')/dt'$  represents the loading program which is summed by the integration process. The response of a linear viscoelastic material to a two-step loading program is illustrated in Figure 1. As illustrated in this figure, each loading event begins a new clock and evokes an independent creep response. The new creep response is on top of (added to) the background of continuing responses to the history of loading events. The idea of a series of loading events activating new responses and starting new clocks at  $t-t'$  will be utilized for explaining the SIM as we shall see shortly.

Figure 1. Boltzman Superposition Principle applied to the case of two loading steps

## 2 THE SIM PROCEDURE

The stepped isothermal method (SIM) procedure for creep consists of a series of timed isothermal creep tests performed

at a sequence of increasing temperatures. These are somewhat analogous to the loading steps of the previous section. As in an ordinary creep test, the load is held constant and the creep strain is measured for the duration of the test. The number, heights and the durations of the temperature steps are designed to produce a master curve of creep compliance (or preferably its reciprocal, the creep modulus) over a long term period defined by the test objective. For the geosynthetics community, long term generally means 75 years or sometimes 1,000,000 hours, which is 114 years. For our work on PET, we've found that 14°C temperature steps and 10,000 second isothermal step durations are convenient and workable for most tests on PET base products. Five 10,000 second isothermal exposures between 26°C and 82°C will usually achieve the desired long term objective. The time step of 10,000 seconds has been used frequently in the literature [see, for example, Murayama et.al (1968)]. Also, in previous work, Thornton, et.al (1997) showed that as the basis for long term extrapolations creep and relaxation modulus curves at 3 hours were as well developed as curves at 24 hours for that purpose. The typical starting temperature of 26°C comes from desiring a temperature above our maximum summer laboratory ambient temperature of 23°C that could be controlled by heating only. The typical ceiling temperature of 82°C came from the temperature usually assigned as the glass transition temperature for PET. Above 82°C one would ordinarily expect to encounter glass transition behavior with PET. However, as we'll see later, at high loads the creep mechanism engages crystalline regions of the polymer which do not participate in the glass transition. Our study of shorter and longer times and higher and lower temperature steps has confirmed that our standard SIM temperature steps of 14°C and time steps of 10,000 sec, while aggressive, are usually acceptable.

Preparation for the SIM test involves mounting the specimen in the grips, achieving temperature equilibrium, and applying a small (< 1%) preload on the specimen. Ramping the load to the predetermined stress level begins the test. This is done rapidly (typically 60%/minute strain rate) to minimize the creep deformation that occurs during the ramp-up process. We've gotten into the habit of "starting the clock" for the first leg of the creep test at the start rather than the end of the ramp. This preserves the ramp-up process for the record. With generally less than 20 seconds involved in the ramp-up and 75 or 114 years the long term objective, a starting time correction from the start to the peak of the ramp has no measurable impact on the final master curves.

The first creep exposure of the SIM procedure is a normal creep test in the sense that the specimen does not have a history of creep loading. The second and subsequent creep exposures are complicated slightly by having the thermal histories of the previous steps. This slight complication however, represents the essence of the SIM method. Since recovery is not permitted during the time that the temperature step takes place, and since the temperature step is accomplished rapidly, within 1 to 2 minutes, the mechanical

state of the sample is nearly the same after the temperature step as it was before the temperature step took place. Inherent in the SIM is the necessity that the corresponding states at both the lower and the higher temperature are stable ones that would be readily achievable under, say a conventional TTS approach. That condition would not be achieved if, for example, the temperature step was so large that the sample had to undergo a rapid change to achieve a steady state creep rate.

Just as each loading step is treated as an independent event for Boltzman's Principle, we assign a starting time,  $t'$  on the old clock to each temperature step. The time on the new clock starts at 0 which is obtained by setting  $t-t' = 0$ . The response history for the thermal steps is easier to account for than with the loading steps because the load has not changed. The assumption is that with the temperature step only the rate of creep has been changed, not the mechanism. Based on the notion that for a pair of corresponding states obtainable at two temperatures, the one at the higher temperature must have occurred at an earlier time than the one at the lower temperature, we begin the rescaling procedure by finding that earlier time,  $t'$ , that represents the virtual starting time of the higher temperature step. Exactly how we choose  $t'$  is illustrated in Figure 2.

Figure 2. Strain response for two temperature steps

Here, we see the strain response for two temperature steps. In Figure 2 the precise time of the application of temperature step  $n + 1$  is  $t''$ . In the SIM at  $t''$ , the effect of history has been to bring the strain response to  $e^n$ . In a hypothetical independent creep test at the temperature of step  $n + 1$  the creep strain  $e^n$  would have been achieved at a time  $t_i$  after the start time. Overlaid on Figure 2, the starting point of that hypothetical creep curve would be at  $t'$ . Thus,  $t_i = t' - t''$ . We refer to the value of  $(t-t')$  at the beginning of the step (i.e. at  $t = t''$ ) as the initial value of  $t-t'$ . We know that we have the best value for  $t'$  if the slopes of the creep curves in semi logarithmic representations are the same before and after the temperature change.

In the SIM procedure it is necessary to remove the effects of thermal expansion to insure that the strain response is due to loading effects only. This is accomplished by a simple vertical shift for each temperature change.

The final SIM procedural step is the horizontal shifts to achieve juxtaposition of the creep modulus segments. If the rescaling step has achieved the slope matching boundary condition, then there will be little if any effort needed to determine the horizontal shifts needed. In practice, we generally do the rescaling and the horizontal shifting steps together in an iterative fashion to achieve a smooth creep modulus master curve.

The SIM procedure just described for processing creep modulus data is summarized in bullet form in Table 1.

Table 1. SIM procedure for processing creep modulus data

- Plot the creep strain and creep modulus data as function of linear time to identify the times for the temperature step changes.
- Using creep modulus as the parameter of interest, plot this parameter vs. log time.
- Rescale the times for the individual creep modulus segments by plotting them vs. the logarithm of the initial value of  $(t-t')$  where  $t'$  is adjusted to account for history. This will be achieved when the slope of the beginning of a new segment is exactly the same as the ending slope of the previous segment.\*
- Remove thermal expansion effects by vertical shifts.
- Shift horizontally to achieve exact juxtaposition of the rescaled and vertically shifted individual creep modulus segments.\*

\*the rescaling and shifting steps may require some iteration.

### 3 OBJECTIVE

The objective of this paper is to introduce the SIM and a standard protocol for its use. This will be accomplished by first comparing SIM results using the standard protocol to conventional TTS results and next by examining the effects of variations from the standard protocol. Finally, demonstrating the effectiveness of SIM by using it to characterize the long term creep and creep rupture properties of a polyester yarn, completes this introduction.

### 4 MATERIALS AND METHODS

Figure 3 represents stress vs. strain and secant modulus vs. strain curves for a 3 ply polyester yarn chosen for the current investigation on the basis of its well behaved creep properties and commercial importance. The rapid loading secant modulus is included in this illustration because the creep modulus is a secant modulus. When the loading path up a stress-strain curve is interrupted at a particular stress for a creep test, the beginning creep modulus for the creep test will

Figure 3. Stress and secant modulus vs. strain for the 3 ply, 1000d polyester yarn under rapid loading conditions.

be the same as the rapid loading secant modulus at that stress. Most of the tests reported in this paper were conducted in the vicinity of the second modulus peak at stresses between 5 and 7 g/d. Note that the secant modulus varies only within a range of about 3% around 70 g/d, in that stress range. The creep mechanism probably involves some straightening and breaking of tie molecules between crystalline regions in vicinity of the second modulus peak. Even for creep tests at stresses as low as 3 g/d the mechanism is probably similar to that of the higher stresses. At stresses below about 1.5 g/d the creep mechanism is associated more with the initial modulus peak and involves conformational changes involving the breakdown of the entanglement network as well as molecular uncoiling [Van den Heuvel et.al. (1993)]. This figure shows that initial creep modulus for tests at less than 1.5 g/d applied stress will be substantially higher than tests at above 3 g/d applied stress.

The creep tests were all performed in a Model 3111 Instron environmental chamber modified with a Watlow Series 982 temperature controller at a series of temperatures 14°C apart ± 0.5°C. The 26°C starting temperature was sufficiently above laboratory ambient temperature that adequate temperature control could be achieved by heating only. The tests were performed in an Instron 4505 Load Frame under computer control. Strain was computed from cross head travel and a 10 inch gage length. Instron Model 2111 "horn" grips were used along with an Instron load cell with a rated load capacity of 224 pounds. The specimen and the grips were completely enclosed in the environmental chamber.

## 5 RESULTS AND DISCUSSION

### 5.1 Conventional TTS

As a special case of TTS, SIM should provide master curves as good as and potentially better than the conventional procedure. Thus, the ability of SIM results to match exactly those of conventional TTS is not the goal; to show they give

Figure 4. Conventional master creep modulus curve.

comparable results, builds confidence in both procedures.

A total of 15 polyester yarn specimens, consisting of 3 each at the temperatures of 26, 40, 54, 68, and 82°C were tested for creep at an average stress of 62% of UTL over time periods of 10,000 to 60,000 sec. The resulting creep modulus curves were shifted to obtain a good visual representation by a conventional master creep modulus curve. These results are shown in Figure 4. Note the range of the individual modulus values is 3 to 5% of the master curve values. The conventional master curve appears in some of the subsequent figures to provide a comparison with SIM master curves.

### 5.2 Standard SIM Steps

Figures 5 through 9 illustrate the SIM applied to a yarn specimen subjected to a constant stress of 5.21 g/d, which is about 62% of the ultimate tensile strength (UTS) of this material. Figure 5 shows the measured creep strain and the computed creep modulus as a function of linear time. Each time step is approximately 10,000 sec and each temperature

Figure 5. Creep strain and creep modulus vs. linear time for a specimen tested at 62% of UTS.

Figure 6. Enlargement of a portion of Figure 5 showing a thermal contraction after a 13.9°C temperature step.

step approximately 14°C beginning at 25.9°C and ending with 81.5°C as shown along the bottom of the figure. There are tiny cusps at the temperature step change points which are manifestations of a negative thermal expansion coefficient ( $\alpha_T$ ). One of them is shown in enlarged scale in Figure 6. The magnitude of  $\alpha_T$  for this example is about 7ppm/°C. Such negative thermal expansions are easy to identify because they produce length changes opposite to the creep strains. Positive thermal expansions may require separate experiments to quantify. Next, Figure 7 presents the creep modulus data as a function of log time. The effect of the time rescaling step is illustrated in Figure 8. Rescaling has a dramatic effect on the shapes of the curve segments. Part of this is due to the nature of logarithmic scales, but as indicated earlier, the initial slopes of the rescaled curves are influenced by the new starting times. Figure 9 gives the master creep modulus curve resulting from the horizontal shifts. The abscissa is now labeled LOG  $A_T [t-t']$  to indicate the data has been both rescaled and shifted.

Figure 7. Creep modulus data from Figure 5 plotted vs. log time.

Figure 8. Creep modulus data from Figure 7 rescaled for new starting times vs. log  $[t-t']$

### 5.3 Effect of the Choice of $t-t'$ on $A_T$

The purpose of this section is to explore the effect on  $A_T$  of non optimum selections of rescaling times  $t-t'$ , when generating master curves.

Figure 10 displays the influence of three choices for rescaled times  $t-t'$  on the shapes of the resulting creep modulus master curves. The middle curve, labeled 600s, for the initial value of  $t-t'$ , is near optimum, and this is the same curve displayed in Figure 9. The other two do not show slope continuity at the points of juxtaposition. One of these shows concave features for  $t-t'$  considerably larger than optimum, in this case 1500s, the other convex features for  $t-t'$  considerably smaller than optimum, here 300s. The reach of the master curves is governed by the horizontal shift factors, and by inspection we observe that a smaller value for  $t-t'$  requires a larger log  $A_T$  to achieve juxtaposition, and visa versa. A quantitative relationship between the initial value of  $t-t'$  and the average log shift factor per degree of temperature

Figure 9. Creep modulus data from Figure 8 horizontally shifted to achieve the master curve shown.

Figure 10. Effect of choice of rescaling times on the shape of the creep modulus master curve.

step, is given in Figure 11.

Figures 10 and 11 show that while it is possible to generate master curves that achieve juxtaposition with a wide combination of  $t-t'$  and  $A_T$  selections, there will be a much limited selection of combinations (perhaps only one optimum combination) where the slopes of the adjacent curve segments will match at the points where they meet. For clarity, we have exaggerated the effects on  $A_T$  and the resulting master curves by illustrating the effects of large deviations from optimum selections of  $t-t'$ . Near optimum selections of  $t-t'$  are easy to achieve, however, and uncertainties in the reach of resulting master curves are not expected to be above 0.1 log cycle.

#### 5.4 Effect of Time and Temperature Step Magnitudes

When designing a SIM test it is important to pick the times at each temperature increment and the size of the temperature changes imposed to achieve the desired results. One of the important requirements is that the temperature step bridges

Figure 11. Effect of rescaling times on the horizontal shift factors used to construct master curves.

two corresponding states. The only way we know to effect this is to insure that both states be very nearly steady states, by which we mean that the creep rates are not changing (at least not rapidly) with time. Thus, the creep rate,  $de/d\log t$ , before a temperature step would be ideally, exactly the same as after the step. This situation we desire will be more achievable for small temperature steps and large time steps, but that is the direction of higher cost.

The matrix of SIM tests we conducted to explore the effect of time and temperature step magnitudes is given in Table 2. The conditions studied were A through G. The two not studied were cases Y and Z, the conditions for which were considered too extreme to be instructive. The A through G tests were conducted on yarn specimens loaded to 62% of UTS. The number of steps and the maximum temperature

Table 2. Matrix of SIM tests on variable time and temperature steps

Step times, sec	7°C steps	14°C Steps	28°C Steps
1000	A(9)[82]	B(5)[82]	Y
10,000	C(7)[68]	D(5)[82]	E(3)[82]
100,000	Z	F(4)[68]	G(3)[82]

achieved in the SIM tests are given in parentheses and brackets respectively. All tests were started at 26°C. The results of the SIM tests are presented in Figure 12. The SIM results have been normalized to a creep modulus of 62.4 g/d at log time 2 and are presented with a creep modulus curve developed by conventional TTS which was also normalized to 62.4 at log time 2. We note that three of the SIM results compare favorably with the conventional results, these are conditions C, D and F. Conditions A and B result in smooth

Figure 12. Resulting creep modulus master curves from the variable time and temperature steps of the Table 1 Matrix, compared to the conventional master curve of Figure 4. All curves have been normalized to a modulus of 62.4 g/d at log time 2 (sec).

Figure 13. Characteristic curve shapes for an excessive temperature step (condition E of Table 2).

master curves, but the short reach of these curves indicate clearly that the time steps are inadequate for stable creep conditions to have been achieved. Conditions E and G do not result in smooth master curves despite achieving both the slope matching and juxtaposition boundary conditions. Condition E is examined in more detail in Figure 13.

Slopes are matched at the points of juxtaposition in curve E of Figure 13, yet a convex curvature followed by a concave curvature indicates that the creep rate accelerated immediately after the temperature step change. A larger shift factor would bring the steady state regions of the curves into a better alignment with the conventional TTS data as shown in curve E' but at the expense of slope matching at the points of juxtaposition.

SIM tests conducted with inadequate temperature or time steps will result in master curves of shorter reach than those with adequate steps. The exaggerated examples investigated here would be easy to identify and rectify by substituting tests utilizing smaller temperature and/or longer time steps. More

Figure 14. Creep modulus master curves as a function of stress level.

subtle inadequacies might go undetected, but would result in master curves that would err on the conservative side.

Conditions C, D, and F yield satisfactory SIM master curves. Condition D, as the most economical is recommended as a standard protocol for PET.

### 5.5 Effect of Stress Levels

To assess the effect of stress levels on the master creep modulus curves and the associated shift functions, over twenty-five creep tests were performed at stress levels between 6% and 85% of the 26°C UTS. Nine of the specimens were taken to rupture. These nine were among the ones tested at above 67% of UTS. Following the SIM procedure, the raw creep data was converted to master creep modulus curves, and the resulting family of curves is presented in Figure 14. Note that at the very lowest stress (6%) the beginning creep modulus values are higher than those at the higher stresses. Also, note that the modulus curve of 20% falls below the one at 40%. These are natural consequences of the trend in the secant modulus curve in Figure 3. The shift factors for those master curves are graphed against the step temperatures in Figure 15. The results presented in Figure 15 indicate that the shift factors for the low stress master curves are higher than those generated at higher stress levels. This may be understood in terms of the differences in the creep mechanisms operative at the different stress levels. Refined creep strain curves, computed from the master creep modulus curves of Figure 14 are presented in 16.

The several creep ruptures indicated in Figure 16 are associated with creep strain curves that display higher creep rates but otherwise appear as reasonable creep curves. The shift factors used to generate the curves leading to rupture are not distinguishable from those at lower stresses down to 61% of UTS, most of which do not lead to rupture (see Figure 15, Stress > 61%).

Figure 15. Shift factors vs. temperature for the master curves of Figure 14.

Figure 16. Creep strain vs log time curves computed from the master curves of Figure 14

The plot of creep rupture stress vs. log time to rupture is presented in Figure 17. Nine rupture points are indicated along with three run out points. Significantly, one data point goes well beyond the 75 year time line, so that the 75 year intercept is a conservative interpolation rather than an extrapolation. The 75 year intercept of the regression line is at 68% of the 26°C UTS. Table 3 provides a guide to the shifted rupture times of Figure 17.

Table 3. Logarithm of the shifted times at the reference temperature (26°C) vs the unshifted times at the exposure temperatures.

Shifted time Range $\log A_T(t-t')$	Maximum values (approximate)	
	Exposure Temperature, °C	Unshifted cumulative time, sec
0.0-4.0	26	$1 \times 10^4$
4.0-5.3	40	$2 \times 10^4$
5.3-6.7	54	$3 \times 10^4$
6.7-8.0	68	$4 \times 10^4$
8.0-9.3	82	$5 \times 10^4$

## 6 CONCLUSIONS

- Utilization of SIM for TTS reduces the uncertainty of the shift factors used to construct master curves.
- Both the conventional and the stepped isothermal methods of time-temperature superposition can produce master curves that extend well beyond 100 years.
- Utilization of SIM reduces greatly the test time needed for characterizing long term creep properties over conventional TTS or extrapolation methods.
- The time and temperature steps of 10,000 sec and 14°C appear to be acceptable for SIM creep testing of PET yarn under most conditions.
- Inadequate temperature and or time steps result in master

Figure 17. Creep rupture data and regression line for the polyester yarn.

curves with shorter reach than curves generated from tests with adequate steps, but such inadequacies will be conservative.

- The shift factors for creep display a linear direct dependence on temperature and an inverse dependence on stress, the latter may be caused by a difference in creep mechanism between low and high applied stress levels.
- Since creep rupture is merely an event that takes place at the end of a creep strain curve, the shift factors used to generate the creep strain vs. shifted time curves are the factors that determine the shifted time of the rupture event.

# Modeling and Extrapolation of Creep Behavior of Geosynthetics

Te-Yang Soong

Robert M. Koerner

Professor and Director, Geosynthetic Research Institute, Drexel University, Philadelphia, Pennsylvania, USA

**ABSTRACT:** The creep behavior of geosynthetic materials can be described by a rheologic model consisting of a finite number of Kelvin units connected in series, i.e., the so-called Kelvin-chain model. With properly selected spring moduli and dashpot viscosities, the combined effect of all Kelvin units in the model can be used to describe the results of experimental creep data. Once such a model is established, it can then be used to extrapolate the creep behavior of the tested material beyond the laboratory measured time frame. This paper presents a systematic procedure for obtaining the optimum model based on relatively short-term creep data. The long-term predicting capability of the model is then justified by supplemental experimental data.

**KEYWORDS:** Creep, Modeling, Geotextile, Geogrid, Geomembrane, Geosynthetic Clay liner, Geocomposite Edge Drain

## 1 INTRODUCTION

Whenever stresses are imposed on a viscoelastic material like geosynthetics (via tension, compression, shear, torsion, bending, etc.), they must somehow be internally sustained by the material's molecular structure. If the stresses remain constant over a sufficiently long period of time, the molecular structure will attempt to accommodate them via some type of deformation, e.g., the creep phenomenon. Examples of applications where creep is of concern are the following:

- Tensile creep of geotextiles in mechanically stabilized earth structures,
- Tensile creep of geogrids in mechanically stabilized earth structures,
- Compressive creep of geonets and drainage geocomposites in the liner systems of landfills,
- Out-of-plane deformation of geomembranes in landfill and waste pile covers due to differential settlement and up-lifting gases,
- Internal creep shear of geosynthetic clay liners on steep side slopes
- Compressive deformation (creep) of geopipes in various situations.

In actual designs, creep is generally included via reducing the allowable stress by a proper creep reduction factor, Koerner (1998). In an ideal situation, the creep reduction factors are determined experimentally, e.g., conducting 10,000-hour (or longer) creep test at several stress levels.

Unfortunately, creep tests are by their nature time-consuming and thus expensive. Furthermore, accurate creep tests are difficult to perform owing to the difficulty in maintaining the desired environment over a long period of time. In this study, a rheologic model which provides long-term prediction capability is presented. It is hoped that via careful interpretation and extrapolation of short-term creep data, accurate long-term creep behavior can be predicted.

## 2 THE KELVIN-CHAIN MODEL

It has been shown that the creep behavior of a wide range of materials can be described by a Kelvin-chain model which consists of a finite number of Kelvin units in series, Roscoe (1950). In addition, a spring can be added to the original Kelvin-chain model. This provides to the model the capability of simulating the initial instantaneous (elastic) strain which is typically seen in creep measurements. Figure 1 shows the modified Kelvin-chain model used in this study.

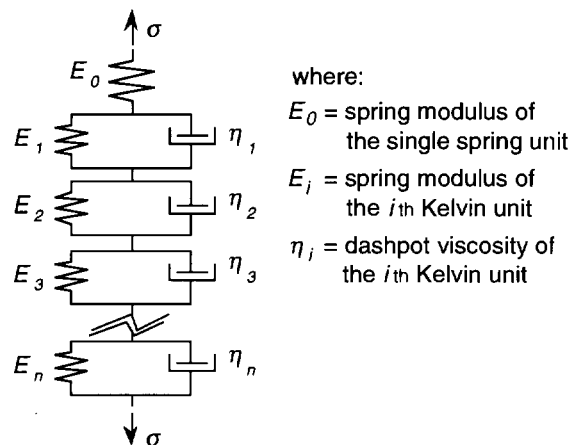

Figure 1. The Kelvin-chain model

A Kelvin unit consists of a spring and a dashpot in parallel. In the Kelvin-chain model, each Kelvin unit is identified by the letter "i" and characterized by a retardation time,  $\tau_i$ , where  $\tau_i = \eta_i / E_i$ . Experiences show that in an ideal Kelvin-chain model, the spring modulus in each Kelvin unit is generally inversely proportional to its corresponding dashpot viscosity. In other words, Kelvin units consisting of high-modulus springs possess dashpots with low viscosities. The relative degrees vary. When such

a model is subjected to an external stress,  $\sigma$ , as seen in Figure 1, an instantaneous deformation is created in the single spring. Note that this deformation stays constant regardless of the time scale as long as the applied stress remains. Subsequently, the Kelvin units with higher spring moduli and lower dashpot viscosities will be deformed. Note that such deformations will also be retarded more rapidly. Succeedingly, the units with lower spring moduli will respond to the external stress owing to the higher resistance from the dashpots. However, continuous deformations will be observed in these units over a longer period of time, until their corresponding retardation times are reached.

Figure 2 illustrates the above concept by plotting a set of creep data along with the calculated curve corresponding to a Kelvin-chain model consists of four Kelvin units and a single spring. It is seen that the calculated curve (a superposition of five individual curves) accurately modeled the experimental data. The individual behavior of each component in the model is also shown in the figure where the concept of "retardation time" is clearly demonstrated.

### 3 THE MODELING PROCEDURE

To utilize a Kelvin-chain model, the creep behavior is viewed as a so-called strain function:

$$\epsilon(t) = \epsilon_0 + \sum_{i=1}^n \frac{1}{E_i} (1 - e^{-t/\tau_i}) \quad (1)$$

where:  $\epsilon_0 = 1/E_0 =$  the elastic strain (i.e., strain induced immediately after the stress is applied) caused by a unit stress (i.e.,  $\sigma = 1$ ). Note that the end of the elastic deformation portion of the experimental data, i.e.,  $\epsilon_0$ , is defined herein as the point of which the second derivative first changes its sign, generally from negative to positive. In Equation 1, the retardation times,  $\tau_i$ 's, are values which can be arbitrarily chosen providing some restrictions are satisfied, Bazant (1988), Bazant and Prasanna (1989). However, any two adjacent Kelvin units having a relationship of  $\Delta(\log\tau_i) = 1$  generally gives sufficiently smooth creep curves; Bazant and Xi (1995). That is to say, if the smallest retardation time is chosen as  $10^{-3}$  hour, the subsequent retardation times will generally be selected as  $10^{-2}$  hr.,  $10^{-1}$  hr.,  $10^0$  hr.,  $10^1$  hr., etc.

Furthermore, an "N"-unit Kelvin-chain model can generally simulate creep data of "N" orders of magnitude on the time scale. Note, however, if extrapolation of the experimental data is desirable, more Kelvin units are necessary. For example, if a extrapolation out to  $10^4$  hours is desirable using a 1000-hour creep data (i.e., one-order extrapolation), one additional Kelvin unit with retardation time of  $10^4$  is necessary.

Figure 2. Creep data simulated by a Kelvin-chain model consisting of four Kelvin units and one single spring.

As to the selection of  $E_i$ 's, it is determined by optimum fitting of the creep data under the constraints of the pre-selected retardation times.

It is clear that a regression analysis (optimum fitting) for determining six or more unknowns (numbers of  $E_i$ 's, in this case) can be extremely time consuming. A procedure which reduces the numbers of the independent variables to only two, regardless the actual number of  $E_i$ 's, is recommended herein.

The following expression is proposed to serve the aforementioned purposes [see Bazant and Xi (1995) for detailed mathematical derivations]:

$$\frac{1}{E_i} = 1.151(a)(3\tau_i)^3 \left[ \frac{-2n^2(3\tau_i)^{2n-3}(n-1-(3\tau_i)^n)}{(1+(3\tau_i)^n)^3} + \frac{n(n-2)(3\tau_i)^{n-3}(n-1-(3\tau_i)^n) - n^2(3\tau_i)^{2n-3}}{(1+(3\tau_i)^n)^2} \right] \quad (2)$$

In Equation 2, “a” and “n” are the new targeted unknowns (instead of  $E_i$ 's) associated with the modeled creep data. Note that the new fitting involves only two variables and is obviously much simpler.

By varying the two independent variables “a” and “n” in Equation 2, different combinations of  $E_i$ 's with respect to the pre-selected retardation times,  $\tau_i$ 's, can be obtained. This allows a comparison of each calculated result of Equation 1 to the actual experimental data. The calculated result is then optimized using the least-squares approximation (weighting by “time” is recommended) and iteration of this process will eventually converge on the actual experimental data. The resulting optimum model can then be used to predict experimental creep behavior beyond the actual measured data.

#### 4 EXAMPLES

Six sets of very different geosynthetic materials creep data were used to verify both the simulating and the long-term predicting capabilities of the proposed Kelvin-chain model. They are the following geosynthetic materials:

- (a) 1500-hr tensile creep of a nonwoven needle-punched PP geotextile at 50% of its wide-width tensile strength at a temperature of 22°C [Allen et al (1982)],
- (b) 10,000-hr tensile creep of a PET geogrid at 70% of its short-term tensile strength at a temperature of 23°C (data courtesy of Strata Systems, Inc.),
- (c) 1000-hr confined tensile creep of a stiff, unitized HDPE geogrid at 60% of its ultimate tensile strength under a normal stress of 28 kPa at approximately 23°C [Wilson-Fahmy et al (1995)],
- (d) 20,000-hr biaxial tensile creep of a HDPE geomembrane under a constant stress ( $\approx 60\%$  of its ultimate strength) at approximately 23°C [Duvall (1993)],
- (e) 1,000-hr internal shear creep of a geosynthetic clay liner (GCL) at 40% of its short-term shear strength at approximately 23°C,
- (f) 1,000-hr compressive creep of a edge-drain geocomposite at 45% of its short-term compressive strength at approximately 23°C (data courtesy of Monsanto Company).

The results are shown in Figures 3 to 8 corresponding to each of the above tests, respectively. Note that the results shown in Figure 4 are plotted on a logarithmic scale to give a different perspective. Seen in each of the figures are (1) initial portion of the data (one order of magnitude shorter in time than the entire data), as solid circles, for establishing the Kelvin-chain model; (2) the optimum Kelvin-chain model calculated creep behavior, as solid curves; (3) one order of magnitude extrapolation using the established model, as dashed curves and (4) the rest of the creep data, as

open circles, for verifying the predicting capability of the model.

## 5 SUMMARY AND CONCLUSIONS

Geosynthetics, being viscoelastic materials, must be evaluated for their creep sensitivity under a variety of constant stress situations. Laboratory tests can be performed for relatively long time periods, yet extrapolation to site specific lifetimes is usually necessary and the technique used is obviously critical. The Kelvin-chain model presented in this paper, and its application to a wide variety of geosynthetic materials, is shown to result in an accurate prediction of the data and is recommended for general use. This model is shown to be viable for at least one order of magnitude based on the results presented herein. Analytically it is possible to extrapolate beyond one order of magnitude, but substantiate data is sparse and further corroboration is required in this regard.

# Slow Strain Rate Modulus Assessment Via Stress Relaxation Experiments

Te-Yang Soong

Research Engineer, Geosynthetic Research Institute, Drexel University, Philadelphia, Pennsylvania, USA

Arthur E. Lord, Jr.

Professor, Department of Physics & Atmospheric Science, Drexel University, Philadelphia, Pennsylvania, USA

**ABSTRACT:** Geosynthetics are usually deformed very slowly in actual applications. Conversely, most mechanical properties (e.g., modulus) are determined in the laboratory under relatively fast strain rates. The use of such experimental values in engineering design is felt to give an inaccurate assessment of actual behavior. This paper presents a procedure to simulate laboratory generated stress relaxation test results by the Maxwell-Weichert rheologic model. Once such a model is established and calibrated, it can be used to determine the more realistic, “design-oriented”, modulus of the tested material. In this paper, the 0.3% secant modulus of a 1.5 mm HDPE geomembrane tested at various strain rates was successfully predicted using the Maxwell-Weichert model. It is felt that the same approach can be applied to other geosynthetic materials for determining realistic moduli values for use in engineering design.

**KEYWORDS:** Modeling, Geomembranes, Modulus, Stress relaxation

## 1 INTRODUCTION

Geosynthetics are usually deformed very slowly (i.e., on the order of weeks, months or years) in actual applications. Conversely, most mechanical properties (e.g., modulus) are experimentally determined in the laboratory under relatively fast strain rates (i.e., on the order of seconds, minutes or hours). Since it is well known that the mechanical properties of viscoelastic materials like geosynthetics are strongly strain-rate dependent, the use of such experimental values in actual engineering design is a concern in that changing in the polymer structure, e.g., stress relaxation, cannot occur as it likely does in the field.

In this paper, a Maxwell-Weichert rheologic model established using laboratory generated stress relaxation test results at fast strain rates, is presented. Once such a model is established and calibrated, it can be used to calculate values of modulus at slow strain rates. It is hoped that via the above procedure, more suitable initial moduli values for the use of engineering design can be determined.

## 2 BACKGROUND

The strong dependence of mechanical properties on how fast the material is deformed (time scale) is a result of the viscoelastic nature of geosynthetics. Two well-known examples of such dependence are the stress relaxation behavior and the strain-rate dependent modulus. Both phenomena are illustrated graphically in Figure 1. Conceptually, two replicate specimens are deformed to a specific strain level,  $\epsilon_0$ , under two different strain rates, i.e.,  $\dot{\epsilon}_1$  and  $\dot{\epsilon}_2$ . This strain level is then held constant for both cases and the stresses are monitored over time. Eventually, after considerable time, the curves come to the same equilibrium residual stress level. It is seen, in the left-hand

Figure 1. Viscoelastic nature of geosynthetics illustrated by the strain-rate dependent secant modulus and the stress relaxation behavior.

portion of the curves, that the modulus (in this case, a secant modulus) of the tested material is proportional to the strain rate. Regarding the right-hand portion of the curves, the trend of decreasing stresses with time demonstrates the concept of stress relaxation.

It is reasonable to assume that the above two phenomena are inter-related since both of them are results of the unique viscoelastic nature of the tested material. It is also reasonable to assume that using the result of one experiment (e.g., a stress relaxation test) one should be able to predict the result of a related test (e.g., the strain-rate dependent modulus). The objective of this study is to develop the above concepts.

## 3 THE MAXWELL-WEICHERT MODEL

Figure 2 shows the Maxwell-Weichert rheologic model used in this study, Aklonis et al (1972). A typical model consists of “N” Maxwell units, which are springs and dashpots in series, placed in a parallel combination with a single spring at the end. The springs represent the elastic properties ( $E$  is the elastic modulus) and the dashpots represent the viscous properties ( $\eta$  is the dashpot viscosity) of the modeled material. In this study, the units become less strong and more viscous as one moves to the right in the parallel combination. Each Maxwell unit is characterized by a spring modulus,  $E_i$ , and a corresponding retardation time,  $\tau_i$ , where  $\tau_i = \eta_i/E_i$ . The final spring, with an elastic modulus of  $E_R$ , represents the totally relaxed or residual modulus value.

Figure 2. A Maxwell-Weichert model subjected to a constant strain.

In a typical stress relaxation test, it takes an initial stress to deform a Maxwell-Weichert model to reach the desired strain because of the resistance of all Maxwell units has to be overcome. In stress relaxation tests, this is the maximum stress. Once the desired strain is reached, the dashpots start to flow and therefore release the stresses in the springs. As a result, the stress required to maintain a constant strain decreases with time. Since the units in a Maxwell-Weichert model consist of dashpots with viscosities over a wide range, i.e., some dashpots can be easily stretched and others are more difficult, they can be used to simulate stress relaxation of geosynthetics at different stages. Ultimately, when the stresses in all Maxwell units are fully dissipated, the residual stress is modeled by the final spring.

When a Maxwell-Weichert model is subjected to a constant strain, as in a stress relaxation test, the following expression can be used to describe the stress/strain relationship in each of the Maxwell units:

$$\frac{d\varepsilon_i}{dt} = \frac{d\varepsilon}{dt} = \frac{1}{E_i} \frac{d\sigma_i}{dt} + \frac{\sigma_i}{\eta_i} = 0 \quad (1)$$

where  $\varepsilon_i$  = strain in unit “i”,  $\varepsilon$  = the constant strain applied and  $\sigma_i$  = stress in unit “i”.

The solution of Equation 1, which represents the stress in unit “i” at any time “t”, is as follows:

$$\sigma_i(t) = \sigma_{i0} e^{-\frac{t}{\tau_i}} \quad (2)$$

where  $\sigma_{i0}$  = the initial stress in unit “i”.

The total stress at any time “t” in the entire Maxwell-Weichert model, is the sum of the stresses in all of the elements, i.e.,

$$\sigma(t) = \sigma_{10} e^{-\frac{t}{\tau_1}} + \sigma_{20} e^{-\frac{t}{\tau_2}} + \dots + \sigma_{N0} e^{-\frac{t}{\tau_N}} + \sigma_R \quad (3)$$

where  $\sigma_R$  = the stress in the final single spring.

Alternatively, the stress relaxation process can be described by a time-dependent relaxation modulus,  $E(t)$ , where

$$E(t) = \frac{\sigma(t)}{\varepsilon} = \sum_{i=1}^N \left( \frac{\sigma_{i0}}{\varepsilon} e^{-\frac{t}{\tau_i}} \right) + \frac{\sigma_R}{\varepsilon} \quad (4)$$

or

$$E(t) = \sum_{i=1}^N (E_i e^{-\frac{t}{\tau_i}}) + E_R \quad (5)$$

Equation 5 can then be used to simulate the stress relaxation test results. Figure 3 illustrates the modeling concept by plotting a set of stress relaxation data along with the calculated curve corresponding to a Maxwell-Weichert model. This example consists of four Maxwell units and a single spring. It is seen that the calculated curve (a superposition of five underlying individual curves) accurately modeled the laboratory data. The individual behavior of each unit in the model is also shown in the figure.

In Equation 5, the retardation times,  $\tau_i$ 's, are values which can be arbitrarily chosen. If we choose adjacent Maxwell units to have a relationship of  $\Delta(\log \tau_i) = 1$ , it generally gives satisfactory simulation. That is to say, if the smallest retardation time is chosen as  $10^{-3}$  hour, the subsequent retardation times will generally be selected as  $10^{-2}$  hr.,  $10^{-1}$  hr., 1 hr.,  $10^1$  hr., etc. As to the selection of  $E_i$ 's, they are determined by optimum fitting of the stress relaxation data under the constraints of the pre-selected retardation times.

#### 4 MAXWELL-WEICHERT MODELING OF HDPE GEOMEMBRANES USED IN THIS STUDY

Large-scale stress relaxation test results on a commercially available 1.5 mm thick HDPE geomembrane were used to illustrate the use of Maxwell-Weichert model. See Soong, et al (1994) for a detailed description of the laboratory test setup and conditions. The tests were conducted at five

Figure 3. Stress relaxation data simulated by a Maxwell-Weichert model consisting of four Maxwell units and one single spring.

different temperatures under a constant tensile strain of 3%. Seven Maxwell units with retardation times varying from  $10^{-4}$  to  $10^2$  hours and one additional spring were used in each of the five models for five different temperatures. The values of  $E_i$ 's in all of the models were determined by applying a least-squares regression procedure, under the restraints of the pre-selected retardation times, until the calculated behavior converged to the laboratory results. The laboratory data along with the calculated relaxation behavior are shown in Figure 4 by plotting the relaxation modulus against time on a log-log scale. There is excellent agreement between the laboratory and the calculated results.

Once a Maxwell-Weichert model is established, it can be used to calculate the modulus of the modeled material at different values of strain rate. The following section presents the detailed procedure.

## 5 CALCULATING THE STRESS UNDER VARIOUS STRAIN RATES

When the modeled material, e.g., a geomembrane, is deformed under a constant strain rate "C", the following expression can be used to describe the stress/strain relationship in each of the Maxwell unit:

$$\frac{d\epsilon_i}{dt} = \frac{d\epsilon}{dt} = \frac{1}{E_i} \frac{d\sigma_i}{dt} + \frac{\sigma_i}{\eta_i} = C \quad (6)$$

Figure 4. Laboratory generated (open circles) and calculated stress relaxation behavior (solid lines) of a 1.5 mm thick HDPE geomembrane at various temperatures.

Equation 6 can be solved as:

$$\sigma_i(t) = C\tau_i E_i (1 - e^{-\frac{t}{\tau_i}}) \quad (7)$$

Consequently, the expression for the entire model can be written as:

$$\sigma(t) = C \left[ \sum_{i=1}^N \tau_i E_i \left( 1 - e^{-\frac{t}{\tau_i}} \right) \right] + C(E_R)t \quad (8)$$

Since the experimental data was developed at 3% strain, we must modify Equation 8 if it is to work for general values of strain (e.g., 0.3% strain).

Popelar, et al (1990) presented an empirical relationship to incorporate the strain dependence in the establishing of viscoelastic models for HDPE pipes. The relationship was interpolated and extended for this study and the following expression, a modification of Equation 8, results:

$$\sigma(t) = C \left[ \sum_{i=1}^N \tau_i \left( \frac{E_i}{a + b(Ct)} \right) \left( 1 - e^{-\frac{t}{\tau_i}} \right) \right] + \left( \frac{E_R}{a + b(Ct)} \right) Ct \quad (9)$$

where  $Ct = \epsilon =$  strain at time "t".

Table 1 lists values of the constants "a" and "b" corresponding to various strain levels used for conducting the stress relaxation tests. Note that when the desired strain level is equal to that used in the stress relaxation test, no modification is necessary.

Table 1. Constants in Eq. 9 as a function of strain level

Strain level used in the stress relaxation test, $\epsilon_p$	Constants <sup>1</sup> in Equation 10	
	a	b
1.0%	0.70	30.5
2.0%	0.53	23.3
3.0%	0.43 <sup>2</sup>	18.9 <sup>2</sup>
5.0%	0.31	13.7
7.5%	0.23	10.2
10.0%	0.19	8.1

1. Values are for modulus in units of MPa.

2. Appropriate constants for this study.

## 6 JUSTIFICATION OF CALCULATED INITIAL MODULUS VALUES

The 0.3% secant modulus of the tested HDPE geomembrane can be determined as follows:

1. A strain rate, i.e., a value of "C", is assumed.
2. The relation " $0.3\% = Ct$ " gives the value of "t".
3. The time "t" is inserted into Equation 9 to obtain the corresponding stress,  $\sigma(t)$ , at 0.3% strain.
4. The relation " $\sigma(t)/0.003$ " gives the 0.3% secant modulus of the modeled material.

The above procedure was applied to five separate Maxwell-Weichert models corresponding to five different temperatures over a range of strain rates from 0.0001% to 100% per minute. The results are shown in Figure 5 by plotting the 0.3% secant modulus against strain rate on a log-log scale. The experimental values of some supplementary tensile tests conducted at 30°C under various strain rates are also shown, in open circles, to exam the validity of the aforementioned prediction procedure. As seen in the figure, the agreement between the experimental data and the calculated values is quite satisfactory.

Figure 5. Strain-rate dependent 0.3% secant moduli of the 1.5 mm HDPE geomembrane used in this study.

Also seen in Figure 5 is that at a given temperature, the values of 0.3% secant modulus of the tested HDPE geomembrane remain practically unchanged when strain rates are slower than 0.01% per minute. Such values are considered more suitable in engineering design than those obtained routinely in the laboratory. Such recommended design moduli of the tested HDPE geomembrane are collected and re-plotted against temperature in Figure 6. It is felt that this type of data, shown here for modulus, is the type of data that should be used in design to simulate field conditions.

Figure 6. Design modulus of the HDPE geomembrane used in this study (corresponding to a very slow strain rate, i.e.,  $\leq 10^{-2}\%$ /min simulating a situation of stress relaxation).

## 8 CONCLUSIONS

This paper presents a recommended procedure to simulate stress relaxation test results by the Maxwell-Weichert rheologic model. Once such models are established and calibrated, they can be used to determine realistic, "design-oriented", moduli of the modeled material and thereby assess the stress relaxation phenomenon. To verify the procedure, the 0.3% secant moduli of a 1.5 mm HDPE geomembrane at various strain rates were successfully predicted.

## 9 ACKNOWLEDGMENT

The funding for the preparation of this paper was provided by the Geosynthetic Institute's consortium of member organizations and the U.S. EPA. Financial support via David A. Carson under contract CR-821448 is sincerely appreciated.

**ABSTRACTS:** Amongst the many composite materials, soft composites containing a thermo-plastic matrix with textile reinforcement are used in civil engineering and building construction in the form of tensile membranes.

To justify permanent use of these structures, it is necessary to know their stiffness and failure behavior, and to predict their long term behavior under combined loading. So we must develop experimental characterization techniques and rheological models taking into account the specific properties of these materials and their long term behavior.

The material studied is a polyvinylchloride reinforced with high tenacity polyester plain weave fabric and is used for tensile or inflatable structures.

**KEYWORDS:** Durability, Soft composite, Biaxial loading, Creep, Rheological behavior

## 1 INTRODUCTION

The aging of reinforced PVC fabrics is caused mainly by superficial cracks of the matrix. The exposed fibers are then attacked by U.V.. The main characteristics affected are the tensile strength and the tear strength. These characteristics can fall by up to 60%. So it is necessary to characterize, to predict and to model this aging to take it into account in the time of building conception.

This paper presents a theorico experimental method for the characterization of long term behavior of soft composites. The study is made on a coated fabric but the method can easily be apply to every kind of soft composites

As it is shown on figure 1 this characterization can be done by accelerated tests at the scale of the constituents (fiber, matrix) or at the scale of the textile architecture. The prediction must be validated by real time tests.

Figure 1 : Study organigram

## 2 MATERIAL STUDIED

The material studied is a high tenacity plain weave polyester (ref. ENKA 174 S) coated with PVC. The weight of the coated fabric is 800 g/m<sup>2</sup> for a thickness of 0.6 mm and a fiber content of 24%. The PVC has no mechanical properties, is only used to protect the polyester from U.V. attack. The material is orthotropic on the scale of the textile architecture and behaves as a membrane.

## 3 VISCOELASTIC MEASUREMENT

### 3.1 Elaboration of rheological model

Simple viscoelastic tests were performed at different frequencies with a DMTA (Dynamic Mechanical Thermal Analysis).. To choose a well suited model, we draw with the experimental results Cole-Cole diagrams (Cole et al. 1941) and we compare those diagrams with model ones. The results are shown on figure 2. The complex modulus  $E^*$  can be written

$$E^* = E' + iE'' \quad (1)$$

Cole-Cole diagrams are made by plotting  $E''$  modulus as a function of  $E'$  modulus.

Figure 2 : Evolution of  $E'$  and tangent  $\delta$  with temperature

Our experimental results can be approached by a Zener bipolarabolic model (Huet et al. 1984). This model can be done either with an assembly in series or/and parallel of springs and dashpots or with an assembly in series or/and parallel of fractional elements. The basic fractional is a model of one mechanism (spring pot) which constitutive law satisfies : (Koller 1984)

$$K.D_t^\alpha . X(t) = F(t) \quad (2)$$

where  $\alpha$  is the order of the fractional derivation ( $0 \leq \alpha \leq 1$ ). After several mathematical operations we obtain the equation of the model. (equation 3 and figure 3)

$$E^*(i\omega) = E_0 + \frac{E_\infty - E_0}{1 + (i\omega\tau)^{-k} + \delta(i\omega\tau)^{-h}} \quad (3)$$

Figure 3 : Limited biparabolic Zener

The values of the parameters  $h, k, E_0$  are determined by enlarging the external parts of Cole-Cole diagrams. In order to determinate the value of  $E_\infty$ , we divide every part of Cole-Cole diagram in two zones. The first one corresponding to high frequencies is approximated to an arc of a circle whose center is under the real axis, the second corresponding to low frequencies is approximated to an arc of a circle whose center is under the real axis and cuts it in  $E_\infty$ .

Figure 4 : Determination of the different parameters

To determinate the value of  $\delta$ , we give arbitrary values of the term  $\omega\tau$  and we adjust the value of  $\delta$  until the experimental and calculated values are matched. (figure 5)

Figure 5 : Experimental/theoretical Cole-Cole

Table 1 gives the values of the parameters of the model for the polyester fibers.

zone 1					zone 2				
E0 GPa	E∞ GPa	h	k	δ	E0 GPa	E∞ GPa	h	k	δ
2.9	11	0.22	0.13	2.5	9.9	25	0.14	0.14	1

From equation (3) of Zener model it is possible to find temporal expressions (relaxation modulus  $E(t)$  and creep modulus  $J(t)$ ). Operational relaxation and creep modulus can be expressed with the help of Carlson Laplace transforms'. (Boufera et al. 1990), (Cost 1964) Equations 4 and 5 give us the temporal expression of the relaxation ( $E(t)$ ) and creep ( $J(t)$ ) functions.

$$E(t) = E_0 + \frac{E_\infty - E_0}{1 + \left(\frac{t}{\tau}\right)^k + \delta\left(\frac{t}{\tau}\right)^h} \quad (4)$$

$$J(t) = \frac{1 + \left(\frac{t}{\tau}\right)^k + \delta\left(\frac{t}{\tau}\right)^h}{E_0\left(1 + \left(\frac{t}{\tau}\right)^k + \delta\left(\frac{t}{\tau}\right)^h\right) + E_\infty - E_0} \quad (5)$$

### 3.2 Time temperature superposition

In the second part of this investigation, we determine the time variation of  $E(t)$  by application time temperature superposition. The tests are made on the DMTA between -150 °C and 200 °C at five frequencies (0.3 to 30 Hz). Superposition of the data curves permits us to obtain a master curve for a reference temperature of 25 °C.

Figure 6 : Test at several frequencies on polyester fiber

Figure 7 : Master curve at 25 °C for polyester fiber

This master curve can be fitted with an exponential function (Kabir 1984).

$$E = E_0 \cdot t^a \quad (6)$$

where  $\log E_0 = 10.09$  Pa and  $a = -0.013$  Pa/s.

In this part we have determined the creep curves of polyester fibers either by applying the time temperature superposition principle or by mechanical spectrometry and definition of a rheological model.

#### 4 THERMOSTIMULATED CREEP ON LARGE DIMENSION SPECIMENS

The Institut Textile de France in collaboration with the Laboratoire Mécanique et Matériaux Université Lyon 1 (with the support of the Région Rhône Alpes) have developed a biaxial testing apparatus to carry out tests on large dimension specimens on soft or stiff composites. (Mailler 1996)

Figure 8 : Biaxial testing apparatus

The mains characteristics of this apparatus are given below.

- maximum load of 15 000 daN,
- sample of  $1 \times 1 \text{ m}^2$  with a maximal deformation of 50%,
- four step by step motors permit to drive the apparatus either in displacement or load with several load or displacement ratio between the two axes,
- a thermal enclosure permits us to realize test between  $-40 \text{ }^\circ\text{C}$  to  $200 \text{ }^\circ\text{C}$ .

We made a series of creep test in the following conditions:

- 1/1 320 daN/30 cm in warp and 320 daN/30 cm in weft,
- 2/1 320 daN/30 cm in warp and 160 daN/30 cm in weft,
- 1/2 160 daN/30 cm in warp and 320 daN/30 cm in weft.

The displacements are measured in the central part of the specimen with an optical method. Using a CCD camera, we follow the displacement of the barycentre of marks drawn on the surface of specimen.

Figure 9 : Biaxial specimen (marks on surface)

The strains are then calculated using a pseudo finite element made with four points. These strains are calculated in the center of these elements and take into account the large deformations of this kind of material.

Figure 10 illustrates biaxial creep curves at  $25 \text{ }^\circ\text{C}$  for a load ratio of 1:1.

Figure 10 : Biaxial creep curve at  $25 \text{ }^\circ\text{C}$  (1/1)

With similar curves at several temperature we construct a master curve taking into account the stresses applied in the central part of the specimen and using an inverse method to calculate the E modulus. The basis of this method is given below.

At a given time we have,

$$\begin{bmatrix} \sigma_1 \\ \sigma_2 \end{bmatrix} = \begin{bmatrix} \varepsilon_1 & \varepsilon_2 & 0 \\ 0 & \varepsilon_1 & \varepsilon_2 \end{bmatrix} \times \begin{bmatrix} C_{11} \\ C_{12} \\ C_{22} \end{bmatrix} \quad (7)$$

where  $\sigma_i$  are the stress,  $C_{ij}$  are the coefficients of the rigidity matrix and  $\varepsilon_i$  the strain.

If we consider two different times on two different tests (for example two load ratios) we have,

$$\begin{bmatrix} \sigma_{11}^1 \\ \sigma_{21}^1 \\ \sigma_{11}^2 \\ \sigma_{21}^2 \end{bmatrix} = \begin{bmatrix} \varepsilon_1^1 & \varepsilon_2^1 & 0 \\ 0 & \varepsilon_1^1 & \varepsilon_2^1 \\ \varepsilon_1^2 & \varepsilon_2^2 & 0 \\ 0 & \varepsilon_1^2 & \varepsilon_2^2 \end{bmatrix} \times \begin{bmatrix} C_{11} \\ C_{12} \\ C_{22} \end{bmatrix} \quad (8)$$

Figure 11 : Biaxial master curve at 25° C

These curves can be fitted by a logarithmic function:

$$E(t) = E_0 + a \log t \quad (9)$$

where a warp = -170 MPa/s , a weft = -165 MPa/s ,  $E_0$  warp = 2400 MPa,  $E_0$  weft = 2060 MPa

In an attempt to validate this predicted creep curves, we carried out real time tests on specimens exposed during 380 days in situ at Lyon. We measured the displacement under a constant load and we defined the creep curves (Figure 12). The knee indicates an augmentation of deformation du to higher temperatures in summer time.

Figure 12 : Creep curves obtained by real time tests

## 5 CONCLUSION

All those results can be compared with real time tests (Figure 12). The three different approaches (at the scale of the constituents, at the scale of the textile architecture and the real time tests) give us similar results.

In a general point of view this results are similar to the literature (Toyada et al 1990,1992,1994) and give a residual tension stress of 50% in 3 years with a little evolution in 7 years. This is in accordance with our results which show us an asymptotic stabilization of creep.

This work permits the designers to take the durability into account during the design process.

# A Model for the Ultimate Pull-out Resistance of Geogrids

R.H. CHEN

Professor, Institute of Civil Engineering, National Taiwan University, R.O.C.

Y.S. LEE

Ph.D. Candidate, Institute of Civil Engineering, National Taiwan University, R.O.C.

**ABSTRACT:** A three-parameter model is proposed to predict the ultimate pull-out resistance of geogrids. Twenty-seven pull-out tests were performed using three types of geogrids embedded in Ottawa Sand and kaolinite clay. The proposed model can take into account the nonlinear relation of the ultimate resistance with the normal stress. Using this model and analyzing the test results, the above mentioned phenomenon can be described and the ultimate resistance can be predicted very well.

**KEYWORDS:** Pull-out test, Ultimate pull-out resistance, Geogrid.

## 1 INTRODUCTION

In the design of reinforcements, laboratory pull-out tests are performed to understand the pull-out resistance of reinforcements in soils. The parameters needed in the limit equilibrium methods, such as apparent cohesion  $c$  and frictional angle  $\phi$  are obtained. It is a common practice to employ the Mohr-Coulomb criterion for the design. However, this criterion does not usually predict the ultimate pull-out resistance very well. Hence, a three-parameter model for predicting the ultimate pull-out resistance is presented in this study to take into account the deformation modulus of geogrids and applied normal stress. This model was verified by twenty-seven pull-out tests. According to the results verified, this model can describe the relation between the ultimate pull-out resistance and the applied stress, and predicts the ultimate pull-out resistance of other geogrids.

## 2 THE PROPOSED MODEL

In design practice, the assumptions on the pull-out resistance of geogrids in soils are: (a) the shear stress at the interface between geogrid and soil is constant, (b) the shear stress at the interface follows the Mohr-Coulomb criterion. Hence the pull-out resistance is presented as:

$$\tau = c + \sigma \tan \phi \quad (1)$$

$$P = 2 A \tau \quad (2)$$

where:

$\tau$ : the shear stress at the interface

$c$ : apparent cohesion intercept

$\sigma$ : applied normal stress

$\phi$ : frictional angle

$P$ : ultimate pull-out resistance

$A$ : embedded area of geogrids

On the other hand, the proposed three-parameter model is

as follows:

$$\tau = \sigma \left[ a_1 + a_2 \exp\left(-a_3 \frac{\sigma}{E}\right) \right] \quad \text{for sandy soils} \quad (3)$$

$$\tau = a_1 + \sigma a_2 \exp\left(-a_3 \frac{\sigma}{E}\right) \quad \text{for cohesive soil} \quad (4)$$

$$E = \frac{T}{\epsilon} \quad (5)$$

where:

$a_1, a_2, a_3$ : parameters to be determined.

$E$ : deformation modulus of geogrid, which can be determined by Eq.(5).

$T$ : the tensile force of geogrid in the tensile strength test.

$\epsilon$ : the strain of geogrid in the tensile strength test.

In this model, the  $a_1$ ,  $a_2$  and  $a_3$  parameters are obtained by pull-out tests. Eq.(3) is suitable to sandy soils, and Eq.(4) is suitable to cohesive soils. This proposed model compared with the Mohr-Coulomb criterion has the following characteristics:

1. The model uses the applied normal stress  $\sigma$  and the geogrid deformation modulus  $E$  to describe the ultimate pull-out resistance.
2. If the modulus of geogrid is infinite, the pattern of the simplified proposed model is similar to the ordinary shear strength model such as Mohr-Coulomb criterion.
3. The expansion of the exponential function in Eq.(3) or Eq.(4) has infinite terms. For this reason, the proposed model is convenient to describe test results smoothly, compared to the Mohr-Coulomb criterion that has only two parameters.

Table 1. Fundamental properties of geogrids.

Item (kN/m)	Grid A	Grid B	Grid C
Ultimate tensile strength	110	80	55
Deformation modulus at 5% strain	1320	960	660
Deformation modulus at 10% strain	880	640	440

Figure 1. Normal stress versus ultimate pull-out resistance for grid A embedded in Ottawa Sand ( $D_r=85\%$ ).

### 3 TEST EQUIPMENT AND TEST MATERIAL

The dimension of the pull-out box is 60cm  $\times$  35cm  $\times$  20cm (length  $\times$  width  $\times$  height). The range of pulling rate is from 0.0006 to 107 mm/min. The capacity of pulling force is 12.5 tons applied by electric motor. The vertical load system consists of a rubber air bag and a jack. Load cells and LVDT are used to measure the pulling force and the displacement. A data acquisition device, an AD card, and a personal computer are used for test controlling and recording. Test materials include geogrid, sand, and clay. The material properties of three types of Tensar geogrid used in the tests are summarized in Table 1. The sand is Ottawa sand (No. C109) that has specific gravity 2.65, maximum void ratio 0.732, and minimum void ratio 0.387. The strength parameters are  $c = 0.7 \text{ kN/m}^2$ ,  $\phi = 36^\circ$ , for relative density  $D_r = 85\%$ ; and  $c = 5 \text{ kN/m}^2$ ,  $\phi = 32^\circ$ , for  $D_r = 50\%$ . The clay is kaolinite that has specific gravity 2.62, maximum dry density 12.8  $\text{kN/m}^3$ , the optimum water content 31.5%. The strength parameters from the consolidated undrained test are  $c = 18 \text{ kN/m}^2$ ,  $\phi = 15.6^\circ$ , for dry unit weight  $\gamma_d = 12.4 \text{ kN/m}^3$  and water content  $\omega = 29\%$ .

The dimension of geogrid specimen is 45 cm  $\times$  10 cm (length  $\times$  width), there are three apertures in the longitudinal direction and five apertures in the transverse direction. The distance between the first transverse rib and the front wall of

300	43.0		

the pull-out box is 12 cm. The pulling rate is 1 mm/min.

### 4 TEST RESULTS AND ANALYSIS

The ultimate pull-out resistance of test results is summarized in Table 2. According to the test results, the ultimate resistance increases with the normal stress but the relation is not proportional. The example using the Mohr-Coulomb criterion together with the pull-out test result is shown in Figure 1. From the figure, the Mohr-Coulomb criterion does not appear to be very accurate in regression result, but also the cohesion intercept is greater than zero in sands. Considering the aforementioned phenomenon, a three-parameter model is therefore proposed. The procedure used to analyze the test result is described in the following:

#### 1. Determine the deformation modulus.

Geogrid is a flexible material, and its modulus varies with strain. Hence a predictive model must take this behavior into consideration. For simplicity, the proposed model adopts the deformation modulus as the secant modulus at 5% strain when the strain is less than 5%, and the secant modulus at 10% strain for strain more than 5%.

#### 2. Determine $a_1, a_2$ and $a_3$ parameters.

The three parameters are to be determined by using Eq.(3) for sands, and using Eq.(4) for clays.

#### 3. Compute the ultimate pull-out resistance.

(a) Grid A

(a) Grid A

(b) Grid B

(b) Grid B

Figure 2. The comparison of the proposed model and Mohr-Coulomb criterion for pull-out tests in Ottawa Sand ( $D_r=85\%$ ).

Figure 3. The comparison of the proposed model and Mohr-Coulomb criterion for pull-out tests in clay.

The ultimate pull-out resistance is computed considering various modulus and normal stress using Eq.(3) for sands and Eq.(4) for clays.

The parameters for computation are summarized in Table 3. The comparison of the proposed model and the Mohr-Coulomb criterion for the ultimate pull-out resistance of geogrids in sands are shown in Figure 2.

It is obvious that the proposed model is better than the Mohr-Coulomb criterion. For instance, the proposed model describes the relation of the ultimate pull-out resistance and the normal stress very well and the apparent cohesion intercept is zero. The model also describes non-proportional relation of the ultimate pull-out resistance with the normal stress. In the other case for kaolinite clay, the comparison is

shown in Figure 3. Analyzing and comparing the result, the result from this model is similar to that of the Mohr-Coulomb criterion. Besides, this model predicts the ultimate pull-out resistance well.

From the above mentioned results, the proposed model is a good application to predict the ultimate resistance for alternating normal stress.

Furthermore, the proposed model seems also be able to predict the ultimate pull-out resistance of other geogrids. For instance, it predicts the ultimate resistance of geogrid B by using the parameters of geogrid A or C. The results of this prediction are shown in Figure 4. It is found that the predictions are within 10%~20% error. In engineering practice, it seems acceptable.

(b) Grid B/Ottawa Sand (Dr=85%)

Figure 4. The result of the proposed model predicting the ultimate pull-out resistance.

## 5 CONCLUSIONS

Summarizing from the mentioned explanation and discussion, the advantages of the proposed model are as follows:

1. The dimensionless term  $\sigma/E$  is used to describe the ultimate pull-out resistance, and its application on studying test result shows good.
2. Although there are three parameters in this model, more than two parameters in the Mohr-Coulomb criterion, the convenience and power of this model is justified.
3. As the modulus  $E$  approaches infinity, the model can be simplified to become a special case of the Mohr-Coulomb criterion.
4. The model predicts the ultimate pull-out resistance of

geogrids more well than the Mohr-Coulomb criterion. It also can be used to predict the ultimate pull-out resistance of other geogrids within acceptable error.

5. Using this model, the non-proportional relation of the ultimate resistance with the normal stress can be described.

**ABSTRACT:** The pull-out resistance of geotextiles is generally the result of complex phenomena occurring at the soil-geotextile interface. In this study, an attempt is made to analyze the pull-out resistance by considering that soil shearing and soil-geotextile friction at the interface are liable to develop the resistance. The usefulness of this approach is pointed out in terms of the prediction of pull-out resistances of soil-geotextile system. For illustration, the pull-out resistances of two woven geotextiles with Toyoura sand are predicted, and compared with those of experimental values. The surface asperity of geotextile is identified as an important factor influencing shearing and friction components at the interface.

**KEYWORDS:** Friction, Geotextiles, Pull-out Resistance, Shear Strength, Woven Fabrics

## 1 INTRODUCTION

The operational circumstances of many soil structures reinforced with geotextiles reveal that the geotextile is at least partly subjected to a pull-out force. This is leading to the pull-out method which is used for the evaluation of soil-geotextile interfacial interaction. The results of a pull-out test are, however, difficult to interpret because of complex interactions at the interface. Nevertheless, a few attempts at a numerical approach have been made to analyze the behavior involved in the pull-out operation of a geogrid (Wilson-Fahmy and Koerner 1993; Yogarajah and Yeo 1994), but hardly any attempts have ever been made for a geotextile. This is probably because of the structural complexities that a geotextile presents compared with a geogrid. In this study, a semi-empirical approach is adopted to analyze the pull-out resistance developed by the woven geotextiles with sand. The structural parameters of the geotextiles and their interactions with the sand are well accounted for in this approach.

## 2 ANALYTICAL PROPOSITION

The pull-out resistance is assumed to be developed due to interactions comprising soil shearing and soil-geotextile friction. Therefore, pull-out resistance (P) could be written as

$$P = S + F \quad (1)$$

where, S = shearing force, F = frictional force. Let the total area at the interface be A, out of which the areas responsible for soil shearing and soil-geotextile friction are A1 and A2, respectively. Thus, Equation (1) becomes

$$P = \tau \cdot A1 + f \cdot A2 \quad (2)$$

where,  $\tau$  = soil shear stress, f = soil-geotextile frictional force per unit area. The relationship for the determination of frictional force is

$$f = \mu_f \cdot N \quad (3)$$

where,  $\mu_f$  = coefficient of friction between soil and raw material of geotextile (hereafter the raw material frictional behavior is termed as 'skin-friction'), N = normal stress.

To predict pull-out resistance, therefore, we need the values of  $\tau$ ,  $\mu_f$  and shearing/friction area at the interface.

## 3 MODEL ILLUSTRATION

For illustration, two plain woven geotextile samples were considered, and their interactions with Toyoura sand were taken into account. A few details of the geotextile samples and sand are given in Table 1 and Figure 1, respectively.

A prototype apparatus (Kabeya et al. 1993) was used for conducting the pull-out experiments. Four levels of normal pressure, e.g., 2.5, 5.0, 7.5, and 10.0 kPa, were maintained on the soil-geotextile-soil system during experiments (low pressures were to avoid fabric deformation inside soil).

Table 1 Specifications of woven geotextile samples.\*

Descriptions	Sample (S1)	Sample (S2)
Polymer type	Polypropylene	Polyester
Yarn type	Flat tape	Multi-filament
Yarn count (Tex)	130 × 120	530 × 530
Yarn crimp (%)	4.3 × 1.6	5.5 × 3.7
No. of yarns (/cm)	6.3 × 6.3	5.6 × 5.6
Thickness (mm)	0.60	1.00
Area density (g/m <sup>2</sup> )	170	600

\*Samples were obtained from Taisei Corporation, Japan

Figure 1 Grain size distribution of Toyoura sand.

Figure 2 Skin-frictional coefficient with Toyoura sand.

### 3.1 Frictional Experiments

The polymer types of the two selected geotextiles were polypropylene (sample S1) and polyester (sample S2). Consequently, the pull-out tests on polypropylene (PP) and polyester (PET) films with sand were carried out for determining the sand-geotextile skin-friction coefficients. By this method, however, the frictional representation may not be truly possible, as finishes in the geotextile and the film are necessarily different. Thus, to find out the actual frictional coefficients, the following approach was used.

The individual yarn was unraveled from the geotextile sample and heat-set under decrimped-taut condition. The decrimped yarn was then used in the pull-out experiments with Toyoura sand. In pull-out experiments, therefore, the occurrence of soil shearing at the interface which may be initiated by the crimps was very unlikely, as the yarn was decrimped and merely tape or filament (with marginal twists) in kind. Consequently, the yarn-sand pull-out resistance development was thought to be solely due to friction. The sand-film (geotextile) skin-friction coefficient is obtained by using the following empirical relationship

$$\mu_f = F' / (A' \cdot N) \quad (4)$$

where,  $\mu_f$  = coefficient of skin-friction,  $F'$  = frictional force,  $A'$  = interfacing area,  $N$  = normal stress.

The results are shown in Figure 2 where it may be seen that the set of values obtained by the above approach are higher than those obtained with the respective films. These differences in values could be attributed to their different surface textures. However, the coefficients of skin-friction obtained here could reasonably be taken as actual values.

### 3.2 Shearing Experiments

For characterizing the shear behavior of sand, generally, we conduct direct shear box tests in laboratory. However, possibly a different state occurs due to different shearing

situations at the soil-geotextile interface in the pull-out method, and at the interface of the two boxes in the direct shear box method. At the soil-geotextile interface, the soil shear behavior is believed to be influenced by the presence of the surface concavities of the geotextile. The concavity wall may put up passive bearing resistance to the soil shear stress. As concavities are numerous, so the contribution of passive bearing resistance to soil shear stress is also significant. In the direct shear box test, such resistance comes only from the back wall of the shear box for total interface area, and consequently, the shear stress occurring with this method is lower in value. Thus, it is important to conduct shear tests under simulated pull-out interfacing conditions, so that the passive bearing resistance of soil brought by cross elements could be taken into account.

For this, channel-like parallel serrations were engraved on acrylic plates (Table 2). Each plate was then used as the reinforcing element in the pull-out experiments. The conditions maintained in the experiments were similar to those during soil-geotextile pull-out testing. The engraved area on the plate (channel) is believed to be responsible for soil shearing, and the flat area to be responsible for friction in the pull-out operation. With defined areas for shearing and friction on the plate, it was possible to distinguish the soil shearing and soil-acrylic plate friction components, provided the sand-acrylic plate frictional coefficient was known. For the sand-acrylic plate frictional coefficient, the pull-out tests on smooth acrylic plates with Toyoura sand were conducted.

Figure 3 was drawn to show the trend of soil shear stress against serration width in the acrylic plate for different levels of normal pressure. The shear stress corresponding to the pitch of respective geotextile samples could now be obtained from this figure by extrapolating the respective trends. It is noteworthy to mention at this stage that as the shear area in the acrylic plate decreases, the variability in pull-out resistance (i.e., soil shear stress) increases. This is one of the reasons why we did not use acrylic plates with serration widths of less than 5 mm in this study.

Table 2 Specifications of serrated acrylic plates.

Designation of plates	P20	P15	P10	P5
Number of serration	2	3	4	5
Serration length (mm)	48	48	48	48
Serration width (mm)	20	15	10	5
Serration depth (mm)	5	5	5	5
Shearing area (cm <sup>2</sup> )	23.2	26.1	23.2	14.5
Ridge width (mm)	10	10	10	10
Friction area in 10 cm embedded length (cm <sup>2</sup> )	92.8	89.9	92.8	101.5

### 3.3 Interfacial Shearing and/or Friction Area

Evaluating the shearing/friction area at the soil-geotextile interface is a two stage process, namely, the measurement of the surface roughness of geotextile samples, and the correlation between surface roughness and soil properties involved in the interface interaction process. The brief description for each of the stages is given below.

#### 3.3.1 Evaluation of surface roughness

An empirical approach was followed for measuring the surface roughness of geotextile samples because the two other commonly used methods e.g., mechanical scanning and laser scanning methods, were tried, but they failed to give definite outcomes, due to procedural limitations. In this method, replicas of the two geotextile samples were reinforced with a contrasting color matrix to form a solid block. The block was then milled gradually (in cross-plane direction) at regular intervals. For milling, a precision end-milling machine was used in our laboratory. The milling was done for a cut-out thickness of 0.1 mm in each step. Therefore, it may be said that the technique used here characterizes the surface as a combination of undulating lines, as may be obtained in other scanning methods. The photograph of each milled surface (i.e., at steps of 0.1 mm milled thickness) was taken with a camera fixed to the milling machine. As a next process, each photographic negatives was enlarged by a projector and imaged over the sensitive screen of a digitizer. The digitizer was interfaced with a computer, by which undulating lines were digitized into corresponding numerical values of  $X_i$ , as the distance along the fabric plane, and  $Y_i$ , as the distance of surface contours from the top fabric plane (see inset of Figure 4).

Figure 3 Effect of serration width on shear stress.

Consequently, two dimensional arrays ( $X_i$ ,  $Y_i$ ) for each undulating line were obtained. The reassembling of these undulating lines by a computer program gives a view of the surface of the geotextile sample, as shown in Figure 4.

#### 3.3.2 Correlation of surface roughness with soil properties

The two parameters, namely, the depth, and the slope of surface concavities were used for expressing the surface roughnesses of geotextile samples. These two parameters were then weighed, as stated below, against the two soil parameters, viz., the average soil particle diameter ( $D_{50}$ ), and the soil shear angle ( $\phi$ ) of Toyoura sand, respectively, for determining interfacial shearing/friction area.

The measurements of concavity depths at different points at distances 0.1 mm apart yield a frequency distribution for each of the geotextile samples. It is assumed that when the absolute concavity depth at any point (element) is more than the size of soil particle employed, then that element will be responsible for soil shearing at the interface. On the other hand, if the concavity depth is less than the size of the soil particle, the element will be responsible for friction at the interface. Thus, corresponding to the value of concavity depth equals to average soil particle diameter ( $D_{50}$ ) of Toyoura sand, the percentage of elements causing shearing and friction at the interface may be found out. By knowing the total embedded area maintained during experiments (both faces of the geotextile), we were able to calculate the interfacial shearing and friction area.

Similarly, the concavity slopes calculated between any two consecutive measuring points (0.1 mm apart) give a frequency distribution for each geotextile sample. It is our assumption that when the calculated slope is less than the angle of soil shearing ( $\phi$ ), that slope will be responsible for soil-geotextile friction, and when the slope is more than the angle of soil shearing, that slope will be responsible for soil shearing at the interface. Using the same line of action stated above, therefore, we were able to draw a partition in the population of concavity slope distribution.

Figure 4 Surface view of geotextile samples.

However, it is a common perception that the interfacial interactions between soil and geotextile are quite complex phenomena, and the ways we tried to correlate concavity depth and concavity slope with soil properties individually may not be totally justified. This is because, even if there is sufficient concavity depth (greater than particle diameter), interfacial soil shearing may not occur when the slope at that point is less than the shear angle of the soil. Similarly, it may be argued that, even if the concavity slope is higher than the soil shear angle, the interfacial shearing may not occur when the concavity depth is less than the particle diameter. For this reason, therefore, an attempt was also made to introduce the interaction between concavity depth and concavity slope, for finding the correct shearing and/or friction area at the interface.

### 3.4 Calculated Pull-out Resistance

Using the three sets of shearing/friction areas, obtained from the concavity depth distribution, the concavity slope distribution, and the interaction of the two, the pull-out resistances were calculated. It were observed that the pull-out resistances calculated using the areas corresponding to depth distribution and slope distribution were in poor agreement with those obtained experimentally, although the general trends were found the same. In contrast, the pull-out resistances calculated using the interaction induced shearing/friction areas were in good agreement with the experimental pull-out resistances (Figure 5). As stated before, the reason for this may be the interactive effects due to both the depth and the slope of surface concavities of geotextiles, rather than individual actions.

## 4 SUMMARY

With the multiplicity of structural parameters of geotextiles and complexities in the design procedure for geotechnical applications, we very often encounter the

Figure 5 Experimental/calculated pull-out resistance.

need to know the pull-out force that a geotextile will exert with the soil type. Using the proposition described before, we may have the option of dealing with the problem of determining pull-out resistance. By knowing the soil-geotextile skin-friction behaviors, the soil shearing properties, and the interfacial shearing or friction areas for the soil-geotextile system, we could proceed to calculate the constituents shearing and friction at first, and then the pull-out resistance.

The illustration reported in this study indicates that depending on the surface asperities of the geotextile, and their interactions with the soil, the contributions of shearing and friction in the pull-out resistance will vary. It is identified that the effect of the surface asperity of the geotextile is merely to influence the shearing and friction area at the interface. Comparisons of experimental and calculated values of the pull-out resistance show that the correlation between surface asperities and soil properties for evaluating the interfacial shearing and/or friction area is an interactive process of factors such as depth and slope of surface concavity of geotextiles.

**ABSTRACT:** A nonlinear elastic finite element model was developed using GAP elements to investigate the failure criteria and the separation behavior at the soil-geotextile interface during pullout tests. Pullout resistance calculated from this model was compared to that obtained from laboratory pullout tests reported earlier in the literature. The data showed the pullout resistance obtained from the finite element model was approximately equal to that obtained from the laboratory pullout tests. Results from the model also indicated the existence of material nonlinearity close to pullout load application point.

**KEY WORDS:** Finite element, Numerical modeling, Interface-element, Geotextile, Pullout

## 1. INTRODUCTION

When a geotextile is used as reinforcement material in a slope, one of the predominant causes of failure is the slippage or pullout of geotextile from the soil mass. Such a behavior can be modeled by the pullout tests in a laboratory. A simple experimental set-up was designed and pullout tests were carried out in the laboratory (Mallick et. al, 1997). In conjunction with experimental study a theoretical model is required to visualize the pullout mechanism. Such a model can be validated against the results obtained from the laboratory pullout tests.

Finite element analysis conducted by Katagiri et. al (1990) has shown a linear relationship between normal pressure and shear stiffness of the soil-geotextile interface. A joint element technique was used to connect the upper and lower surface of the geogrid with the soil particles. The results showed that the analyzed strain sufficiently agreed with the measured strain. Floss and Gold (1990) conducted a finite element analysis on the efficiency of a single geotextile reinforced two-layer system. Soil continuum was modeled by an eight node isoparametric element with quadratic shape functions. The geotextile was modeled with isoparametric bar elements. To model the soil-geotextile interaction, thin-layer elements were used at the interface. An elastoplastic nature of analysis with

Mohr-Coulomb yield criterion was adopted to limit the transfer of load from the soil to the geotextile.

Wu ( 1987) also developed a finite element model to predict the stress-deformation behavior of a soil-fabric system. The interface region was modeled by connecting the nodes with unilateral normal and tangential springs. The fabric was represented by a special element which could only withstand tension. No resistance to bending and compression was allowed in this element. To simulate the viscoelastic behavior of the polymeric geogrid, varying elastic moduli was used for different sections of the geogrid in a finite element analysis. The residual shear modulus at the interface was selected on the basis of the assumption that the partial slippage would occur once the shear strength was reached.

A review of literature shows that the behavior of the soil-geotextile interface depends on the successful modeling of load transfer mechanism from geotextile to soil. This mechanism is again dependent on the choice of a proper element to model the soil-geotextile interface. This study was carried out to investigate the applicability of a new type of interface element in modeling a pullout test with geotextiles.

## 2. MODELING OF INTERFACE WITH GAP ELEMENTS

In the numerical model developed in this study a new type of element was used to model the soil-geotextile interface.

Ten isotropic GAP elements were used to model the load transfer mechanism at the soil-geotextile interface. Slip-separation behavior of the interface is governed by the status of the GAP elements. The GAP or friction element (available in the element library of MSC/NASTRAN) has several advantages over the thin-layer or spring elements previously used to model the soil-geotextile interface. This is because GAP elements can simulate several situations which are observed in a pullout test. These situations are:

Open GAP: Simulates no contact at the interface

Closed GAP: Simulates the contact between soil and geotextile at the interface under vertical loading

GAP sticking with static friction: Simulates the building of pullout resistance at the interface.

Resistance increases until the pullout load overcomes the static friction at the interface. After the static friction is overcome, GAP elements start slipping with kinetic friction and pullout resistance drops as the reinforcement is pulled out of the soil layers. A horizontal shear stiffness for the gap element was used to simulate the frictional force at the interface. As the load was applied, the stick-slip behavior of the interface was examined with the behavior of GAP elements under the specified loading condition.

### 3. NUMERICAL MODELING OF PULLOUT MECHANISM

A two dimensional plane strain nonlinear model was developed to simulate the stress-strain behavior of a geotextile subjected to a pullout load (Figure 1). A large scale general purpose computer program, MSC/NASTRAN, was used to analyze the model. The above model was tested for initial pullout displacement of 40 mm. For this displacement, stress-strain relationship for soil and geotextile materials were considered to be linearly elastic. For the correct simulation of stick-slip behavior of the interface, geometric nonlinearity was incorporated in the model.

### 4. ELEMENTS AND PARAMETERS USED FOR THE MODEL

Soil: Cover material was modeled using a elastic, four node, isotropic, quadrilateral element. The following material properties were used for the quadrilateral elements:

Modulus: 100 Mpa  
Poisson's ratio: 0.3  
 $\phi$ : 32 degrees  
c: 0 (dry sand)

Interface Element: The following parameters were selected as the properties of the GAP elements.

axial stiffness: 80.E+7 N/m<sup>2</sup>  
transverse stiffness: 9.E+7 N/m<sup>2</sup>  
coefficient of static friction: 3.0  
coefficient of kinetic friction: 0.1

Reinforcement: Reinforcement was modeled with four one dimensional linear rod elements with no bending stiffness. The following parameters were selected as the properties of the rod elements.

thickness: 0.001m  
modulus: 5250 kN/m

Loading: The above model was tested for a 7 kPa normal pressure and 40 mm pullout displacement at the tension end of the geotextile. Ten iterations were used in the model to reach 40 mm forced displacement.

## 5. EXPERIMENTAL

Details of the experimental study can be found from Mallick et. al (1997). A simple pullout box was designed and pullout tests were conducted with different types of geotextiles and sands. Figure 2 shows the details of the experimental set-up. A pullout load was applied at the rate of 1 mm/min at the tension end of the geotextile. Pullout load and the corresponding front end displacement were measured during a pullout test.

## 6. RESULTS

Figure 3 shows the calculated (from finite element model) and measured load-displacement behavior at the front end of the geotextile. From the output it was observed that the calculated load response of the geotextile at different displacement levels are very close to the load measured during the experiment. Calculated loads are slightly higher than the measured loads at all displacement levels.

Figure 4 shows the calculated pullout resistance along the length of the geotextile. From the results it can be noted that the pullout resistance obtained from element number two is smaller than that obtained for element number one. This discrepancy in the output shows the need for a varying modulus input for the different sections of the geotextile. As the pullout resistance sharply increases from element 3 to element 4, nature of the load response graph shows a need for nonlinear modeling for the geotextile material close to the load application point.

Figure 1. Finite Element Model

Figure 3. Calculated and Measured Load-Displacement Behavior at the Front End of Geotextile (Element No. 4)

Note: all dimensions are in mm

Figure 2. Experimental Setup

Figure 4. Calculated Pullout Resistance along the Length of Geotextile

From the force-displacement output of GAP elements it was observed that up to 15 mm displacement, all ten GAP elements were sticking to the rod elements and no slip was calculated at the interface. At 15 mm displacement, GAP elements 5 and 10 (both at the load application point) started slipping with kinetic friction. No sliding was observed from the analysis.

Analysis of Fabric Reinforced Sand", Ph.d. Dissertation, 1987, The University of Michigan, Ann Arbor.

## 7. SUMMARY AND CONCLUSION

A finite element model was developed to simulate the behavior of a geotextile under pullout load. GAP or friction elements were used to simulate the contact problem at the soil-geotextile interface. Data showed that the model can accurately predict the pullout resistance developed at the front end of the geotextile. Analysis results show that the pullout resistance in the reinforcement increased sharply from element three to element four (at the load application point). This sharp increase in the load response indicate that a nonuniform stress distribution due to a nonlinear stress-strain behavior exists close to tension end of the geotextile. This particular stress-strain behavior can be modeled with localized nonlinear-elastic stress-strain relationship.

From the results of the analysis it can be concluded that, even for the small displacement of 40 mm at the front end of the geotextile, local material non-linearity should be incorporated into the model. GAP element properties should be selected with extreme caution because the performance of the model depends on the correct stick-slip behavior of the gap elements.

**ABSTRACT:** Despite the increased use of geogrids in modern engineering practice, there is a lack of information on their in-situ performance. The performance of geogrids vary based on manufacturing and design conditions. Each type of geogrid has a different grid configuration or aperture sizes. To assure a sufficient design one should learn about the basic mechanism of soil/geogrid interaction and influence of their configuration on their performance. This paper presents the results of a study of the influence of grid configuration on the direct shear strength of geogrid-soil interfaces. The results demonstrate that there is an optimum configuration which offers the optimum interaction between soil/geogrid. The results of this study have been the basis of development of a new soil/geogrid interface finite element.

**KEYWORDS:** Friction, Finite Element Analysis, Geogrids, Reinforcement, Shear Strength

## 1 INTRODUCTION

Over the last two decades, inclusion of geosynthetics in soil reinforcement has greatly increased. Their material properties allow for an increased stability of foundation soils, retaining walls, and many other earth structures. Practical experience coupled with field performance has demonstrated the positive impact of geosynthetic inclusions in regard to economics and stability of the reinforced continuum.

Structures are increasingly built on difficult soils and larger and higher walls are being built; the need for reinforcement mechanisms such as geosynthetics becomes more apparent.

Inclusion of this media in design introduces a tensile strength factor to a soil mass which previously was largely only able to support compressive stresses.

Due to their ability to carry large tensile stresses, geogrids are being used more frequently especially in the design of retaining walls. However, their behavior in shear and pullout conditions is complex and still not clearly understood.

In addition to the adhesion and friction components acting on the interface surfaces of the geogrids with soil, other shear stress components can also affect the

interaction behavior of geogrids. Passive stresses due to the interlocking of soil particles along the cross ribs would definitely influence the measured resistance.

In general, the geogrids offer a three-fold advantage as a reinforcement:

1. offers tensile strength to soil;
2. offers shear resistance due to the friction between the transverse and longitudinal ribs of the grid;
3. offers additional pull-out resistance due to the bearing resistance of the soil interlocked within the grid holes.

When employing a geogrid into a design, there are two potential failure mechanisms:

1. "Bond Resistance Mechanism". The geogrid must be properly anchored into the soil. If there are no provisions made for this, the geogrid would have the potential to "slide out". Then, failure will occur above and below the soil reinforcement interface.
2. "Direct sliding". If the reinforcement interface does not have a large enough interface frictional strength, the soil either above or below the

reinforcement would have the potential to slide along the reinforcement. This occurs when the soil/reinforcement strength is less than that of the actual soil by itself.

Design of geogrids changes according to their function and manufacturing process. Each geogrid may differ in aperture size, configuration, and tensile strength. Geogrids available today have uniaxial or biaxial configurations.

Configuration of the geogrid openings plays an important role in their performance. The ratio of the open space area to the total surface area, dimensions of the openings, and orientation of the openings are some factors that would affect a geogrid performance.

In order to have optimum benefit of geogrids, the designer must have a general knowledge of the characteristics of both the "pullout" and "direct shear" capabilities of the specific geogrid. At the present time, there is little information to be found concerning these capabilities for a general type of geogrid. In addition, there is not enough information on in-situ behavior of geogrids.

To provide a step towards understanding basic understanding of soil-geogrid interaction, this research concentrated on the effects of varying the grid configuration and hole size in a series of direct shear tests while keeping the aperture ratio fairly constant. Thus, any variance seen in the shear strength capability would be a direct result of the configuration alone and is, therefore, indicative of the passive resistance during shearing. Due to time limitation, pullout resistance was not investigated.

As mentioned earlier, it would be impossible to test every possible configuration of geogrids. Currently, work is in progress to create a finite element model which would simulate the various types of soil/geosynthetic interface reactions (Abdel-Rehman 1997). The experimental data presented in this paper has been used to verify the finite element.

The results reported in this paper will be used to verify a numerical interface model and element with more applicable postulates to accurately describe the geogrid performance in a finite element analysis. Once the model has been proven, it can be used to simulate many configurations and situations.

## 2 LITERATURE REVIEW

Rowe and Fisher (1985) conducted tests concerning both the pullout and shear strength characteristics of geotextiles and geogrids. For testing purposes, a geogrid with openings representing approximately 55

percent of the gross area of the material was used. Thus, the ribs represented 45 percent of the gross area.

In shearing of geogrid/soil, Rowe and Fisher (1985) observed that "the soil adjacent to the geogrid moves relative to both the ribs of the geogrid and the soil in the openings of the ribs". In their research, "recognizing that the rib-soil interface represents approximately 45 percent of the gross area, the apparent friction angle can be determined from:

$$\tan^{-1} (0.45 \tan \phi_{\text{rib-soil}} + 0.55 \tan \phi_{\text{soil}}) \quad (1)$$

where:  $\phi$  = interface friction angle. They observed that in direct shear tests the interface friction angles were similar whether the grid was sheared in the longitudinal direction or the transverse direction ( $\phi_{\text{rib-soil}} = 31.5^\circ$ ). Also, the angle was similar to that of the soil itself ( $\phi_{\text{soil}} = 31-32^\circ$ ).

Reasoning presented for such behavior was that "in direct shear, the entire rib-soil interface and soil-soil interface between ribs is mobilized and hence the apparent friction angle is close to that of the soil". The work by Rowe and Fisher was one of the first to focus on geogrid/soil interaction. However, they did not focus on different configurations of the geogrid. Bergado et al. (1993) also conducted research on geogrid/soil interaction. With geogrids, "the direct shear interaction mode is controlled not only by the friction between the soil and the grid surface but also by the friction of the soil itself" (Bergado et al. 1993). The resistance due to direct shear has two components including the shear resistance between the soil and the reinforcement-plane surface area, and the soil-to-soil shear resistance at the grid opening (Jewell et al. 1984). Jewell et al (1984) and Bergado et al. (1993) also provided understanding on the interaction of soil/geogrids mechanics during shearing. The direct shear resistance can be quantified as:

$$P_s = \sigma_n A [\alpha_{ds} \tan(\delta + (1 - \alpha_{ds}) \tan \phi_{ds})] \quad (2)$$

where:  $\phi_{ds}$  = friction angle of soil in direct shear;  $\delta$  = skin-friction angle between soil and reinforcement shear surface;  $\alpha_{ds}$  = ratio between reinforcement shear area and total shear area;  $\sigma_n$  = normal stress at the shear plane; and A = total shear area.

From this research, Bergado et al. concluded that depending on the apertures of the grid, the shear resistance between the grid and soil can be equal to or larger than the shear resistance of the soil itself (1993).

This added resistance would come from the passive resistance created along the rib interface.

### 3 SCOPE OF RESEARCH

#### 3.1 Test Apparatus

The device used for direct shear testing was built specifically to test the interface properties of geosynthetics, including geogrids. The equipment consists of a computer, a control panel, and a split shear box. The machine is fully automated and computer controlled and built according to ASTM D5321 standards for direct shear testing.

The control panel is used to operate the split shear box. It displays the normal load being applied by a set of pneumatic pistons located below the shear box. It also displays the horizontal and vertical displacements occurring during the testing. LVDTs are placed in contact with the upper shear box for horizontal displacement measurement and in contact with the loading yoke for vertical displacement measurement. The control panel also controls the rate of shear displacement via a worm gear connected to the lower box.

The split shear box consists of top and bottom parts. The top part, which remains stationary at all times, has the dimensions of 30.5 by 30.5 by 5.1 cm. The bottom part, which is displaced, has dimensions of 40.6 by 30.5 by 5.1 cm. The bottom part is longer than the top part to allow for a larger displacement area. The top and bottom parts are slightly separated to eliminate added friction.

#### 3.2 Soil Properties

Soil used for the testing is a mostly fine grained sand. Properties are as follows:  $C_u = 0.45$ ;  $C_c = 1.23$ ;  $d_{10} = 0.52$  mm;  $d_{40} = 0.29$  mm;  $d_{60} = 0.15$  mm;  $\phi_{soil} = 32.3^\circ$ .

#### 3.3 Geogrid Configurations

Simulated geogrid sheets were using in the tests. The geogrids are made from samples of high density polyethylene (HDPE) solid sheets (geomembrane). The HDPE is a 60 mil. HDPE sheets were cut to the dimensions of 33 by 47 cm. The different geogrid patterns are then designed and cut into the sheet

Nine patterns were tested. The patterns were determined such that constant opening areas are maintained as much as possible. In doing so, any differences in the results among the different configurations would be a result of additional passive stresses of the new configuration.

Each hole, independent of the pattern, was cut to be 25 cm<sup>2</sup>. Three different holes sizes are used: Series A (5 by 5 cm), Series B (2.5 by 10 cm), and Series C (4

by 6.4 cm). Each sample of a particular hole size has an increasing number of rows of holes.

The nine samples were as follows: 5 by 5 cm holes with 1, 3, and 5 rows (Figure 1); 2.5 by 10 cm holes with 1, 2, and 3 rows oriented longitudinally; and 4 by 6.4 cm holes with 2, 4, and 6 rows oriented transversely.

Pattern 1

Pattern 2

Pattern 3

Figure 1. Typical configuration of geogrids (Series A).

### 4 TESTING PROGRAM

Several tests were performed to ensure the repeatability of the tests. For the geogrids/soil tests the bottom part of the direct shear machine was filled

with sand and tamped by hand for compaction. The geogrid was secured to the bottom part of the machine. Only the end of the geogrid being pulled (closest to the control panel) was securely clamped. This is done to limit stretching of the sample. The opposite end is left free. The top part is then placed on top and filled with sand. Again the sand is tamped by hand. The top part is slightly raised after the addition of the sand to eliminate added friction between the two metal surfaces of the top and bottom parts of the direct shear machine. The loading apparatus is then added to apply the normal load.

Tests were conducted in the dry state. Each test was run at a normal load of 69.64 kPa, representing an average normal stress.

During shearing, the bottom part of the machine is pulled at a displacement rate of one mm/min. Total testing time was approximately one hour with the data acquisition recording performance every minute.

Several experiments were conducted on a pure sheet of HDPE geomembrane (60 mil) to provide a reference for tests on the geogrids. The interface friction angle of the HDPE geomembrane with the same sand used in the rest of the testing was measured to be  $\delta_{\text{nb soil}} = 23.5^\circ$ .

Each geogrid is tested at least three times while attempting to keep all conditions the same. Figure 2 shows the full set of results of three tests under the same conditions. The subsequent figures represent average values of three identical tests.

Figure 2. Shear stress vs. displacement (5 by 5 cm holes and 5 rows) (See Figure 1).

As can be seen in Figure 2, results of the three tests are fairly consistent. The slight variations can be attributed to minor differences in normal loading application or set up of the test. For example, the degree of compaction may vary since it is performed manually.

## 5 TEST RESULTS

The results are presented in Figures 3, 4, and 5, and in these figures each curve represents an average of three tests. Results for the geomembrane are also the average of three tests.

### 5.1 Geogrid Sample A: 5 by 5 cm Holes

As can be seen below, the holes in the geogrid provided an added component of resistance over the geomembrane (Figure 3). However, it is not until five rows of squares in the geogrid are used that a substantial increase is evident. There is a slight increase in resistance on the membrane for geogrids with one and three holes. The first two patterns did not show a peak in shear strength. This could be due to the thin width of the grid between holes which may have resulted in some stretching during the testing.

Figure 3. Results of sample A: shear stress vs. displacement (See Figure 1).

### 5.2 Geogrid Sample B: 2.5 by 10 cm Holes

For this sample, there was a steady increase in the added component of resistance over the geomembrane (Figure 4). However, in all geogrids with one row, there was no real added resistance. It should be noted that as the shearing continued the patterns showed a distinct peak and increase in resilience, however, the residual shear strength for both were very similar. The third pattern with five rows of holes reached and maintained a much larger shear resistance over the membrane.

Figure 4. Results of sample B: shear stress vs. displacement.

### 5.3 Geogrid Sample C: 4 by 6.4 cm Holes

This test showed similar results as for Sample B. However, shear resistance was slightly larger than for Sample B.

Figure 5. Results of sample C: shear stress vs. displacement.

## 6 DISCUSSION

All samples (A, B, and C) were prepared such that the aperture ratio stayed approximately similar for the different patterns (Table 1). The aperture ratio is the ratio of the area of the holes to the total area of the sample before cutting.

For the first test of each series (aperture ratio in the range of 8 to 13 percent), there is no noticeable amount of added resistance.

For Series B and C, there is some added resistance as the ratio increased to approximately 25 percent. However, in Series A there was not much of an advantage to increasing the aperture ratio to 25 percent.

Once the ratio increased to 40 percent, there is a significant resistance added by the grid.

The results given in Table 1 demonstrate that the configuration of the grid does have an effect on the shear resistance of the continuum.

Table 1. Calculated Data for the various grid configurations.

Series	Pattern	Aperture Ratio	$\delta_{\text{measured}}^*$	$\delta_{\text{measured}}^{**}$
"A" 5 by 5 cm holes	1 row	8%	24.3	31.7
	3 rows	24%	25.7	31.4
	5 rows	40%	27.2	38.6
"B" 2.5 by 10 cm holes	1 row	13%	24.7	27.3
	2 rows	26%	25.9	31.5
	3 rows	39%	27.1	37.5
"C" 4 by 6.4 cm holes	2 rows	13%	24.7	29.2
	4 rows	23%	25.7	33.6
	6 rows	34%	26.7	37.8

Notes: \*See equation (1). \*\*See equation (3).

Values for the "apparent" friction angle ( $\delta$ ) were determined using the equation provided by Rowe and Fisher (1985) and given in Table 1. To determine the "measured" friction angle from the test results, the maximum shear stress was obtained for each configuration, assuming cohesion equal to zero:

$$\delta_{\text{measured}} = \tan^{-1} (\tau_{\text{max}} / \sigma) \quad (3)$$

where:  $\sigma$  = normal stress.

Figure 6. Apparent versus measured friction angles.

Figure 6 shows that the apparent friction angle was always less than the measured friction angle (calculated using equations 1 and 3 respectively). At times, these values may even exceed the interface friction angle of the soil alone. This can be attributed to many factors.

After conducting a test, it was often observed that the sand particles have moved up and long the surfaces of the ribs. This may cause the friction angle

to increase as it would if the membrane were textured in that area.

Also, it was noted that the sand had to move up and then along the ribs before the shearing could occur. This created an almost wave-like pattern on the membrane which offered an extra resistance surface. As the number of holes in a pattern increases, the resistance magnifies creating the large measured friction angle.

It was also observed that holes near the edge of the pattern did not contribute as much resistance as did the holes in the center. Thus, when patterns were tested with holes only in the center there is a large increase in measured resistance. To verify this, a pattern was cut in which one row of square holes (50 by 50 cm) was placed only in the center of the grid (see results in Figure 7).

Figure 7. Testing with one row of squares in center of grid: shear stress versus displacement.

As can be seen when comparing results of Figures 3 and 7, the maximum resistance obtained was greater when the holes were in the center. This indicates that more resistance is generated by the center holes.

In the case of Series A (Figure 1), the ribs between the holes were relatively thin. Some stretching or twisting may have occurred during shearing. This may explain the lack of a defined peak shear strength in the first two patterns in the series (Figure 3). Because of the lack of a definite peak value, it is difficult to evaluate the measured friction angle accurately.

This being the case, it appears that Series C offered the most benefit, since the apparent friction angles versus measured are the most similar.

This research provides a basic study on the mechanisms of geogrids/soil. The results are being used by Tulane University to test and verify a finite element model being developed (Abdel-Rehman, 1997). In order to develop such a model, basic test results such as this one are necessary for verification. Ongoing research is being conducted in this field by

the two universities involved in this research. It is promising that the model will allow for even more definite results of a most suitable configuration of geogrid based on actual design criteria.

## 7 CONCLUSION

The results presented show that grid patterns, location, and aperture ratio significantly influence interface frictional resistance. The following general conclusions can be determined:

1. Grid configuration plays a vital role on the shear strength capability of a geogrid. Certain configurations provide larger amounts of passive resistance over other patterns.
2. The results of this study has been used as a basis of a finite element program being developed for modeling soil-structures reinforced with geosynthetics.

## ACKNOWLEDGMENTS

The writers would like to thank those individuals who helped with this research. Especially, we would like to thank Ms. Kristen Refkofsky for the many hours spent on testing geogrids.

R. Swan  
GeoSyntec Consultants, USA

**ABSTRACT:** Geosynthetic design in soil reinforcement applications require that the soil interaction characteristics of the reinforcement product be evaluated. The soil interaction characteristics are determined by performing direct shear and pullout tests under a specific soil condition and range of normal pressures. Polymeric reinforcement products used in soil reinforcement applications consist of geotextiles and geogrids which vary in texture, flexibility and open area. This paper presents soil interaction data of geotextiles and geogrids in both cohesionless and cohesive soil types. The data is used to compare soil interaction properties for various geosynthetic reinforcement products in both cohesionless and cohesive soils. Results indicate that geogrids and geotextiles offer similar soil interaction values. Interaction coefficients range from 0.9 to 1.0 in sands and from 0.6 to 0.9 in clays depending on geosynthetic surface texture, stiffness and applied normal stress.

**KEYWORDS:** Friction, Geogrids, Geotextiles, Pull-out resistance, Pull-out test, Reinforcement, Shear strength, Woven fabrics

## 1 INTRODUCTION

Geogrids and geotextiles are often used to construct reinforced retaining walls, steepened slopes, embankments on soft foundations, vertical landfill expansions, and soil veneer covers of landfills. However, a generally accepted but incorrect belief exists among Civil engineering professionals that geogrids interact or interlock with the soil being reinforced better than do geotextiles such as woven polyester fabrics. As a result, geogrids are often chosen over equally well-suited geotextiles. In order to curtail such mis-selection of materials and encourage accurate selection of design parameters, the interaction between the soil and the geosynthetic reinforcement must be evaluated.

Today, soil reinforced structures are designed with a variety of geosynthetics and soil types. The soil interaction characteristics between various geosynthetics and fine grained (clay) soils becomes increasingly important as more and more reinforced soil structures are designed with marginal (cohesive) fill materials and various types of geotextiles and geogrids. As a result, quantifying the soil interaction characteristics between these materials and developing design values for various soil and geosynthetic combinations is essential.

In keeping with current state-of-practice design references (AASHTO (1992), Christopher et. al. (1990), Simac (1993)), minimum anchorage lengths ( $L_a$ ) may vary from 0.3 to 1 meter (1 to 3 ft). The actual required embedment length is a function of the amount of effective overburden (i.e. depth of reinforcement), soil type above and below the

geosynthetic, and the interaction properties between the soil and geosynthetic.

Many researchers (Batt (1991), Cowell (1993) Geoservices (1990), Ingold (1983), Jewell (1980), Juran (1988), Koerner (1986), O'Dowda (1987), Palmeira (1990), Rowe (1985), Swan (1987)) have investigated the soil interaction characteristics between geosynthetics and sand. Cowell and Sprague (1993) presents a comparative study of pullout data and soil interaction values between woven polyester geogrids and high-strength, high-modulus polyester geotextiles in a uniform fine sand. The results presented by Cowell and Sprague (1993) and of previously published research show that geogrids and geotextiles provide similar soil interaction coefficients in sand between 0.90 and 1.0.

To supplement the research documented by Cowell and Sprague (1993) and others, direct shear testing of various high-strength polyester and polypropylene geotextiles in sand was conducted as well as both direct shear and pullout testing of polyester geogrids and high-strength polyester and polypropylene geotextiles in a lean clay. The data can be used to compare the results obtained by direct shear and pullout testing for determination of the coefficient of interaction. The data can also be used to compare the soil interaction properties of various geosynthetic reinforcement products and to develop recommended design soil interaction properties in different soil conditions.

## 2 TESTING CONCEPTS, AND TYPICAL RESULTS

### 2.1 Purpose

The direct shear and pullout tests measure the total resistance to sliding and pullout of a geosynthetic with a soil substratum and superstratum. Total sliding and pullout resistance may be a combination of sliding, rolling, interlocking of soil particles and geosynthetic surfaces, and shear strain within the geosynthetic specimen. The data developed can be used in the design of geosynthetic-reinforced retaining walls, steepened slopes, and embankments constructed on weak foundation soils. The data is also useful for applications in which the geosynthetic is subject to sliding such as applications which require the geosynthetic to be placed on a slope and for determination of geosynthetic overlap requirements.

The interaction developed between the soil and the geosynthetic is determined by performing direct shear and pullout tests under various soil types and a range of normal pressures. The data obtained is used to determine the coefficient of shear-stress-interaction,  $C_i$ , which measures a reinforcement product's efficiency in transferring stresses from adjacent soil particles to the geosynthetic reinforcement. The coefficients are simply the percentage of the internal shear strength of the soil that can be mobilized at the soil/geosynthetic interface as shown by equation (1).

$$C_i = \tau_i / \tau_s = (c_a + \sigma_n \tan \delta) / (c + \sigma_n \tan \phi) \quad (1)$$

where:

- $\tau_i$  = shear stress at interface
- $\tau_s$  = shear stress of soil
- $\delta$  = interface friction angle
- $\phi$  = internal friction angle of soil
- $c_a$  = interface adhesion
- $c$  = soil cohesion
- $\sigma_n$  = normal soil pressure

The coefficient of interaction is used in reinforced soil structure design to determine required reinforcement embedment lengths beyond the anticipated failure plane to prevent pullout of the reinforcement. A commonly accepted method of calculating this embedment length beyond the failure plane,  $l_a$ , is indicated by equation (2).

$$l_a = (P \times FS_{po}) / (2 C_i (c + \sigma_n \tan \phi)) \quad (2)$$

where:

- $P$  = Pullout force per unit length of reinforcement
- $FS_{po}$  = Design factor-of-safety with respect to pullout

The coefficient of soil and geosynthetic interaction can be expressed only in terms of the soil used in testing and is a function of the applied normal stress, soil gradation,

plasticity, in-place density, and moisture content, as well as the unique physical and mechanical characteristics of the geosynthetic. However, it is useful for design guidance to be able to characterize  $C_i$  values by geosynthetic and soil "type".

### 2.2 Direct Shear

The direct shear test used to determine the shear resistance of a soil/geosynthetic combination is ASTM D5321-92, "Standard Test Method for Determining the Coefficient of Soil and Geosynthetic or Geosynthetic and Geosynthetic Friction by the Direct Shear Method". The coefficient of friction between a geosynthetic and soil is determined by placing the geosynthetic and one or more contact surfaces, such as soil, within a direct shear box. A constant normal stress is applied and a tangential (shear) load is imposed on the apparatus such that one section of the box moves in relation to the other. Shear loading is applied via a 10 cm/min (0.04 in/min) constant rate device capable of measuring load.

The shear force is recorded as a function of the horizontal displacement of the moving section of the shear box. The test is performed for a minimum of three different normal stresses. The peak and/or residual shear stress is plotted against the applied normal stresses with the test data represented by a "best fit" straight line whose slope is the coefficient of friction between the two materials where the shearing occurred. The y-intercept of the straight line provides the 'adhesion' as measured by the test.

### 2.3 Pullout

The general test method used to determine the pullout resistance of a geosynthetic in soil is GRI GG-5/GT-6 - "Geogrid/Geotextile Pullout". The pullout test is performed by compacting soil in the lower half of the pullout box with subsequent placement of the geosynthetic specimen on top of the compacted soil and attached to a loading harness. The soil is then compacted in the upper half of the pullout box. The specific normal stress is applied to the upper layer of compacted soil through the use of a rigid loading platen and dead weight for the normal stress or through the use of an air bladder loading system. After application of the normal stress, the pullout specimen is immediately subjected to a 10 cm/min (0.04 inch/minute) constant rate of extension "pullout" force. Pullout displacement continues until a constant or decreasing load is recorded or the geosynthetic sample fails in rupture. Tests which fail in rupture would require re-doing at lower normal stresses in order to induce slippage and hence measurement of resistance to sliding.

The pullout force is recorded as a function of the horizontal displacement of the pullout specimen. The test is performed for a minimum of two different normal stresses. The peak pullout force is plotted against the applied normal stresses used for testing. The coefficient of interaction,  $C_i$ ,

is back-calculated using equation 3.

$$C_i = (P)/(2 I_a (c + \sigma_n \tan \phi)) \quad (3)$$

### 3 TEST PROGRAM

#### 3.1 Geosynthetic Types

The reinforcement products chosen for this research consist of a woven polypropylene geotextile (W, PP, GT), woven polyester geotextiles (W, PET, GT) and polyester geogrids (W, PET, GG). Table 1 summarizes the geosynthetic types investigated.

Table 1. Summary of Geosynthetic Materials Investigated

P r o d	Type <sup>1</sup>	Weight, g/m <sup>2</sup> (osy)	Ultimate strength, kN/m (lbs/ft)	Weave
A	W, PP, GT	420 (12)	70 (4800)	twill
B	W, PET, GT	440 (13)	105 (7200)	plain
C	W, PET, GT	680 (20)	200 (13800)	twill
D	W, PET, GT	950 (28)	300 (20580)	basket
E	W, PET, GG	186 (5.5)	39 (2700)	knitted
F	W, PET, GG	390 (12)	109 (7460)	knitted

<sup>1</sup>W = woven, PET = polyester, PP = polypropylene, GT = geotextile, GG = geogrid

The products were chosen based on their different structure, weave pattern and polymer type. This range of products also compliments the matrix of products tested and presented by Cowell and Sprague (1993). They ranged in ultimate tensile strength from 73 kN/m (5000 lbs/ft) to 364 kN/m (25000 lbs/ft).

The woven polypropylene geotextile evaluated in the program is characterized as being relatively stiff, having a rough surface texture and exhibiting a low percent open area (<30%). The woven polyester geotextiles evaluated are characterized as being flexible, having a smooth surface texture and exhibiting a low percent open area. The coated polyester geogrids evaluated are characterized as being flexible with a high percent open area (>30%). The samples tested cover a range of weights, tensile strengths and weave patterns as noted in Table 1 for detailed evaluation and comparison.

#### 3.2 Soil Types

The two soil types tested in conjunction with the geosynthetic products referenced above include a uniform fine sand (SP) and a lean clay with sand (CL). Figure 5 illustrates the gradations of the two soil types.

Figure 5. Soil Gradation Curves

#### 3.3 As-tested soil properties

A modified proctor was performed on the sand in accordance with ASTM D1557. The maximum dry density was determined to be approximately 18.4 N/m<sup>3</sup> (117 pcf) at an optimum moisture content of 8.8%. Post test evaluations indicated an average 94% of maximum dry density at an average moisture content of 17.4% had been achieved.

The clay soil used for direct shear and pullout testing had a liquid limit (LL) = 24.8; plastic limit (PL) = 12.1; plasticity index (PI) = 12.7; maximum dry unit weight of 18.6 N/m<sup>3</sup> (118.5 pcf); and optimum moisture content of 12.5%. The clay was moisture conditioned for compaction to 95% of the maximum dry unit weight and 1% dry of the optimum moisture content based on ASTM D698.

#### 3.4 Matrix of Test Conditions

Tables 2 and 3 summarize the program matrix and conditions for direct shear and pullout testing, respectively. All direct shear samples were 30.5 cm wide by 30.5 cm long.

Samples used in pullout testing are noted below. Pullout samples had dimensions of 45.7 (wide) by 91.5 (long) cm. An exception to the above was in test number 1 where the sample was 46.5 cm by 92.7 cm.

**Table 2. Summary of Direct Shear Test Conditions**

Test no.	Soil type	P r	Initial soil conditions <sup>1</sup>		Normal stress (Pa)
			$\gamma_d$ , kN/m <sup>3</sup>	$\omega$ , (%)	
1	Sand	A	17.2	17.4	34, 69, 103
2	Sand	B	17.2	17.4	34, 69, 103
3	Sand	C	17.2	17.4	34, 69, 103

## 4 RESULTS

A summary of the direct shear results in sand (TRI, 1995) is shown in Table 4. Soil interaction coefficients via direct shear testing range between 0.92 and 1.0.

A summary of the direct shear and pullout test results in clay (GeoSyntec, 1996) are shown in Tables 5 and 6, respectively.

The soil interaction coefficients for the flexible polyester geotextiles and geogrids range from 0.71 to 0.93 in direct shear and from 0.82 to 0.91 in pullout under the full range of normal stresses tested. The soil interaction coefficients for the woven polypropylene geotextile range from 0.58 to 0.64 in direct shear and 0.66 to 0.71 in pullout.

**Table 4. Summary of direct shear results in sand - peak sliding resistance (N/m<sup>2</sup>) vs normal stress**

Test No.	Soil	P r	Normal Stress, Pa			Friction angle, $\delta$	C <sub>i</sub>
			34	69	103		
	C/S <sup>1</sup>	-	26	44	65	32 °	-----
1	Sand	A	25	44	61	30 °	0.9
2	Sand	B	38	65	92	32 °	1.0
3	Sand	C	35	55	78	32 °	1.0

<sup>1</sup> C/S = Control Sand

### 4.1 Interpretation of results

The results demonstrate that direct shear and pullout testing in sand will yield similar soil interaction coefficients for all geosynthetic types tested. These values are typically in excess of 0.90 and provide good agreement with results of pullout testing presented by Cowell and Sprague (1993) on similar products.

Similar results which demonstrate high sand-geosynthetic action values are abundant in the literature. No significant correlation appears to exist between percent open area, reinforcement geosynthetic texture, its stiffness or other such properties. All reinforcement geosynthetics seem to do well in sand.

Results of direct shear testing in clay provide interaction values ranging from 0.71 to 0.93 for polyester products and somewhat lower values of 0.58 to 0.64 for polypropylene product A. The results demonstrate a lack of correlation between interaction behavior and percent open area or geosynthetic structure. However, the data suggests superior polyester performance when compared to polypropylene. In fact, the high-strength polyester geotextiles provide interface shear strengths as great as the internal shear strength of the soil itself. Further, the peak interface shear strengths were all mobilized at approximately the same displacement (5 cm) as was the peak strength of the soil itself. Good compatibility exists between each geosynthetic type and sand.

In general, the results of pullout testing in clay are in agreement with those noted above for direct shear testing in clay.

Compared to direct shear results, pullout testing provides approximately 13% to 17% higher soil interaction values at low normal stresses of less than 20 Pa (< 4 psi) and essentially the same soil interaction values at higher normal stresses (>28 Pa (4 psi)).

The flexible polyester geosynthetics provide approximately 25% higher soil interaction values when compared to the stiff woven polypropylene geotextile. The

woven polyester geotextiles provide similar soil interaction values when compared to the geogrids.

Observations from the test results indicate that the percent open area of the geosynthetic has negligible, if any, influence on the soil interaction coefficients in clay. However, the surface texture and stiffness or rigidity of the geosynthetic has a significant effect on the soil interaction within clay. The geotextile weave pattern has negligible, if any, effect on the soil interaction characteristics of the geotextile.

## 5 DESIGN RECOMMENDATIONS

Table 7 provides soil interaction coefficients for use in conservative design of reinforced soil structures. Values are subject to verification testing during construction.

The results provided herein and found in the literature suggest that relatively high interaction values can be confidently employed with all reinforcement geosynthetics irrespective of texture, percent open area or polymer type. An interaction coefficient in sand of 0.9 is recommended.

Greater variability is observed in interaction testing in clay. Test results incorporating polyester reinforcement geosynthetics range from 0.7 to 0.9+. Therefore, a

conservative guidance value of 0.7 appears to be reasonable.

A slightly lower design interaction value of 0.6 is recommended for polypropylene products used in clay.

Design values recommended above range from 0.6 to 0.9 with values used for critical structures being verified by actual soil-geosynthetic testing during construction. However, it is also recommended that validation testing during construction be required on a selective basis with great consideration for its true impact on design. A parametric study of most reinforcement applications will demonstrate that the greatest factor affecting required embedment length is normal stress (i.e. reinforcement depth), not  $C_i$ . In practice, its affect on structure design and performance is only significant in the upper portions of reinforced soil structures. In fact, once below a depth of about 1 m (3 ft), the embedment length of most commonly marketed reinforcement geosynthetics is governed by minimum embedment length criteria rather than  $C_i$  or pullout.

Recognizing the true impact of soil-geosynthetic interaction for each design scenario will guide the designer in evaluating whether to use the above recommended values or require testing during construction.

Table 5. Summary of Direct Shear Results in Clay - Peak Sliding Resistance ( $N/m^2$ ) vs. Normal Stress (psi)

**ABSTRACT:** Three full scale test embankments were constructed to failure on soft Bangkok clay. One of the embankments was unreinforced and served as control embankment. The second embankment was reinforced with multi-layer reinforcements consisting of four layers of low strength nonwoven geotextiles. The third embankment was reinforced with one layer of high strength (200 kN/m ultimate strength) nonwoven/woven geotextile at the base. The test embankments were constructed using silty sand and were fully instrumented. The geotextile reinforcements were also instrumented to measure their deformations. Back-analyses were made using the limit equilibrium method. The primary failure occurred at the same deformation as the unreinforced embankment during the bearing capacity failure in the foundation. Just prior to this stage, the limiting strain in the geotextile can be taken equal to the critical strain at 3% and the direction of the reinforcing force can be taken as horizontal. The secondary failure occurred at the embankment collapse coinciding with the rupture of the reinforcement and the limiting strain can be taken as the sum of the critical strain during primary failure and localized strain during secondary failure and the direction of the reinforcing force can be taken as bisectonal. The results confirmed the existence of soil/geotextile composite behavior that modified the soil shear strength at the intersection of the failure plane and geotextile reinforcement. Consequently, the respective collapse heights of the multi-layer and high-strength geotextile-reinforced embankments were 1.1 and 1.6 times the unreinforced embankment.

**KEYWORDS:** Geotextiles, Nonwoven fabrics, Reinforcements, Embankments, Soft soils

## 1 INTRODUCTION

In this paper, the performances of 3 full scale test embankments, constructed on soft Bangkok clay, have been described and analyzed. All three test embankments have been built to failure. The unreinforced embankment served as control embankment and was designated as CE embankment. The second embankment, designated as MGE embankment, was reinforced with 4 layers of low strength, nonwoven, needle-punched geotextile consisting of one layer of TS700 (280 g/m<sup>2</sup> and ultimate strength of 19 kN/m) and 3 layers of TS420 (130 g/m<sup>2</sup> and ultimate strength of 9 kN/m). The third embankment, the HGE embankment, was reinforced with one layer of high-strength, woven/ nonwoven (composite) geotextile (PEC 200) with nominal mass of 700 g/m<sup>2</sup> and ultimate strength of 200 kN/m. The geotextile instrumentations and preliminary theoretical analyses have been published previously (Bergado et al, 1994; Loke et al, 1994). The objectives of this paper are to present, evaluate, and analyze the performances of all 3 test embankments based on the measured and monitored data and subsequent theoretical back-analyses using the limit equilibrium method (LEM). Most of the data and results presented in this paper were derived from the work of Long (1997) under the supervision of the first author.

## 2 SITE CONDITION AND SOIL PROFILE

The layout of the test embankments is given in Figure 1. The embankment designations CE, MGE, and HGE have been defined previously. Two boreholes down to 12 m depth and 6 field vane tests down to 10.5 m depth were done. The locations of boreholes and vane tests are also shown in Figure 1. Continuous Shelby tube (inside diameter = 0.075 m) samples were obtained from the boreholes while undrained shear strength at 0.50 m intervals were obtained from the vane tests. The generalized soil profile and soil properties are presented in Figure 2. The uppermost 11 m in the soil profile can be divided into 3 sublayers. The weathered crust forms the topmost 2 m thick sublayer consisting of heavily overconsolidated reddish-brown clay. This sublayer is underlain by a soft, grayish clay sublayer down to about 8 m depth with natural water content varying from 60 to 80%. The medium stiff clay sublayer with silt seams and fine sand lenses can be found from 8 to 11 m depth. The liquid limit of the soft clay ranges from 70 to 102% and the plasticity index is about 60%. The groundwater level at the test site varied seasonally from 0.50 m depth in the rainy season to 1.50 m depth in the dry season. The undrained shear strength from field vane test are also given in Figure 2.

Figure 1. Layout of test embankments with locations of field investigations.

Figure 2. General soil profile and soil properties at the site.

Figure 3. Cross-sections of three test embankments.

### 3 EMBANKMENT DESIGN AND INSTRUMENTATIONS

The cross-sections of the three test embankments are given in Figure 3. All embankments were designed with side slopes of 1V to 1.5 H. A canal was excavated to 2 m deep and 7.5 m wide along the toe of the test embankments to reduce the volume of fill required to reach failure and to ensure that the failure will occur in the canal side.

The silty sand, widely used locally for highway construction, was utilized as embankment material. Using standard Proctor compaction, the maximum dry density and optimum moisture content were obtained as 18 kN/m<sup>3</sup> and 10%, respectively. The failure envelopes from large (shearing area = 0.54 m<sup>2</sup>) and conventional (shearing area = 0.0032 m<sup>2</sup>) shear box tests for the embankment material compacted to 95% of standard Proctor compaction with water contents of 9.5% and 13.0% are plotted in Figure 4. The conventional and large shear box test results correspond to peak and critical state strength parameters, respectively.

The foundation instrumentation of MGE and HGE embankments is presented in Figure 5. The same instrumentation system was used for CE embankment except for surface settlement, S2, and standpipe piezometers SP4, SP5 and SP6. The instruments consisted of piezometers, surface and subsurface settlement plates, and inclinometers for measuring pore pressures, vertical settlements and lateral displacements, respectively. The displacements in the geotextiles reinforcements were measured by wire extensometers, Glotzl extensometers, and 100 mm long special strain gages (Figure 6).

### 4 EMBANKMENT CONSTRUCTION TO FAILURE

Before the embankment construction, the ground surface was cleared by excavating to 0.20 m depth and levelled. Then, the canal was excavated. Immediately, thereafter, the control embankment (CE) was constructed in layers with compaction lift thickness of 0.30 m. The sequences of embankment construction are shown in Figure 7. Very small deformations were observed at embankment height lower than 2.50 m. The magnitudes and rates of vertical settlements as well as the lateral movements increased significantly when the embankment height exceeded 3.5 m corresponding to 65 kPa embankment loading. The CE

Figure 4. Failure envelopes of embankment fill from conventional and large scale direct shear tests.

Figure 5. Foundation instrumentations of the embankments.

embankment reached a net height of 4 m (or 80 kPa embankment loading) at failure. The measured excess pore pressures from pneumatic piezometers are plotted in Figure 8 together with the rate of embankment loading. The cross-section measured after failure is plotted in Figure 10 including the failure locations indicated by bamboo stakes and by inclinometer.

Both MGE and HGE embankments were built at the same time with the same rate of filling, construction procedure and quality control as the CE embankment (see Figure 7). Up to the embankment height of 3.75 m or 75 kPa embankment load, the measured strains in the geotextiles were smaller than 1.0%. The rates of vertical and lateral displacements as well as geotextile strains increased significantly when the embankment height exceeded 3.75 m. At this stage, the maximum strains in the geotextile reinforcements were 3% and 2.3% in the MGE and HGE embankments, respectively. The failure of MGE embankment occurred at 4.2 m height (88 kPa embankment loading) that completely ruptured the low strength geotextile reinforcement. The MGE embankment failure induced deformations in the HGE embankment. The cross-section of MGE embankment at failure as compared with CE embankment is also shown in Figure 10. During the failure stage of MGE embankment, the measured maximum strain in the high strength reinforcement was 8.5% which indicated that the induced failure caused 6% additional strain in the high strength reinforcement. The HGE em-

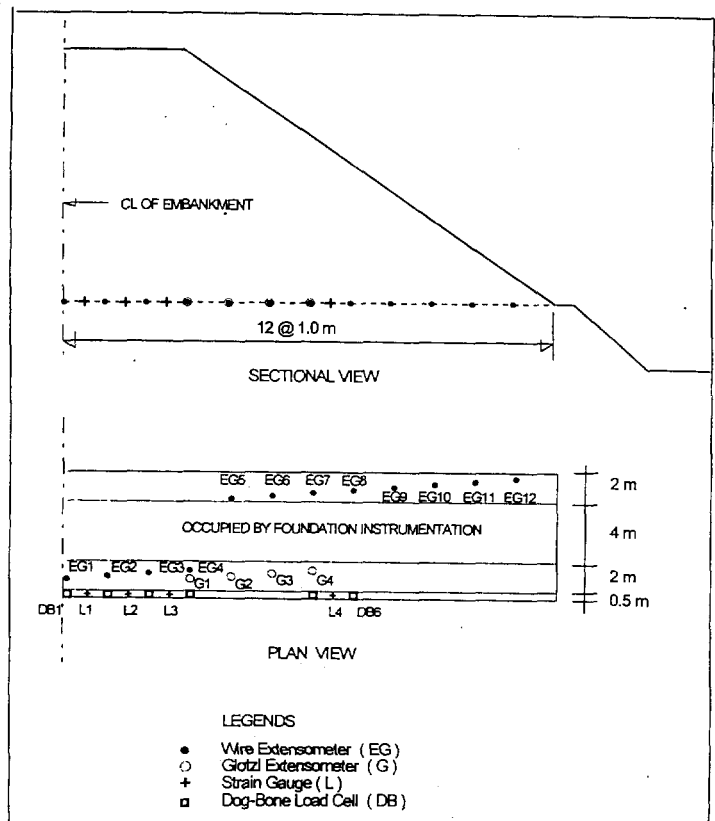

Figure 6. Geotextile instrumentations in HGE embankment.

Figure 7. Construction sequences of three test embankments.

bankment height was further increased until a net height of 6 m (or 128 kPa embankment loading) was reached wherein the maximum recorded displacement was 670 mm corresponding to 12% strain and rupture of the high strength reinforcement. The excess pore pressures from pneumatic piezometers underneath the HGE embankment are given in Figure 9 together with the rate of embankment loading. The measured displacements in the high strength reinforcements at selected locations from wire extensometers are plotted in Figure 11 together with the base of embankment construction.

The collapse height corresponds to the maximum net embankment height that can be constructed. The net embankment height is defined as the difference between the current embankment crest elevation and the original elevation of the embankment base. The critical height, on the other hand, is the height at which the deformations in the foundations are equal to that of the unreinforced embankment prior to failure. Thus, the critical height and the collapse height can be considered as the embankment heights corresponding to the bearing capacity failure of the founda-

tion (primary failure) and the collapse of the reinforced embankment together with its foundation (secondary failure), respectively.

There were 35 rainy days during the construction of MGE and HGE embankments as compared to none for CE embankment. Thus, the actual collapse loads of MGE and HGE embankments were 88 kPa (4.6 m fill thickness) and 128 kPa (6.7 m fill thickness) which are, respectively, 1.1 and 1.6 times higher than the CE embankment.

## 5 CRITICAL STRAIN IN GEOTEXTILE REINFORCEMENT

The critical strain in geotextile reinforcement,  $\epsilon_c$ , is defined as the maximum strain mobilized in the reinforcement when the reinforced embankment reaches the critical height (prior to primary failure). The measured strains prior to primary failure of HGE and MGE embankments are 2.3% and 3.0%, respectively. The Almere test embankment (Rowe, 1992) reinforced by one layer of geotextile yielded the strain of 2.5% at critical height of 2.05 m. The Sackville embankment (Rowe et al, 1995) using one layer of polyester woven geotextile yielded 3% strain at 5.7 m fill thickness when primary failure occurred. The critical strain of 3% was also obtained at Guiche test embankment (Delmas et al, 1992) with one layer of woven/nonwoven geotextile. Thus, the critical strain lie in a small band of values ranging from 2.3 to 3.0% for a very large range of geotextile stiffness ranging from 350 kN/m to 5,000 kN/m in various soil profiles.

## 6 BACK-ANALYSES OF STABILITY USING LIMIT EQUILIBRIUM METHOD

The limit equilibrium method (LEM), assuming circular slip surface, was used for back-analyses of stability in both

Figure 8. Excess pore pressures from pneumatic piezometers in CE embankment.

Figure 9. Excess pore pressures from pneumatic piezometers in HGE embankment.

unreinforced and reinforced embankments. The computer software PCSTABL6 (Purdue University) based on Bishop's simplified method (Bishop, 1955) with modification to include the effect of the reinforcement, was utilized.

For the CE embankment, the field compaction have total unit weight ( $\gamma$ ) of 18.5 kN/m<sup>3</sup> and moisture content ( $\omega$ ) of 9.5%. Corresponding to this condition, the peak strength consists of 40 degrees friction angle and 22 kPa apparent cohesion and the corresponding critical state values were 30 degrees friction angle and 15 kPa apparent cohesion (see Figure 4). The mean values of the field vane shear strength with correction factor of 0.80 were used as undrained strengths of the soft clay foundation. The calculated factor of safety for the actual slip surface of CE embankment at 4.0 m net height were 1.02 and 0.98 for the strength parameters of embankment fill at peak and post-peak, respectively.

For the stability of MGE and HGE embankments, the reinforcing force can be either assumed as a free-body force or a force modifying the soil strength. Following the approach of Bonaparte and Christopher (1987), the former assumption was applied in the HGE embankment and the latter assumption was used in the MGE embankment. For the case of the reinforcement modifying the soil shear strength, the resultant force in the direction tangent to the slip surface,  $T_R$ , can be calculated as follows:

$$T_R = T(\cos \alpha + \sin \alpha \cdot \tan \phi) \quad (1)$$

in which  $\alpha$  is the angle between the direction of the reinforcement and the tangential direction of the slip circle, and  $\phi$  is the friction angle of the embankment fill.

The direction of reinforcement force at the onset of failure can be represented by the inclination factor,  $I_f$ , defined as follows:

$$I_f = 1 - \alpha/\alpha_0 \quad (2)$$

where  $\alpha_0$  is the angle between the initial (horizontal) direction of the reinforcement and the tangential direction of the slip surface. The values of  $I_f$  of 0, 0.5, and 1.0 correspond to horizontal, bisectonal, and tangential directions, respectively. The reorientation of the reinforcement is caused mainly by the bending of reinforcement due to local deformation. Thus, the value of inclination factor,  $I_f$ , should be selected according to the magnitude of the localized strain in the geotextile,  $\epsilon_{lc}$ , at the vicinity of the slip surface. From the results of large direct shear tests and finite element modeling (FEM), Bergado et al (1996) suggested that the maximum value of  $I_f$  is 0.50 corresponding to the bisectonal direction. The bisectonal direction has also been successfully assumed by Rowe and Soderman (1984), Low and Duncan (1985) and Rowe (1992).

Figure 10. Cross-section of CE and MGE embankment after failure.

Figure 11. Displacements in geotextile measured by wire extensometer.

The ultimate reinforcement force,  $T_{ult}$ , was computed corresponding to the value of the limiting strain,  $\epsilon_{lm}$ , which includes the localized strain,  $\epsilon_{lc}$ , whenever  $I_r$  is greater than 0. The strength parameters of backfill soil correspond to the field compaction condition ( $\gamma_t = 19.2 \text{ kN/m}^3$  and  $w = 13\%$ ) influenced by rainy days. The corresponding friction angle ( $\phi$ ) and apparent cohesion ( $c$ ) were  $\phi = 38$  degrees and  $c = 17 \text{ kPa}$  at peak strength, respectively, and  $\phi = 30$  degrees and  $c = 10 \text{ kPa}$  at critical state, respectively. The undrained strengths in the soft clay foundation were similar as the CE embankment.

The failure of MGE embankment at 4.2 m net height was back-analyzed. At the critical height, assuming peak strength parameters of embankment fill, no localized geotextile deformation ( $\epsilon_{lc} = 0$ ) and horizontal direction of reinforcing force ( $I_r = 0$ ) with measured strain of reinforcement of 3%, the factor of safety (FS) was 0.98. At the onset of failure (FS = 1.0) with  $I_r = 0.5$  (bisectonal direction of reinforcing force and using critical state strength parameters of embankment fill, the back-analyzed geotextile strain was found to be 13%.

The stability of HGE embankment at net embankment heights of 4.2 m (critical height) and at 6.0 m (collapse height) were back-analyzed. Using the measured strain in the geotextile of 2.3% and assuming  $I_r = 0$  and peak strength parameters for embankment fill, the calculated FS was 1.0. This indicates that the HGE embankment reached critical height at 4.2 m and the bearing capacity failure (primary failure) was unavoidable, even without the interference of MGE embankment. After induced failure of adjacent MGE embankment, the measured strain in the high strength geotextile was 8.5% corresponding to tensile strength of 145 kN/m. At this stage, assuming  $I_r = 0.5$  and using critical strength parameters of embankment fill, the safety factor of 1.25 was obtained. Therefore, the embankment construction can be continued which was done. The HGE embankment collapse at net embankment height of 6 m with measured strain in the geotextile of 12 to 14% corresponding to rupture strength of 200 kN/m for high

strength geotextile. At 6 m net height, the FS value for HGE embankment was found to be 1.0 using either the actual failure surface or the most critical and deeper failure surface. Therefore, regardless of the influence of MGE embankment failure at net height of 4.2 m, the HGE embankment should fail at net embankment height of 6.0 m.

## 7 MAGNITUDE AND ORIENTATION OF REINFORCING FORCE

Two important variables are involved in the circular slip stability analyses, namely: the inclination factor,  $I_r$ , and the limiting strain,  $\epsilon_{lm}$ , at the onset of failure. Based on the measured strain, the results of back-analyses by LEM indicated that reinforcing force can be horizontal direction ( $I_r = 0$ ) at critical height just prior to bearing capacity failure (primary failure) as well as the reinforcing force can be bisectonal ( $I_r = 0.50$ ) at collapse height. Rather than assumed arbitrarily, an improved method is introduced to estimate the limiting strain,  $\epsilon_{lm}$ , as follows:

$$\epsilon_{lm} = \epsilon_c + \epsilon_{lc} \quad (3)$$

in which  $\epsilon_c$  is the critical strain corresponding to the critical height (just prior to bearing capacity failure or primary failure) and  $\epsilon_{lc}$  is the localized strain associated with the slip failure. The value of  $\epsilon_c$  was found to be 2.3% to 3% as mentioned previously. Based on large direct shear tests and subsequent FEM modeling, Bergado et al (1996) proposed a new method to calculate the localized strain,  $\epsilon_{lc}$ , as follows:

$$\epsilon_{lc} = 225 (I_r) (S^{-0.4}) \quad (4)$$

Figure 12. Localized strains in geotextile from field data and as predicted by Equation 4.

The value of  $S$  is the total stiffness of all reinforcement layers in the embankment and should be determined as secant stiffness at 5% strain. The value of  $I_r$  can be assumed as  $I_r = 0$  or  $I_r = 0.50$  corresponding to critical embankment height and collapse height, respectively. Equation 4 is plotted in Figure 12 for various values of stiffness,  $S$ . The data derived from Sackville (Rowe et al, 1995) and Guiche (Delmas et al, 1992) embankments are also included in Figure 12.

## 8 CONCLUSIONS

The full scale test embankment program including the site conditions, instrumentations, and embankment construction have been described. The test embankment program yielded valuable data which can be used to improve the design method of geotextile reinforced embankment on soft ground. Based on the results, the following conclusions can be made:

1. The geotextile reinforcements improved the collapse heights of MGE and HGE embankments by 1.1 and 1.6 times, respectively, higher than CE embankment.
2. The critical strain,  $\epsilon_c$ , in the geotextile reinforcement just prior to bearing capacity failure or primary failure of foundation soil can be taken as 2.3 to 3% irrespective of geotextile stiffness and condition of the foundation soil.
3. The limiting strain,  $\epsilon_{lm}$ , at slip failure can be taken as the sum of critical strain,  $\epsilon_c$ , and the localized strain,  $\epsilon_{lc}$ , associated with the slip failure.
4. The geotextile reinforced embankment on soft ground with limitation on foundation deformation not exceeding the unreinforced embankment just prior to the bearing capacity failure or primary failure (embankment height,  $H < \text{critical height, } H_c$ ), the mobilized tensile force in the reinforcement can be obtained assuming the limiting strain equal to critical strain which can be taken as 3% ( $\epsilon_{lm} = \epsilon_c = 3\%$ ). The direction of reinforcing force can be taken as horizontal ( $I_r=0$ ) and the peak strength parameters of embankment fill are suitable.
5. For embankments designed with allowable large deformations where the embankment height,  $H$ , can exceed the critical embankment height,  $H_c$ , the mobilized reinforcing force should correspond to the limiting strain,  $\epsilon_{lm}$ , which is the sum of critical strain,  $\epsilon_c$ , and localized strain at failure,  $\epsilon_{lc}$ . The value of  $\epsilon_{lc}$  can be obtained from the in-soil stiffness of the reinforcement using  $I_r = 0.50$  and using the shear strength parameters of embankment fill at critical state.
6. For single layer reinforcement placed directly on the ground at the base of embankment, the reinforcing force can be taken as free-body force. For multi-layer reinforcements with frictional embankment fill, the effects of reinforcing force in modifying the soil strength at the vicinity of failure surface should be considered.

## ACKNOWLEDGEMENTS

The authors are deeply indebted to the generous financial support of Polyfelt Geosynthetics, Austria and to their past and present staff such as G. Werner, K.H. Loke, J. Smith, P. Delmas, and B.R. Christopher for their technical advises and suggestions.

**Abstract:** This paper describes a case study of a reinforced piled embankment and presents a proposed calculation model. The height of the embankment was 1.7 m, which is lower than that normally accepted for embankment piling according to Swedish regulations. The project includes a field study of displacement and strain in the reinforcement for the alternatives soil fill and cavities below the reinforcement. The cavities were simulated by using foam mattresses below the reinforcement. Displacements at the reinforcement level in the area with soil fill were about 20 mm, while displacements over the mattresses were about 200 mm, i.e. 10 times larger. Calculations were carried out using two analytical models, BS 8006 and Carlsson, and a finite difference method, FLAC. Comparisons are made between measured values and calculated values. In this case the FLAC calculations are judged to give a good picture of the actual behaviour in the construction. The analytical models are too conservative because they do not take the foundation support from the soil beneath the reinforcement into account. The various calculation models were compared to each other and a suggestion for design using an analytical model is made. The model is two-dimensional but an attempt was made to take the three-dimensional behaviour into account. This was done in this case by taking the three-dimensional load and distributing it over the two-dimensioned surface. Aspects of design are provided.

## 1. MÖNSTERÅS CASE STUDY

Embankment piling has been used in Sweden for many years. During recent years some projects have been carried out with reinforcement over embankment piling or deep stabilisation. Monitoring has been carried out in an embankment at Mönsterås.

The case study was of a reinforced piled embankment constructed in 1996 on a section of Route 632 in Mönsterås, Sweden. The Swedish National Road Administration (SNRA) ordered the construction, Scandiaconsult managed it and the Nordic Construction Company was the contractor. The field studies were carried out by Scandiaconsult and the Swedish Geotechnical Institute (SGI). A number of different alternatives were studied in the process of selecting soil improvement on the stretch of road in question, explained below.

- Excavation/refill. Discarded because of the effects this would have on the surroundings. Both on the nearby quay construction and the environment. Furthermore, it would require considerable heavy truck traffic in central Mönsterås.
- Light fill. For sufficient load relief, the light fill would cause uplift at the maximum groundwater level.
- Concrete mat foundation on piles. Feasible but expensive, about twice as expensive as embankment piling.

### 1.1 Soil conditions

The soil consisted of an upper layer of 1 to 3 m of fill beneath which was 2 to 4 m of loose sediments of gyttja and clay which rest on sand and till. The depth to the bedrock was not carefully examined but is probably limited. The thickness of the soil layer in a cross-section of the embankment area varies.

The fill was deposited over a long period of time. The oldest part of the fill was placed with a grillage beneath it. The fill consisted mainly of non-cohesive soil but there was also some

wood and construction waste. The fill varied in stiffness. For design calculations, a dimensioning friction angle of  $32^\circ$  was used.

The gyttja, the thickness of which varies between 0.5 and 2.0 m, contained layers of silt and fine sand. The gyttja was loose with an uncorrected shear strength, according to field vane shear tests, between 10 and 50 kPa. The water content varied between 40 % and 200 % with one measurement of 430 %. For design calculations, a dimensioning, undrained shear strength of 8 kPa was used.

The clay, the thickness of which varied between 0.5 and 2.0 m, contained layers of fine silt. The uncorrected shear strength of the clay varied, according to vane shear tests, between 10 and 70 kPa. The water content varied between 20 % and 60 %. For design calculations, a dimensioning, undrained shear strength of 10 kPa was used.

Both the gyttja and the clay were assessed as being normally consolidated for the existing conditions.

The composition and thickness of the till were not closely examined, but generally it had a high relative stiffness. However, in some areas there were looser layers of sand in the upper surface of the till. For design calculations, a dimensioning friction angle of  $35^\circ$  was used.

Parts of the embankment area have been flooded at the maximum groundwater levels.

### 1.2 Design and construction

The construction consisted of precast concrete piles which were driven down to a firm bottom. The length of the piles was 3 to 6 m. Pile caps were placed above the piles covering 25 % of the embankments surface area. The reinforcement consisted of a biaxial polyester geogrid, with 84 kN/m tensile strength at break and a tensile strength of 16 kN/m at 3 % strain according to EN ISO 10319 (TexGrid TG 75-75). The geogrid was laid in one layer. The embankment fill consisted of crushed rock, 0 to 200 mm. A cross-section of the construction is shown in

Figure 1. The height of the embankment is 1.7 m which is lower than that normally accepted in Swedish regulations. In order to obtain permission to build the construction, the designer was forced to verify that the design would function as intended. Verification took place through calculations supplemented with field monitoring.

The embankment fill was compacted with a 2-ton roller. The first layer over the reinforcement was 0.5 m when compacted. Thereafter compaction took place in 0.3 m lifts. In the area with measurement equipment, a 600 kg vibratory plate compactor was used in order not to destroy the monitoring equipment. The fill was placed in two stages. In the first stage fill was placed to 0.7 m over the reinforcement and in the second stage to the total of 1.6 m above the reinforcement.

### 1.3 Design

For design of the soil reinforcement, calculations were carried out according to British Standard (BS 8006, Draft) 1995, Equation 1 and according to (Carlsson 1987), Equation 2. The most significant differences between the models are the forces in the reinforcement due to the vertical load. These differences arise from the way that the models analyse the arching effect. These forces are compared in Table 1. The results differed, in this case with the lowest forces in the reinforcement according to BS 8006. The procedure used in BS 8006 produces relatively large jumps in the calculation results at certain embankment heights. The jumps depended on whether or not an arching effect arose and how the load was distributed between piles and reinforcement. Care should be taken, especially with new standards and results should be checked which are near such limits. The geometry of the Mönsterås project was close to such a limit. The SNRA therefore decided to carry out such a check within the framework of the SGIs planned work on the regulations for the SNRA in Sweden.

The calculations according to BS 8006 are as follows:

For  $H > 0.7$  (c-a) the distribution over pile load/soil load is;

$$p'_c / \sigma'_v = (C_c \cdot a / H)^2$$

For  $H > 1.4$  (c-a) the distributed load on and the force in the soil reinforcement are;

$$W_T = \frac{1.4c f_{fs} \gamma (c-a)}{c^2 - a^2} [c^2 - a^2 (p'_c / \sigma'_v)]$$

$$T_{rp} = \frac{W_T (c-a)}{2a} \sqrt{1 + \frac{1}{6\epsilon}} \quad (1)$$

The calculations according to Carlsson are as follows:

$$d = (c-a) \sqrt{\frac{3\epsilon}{8}}$$

$$P_b = \frac{(c-a)^3}{16 \tan 15^\circ} \gamma \frac{1}{2d} \sqrt{1 + \frac{16d^2}{(c-a)^2}} \quad (2)$$

- Where  $H$  = embankment height (1.7 m)  
 $c$  = centre distance between pile caps (2.4 m)  
 $a$  = pile cap width (1.2 m)  
 $d$  = displacement (d)  
 $C_c$  = pile type factor, end-bearing piles ( $1.95 H/a - 0.18$ )  
 $\gamma$  = unit weight of embankment fill ( $20 \text{ kN/m}^3$ )  
 $f_{fs}$  = partial coefficient for soil load (1.0)  
 $\epsilon$  = strain  
 $W_T$  = the distributed vertical load acting on the reinforcement (kN/m)  
 $T_{rp} = P_b$  = force in the reinforcement (kN/m)

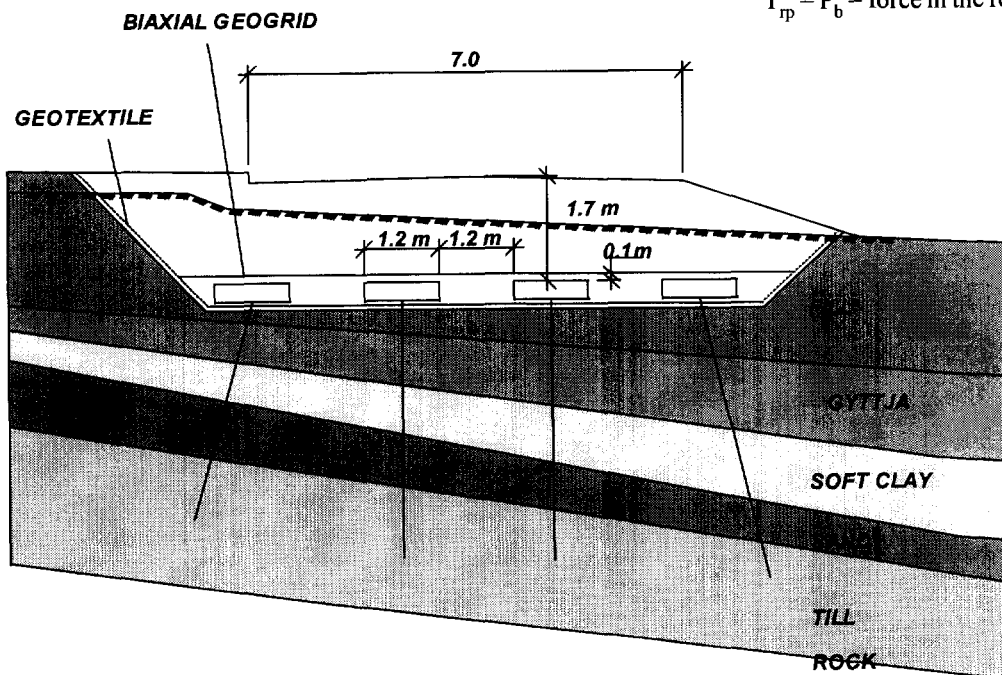

Figure 1. Cross-section of Route 632 in Mönsterås.

Calculations using the BS 8006-model (fictive three-dimensional) gave a force on the basis of the vertical load between the pile caps of 18 kN/m at a strain of 6 %. Calculation according to Carlsson (two-dimensional) gave a force of 26 kN/m and a displacement of 0.18 m at a corresponding strain. In order to verify these results, other calculations were carried out using the two-dimensional finite difference program, Fast Lagrangian Analysis of Continua (FLAC), Version 3.30 (Itasca 1995). The calculations showed that there was arch formation, even for the low embankment height studied here, and that the displacement at the road surface was negligible. Calculations were carried out for cases with both cavities and soil fill under the reinforcement. The elastic modulus times area, EA = 400 kN/m, was used for the FLAC calculations. In implementation, however, a somewhat more rigid reinforcement was used. Table 1 shows the results from the calculations.

Table 1. Design results of the analytical and finite difference models.

Method	Strain $\epsilon$ (%)	Displacement d (m)	Force $F_v$ (kN/m)
Carlsson	2	0.10	42
	6	0.18	26
BS 8006	2	0.10	28
	6	0.18	18
FLAC Foundation support cavity	0.08	0.01	1
	3.5	0.13	14

#### 1.4 Field monitoring of strain and displacement in the reinforcement

The quality control was supplemented with measurements in an attempt to clarify the effect of the reinforcement and compare measured values with the calculation models. The monitoring was carried out in two areas of the embankment, as shown in Figure 2. One area consisted of the normal construction with soil fill between the pile caps. The other area consisted of foam mattresses between two rows of pile caps in order to simulate a cavity under the reinforcement. The mattresses were 0.55 m high and had an area of 1.2 m by 6.0 m. The monitoring consisted of vertical displacement and strain measurements in the reinforcement and displacement measurements on the road surface.

Figure 2. Plan of field monitoring area for Route 632 in Mönsterås.

The vertical displacements of the reinforcement were measured using settlement gauges, type SGI. The measurement results are shown in Figure 3. The displacement in the area with the soil fill was about 20 mm. Displacement measured over the mattresses between the pile caps was 173 and 206 mm while displacement on the diagonal was 212 and 213 mm. The larger displacement on the diagonal is probably due to three-dimensional effects. However, the full effect is not obtained since the mattresses are only lying between the pile caps in one direction and soil fill is between the pile caps in the cross direction.

The strains in the geogrids were measured with Bison coil strain gauges screwed into the geogrids. They are designed for synthetic geogrids and have a measurement accuracy of 2.5 micrometers. Theoretically, the largest strains are obtained at the cap edge. Where there is a cavity under the reinforcement, the strain is nearly uniform between the pile caps. To examine the differences between the cap edge and the middle of the cavity, measurements were carried out both between the pile caps and at the cap edge. The strain measurements between the caps also gave the opportunity to compare these with measured displacements. Field measurements of horizontal movements were made, which were then calculated into strains and forces.

The strains are shown in Figures 4 and 5. The strain gauge locations are shown in Figure 2. In spite of a high measurement accuracy in the strain gauges, the distribution of results at the pile cap edge is large. This may be due to edge

Figure 3. Measured vertical displacement in the area with soil fill and foam mattresses respectively.

effects. In the mattress area the strains close to the edge of the pile caps were 0.5, 1.6, 2.1 and 4.5 %. At the midpoint between and along the pile caps the strains were 0.4, 0.6, 0.7 and 1 %. At the midpoint between and across the pile caps they were 1.8, 2.9, 3.0 and 3.2 %. Corresponding tensile forces were 5 to 23, 4 to 9 and 12 to 17 kN/m.

### 1.5 Monitoring of displacements on the road surface

The displacements on the road surface were measured with settlement plates placed 0.7 m under the surface and surrounded by protective tubing. The embankment fill material was assessed as being non-susceptible to frost heave. Measurements of the displacements in the surface did not begin until all the embankment fill had been placed in November 1996. Displacements also occurred during the laying and compaction processes. Unfortunately these displacements could not be documented.

The measured displacements varied between 5 and 10 mm. Most of these were formed within one month after the embankment fill had been completed. No significant differences on the road surface were observed between the area with and without mattresses.

### 1.6 FLAC calculations to evaluate the field behaviour

To find the reasons for the differences between predicted and measured displacements and geogrid strains supplementary FLAC calculations were carried out. The primary aim was to study the case where a cavity arises under the reinforcement between the pile caps.

The embankment was symmetrical about its centre line so only one side of the embankment was modelled. If the mattress had also been used in side sections, rather than just the centre of the embankment, the modelled section could have been reduced to 1.2 m in width. Instead, the modelled section

Figure 4. Measured strains in the reinforcement for case with soil.  
a) along and in the middle between the pile caps.  
b) across and at the pile caps.

Figure 5. Measured strains in the reinforcement for case with soil fill and foam mattresses.  
a) along and at the midpoint between the pile caps.  
b) across the pile caps both at the midpoint between and at the pile caps.

was 3.6 m wide and 2.15 m high. It spanned horizontally from the centre of the mattress area across a footing and soil area to the centre of the second footing. Vertically it spanned from the bottom of the mattress to the top of the fill. The material locations were shown in Figure 1. A variety of grid meshes were tested. A 36 x 28 grid was selected to optimise the calculation time and precision of the results.

The geogrid was modelled using the cable element in FLAC. Values used in this analysis for the cable element are shown in Table 2. The cable element was chosen, rather than the beam element, because the cable element can model the soil/geogrid interaction. The Mohr-Coulomb plasticity model was used for the soil. The mattress was modelled elastically with its moduli based on laboratory unconfined compression tests. Finally, the footings were modelled as null elements with fixed boundary points.

Table 2. Cable element input values used to model a geogrid.

FLAC parameter	Magnitude and units
elastic modulus · area	600 kN/m
perimeter	2 m/m
yield	75 kN/m
kbond	17,000 kPa (maximum)
sbond	0 kPa
sfriiction (assumed = soil)	42°

Ideally the kbond and sbond should be obtained from laboratory and field pullout tests using the fill material. Because these tests were not available, Equation 3, based on the definitions in (Itasca 1995), was used to obtain values for the kbond.

$$kbond = (sbond + perimeter \cdot \sigma' \cdot \tan(sfriiction)) / \delta_{max} \quad (3)$$

The perimeter was chosen to be the maximum of 2 m for the geogrid, as opposed to its surface area, because there is frictional resistance on both the top and bottom of its surface and significant passive resistance where the holes in the grid meet the spanning grid elements.  $\sigma'$  is the overburden pressure at the level of the geogrid. It should be noted that the kbond increases with the overburden pressure as the embankment is constructed. Finally,  $\delta_{max}$  is the geogrid displacement when the maximum pullout resistance is reached. For the geogrid used in this project 3 mm was used.

The maximum displacement occurred at the mattress/geogrid interface at the midpoint between pile caps. The displacement and tensile force distribution in the geogrid are shown in Figure 6.

Compaction of the fill was modelled as a static pressure applied during the construction of the embankment. The compactive effort was modelled by adding an equivalent static load of 20 or 50 kPa and stepping to equilibrium. When equilibrium was reached the load was removed and FLAC stepped again to a new equilibrium. The equivalent static load used in FLAC for compaction was only an estimate. Therefore, two values were chosen in-between the compaction equipment's static load and its centrifugal vibratory force of 12 and 100 kPa, respectively. The incremental displacements and the effect of the static compaction loads for the base case are shown in Figure 7. The compaction was modelled at 0.5, 0.7, 1.0, 1.3 and 1.6 m embankment heights. The effect on displacement at the geogrid was only significant for the first two compactions.

Figure 6. Base case displacement and tensile force distribution in the geogrid.

Figure 7. Base case maximum geogrid settlement versus embankment height.

Figure 7. Base case maximum geogrid settlement versus embankment height.

The arching effect between pile caps reduced the incremental portion of load carried by the geogrid as the fill height increased. Thus the displacement did not increase at the same rate as the embankment was constructed. The arching effect between pile caps is shown in Figure 8. Figures 6 and 8 show that the surface displacement is relatively small.

Five models were analyzed in FLAC. The base case model had the geogrid, mattress, pile caps, and fill all modelled as they are in the field. A fictive 3D model attempted to account for the three dimensional effects of the lateral spacing between pile caps by increasing the weight of the fill by the equivalent increased area of 50 %. Next, air was modelled between all the pile caps to compare the design assumptions with the FLAC results. Because the air was modelled in all the areas around the pile caps the geogrid had relatively high tensile stresses from settlements on both sides of the pile cap. Also the geogrid was not able to move toward either side as it could in the mattress case. Compared to the mattress model, the air model had smaller displacements and higher geogrid tensile forces and strains. The final two models had soil modelled below the geogrid as it was in most of the embankment. Unlike the mattress and air, the soil was stiffer than the gytija below the footing. Therefore much of the displacement

## Soil

Figure 8. Arching effect as shown by y-displacement contours.

occurred in the gytja. Thus the soil models required that the lower fill and gytja be included in the calculations. The material properties of the gytja were not known with much certainty, so the soil model calculations are provided to show only approximate magnitudes.

The results from the FLAC calculations are summarized in Table 3.

In these models the most important input parameters affecting the magnitude of the settlement in the embankment were the following: moduli of the soil or mattress between pile caps, elastic modulus times area of the cable, amount of compaction, depth of fill when compacted, the soil/geogrid bond properties and the fill properties.

## 1.7 Comparison between calculations and field measurements

A comparison was made between the values obtained in design and the values measured for vertical displacements and forces in the reinforcement.

For the case with the mattress the calculated tensile force was 10 kN/m and the displacement about 0.14 m in FLAC. Modelling compaction of the fill increased the displacement between 10 and 50 mm and the tensile force between 3 and 9 kN/m. The forces measured in the area with mattresses were generally somewhat higher than calculated, as was the displacement. One of the causes may be three-dimensional behaviour. FLAC calculations in two dimensions were estimated to give a good understanding of the behaviour of the construction, but it was somewhat uncertain. One way of taking the three-dimensional behaviour into account was to increase the density by 50 %, which corresponds to a load distribution according to Figure 11. Such a calculation gave a displacement of 0.18 to 0.2 m when the compaction effect was taken into account. This was closer to the results in the field which were 0.17 to 0.21 m. The strain in the geogrid in the field between the caps was 3 %, which the FLAC calculation also showed for the compaction case. For the case with soil below the geogrid the displacement according to the FLAC calculation was 12 mm and the tensile force was 0.4 kN/m without compaction. If the fictive three-dimensional effects were taken into account as mentioned above then the calculated displacement was 23 mm. Modelling compaction of the fill increased the displacement between 10 and 45 mm and the tensile force between 1 and 9 kN.

In the soil case the displacements without compaction corresponded better to the field measurements. On the other hand the displacements are small and there are large uncertainties in the properties for the soil below the pile caps. Therefore the model of the case with mattresses is more reliable.

Because the resistance of the foundation soil is considerable the analytical calculation models in this case gave a misguided picture of the actual behaviour of the construction. The FLAC calculations on the other hand gave a good picture of the behaviour on the condition that the pertinent input data was used. If a cavity should arise under the reinforcement then the analytical models are thought to be appropriate, but the three-dimensional effects should be taken into account.

Table 3. Results from FLAC.

Model Description	Maximum Settlement* (mm)	Maximum Cable Tensile Force (kN)	Maximum Cable Strain (%)

## 2. PROPOSED ANALYTICAL CALCULATION MODEL

With an active reinforcement, the size of the caps can be reduced. It is also possible to choose a lower embankment height than the 2.5 metres which is today the lowest permitted in Swedish regulations.

In order to be able to propose a model which is suitable for design of reinforcement over embankment piling, the SGI carried out a pre-study by the assignment of the SNRA where a number of calculation models were compared. In that comparison, BS 8006 appeared to be a promising model. In the second stage of the project, BS 8006 was compared with FLAC calculations to get a closer idea of the actual behaviour. That comparison showed that at the degree of cap coverage which is normally used in Sweden between 20 to 30 % (to be compared with those on which the method is based, which are usually around 8 to 16 %) the calculations did not agree. Better agreement was reached when Carlsson's method was compared to the FLAC calculations. This method had been modified to take into account the three-dimensional effects and reduced embankment heights.

### 2.1 Prerequisites

The calculation assumes arch formation and that the reinforcement is deformed during loading. The reinforcement is assumed to be placed in one layer. The function of the reinforcement is greatest if it is placed closest to the pile caps, but it should for practical reasons be about 0.1 m above the pile caps.

In order to ensure that the displacements in the road surface are not too large, the embankment height should be at least as large as the distance between the pile caps, a minimum of 1.0 m high, and the degree of cap coverage should be at least 10 %.

It is recommended that calculations should be carried out for an initial strain of a maximum of 6 % and with a remaining creep strain after the construction period and during the lifetime of the construction of an additional 2 % at most. Figure 9 shows the symbols used in the proposed calculation model.

Figure 9. Symbols used in the proposed calculation model.

where  $c$  = distance between the pile centres (m)  
 $a$  = side length of the pile caps  
 $Ha$  = embankment's height above the reinforcement (m)  
 $\gamma$  = unit weight of embankment fill ( $\text{kN/m}^3$ )  
 $d$  = maximum displacement of the geosynthetic (m)  
 $s$  = arc length of the displaced geosynthetic (m)

### 2.2 Vertical load transfer

The method is based on the formation of an arch which spreads the soil load onto the pile caps. The cross-sectional area of the soil under the arch, which is the load carried by the rein-

forcement geogrid, is approximated using the soil wedge described in Figure 10. This applies even if the embankment height is lower than  $(c-a)/2 \cdot \tan 15^\circ$ , which is the height of the soil wedge.

Figure 10. The soil wedge which is carried by the geosynthetic.

The weight of the soil wedge,  $W$ , according to Figure 10 is:

$$W = \frac{(c-a)^2}{4 \cdot \tan 15^\circ} \cdot \gamma \quad \text{kN per metre in depth.}$$

The arc length of the geogrid when it is displaced by the load of the soil wedge, can be calculated as follows:

$$s = (1 + \epsilon)(c-a) = c-a + \frac{8}{3} \cdot \frac{d^2}{c-a}$$

where the displacement,  $d$ , is dependent on the strain in the geosynthetic,  $\epsilon$ , according to:

$$d \approx (c-a) \sqrt{\frac{3}{8} \cdot \epsilon}$$

The force in the reinforcement,  $F$ , in two-dimensions is calculated using the catenary equation:

$$F_{2D} = W \cdot \frac{(c-a)}{8d} \sqrt{1 + \frac{16d^2}{(c-a)^2}}$$

The three-dimensional effects are estimated through load distribution according to Figure 11, where the load is distributed over the surface according to the figure and is taken up by the reinforcement along the edge of the pile cap. The force is calculated as follows:

$$F_{3D} = \frac{1 + c/a}{2} F_{2D}$$

where,

$F_{3D}$  = the dimensioned force in the reinforcement due to the vertical load in three dimensions

Figure 11. Load distribution to estimate the forces in the three-dimensional case.

### 2.3 Transverse sliding across the bank and pull-out of the reinforcement

For the necessary reinforcement length on account of transverse sliding across the bank, the bond length and the pull-out length of the reinforcement can be determined according to BS 8006.

## 3. CONCLUSIONS

In design with analytical models, the foundation support of the soil between the pile caps is not normally taken into account, but field measurements showed that the effect can be considerable. For the relatively low embankment height used here, it appeared that the displacement which arises in the reinforcement does not affect displacements in the road surface. In this case, the FLAC calculations are judged to give a good picture of the actual behaviour of the construction. Three-dimensional effects should however be simulated. Here they were fictively simulated by increasing the density of the fill.

Analytical calculation models are judged reasonable if there is a risk that a cavity will arise under the reinforcement. They are though often more conservative than if FLAC calculations are made for cavities. The proposed calculation model has proved to give better agreement with the FLAC calculations than other methods at the degrees of cap coverage which are normally used in Sweden, i.e. 20 to 30 %. Soil with poor properties can give support initially but settlement can arise even after the construction period. Thus in low embankments there is a risk that settlement which arises after the completion of the road could cause displacements in the road surface, and this must be taken into account in design. The force in the reinforcement is also greater if the soil settles than if there is resistance. Future changes to the load situation, e.g. a ground water lowering, can affect the foundation support of the soil and in such cases it should be assumed that a cavity has arisen.

Compaction of the fill above the reinforcement significantly affects the tensile force and moderately affects the displacement of the reinforcement. This is very important if the compaction is carried out at low fill heights above the reinforcement. The effect of compaction is not normally taken into account in calculations but should be considered if foundation support from the soil is assumed.

The results of the field study showed a large difference in the strain measurements close to the pile cap edge, possibly due to edge effects. This makes the cap edge strains difficult to compare with the calculation model. The strains measured in the center of the pile caps show a smaller difference and compare well with the FLAC model. Some effects of three-dimensional behaviour could be seen in the field measurements. A larger area with mattresses would have better simulated what actually happens if a cavity appears under the reinforcement. In this case the measurements were conducted on a road construction and the risk of having to rebuild large areas of the embankment, if the displacement of the road surface proved too great, was not acceptable.

For many cases the analytical calculation models that assume cavities below the geogrid are too conservative in estimating the forces in the geogrid. The finite difference model showed much better agreement with field measurements because it included the soil foundation support beneath the reinforcement. A study by (Jones et al, 1990) concluded that current simplified analytical procedures are conservative due to quantifying the arching mechanism and that they can not accurately take into account partial foundation support. There is a need for finite element or difference methods to model the complex interaction behaviour. Additional full-scale field testing and modelling is necessary to better understand the processes involved here.

The three-dimensional effects should be studied with field studies using larger areas with simulated cavities. Modelling should also be done with three-dimensional programmes to verify the differences between two- and three-dimensions. Until three-dimensional programmes become more common there is a need to model in two-dimensions, with relevant additions to take the three-dimensional behaviour into account.

## ACKNOWLEDGEMENTS

The authors would like to thank Mr. F. Burman, SGI, who carried out the measurements, Mr. M. Åberg, SNRA, assistant project leader, Mr. P-E Bengtsson, SGI, for his views on the choice of parameters and Mr. T. Eng, Engtex, for help with the properties of the reinforcement.

The project described in the article was funded by SNRA and SGI.

Douglas Lindquist's participation in the project was possible thanks to a grant from the Valle Scandinavian Exchange.

# Embankment Support Over Piles Using Geogrids

C G Jenner and R A Austin

Tensar Division, Netlon Limited, New Wellington Street, Blackburn, UK

D Buckland

Clwyd County Council Highways Department, Clwyd, UK

## ABSTRACT:

The construction of embankments over soft ground is a common engineering problem. In situations where the underlying soil is highly compressible or for approach embankments to bridges, minimising the total and differential settlement of a new road construction can govern the method of construction.

The paper describes the use of stiff biaxial polypropylene geogrids within granular fill to support embankment loads above piles and vibro concrete columns, VCCs. This technique has been used successfully on many road embankment projects in Europe due its cost effectiveness and ability to deliver an effective embankment support system within a short time frame.

The design and construction of geogrid reinforced load transfer platforms is discussed, including the platform used on the A525 Rhuddlan Bypass in North Wales, where due to underlying soil conditions, a piled solution employing VCCs was used, to carry the embankment loads through the soft layers into the firmer strata below.

To ensure that the load transfer platform (LTP) performed as expected, instrumentation was included in the platform construction to monitor platform settlement, geogrid strains and deflections. The installation and results of the instrumentation monitoring are described.

**KEYWORDS:** Embankments, Geogrids, Piles, Design, Monitoring

## 1 INTRODUCTION

The growing use of geosynthetic solutions for construction over soft and variable ground confirms their importance in overcoming complex geotechnical problems.

Increasingly utilised under embankments constructed on piles or vibro concrete columns (VCCs), is a geogrid reinforced granular load transfer platform. Used in several major UK projects, the technique is growing in popularity in Europe because it offers a rapid, cost effective solution within a predictable construction programme.

The platform functions by transferring loads imposed by the embankment to pile caps via a grid-reinforced basal layer. Biaxial geogrids, with high stiffness at low strain, are placed in several layers to interlock with, and reinforce the granular fill to create a flexurally stiff platform which distributes loads evenly and reliably to the piles. The supporting piles or VCCs pass through the soft soil layer and transmit load to the stable ground beneath, thus reducing settlement and removing the need to pre-consolidate the ground to remove permanent settlement and improve ground bearing properties.

## 2 LOAD TRANSFER PLATFORM CONCEPTS

The design of a load transfer platform can be carried out in different ways:

1. Tension membrane approach, using high strength tension membrane theory.
2. Improved arching approach, using low strength reinforcement.

The most common approach for embankment support over piles is to adopt the tension membrane approach. This requires the reinforcement to carry the full amount of any vertical load above the geosynthetic, less allowance for load shedding in the overlying fill.

The improved arching approach differs from the tension membrane theory only in respect to the calculation of the vertical load shedding and relies on the ability of the reinforcement used to interlock with the granular embankment fill and enhance the natural arching angle of the fill, thus reducing the vertical load to be supported by the reinforcement. Both design methods can be carried out in accordance with the limit state design principles defined in BS 8006.

When constructing load transfer platforms using the improved arching approach, the mechanism of load transfer is one of arching taking place in the granular platform. The purpose of the geogrids spanning across the pile/VCC heads is to enhance the transfer of vertical loading onto the piles/VCCs and subsequently through the piles/VCCs to the foundation soils.

In order to control differential settlement at the proposed ground surface, the geogrids need to adequately retain the soil between the arching angles of adjacent VCCs. A minimum height of fill above the load transfer platform of at least the platform thickness is normally employed to ensure that the arch is always loaded and that the VCC positions are not reflected up to the ground surface causing surface undulations.

Stiff integral biaxial geogrids, due to their unique element geometry and junction strength, interact with the fill and create a composite beam where the fill's shear strength properties are utilised effectively. The improved arching design approach is specific to a type of integral geogrid which has been proven to enhance the natural arching angle of granular fill when a multi-layer solution is employed, Guido 1987.

Research into the load transfer characteristics of the geogrid/fill composite has shown that the load spread through fill can be conservatively taken as  $45^\circ$  providing that the peak internal angle of friction of the fill is at least this value.

Whichever design approach is used, the design must ensure that the geosynthetic is sufficiently well anchored in the fill material, to permit the transfer of the design load into the reinforcement. This requirement can lead to long anchorage lengths where high strength reinforcement solutions are employed.

Geogrid load transfer platforms designed adopting the enhanced arching approach have been successfully used on a number of major projects in Europe, including the Gdansk Urban Highway, Topolnicki 1996 and the Second Severn Crossing Toll Plaza, Maddison et al. 1996.

### 3.0 CASE STUDY

#### 3.1 A525 Rhuddlan Bypass

Rhuddlan is a small town standing between the coastal town of Rhyl and the main A55 trunk road, in Denbighshire (formerly Clwyd), North Wales. During the summer months large traffic volumes leave the A55 and travel through the centre of Rhuddlan on their way to the coast causing severe congestion.

In May 1995 a two year £11 million contract was started for the construction of 2km of 7.3m wide two lane dual carriageway bypass to the town, which included upgrading an existing section of highway and the construction of a

Figure 1 Typical cross-section through Rhuddlan bypass load transfer platform.

430m long 11-span twin deck viaduct, with a 46m centre span over the River Clwyd.

The approach embankment to one side of the viaduct crossed an area of 7-8m of peat and soft silty alluvial strata overlying sands and gravels. To support the embankment over this area the construction contract specified cast in situ driven piles under a 800mm thick un-reinforced rolled concrete supporting raft. Contractor Edmund Nuttall proposed a VCC and load transfer platform solution as an economic and rapidly constructed alternative to the specified design.

The accepted solution for the embankment support was to install VCCs at the appropriate centres to support the loads from the embankment which varied in height from 4m to 7m. The layout of the VCCs was a triangular pattern with centre to centre dimensions of 2.65m, 2.35m, 2.05m, and 1.75m, the closer centres supporting the higher sections of the embankment.

#### 3.2 Load transfer platform design

The geogrid reinforced load transfer platform varied in height, 650mm, 800mm and 950mm, depending on the particular VCC layout with the number of geogrid layers being 3No. in the 950mm thick sections and 2No. in the 800mm and 650mm sections. As the distance between the VCCs reduced the load transfer platform thickness required for the arching mechanism to develop also reduced.

The LTP was designed assuming a grid strain of 5% in 120 years. This level of strain was assumed to represent the ultimate limit state condition for the platform, which can only occur in conditions where the underlying soil would degrade or collapse, i.e. waste fills. Such conditions did not occur on this site. For the in-service condition some support to the fill beneath the developed arch will always be provided by the underlying soil, leading to a reduced level of strain in the geogrid. A typical cross section through the construction used is shown in Figure 1

Table 1 Properties of Geogrids used in the Rhuddlan Bypass Load Transfer Platform

Grid Property		Tensar SS1	Tensar SS2
		Grid Type 1	Grid Type 2
Quality Control Strength*	LD	12.5 kN/m	17.5 kN/m
	TD	20.5kN/m	31.5 kN/m
Approximate Peak Strain	LD	12.0%	12.0%
	TD	10.0%	10.0%
Load at 2% Strain*	LD	4.5 kN/m	7.0 kN/m
	TD	6.0 kN/m	12.0 kN/m
Load at 5% Strain*	LD	9.5 kN/m	14 kN/m
	TD	15.0 kN/m	23.0 kN/m
Typical Rib Thickness	LD	0.7mm	1.20mm
	TD	0.5mm	0.90mm

\* Determined as a lower 95% confidence limit in accordance with ISO 2602 1980 (BS 2846 Part 2 1981).

and properties of the reinforcement used are given in Table 1. Approximately 18 000m<sup>2</sup> of biaxial geogrid was installed to construct the 6000m<sup>2</sup> of load transfer platform over VCCs installed by Keller Foundations Ltd.

Due to the critical nature of the project the Client, Clwyd County Council requested the Contractors alternative design was subjected to Category II checks and certification. An independent verification of the design was therefore carried out by Clwyd County Council's Design and Construction Division Bridges Group - the designer of the structures.

### 3.3 Monitoring of geogrid strain

To ascertain the performance of the load transfer platform, the bridge designer specified that strain gauges and inclinometers were installed in the reinforced fill. At two locations, inclinometer and strain gauges were installed to monitor development of the arch and geogrid strain.

Prior to installation of the strain gauges, a calibration exercise was undertaken in a tensile testing machine to correlate the strain recorded by the gauges with the actual strain in the grid, Figure 2.

On site, vibrating wire strain gauges were clamped in pairs to both layers of grid, at the centre of the geogrid design span geogrid to measure strain over a 260mm gauge length, Figure 3. At locations A and B, an inclinometer and two pairs of strain gauges were installed on each layer of grid. Station A was under the viaduct bank seat with a vertical pressure of 121 kN/m<sup>2</sup> applied to the top of the reinforced fill. At Station B the platform was supporting a 4m high embankment.

Figure 2 Laboratory calibration of strain gauges.

### 3.4 Results of strain monitoring

Readings taken over a period of one year show that strain developed in the grid during construction, after which the strain remained virtually unchanged, Figure 4 & 5. Once the initial strain had developed during construction the LTP rapidly achieved a state of equilibrium and the grid strains stabilised, with no evidence of creep being apparent. As used in the LTP design, partial support of the fill under the arch was shown to have occurred by a reduced level of strain in the geogrid from that assumed being recorded.

Figure 3 Installation of strain gauges on geogrid

Figure 4 Geogrid strain readings at Station B Lower Grid - Grid Type 2

Figure 5 Geogrid strain readings at Station B Upper Grid - Grid Type 1

One of the simplified assumptions made during the design check was that half the weight of the fill under the arch would be supported by the foundation soil and half by the geogrid layers. It was further assumed that the strain in the upper grid would be less than that in the lower grid. The initial strain calculated by this approach was found to be of similar magnitude to that recorded by the strain gauges over the monitoring period.

#### 4.0 CONCLUSIONS

1. The geogrid reinforced load transfer platform used on the Rhuddlan Bypass project provided a cost effective solution to the problem of embankment construction over soft ground.
2. The monitoring undertaken revealed that the geogrid reinforcement was providing restraint to the fill to enable enhanced arching within the fill to occur.
3. Recorded geogrid strains were as allowed for in the design.
4. Due to the interlock of the geogrid with the fill and the development of a composite material, no evidence of creep of the geogrid was recorded.
5. Higher grid stains were recorded in the lower grid than the upper grid as anticipated in the design.
6. The use of low strength, stiff biaxial geogrids and the enhanced arching design approach is a viable alternative to the use of high strength reinforcement and tension membrane theory, for the construction of embankments over piles.

#### ACKNOWLEDGEMENTS

The Authors wish express their thanks to the Highways and Transportation Department of the former Clwyd County Council and subsequently the Technical Services Department of Denbighshire County Council for the provision of monitoring data for inclusion in this paper.

**ABSTRACT:** Empirical methods have been in use for some time to design geosynthetic materials to carry embankment loads over piles. Some methods have used simple two-dimensional models based on little more than load spreading procedures which generally ignore three-dimensional effects. Other methods have attempted to address the three-dimensional nature of the problem by basing the design method on behaviour observed in experimental work. The paper describes work which has been carried out using two- and three-dimensional finite difference techniques that better represents the problem's full complexity. A study has been carried out which compares the two- and three-dimensional analyses for various piled embankment geometries. A comparison is also made between the two and three-dimensional finite difference analyses and the current British design standard, BS 8006. The paper also gives recommendations for design.

**KEYWORDS:** Design, Embankments, Finite Element Analysis, Geosynthetic Reinforcement, Soft Soils.

## 1. INTRODUCTION

Construction of roads, railways and buildings is increasingly carried out on foundations that would previously have been considered unsuitable. In order to construct these structures with confidence and within the available time it is often necessary to adopt a piled solution. Piles are installed through the soft subsoil material. The piles are much stiffer than the subsoil and therefore differential settlements occur. These differential movements generate shear stresses within the embankment which increase the load on the piles and decrease the load on the subsoil. This mechanism is called arching.

In order to place the relatively expensive piles as far apart as possible, a relatively inexpensive geosynthetic material is included at the base of the fill. The geosynthetic picks up the vertical load not carried directly by the piles and goes into tension. The difficulty in design is to assess the amount of vertical load which is carried by the geosynthetic and the tension which this load generates in the geosynthetic.

A typical piled embankment layout is shown in Figure 1. For analysis and design a two-dimensional (2D) model, Figure 2, has often been used. However, in reality, the problem is three-dimensional (3D), Figure 3.

A research project has been undertaken to better understand the behaviour of the piled embankment system. The finite difference programs FLAC and FLAC<sup>3D</sup> (ITASCA, 1993) have been used to carry out a series of 2D and 3D numerical analyses. These are compared to assess the appropriateness of each approach.

Figure 1. A cross-section through a typical piled embankment.

Figure 2. Two-dimensional representation of the piled embankment problem.

Figure 3. Three-dimensional representation of the piled embankment problem.

Due to the uncertainty of the subsoil behaviour it is generally assumed that the entire vertical load of the embankment is carried by the piles, either by soil arching or transferred by the geosynthetic.

In order to compare design methods a parameter, the Stress Reduction Ratio  $S$  has been defined (after Low, Tang and Choa, 1994). The Stress Reduction Ratio is defined as the ratio of the average vertical stress carried by the geosynthetic  $p_r$  to the average vertical stress  $\gamma H$  due to the embankment fill of height  $H$ :

$$S = \frac{p_r}{\gamma H} \quad (1)$$

The stress reduction ratio  $S$  is written  $S_{2D}$  or  $S_{3D}$  for two- and three-dimensional conditions respectively.

## 2. NUMERICAL ANALYSIS

An initial series of 2D numerical analyses was performed using the finite difference program FLAC. A cross section of the embankment was considered in plane strain for which the pile is represented as a strip foundation. A typical mesh geometry is shown in Figure 4(a).

However, the piled embankment problem is truly 3D (Figure 3); neither plane strain nor axisymmetric analyses accurately reproduce the behaviour. (In axisymmetric analysis, an umbrella shaped arch resting on a single central pile cap is produced). A second series of analyses was performed using the 3D finite difference program FLAC<sup>3D</sup>. A typical mesh geometry for these analyses is shown in Figure 4(b). In 3D the arching can be thought of as producing a dome resting on four pile caps. In both the 2D and 3D analyses, the fill material was modelled as linear elastic with a Mohr-Coulomb yield criterion ( $E' = 20 \text{ MPa}$ ,  $\nu' = 0.2$ ,  $\phi' = 30^\circ$ ,  $c' = 5 \text{ kPa}$  and  $\gamma = 20 \text{ kN/m}^3$ ). The geosynthetic, installed at the base of the fill, consisted of one-dimensional linear elastic elements capable of sustaining axial tension but no bending (a single line of elements in 2D and a grid of elements in 3D with a stiffness  $J = 9500 \text{ kN/m}$ ). In the analyses presented the subsoil was not included (which reproduced

the assumption made in all current design methods), although analyses have subsequently been carried out where the subsoil was included. The pile was assumed rigid with the base of the mesh fixed vertically to represent the pile cap.

For both the 2D and 3D analyses, the embankment fill material was modelled as being installed in a number of lifts. After each lift deformation occurs and the geosynthetic tension increases. The analysis therefore models an embankment constructed very slowly under drained conditions with full consolidation of the subsoil between lifts.

Figure 4. Mesh geometry for (a) 2D analyses, and (b) 3D analyses.

Figure 5. Stress reduction ratio in two-dimensional analyses.

Figure 6. Stress reduction ratio in three-dimensional analyses.

Figure 7. Maximum displacement in two-dimensional analyses.

Figure 8. Maximum displacement in three-dimensional analyses.

Figure 9. Average geosynthetic tension in two-dimensional analyses.

Figure 10. Average geosynthetic tension in three-dimensional analyses.

Analyses were performed in which the pile width  $a$  to pile spacing  $s$  ratio was varied with the fill and geosynthetic properties held constant. The behaviour of the system was assessed in terms of the stress reduction ratio (Figure 5, Figure 6), the average tension generated in the geosynthetic (Figure 7, Figure 8), and the maximum displacement at the base of the embankment (Figure 9, Figure 10), for 2D and 3D analyses respectively.

### 3. DISCUSSION OF ANALYSIS RESULTS

In both the 2D and 3D analyses, the stress reduction ratio decreases as  $a/s$  ratio increases. This is a result of the piles being closer together allowing arching to develop. Also, the stress reduction ratio decreases as the height increases until a critical height is reached after which the stress reduction ratio is virtually constant. This behaviour is explained by the ability of the arching mechanism to develop as the height increases. There is a point at which 'full arching' develops. When this occurs the load carried by the geosynthetic increases proportionally to the embankment height.

The stress reduction ratio determines the maximum displacement and the geosynthetic tension. The higher the stress reduction ratio the larger the maximum displacement and the larger the geosynthetic tension.

The numerical analyses presented demonstrate the need to analyse the piled embankment in 3D rather than 2D. Comparing Figures 6 and 7, it can be seen that the stress reduction ratio is significantly higher in the 3D analyses than in the 2D analyses for any given  $a/s$  ratio. Consequently, the maximum displacement at the base of the embankment and the tension generated in the geosynthetic are underestimated if the 3D nature of the problem is ignored. This behaviour is intuitively correct as the proportion of pile is less in the 3D case ( $a^2/s^2$ ) than in the two-dimensional case ( $a/s$ ).

### 4. BS 8006 DESIGN METHOD

The method used in the current BS 8006, Code of practice for strengthened/reinforced soils and other fills (1995) to design geosynthetics over piles was initially developed by Jones et al. (1990). An assessment of the degree of arching taking place in the embankment fill is made using Marston's formula for positive projecting subsurface conduits (Spangler and Handy, 1973; Young and O'Reilly, 1983). BS 8006 introduces a critical height concept, Figure 11, with the critical height assumed to be equal to  $1.4(s-a)$ , where  $s$  is the pile spacing and  $a$  is the width of the pile cap.

If the embankment height is below the critical height Figure 11(a), the load carried by the geosynthetic is the embankment load reduced due to the arching in the embankment fill plus any surcharge loading on the top of the embankment. For embankment heights greater than

Figure 11. BS 8006 critical height concept.

the critical height, Figure 11(b), it is assumed all loads above the critical height are transferred directly to the piles as a result of arching in the embankment fill.

The load on the geosynthetic is assumed to be a distributed load between adjacent pile caps and the resultant deflected shape of the geosynthetic a parabola. The tension in the geosynthetic, ignoring partial factors of safety, is calculated using the following equation:

$$T = \frac{w_T(s-a)}{2a} \sqrt{1 + \frac{l}{6\varepsilon}} \quad (2)$$

where  $w_T$  is the distributed load on the geosynthetic and  $\varepsilon$  is the strain in the geosynthetic.  $w_T$  can be calculated using one of the following expressions, depending on the embankment height:

For  $H > 1.4(s-a)$

$$w_T = \frac{1.4s\gamma(s-a)}{s^2 - a^2} \left[ s^2 - a^2 \frac{p'_c}{\sigma'_v} \right] \quad (3)$$

Figure 12. Geosynthetic strain from 2D FLAC analyses.

Figure 13. Geosynthetic strain from 3D FLAC analyses.

Figure 14. Geosynthetic tension in 2D based on BS 8006.

Figure 15. Geosynthetic tension in 3D based on BS 8006.

For  $0.7(s-a) \leq H \leq 1.4(s-a)$

$$w_T = \frac{s(\gamma H + w_s)}{s^2 - a^2} \left[ s^2 - a^2 \frac{p'_c}{\sigma'_v} \right] \quad (4)$$

Where  $\gamma$  is the soil unit weight,  $w_s$  is a uniformly distributed surcharge loading,  $p'_c$  is the vertical stress on the pile cap and  $\sigma'_v$  is the average vertical stress at the base of the embankment.  $p'_c/\sigma'_v$  can be calculated using the following expression:

$$\frac{p'_c}{\sigma'_v} = \left[ \frac{C_c a}{H} \right]^2 \quad (5)$$

Where for the end bearing pile used in this study  $C_c$  is defined as:

$$C_c = 1.95 \frac{H}{a} - 0.18 \quad (6)$$

Partial factors of safety have been omitted from the above equations. No account is taken of the subsoil in assessing the load to be carried by the geosynthetic. BS 8006 recommends that the initial design strain should be limited, for practical purposes, to less than 6%.

For comparison purposes the tension in the geosynthetic was calculated for  $H/s$  ratios from 0.2 to 2.0 and  $a/s$  ratios from 0.2 to 0.8. The design strain values used in Equation 2 were taken from both the 2D and 3D FLAC analyses in Figure 12 and Figure 13, respectively. The tensions determined from the BS 8006 design method are presented in Figure 14 for 2D and Figure 15 for 3D.

A marked difference was found between the geosynthetic tensions calculated using BS 8006 and those resulting from the FLAC analyses.

It was found that BS 8006 overestimated the geosynthetic tension for all geometries in 2D and underestimated the tension in 3D. For  $a/s$  between 0.2 and 0.6 and with  $H/s$  between 0.6 and 1.4 the BS 8006 geosynthetic tensions were approximately 30% lower than the 3D FLAC analysis. For the other

geometries the difference was larger. For values of  $a/s$  less than 0.6 BS 8006 gave a negative tension value. If the BS 8006 partial load factor for soil unit weight is applied, all calculated geosynthetic tensions are 30% higher.

## 5. RECOMMENDATIONS FOR DESIGN

The analyses presented have been compared with various design methods (Russell and Pierpoint, 1997). The comparison showed that there is a reasonable agreement with the Terzaghi (1943) and the Hewlett & Randolph (1988) design methods. The other design methods used in the UK, BS 8006 (1995) and Guido (1987), appear to give results that differ significantly from the numerical analyses for some geometries. The most appropriate design method is dependent on the geometry of the particular piled embankment.

The major uncertainty is the vertical load that the soft subsoil can carry in the long term without producing excessive settlement. This is a very difficult prediction to make as the stiffness of the fill, geosynthetic, piles and subsoil all contribute to the distribution of stresses and therefore, displacement. If the subsoil contribution is overestimated then large settlements of the surface of the embankment can result (Azam et al, 1990). Currently the authors recommend a conservative approach to design with the contribution from the subsoil calculated based on the allowable settlement at the surface of the embankment. This contribution may be negligible for high embankments but can be significant for low embankments or lightly loaded building floor slabs.

Research is underway to look at the role of the subsoil in more detail and to provide recommendations for design. In the mean time the use of numerical analysis methods is strongly recommended.

## 5. CONCLUSIONS

A series of 2D and 3D numerical analyses have been carried out to investigate the behaviour of piled embankments. The analyses show large differences between the 2D and 3D cases. A 3D model is required to accurately model the wide range of piled embankment geometries used in practice.

The 3D parametric study has shown that the minimum stress reduction ratio develops at an  $H/s$  ratio of approximately 0.5. A significantly lower stress reduction ratio is calculated in 2D analyses.

A comparison was made between the BS 8006 design method and the 2D and 3D FLAC analyses. BS 8006 overestimated the geosynthetic tension when compared with FLAC 2D and under estimated the tension when compared with FLAC 3D.

Recommendations for design have been made. The major uncertainty is the amount of vertical load that can be resisted by the subsoil. Due to the current lack of

information, the authors recommend a cautious approach. For high embankments, the resistance from the subsoil is likely to be a small proportion of the total load. For lower embankments, or building slabs, the subsoil resistance may be significant but must be assessed with care to ensure that the long term surface settlements meet construction specifications.

# Geogrid and Geocell Reinforced Secondary Road Over Deep Peat Deposit

Juha Forsman

Research Engineer, Viatek Group Ltd, Espoo, Finland

Eero Slunga

Professor, Soil Mechanics and Foundation Engineering, Helsinki university of Technology, Espoo, Finland

Pentti Lahtinen

Development Manager, Viatek Group Ltd / SGT, Luopioinen, Finland

**ABSTRACT:** A reinforced secondary road on the top of a 10 meter thick peat deposit has been constructed at the peat bog of "Leteensuo" in the southern part of Finland. The secondary road contains three different reinforced test sections: two geogrid reinforced and one geocell reinforced sections. This paper presents the description of the construction, field instrumentation and observations of the test sections. The bearing capacity and the settlement of the reinforced roads have been analysed by manual calculation methods. After construction the calculations have been verified on the basis of field observations.

**KEYWORDS:** Unpaved Roads, Geogrids, Geocell, Instrumentation, Case study

## 1. INTRODUCTION

A secondary road (Y607) has been constructed on the top of a peat surface using synthetic georeinforcements. The road forms a part of the Finnish Georeinforcement Research and Development Project, which has been introduced by Friberg et al. (1994).

The secondary road on the top of peat contains three different reinforced test sections: two geogrid reinforced and one geocell reinforced sections. The situation of the test sections is beside the Highway between Helsinki and Tampere at Leteensuo peat bog about 15 km to north-west of the city of Hämeenlinna. The private secondary road is constructed beside the highway at summer 1996.

## 2. TEST SITE

### 2.1 Geology

In the middle of the peat deposit of Leteensuo the thickness of peat layer is 9...10 m and the degree of humification of it is medium (H4-6) or high (H7-10), Figure 1. On the edges of the deposit the degree of humification is high (H=von Post classification). Under the peat layers there is 5...6 m of clay on the top of glacial till. The level of ground water is near the ground level.

### 2.2 Index Properties of the Peat

The index properties of the peat samples [water content ( $w$ ), density ( $\gamma$ ), ash content ( $A_s$ ), acidity (pH), void ratio ( $e$ ) and the degree of humification ( $H$ )] are presented in Figure 2 at station number 244 (Figure 1).

The water content of the peat is about 500...1000 % at the

Figure 1. Profile of the secondary road at Leteensuo.

depth of 1...10 m and 300...500 % at the depth of 0...1 m.

### 2.3 Strength and Deformation Parameters of the Peat

The undrained shear strength of the peat has been determined by vane test ( $c_u$ ) and fall-cone test ( $c_{uk}$ ), Figure 2. Drained and undrained triaxial tests with undisturbed peat have been performed using standard triaxial apparatus. The triaxial tests have been performed at a strain rate of 0,6 %/h and with  $\sigma_3 = 10...20$  kPa. The strength and deformation parameters have been determined at strains  $\epsilon_1 = 1,6..15$  %. The drained Young's modulus varies between 380..150 kPa at strains 1,6..15 % at the depth of 0,8..1,0 m, between 360..100 kPa at the depth of 1,3..2,4 m and between 355..80 kPa at the depth of 3,1..5,3 m.

The undrained Young's modulus varies between 580..140 kPa at strains 1,6..15 %. Cohesion varies between 0.4 kPa and the angle of friction between 3..19°. The peat seems to behave like a yield hardening material, without any rupture.

The strength properties of the peat have been determined also by direct shear tests. One dimensional compression of the peat has been studied by means of incremental loading and constant rate of strain oedometer tests. The results of those laboratory tests have been presented more comprehensively by Lojander et al. (1996).

### 3. TEST STRUCTURES

The secondary road of Leteensuu contains two geogrid and one geocell reinforced test sections.

The reinforcements have been used to increase the bearing capacity and to reduce the settlement differences of the road. The road embankment has been constructed by the Finnish National Road Administration of Häme Region.

The geogrid or geocell reinforced structures are: 1xgeogrid+crushed gravel (Ch 90..200 and 680..750, Fig. 3a), Geocell+LECA (Ch 200..300, Fig. 3b) and 2xgeogrid+LECA (Ch 590..680, Fig. 3c).

The test structures are illustrated as designed. The fulfilled thicknesses of the aggregate layers were mainly higher than designed. The fulfilled layer thicknesses at the instrumented stations, 170, 240 and 650, are presented in the brackets in Figure 3. The fulfilled layer thickness varies quite much at the 1xgrid and 2xgrid -structures. The layer thickness of the geocell structure does not vary significantly. The layer

thickness has been measured by ground penetrating radar (GPR) survey after construction.

The LECA, Light Expanded Clay Aggregate, has been used as a light-weight fill because of the expected large settlements of the road.

## 4. MATERIALS OF THE TEST STRUCTURES

### 4.1 Aggregates

In the 1xgeogrid+crushed gravel -structure there was used crushed gravel with a grain size of 0-65 mm as a bearing layer. In the geocell structure the 500 mm high geocell was filled with blown LECA with a grain size of 4-20 mm. In the 2xgeogrid+LECA -structure there was used about 500 mm layer of LECA with a grain size of 0-65mm. Over the LECA there was a layer of crushed gravel as a bearing layer. Uppermost there was surface layer of gravel (0-16mm). The strength and deformation parameters of the aggregates are presented in Table 1.

### 4.2 Geosynthetics

Geogrid Tensor SS30 (grid A) has been used at the bottom of the test structures 1xgrid+crushed gravel and geocell+LECA. Geogrid Tensor SR55 (grid B) has been used as a vertical grid of the geocell structure. Geogrid Fortrac 35/20 (grid C) has been used in the test structure 2xgrid+LECA. The properties of the grids are presented in Table 2.

Figure 2. Index properties and undrained shear strength of peat and clay of Leteensuu at station 244.

Table 1. Index, strength and deformation properties of the aggregates.

	Crushed gravel 0-65 mm	LECA 4-20 mm	LECA 0-65 mm

$E_{dr}$ [kPa]	47...143	-	56

Polypropylene grid A is extruded biaxially drawn. Polyethylene (HDPE) grid B is extruded uniaxially drawn. Polyester grid C is woven and coated with PVC. The weight of grid A is 300 g/m<sup>2</sup>, grid B 500 g/m<sup>2</sup> and grid C 210 g/m<sup>2</sup>.

## 5. CONSTRUCTION

### 5.1 Installation of the Geogrids

All test structures have been built during May-July 1996 in three sections. Over the levelled subsoil there was first put a needlepunched nonwoven geotextile. Over the textile there

Table 2. Properties of the reinforcements.

was put the base grid A or C. In the 1xgeogrid structure and in the geocell structure the base grid was installed in the longitudinal direction of the road except the 4 pieces of grid in the 1xgeogrid structure. One of those pieces was instrumented with strain gauges. In the 2xgrid+LECA -structure all grids were installed in transverse direction of the road.

Grid B in the geocell structure was cut to a width of 0,5 m. The grid was installed vertically by wooden piles and nylon cord in the transverse direction of the road. Between the transverse grids there were installed other vertical grids. The grids are connected to each other with iron bars. Vertical grids are connected to base grid with cable ties, Fig. 3b.

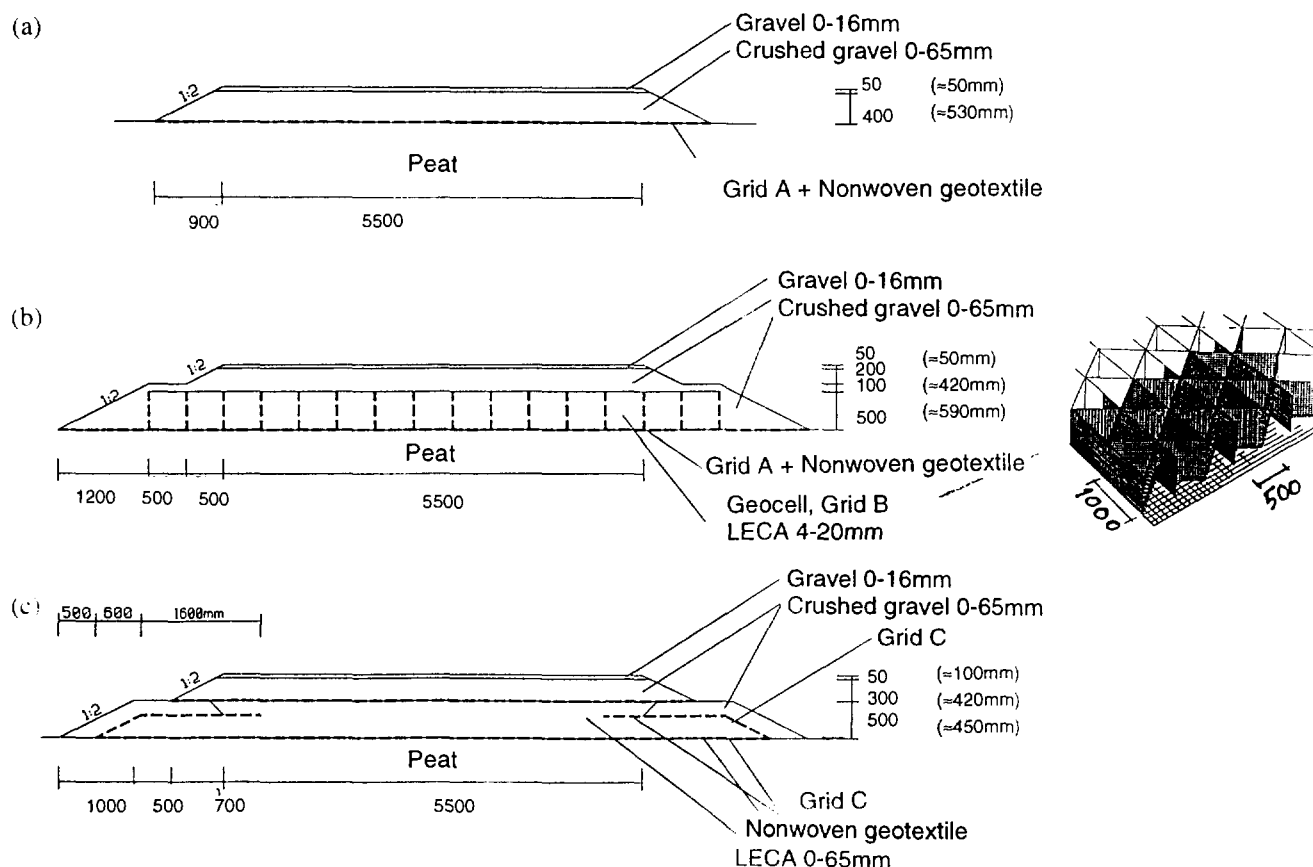

Figure 3. Geogrid and geocell reinforced test structures: (a) 1 x geogrid + crushed gravel, (b) geocell + LECA, (c) 2 x geogrid + LECA. The fulfilled layer thickness are presented in the brackets.

## 5.2 Installation of the Aggregates

The installation of crushed gravel and LECA of the test structures of 1xgrid and 2xgrid+LECA was performed by lorry and excavation machine. The installation of LECA to geocells was performed by blowing.

The precompaction of the aggregate layers was done by the excavation machine with caterpillar tread. All test structures have been compacted by a vibratory roller.

## 6. INSTRUMENTATION

### 6.1 Instruments

The test structures are extensively instrumented. The principles of the instrumentation are presented in Figure 4.

The instrumentation and control methods include: vertical magnetic probe extensometers, horizontal hydrostatic profile gauges, settlement plates, horizontal extensometers, strain gauges, plate load tests and falling weight deflectometer tests (FWD).

### 6.2 Installation of the Instruments

The vertical magnetic probe extensometers were installed at stations 241,5 and 651,5 to measure the settlements of the ground at different depths. An extensometer consists of ring magnets sliding on a central access pipe and fixed in the ground at preselected measuring levels. A special probe travels within the access tube and observes the positions of the magnets outside the tube.

To measure the settlements and the shape of the base of the road embankment there were installed flexible PEH-pipes for the horizontal hydrostatic profile gauges at the peat surface at six stations.

The horizontal extensometers were installed to stations 171 and 651 to measure the horizontal movements of the base of the road embankment about 0,1...0,15 m above the surface of the peat. The measuring units, precision potentiometers, were installed at the centre line of the road and the anchor plates were installed about 1,3 and 2,7 meters to the side from the centre line of the road. When the anchor plate moves the voltage of the potentiometer changes. The changes are converted to millimetres by a calibration factor determined in laboratory.

The strain gauges were glued to grids to measure the strains of the grids at stations 170, 240 and 650. The strain gauges were glued to the elements of the grids. The measured strains are converted to tensions of the reinforcements by a calibration factor determined in laboratory.

At the surface of peat there were installed 4 steel plates ( $\phi=0,45$  m) and at the surface of the LECA 2 steel plates ( $\phi=0,30$  m) for plate bearing tests.

Figure 4. The principles of the instrumentation of the test structures.

Figure 5. Calculated and measured settlement of the geocell structure at station 240.

## 7. RESULTS

### 7.1 Settlements

The settlements at the centre line of the test structures from summer -96 to 8/97 are: 0,41 m at station 174, 0,51 m at station 239..250 and 0,54 m at station 649. The settlements are directly dependent on the thickness of the peat layer (Figure 1). The measured settlements are quite near to the manually calculated settlements during one year, Figure 5. In this case it is really wise to use LECA as a light-weight fill to keep the road surface over the peat surface. The surface of the 1xgeogrid+crushed gravel -structure is now, 1.5 years after construction, about at the same level as the peat surface and in this situation the drainage of the road structure is very bad.

The settlements at different depths in the ground are not illustrated in this article, but they equal quite well to the precalculated deformation distribution.

## 7.2 $E_2$ -modulus

The  $E_2$ -modulus at the surface of the peat and LECA has been measured at stations 170, 240, 650 and 700 in 7-8/96, 9/96 and 8/97. The  $E_2$ -modulus was 2..5 MPa and 27..36 MPa. The  $E_2$ -modulus of the road has been measured at the surface by plate load and by FWD-tests, Table 4. The FWD-tests have been made at intervals of 10 or 5 m about 1 m to both sides from the centre line. By plate load and FWD-test measured  $E_2$ -modulus are very near each other. Plate load and FWD-tests in 7-8/96 were made before the installation of the surface gravel (0-16mm).

When looking at the results of the plate load and FWD-tests one has to keep in mind that the  $E_2$ -modulus changes very much at different stations along the road because of the varying thickness of the embankment and the strength of the peat layer. It can be seen from the Table 4 that the  $E_2$ -modulus of the structure 2xgeogrid+LECA is increasing by the time.

## 7.3 Strains and Tensions of the Georeinforcements

The measuring results of the strain gauges have been converted to tensions by a calibration factor ignoring the potential effects of the creep of the synthetic geogrids and the effects of the confining stress to the modulus of the grid.

The mobilised tension of the base grid of the 2xgeogrid+LECA -structure is illustrated in Figure 6. The tandem-axle with twin tyres is above the strain gauges. The axle-group load of the lorry is approximately over 16 ton. In Figure (a) there is a lorry laden with gravel on the middle of the embankment (Fig. c) and there is illustrated the total mobilised tension of the grid (=tension before the loading + tension caused by the lorry). In Figure (b) there are the changes of the tension of the grid caused by the lorry on the embankment. In Figures (a) and (b) the continuous line illustrates the case when both axles of the tandem-axle are loaded (Fig. d). The dashed line illustrates the case when the whole load is on one axle of the tandem-axle (Fig. e).

The loading with lorry was repeated with all test structures. The mobilised tension of the base grids was 4..5 kN/m in 1xgrid+crushed gravel, geocell+LECA and 2x geogrid+LECA -structures. The mobilised tension of the upper grid of the 2xgeogrid+LECA -structure was about 1..1,5 kN/m. The changes of the mobilised tension of the lower edge of the vertical grid of the geocell were about 3 kN/m.

The lorry loading of the test embankments has been made almost immediately after the construction of the embank-

ment. About 2..4 months later when repeated the loading the mobilised tension has been lower because of the installation of the surface of the road and the strengthening of the peat due to the consolidation.

## 7.4 Deterioration of the Surface of the Test Structures

The rutting and the deterioration in the form of potholes on the surface of the test structures have been observed ocularly. The shape of the surface has also been measured by the means of levelling. On the basis of the observations after 1 year of the construction there are mostly potholes on the surface of the 1xgrid+crushed gravel -structure. On the surface of the 2xgrid+LECA there are very few potholes but on the surface of the geocell -structure there are more potholes. The most rutted test structures are the 1xgrid and geocell -structures while the surface of the 2xgrid+LECA has behaved better.

## 8. ANALYSIS BY MANUAL CALCULATION

The tension of the grid of the 1xgrid structure has been calculated using the methods presented by Giroud & Noiray (1981) and Housby & Jewell (1990). Both methods are for a clay base but in the absence of a better method those are used also for a peat base. In the calculations the next assumptions have been adopted: axle load 100 kN, number of passes 10 000, rut depth 150 mm and the shear strength of the base 25 kPa.

When using the method of Giroud & Noiray the calculated thickness of the embankment is 0,73 m and tension of the base grid is 8 kN/m. When using the method of Housby & Jewell the calculated thickness of the embankment is 0,77 m and tension of the grid is 10 kN/m. The calculated thickness of the road structure is a little bit bigger than the fulfilled thickness ( $\approx 0,6$  m). The calculated tensions of the grid are about twice as big as the measured ones (4..5 kN/m) in the 1xgrid and 2xgrid -structures.

The method of Housby & Jewell is based on the combination of the bearing capacity of the clay subgrade and the effect of the horizontal stresses in the fill/clay interface. The method of Giroud & Noiray is concentrated to the tensioned membrane effect and the bearing capacity of the clay subgrade. According to the theory of Housby & Jewell the tension of the grid is concentrated near the loading point while in the theory of the tensioned membrane the tension is supposed to be distributed evenly to a very large area. When

studying Figure 6 one can see that the tension is not very largely distributed but the tension is concentrated quite near the loading point.

### 9. CONCLUSIONS

When constructing a road on a peat area there are two main problems: the low bearing capacity of the peat and the large settlements. The low bearing capacity can be increased and the differences in settlements can be reduced by geogrids. In the case of Leteensuu an adequate bearing capacity of the road has been achieved by a moderate low embankment with geogrids. One and a half years after the construction of the test structures there are no significant differential settlements at the road surface.

The measured tensions of the base grids are about half of the precalculated ones with the methods presented by Giroud & Noiray (1981) and Houlsby & Jewell (1990). The distribution of the tension agrees quite well with the distribution assumed by the theory of Houlsby & Jewell. On the basis of the test construction of Leteensuu it seems to be possible to use both of the dimensioning methods of Giroud & Noiray and Houlsby & Jewell on the peat base.

### ACKNOWLEDGEMENTS

The authors like to thank the "Georeinforcement" -project for the financing and promoting of the laboratory tests and the instrumentation of the test structures. Thanks are due also to the organisation of the Finnish National Road Administration of Häme Region for the construction of the test structures.

# CONSTRUCTION OF HIGHWAY EMBANKMENT ON SOFT MARINE SOIL USING JUTE GEOTEXTILES

P.Jagannatha Rao

Senior Consultant, Lea Associates South Asia Pvt Ltd., New Delhi

Bindumadhava

Project Manager, Consulting Engineering Services (P) Ltd., New Delhi

N. Venisri

Engineer, Consulting Engineering Services (P) Ltd., Hyderabad

**ABSTRACT** : The paper presents case study of design and construction of 1.5m high embankment resting on 4m deep soft marine clay subsoil layer. In order to ensure adequate initial factor of safety, it was found necessary to provide a reinforcing fabric at the base of the fill and jute geotextile was successfully used for this purpose. Jute being biodegradable the natural fibre fabric suffers loss of strength with time. In the present case, it was found that the post construction gain in the undrained shear strength of the soft clay subsoil is adequate to compensate the loss in the strength of reinforcing fabric after it is placed in the soil. Thus, the factor of safety always remains at the design level. Construction of the embankment was completed in April 1996 and post construction monitoring showed the embankment performance to be satisfactory.

**KEYWORDS** : Jute geotextile, Reinforcement, Embankments.

## 1.0 INTRODUCTION

A major deepwater port was developed at Kakinada in Andhra Pradesh, India and within the port area, a highway network was under construction for transporting cargo from ships to godowns. At the proposed location, subsoil is soft clay upto 4m depth and water table is at about 0.5m below the ground level. The area gets submerged during high tide. Highways constructed earlier faced many problems during and after construction such as subsidence of the fill during construction, excessive post construction settlements, lateral spreading of fill material, etc. It was observed that sometime as much as 30% of the fill sinks into the soft subsoil during spreading of the fill, thus necessitating use of larger quantities of costly granular fill material, pushing up the cost of construction.

In order to mitigate the above problems, various alternatives were examined among which jute geotextile has shown itself to be a promising one from performance as well as cost considerations. The use of geotextiles to improve the performance of embankments over soft subsoil is an effective and well tried form of reinforced soil construction. Geotextiles may be used to improve

- i) embankment stability against bearing capacity failure
- ii) stability against slope failure through the foundation

- iii) allow controlled construction over very soft or difficult foundation soils and make possible more uniform settlement of the embankment.
- iv) act as separator between the embankment material and soft subsoil
- v) function as drainage blanket for draining of pore water during consolidation.

Reinforcement on soft soil is most effective when placed at or close to the foundation surface.

Factor of safety of embankment is usually at its lowest during and immediately after construction and increases thereafter. The increase is a function of the gain in strength of the soft clay. Thus, reinforcement has to be effective only for a short term, the duration depending on the consolidation characteristics of the soft clay layer. In such cases, long term durability of the geotextile reinforcement is of secondary concern.

The reinforcement is needed essentially to improve the stability during construction phase and in the period of consolidation during which the soil attains the required strength. The concept, shown in fig (1) is given by Jewell (1996) and forms the basis of design in the present instance.

Figure 1 : Variation in factor of safety of fill on soft ground, with and without reinforcing fabric. Based on Jewel (1996)

The primary loading from an embankment is due to the self weight of the embankment fill, which causes horizontal stresses in the fill, which in turn produce lateral forces (i.e.) outward shear stresses. The resulting outward shear stresses which act on the foundation surface reduce the bearing capacity of the foundation subsoil. Hence, the primary role of the reinforcement is to resist the outward shear stresses and relieve the foundation of the effect of lateral forces, thereby increasing the allowable height of the embankment. A layer of reinforcement placed in the embankment would resist lateral displacement by exerting an inward shear stress on the foundation surface thus reduce the lateral spreading of the foundation soil. Since the geotextile is placed between the embankment fill and the subsoil, it also performs the function of separator thereby eliminating the possibility of the soft subsoil squeezing upward into the costly granular fill. This geotextile along with a sand cushion also acts as a drainage layer facilitating the escape of pore water during the consolidation phase.

### 1.1 Properties of Subsoil

The subsoil upto a depth of 4m from the ground level is mainly clay with occasional mixture of silty sand. The average liquid limit and plasticity index were 60 and 28 percent respectively. The soil in general was found to have a natural moisture content ranging from 70% to 80% with bulk density varying from 1.3 Mg/m<sup>3</sup> to 1.45 Mg/m<sup>3</sup>. Average undrained shear strength of the soil was found to

be 6.0 kN/m<sup>2</sup> from in-situ vane shear tests, compression index ( $C_c$ ) 0.225 and coefficient of consolidation ( $c_v$ )  $2.0 \times 10^{-7}$  m<sup>2</sup>/ sec.

### 1.2 Design Aspects

Design of geotextile used for reinforcement is based on the methodology given by Jewel (1996) and is as follows:

Height of fill ( $H$ ) = 1.5m

Unit weight ( $\gamma$ ) = 16.6 kN/m<sup>3</sup>,

Angle of internal friction  $\phi = 30^\circ$

Depth of foundation soil  $D = 4.0$  m

Undrained cohesion  $C_u = 6$  kN/m<sup>2</sup>

Thus vertical stress due to fill ( $\sigma_v$ ) =  $16.6 \times 1.5 = 24.9$  kN/m<sup>2</sup>.

Factor of safety (FS) against bearing failure for the unreinforced embankment.

$$= \frac{cN_c}{\gamma H} = \frac{6 \times 3.14}{24.9} = 0.75$$

$N_c = 3.14$  in the unreinforced state.

Thus, the bearing capacity is not adequate without reinforcement at the base level. By providing a geotextile reinforcement, the bearing capacity factor,  $N_c$  increases to  $\pi + 2 = 5.14$

and the factor of safety works out to

$$\frac{6 \times 5.14}{24.9} = 1.23$$

which is a satisfactory value.

The horizontal force to be resisted by tension in the fabric is estimated as

$$P_a = K_a \gamma H^2 / 2$$

$$= \frac{0.33 \times 16.6 \times 1.5 \times 1.5}{2} = 6.16 \text{ kN/m}$$

Hence, required design tension in the fabric = 6.16 kN/m

For a fabric having a tensile strength of 20 kN/m, the factor of safety available is 3.2 and is thus adequate. Once the embankment is in place, the soft clay consolidates and improves in shear strength.

With an average  $c_v = 2 \times 10^{-7}$  m<sup>2</sup>/sec, the time required for 90% consolidation works out to 205 days or about seven months.

Settlement was estimated to be the order of 175 to 200mm, by using standard calculations.

Strength gain at the end of consolidation is of the order of  $\Delta S_u = 0.18 \times \Delta \sigma'_v = 0.18 \times 24.9 = 4.48 \text{ kPa}$

Average undrained cohesion at the end of consolidation would thus be of the order of (6.0 + 4.48) say 10 kPa. Factor of safety of the embankment at the end of consolidation without any reinforcing fabric would thus be

$$FS = \frac{10 \times 3.14}{16.6 \times 1.5} = 1.26 \text{ which is satisfactory.}$$

Thus the use of an even a relatively low strength geotextile helps to maintain the factor of safety at an acceptable level of 1.26.

At the end of 7 months, when the strength gain due to consolidation has occurred, the increased shear strength of the subsoil ensures the minimum required factor of safety. The strength of fabric is no longer needed to provide reinforcing effect.

### 3.0 CHOICE OF FABRIC

In the preceding section, it was demonstrated that a fill can be built on the soft clay by placing a geotextile fabric and a low strength one is adequate. A variety of such geotextiles are manufactured from petroproducts. However, in certain areas of the world, natural fibres such as jute, coir, sisal, kenaf are being increasingly studied and evaluated for use in various geotechnical engineering applications. The objective of such efforts is to make use of desirable properties of above fibres, make a wider variety of fabric products available for geotechnical engineers where suitable use can be found and in some instances with cost advantage, provided performance criteria are met. The 5th International conference on geosynthetics held in September 1994 in Singapore devoted a special session to Natural Fibre Fabrics. This session has clearly impressed the engineers with the potential of natural fibre fabrics for use in geotechnical engineering applications. These fabrics compliment the range of applications of petrobased fabrics.

Since jute is available in India in abundance, a United Nations Development Programme (UNDP) sponsored project on the "Development and Promotion of Jute Geotextile" is in progress in India covering the period 1992-1997. The Indian Jute Mills Association (IJMA) is the coordinating agency for the project. Development of jute and jute based geotextiles, their evaluation and characterization and the use of such fabrics in full scale experimental constructions form objectives of the project. Efforts were concentrated on carrying out full scale field experiments to demonstrate and evaluate the capabilities of selected varieties of jute fabrics for use in surface erosion control of slopes, drainage, separation and to a limited extent, reinforcing function. The fact that jute fabric is

biodegradable, with a limited life and deteriorates in a short period of about two years was always kept in mind in the planning and operation of the project and choice of experimental installations. Full scale field experiments covering these applications have been implemented at different locations in India. Ramaswamy (1994) presents in detail the application of jute geotextiles in erosion control, drainage as well as reinforcement.

As explained in section 1 and shown in design in section 2, in the present instance, it is adequate if the reinforcing function of the fabric is available for period of seven months. The use of fabric has essentially helped in overcoming problems in the placement of the fill and initial low factor of safety. Thus, fabric with a limited life can be tried in this project and its performance evaluated by the field trial. Accordingly, jute geotextile fabric having the basic properties given in Table 1 was chosen for use in the project.

Table 1 : Properties of Jute Geotextile

S.No	Property	Test Value
1	Thickness	3 mm
2	Weight	750 gsm
3	Tensile Strength	20 kN/m
4	Elongation	30%
5	Puncture Resistance	350 N
6	Overlap length	30 cm

The woven jute geotextile fabric was treated with cuproammonium sulphate to increase resistance of the fabric to biodegradability. Talukdar et al (1994) have studied the influence of various chemicals such as copper naphthenate etc. with acrylic binder on the resistance to microbial attack when buried in soil. The results were very encouraging and showed that jute fabrics treated with selected chemicals have better resistance to microbial attack under conditions of burial in soil. Venkatappa Rao et al (1994) have shown on the basis of a careful study that the decrease in the narrow strip tensile strength of soil embedded in soil and remaining in submerged condition is only of the order of 35% after four months. Mohiuddin (1994) provides data to indicate that in jute fabrics treated with copper naphthenate and such other chemicals, the loss of strength is retarded. Thus, it was reasonable to consider that jute fabric used would serve the reinforcing function in adequate measure, in the design life of 7 months.

#### 4.0 INSTALLATION OF GEOTEXTILE

At present, jute geotextile being an experimental product is available in roll width of 0.75m only. Hence, fabrics were stitched at site, using a portable stitching machine to obtain the requisite width. The stitching operation was easy, reliable and fast. Before spreading the geotextile, the site was cleared of any extraneous materials and tree/plant roots. A layer of sand 150 mm thick was spread to serve as a levelling course. The geotextile was laid with its warp direction (strong direction) parallel to the width of the embankment. Top width of the embankment was 7.0m and side slope 1 v1 to 2h1. A trench of size 0.5 x 0.5m was dug in the soil at either toe line of the embankment and along its length. To provide anchorage, the geotextile was placed in the trench. The trench was back filled with sand placed in layers and compacted. The fabric was stretched manually after spreading on the ground so as to render it free of wrinkles and establish good contact with soil and fill. An overlap of 0.30m was provided between two rolls of geotextiles. After spreading the geotextile and anchoring it along the edges, a sand cushion of 30 cm thick was placed to protect the geotextile from damage due to moving vehicles. Placing of fill upto the requisite height was done by rear dumping and spreading. The fill was then compacted by a 6 ton roller. Nearly 300 m of embankment was built under the programme. Construction of the embankment was completed in April 1996. Settlements were observed subsequent to the construction. Simple standpipe type settlement gauge was installed for this purpose. It was found that the settlements conformed to the estimated value. The physical condition of the fill and its surface were monitored periodically and were found to be satisfactory.

The cost of jute geotextile used in the project is of the order of Rs. 18/- or US\$ 0.50 and thus proved to be highly economical compared to products based on petrochemicals, which are costlier in India.

#### 5.0 CONCLUSION

An embankment was built on soft clay subsoil, using geotextile as a reinforcing layer at the base. the geotextile was required to serve as reinforcing fabric for a period of 7 months only. Subsequently the strength gain in the soft clay was adequate to keep the embankment stable. The performance of the fill was found satisfactory. The project demonstrates that where site conditions enable the designer to rely on reinforcing properties of geotextiles for a limited time period, it is possible to use natural fibre geotextile in such applications. This has the effect of finding suitable range of conditions where natural fibre based geotextile can be used in geotechnical applications.

#### ACKNOWLEDGEMENT

The project was carried out as a part of the UNDP sponsored project "Development and Promotion of Jute Geotextiles". The overall coordinating agency was the Indian Jute Mills Association, Calcutta. The work reported herein was carried out by the authors, while they were at the Central Road Research Institute, New Delhi and the senior author was coordinating the project. The authors thank all concerned in the above organisations for their cooperation in successfully completing the project. The authors also wish to thank officials of Kakinada port and JNTU college of Engineering, Kakinada for help at site in various phases of the project.

# PERFORMANCE OF GEOTEXTILE REINFORCED EMBANKMENTS ON VERTICALLY DRAINED SOFT MUDS

K.C. Yeo & J.W. Cowland  
Geotechnical Engineering Office, Hong Kong

**ABSTRACT:** Twenty kilometres of flood protection embankments have been constructed on soft muds in the north-west of Hong Kong, using woven polyester geotextiles as basal reinforcement. Prefabricated vertical drains were installed to accelerate consolidation of the muds. An extensive instrumentation programme was carried out to monitor the performance of the embankments. This paper outlines the design and construction of the embankments. Typical instrumentation results are given, and performance of the embankments are discussed.

**KEYWORDS:** Case Study, Embankments, Soft Soils, Geotextiles, Pre-fabricated Vertical Drains

## 1 INTRODUCTION

The northwestern part of Hong Kong contains a broad alluvial floodplain. Development of this low-lying area generally requires the construction of raised platforms. Provision of major flood drainage is essential for land use planning as flood discharges develop rapidly due to heavy rainfall in the wet season.

A series of drainage channel projects are being carried out in these areas to alleviate the flood problem and to

improve the drainage systems. The case study presented in this paper consisted of the construction of three drainage channels of width 125m to 480m, and of lengths 3.2km(Contract A), 4.4km(Contract B) & 2.3km(Contract C) respectively. Small embankments 4m high were constructed on each side of these drainage channels over an area which had been used extensively for fish farming, with small bunds forming the boundaries of the ponds. Figure 1 shows the location of the site.

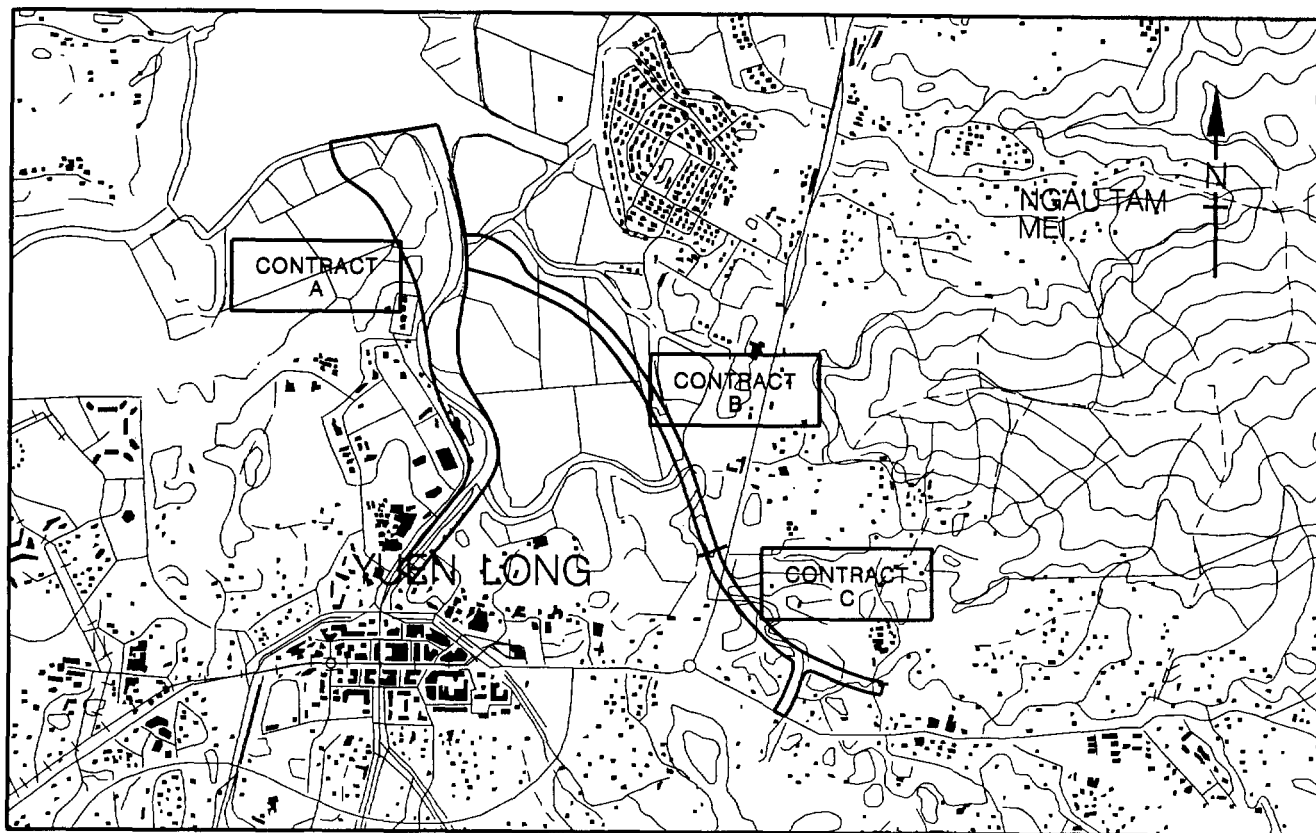

Figure 1. Location of the Site

## 2 GEOLOGY

The geology of the area comprises muds overlying older alluvial sediments which rest on residual weathered rocks of volcanic or meta-sedimentary origin. The stratigraphy of the site can be categorised as follows:

**Fill:** generally granular in nature and exists in the bunds of the fish pond area, with thickness varying from 1 to 3 metres.

**Pond deposits:** generally a very soft to soft dark brown to dark grey silty clay exists at the bottom of the fish ponds for a depth of 1 to 1.5 metres.

**Estuarine/Marine deposits:** generally a very soft dark grey to black silty to sandy clay with shell fragments, with thickness from 2 to 8 metres.

**Alluvial clay/silt:** generally a firm to stiff light grey to pinkish brown with reddish brown mottled sandy silty clay with varied depth.

**Alluvial sand/gravel:** generally a medium dense to dense grey to brownish yellow/light grey silty/ gravelly sand with varied depth.

The thickness of the alluvium was between 10 to 30 metres. It does not possess a uniform succession of strata, but varies from location to location. The insitu materials below the alluvial deposits are coarse tuff/granodiorite. Figure 2 shows the geology of the site.

## 3 DESIGN AND CONSTRUCTION

The embankments were formed by filling on the existing ground. For embankments constructed over soft muds, the stability of the embankments has been improved by a combination of measures, i.e. installation of prefabricated vertical drains (PVD), application of geotextile reinforcement, staged construction with wide berms and partial removal of pond deposits. As the preconsolidation

Figure 2. Geology of the Site

pressure of the alluvium was generally higher than the embankment load, most of the settlement occurred only in the marine sediment. The soil parameters adopted for the embankment design are summarised in Table 1. In general, they are on the conservative side.

Table 1. Geotechnical Design Parameters

Design Parameters				Type of Deposit				
				Marine Deposit	Alluvial Clay	Alluvial Silt	Alluvial Sand	Alluvial Gravel
Unit Weight (kN/m <sup>3</sup> )				16	19	20	19	19
Shear Strength Parameters	Short Term	Undrained Shear Strength	S <sub>u</sub> (kPa)	10	40	40	-	-
	Long Term	Effective Cohesion	c' (kPa)	3	4	0	0	0
		Effective Angle of Friction	φ' (Deg)	25	33	33	35	35
Parameters for Settlement	Preconsolidation Pressure		P <sub>o</sub> ' (kPa)	NC	150 - 300	150 - 300	-	-
	Compression Ratio		C <sub>c</sub> / (1+e <sub>o</sub> )	0.15 - 0.3	0.11 - 0.16	0.12 - 0.18	-	-
Analysis	Recompression Ratio		C <sub>r</sub> / (1+e <sub>o</sub> )	0.015 - 0.03	0.015 - 0.025	0.018 - 0.03	-	-

A typical cross section of the embankment, showing the layout of the geotextiles, prefabricated vertical drains and instrumentation, is shown in Figure 3. The construction adopted both "partial removal of pond deposits" and "no excavation" approaches. The primary basal reinforcements used were a layer of woven polyester geotextile (two different brands) of characteristic strength of 800kN/m or 600kN/m. A second layer of woven polyester geotextiles were used as a separator with characteristic strength of 400 kN/m or 200kN/m. Two different types of PVD (grooved and spun core) were installed to a depth of approximately 15 metres through the marine deposits, to accelerate the consolidation of the foundation soil.

They are simple to read and can be read from a station which is remote from the work area with little interference to the construction activity. However, they are not robust and some of the piezometers were damaged during construction. A number of the pneumatic piezometers were found to malfunction after installation, and yielded erratic results. Therefore it is important to consider the use of more than one type of piezometer for cross checking. For future projects it would be advisable to install some standpipe piezometers to supplement pneumatic piezometers at selective locations for reference.

Figure 3. Typical Section of the Embankment

#### 4 INSTRUMENTATION

An extensive network of geotechnical instrumentation was installed, to monitor ground deformation and groundwater pressures during construction of the embankments. More than fifty cross-sections (at 100 metres interval) along the embankments were monitored using pneumatic piezometers, inclinometers (with and without extensometers) and settlement plates, during and after construction.

For embankments constructed over pond and estuarine/marine deposits, monitoring of the excess pore water pressure dissipation within the mud was critical for controlling the filling rate of the embankment. In addition, there were fish ponds along both sides of the channels, and lateral movement of the soft deposits may have damaged the bunds of the fish ponds. Thus it was important to monitor this movement. It was also important to measure the settlement of the mud over time, so that the timing of laying the black top of the service road on the crown of the embankment could be determined.

##### 4.1 Piezometers

Pneumatic piezometers were widely used in this project.

##### 4.2 Inclinometers and Extensometers

Inclinometers were installed to monitor the magnitude and the rate of lateral movement of the foundation soils below the embankment. Casing inclination data were provided in two mutually perpendicular near-vertical planes. Horizontal deformation of the transverse sections was of particular interest as the behaviour of the embankment would be assumed to be in plane strain.

Extensometers were used in conjunction with inclinometers to monitor the changing distance between two to four positions beneath the vertical axis of a particular section, i.e. vertical compression of the foundation soils. Two different types of extensometers were used, i.e. spring anchor extensometers attached outside the inclinometer casing, and flexible corrugated polyethylene pipe with induction coil rings where inclinometer casing was inserted inside the pipe. As the accuracy of extensometers is only 10 - 20 mm. Settlement plates are a useful alternative.

##### 4.3 Settlement Plates

Settlement plates were used to quantify the magnitude of settlement of the embankments with time. Two types of

settlement plates were used, i.e. shallow settlement plates and deep settlement plates. The shallow settlement plate was a 1m x 1m steel plate welded to a hollow tube which was extended with fill height, installed at the base of the embankment before filling. The deep settlement plate was a 110 mm diameter circular plate welded to an steel bar, which was also extended, and installed at the base of the soft deposits by drillhole. The settlement of the plates were monitored using surveying techniques throughout construction. The difference between the settlement measured by the shallow and the deep settlement plates represented the actual settlement of the layer of the soft deposits at any time.

The accuracy of the plate settlement measurement using conventional surveying equipment was found to be close to millimetres.

## 5 TYPICAL INSTRUMENTATION RESULTS

A typical set of instrumentation results is shown in Figures 4 to 9. Figure 4 summarises the locations of all the instrumentation. The fill level was increased to approximately 4m at the crown in October 1995, as indicated in Figure 5, and a typical set of piezometer measurements shows that the excess pore pressure has built up slowly, and then dissipated over the next three months, as shown in Figure 6. This indicates that the prefabricated vertical drains were working satisfactorily. The ground water re-established at a new level after that, and then fluctuated with seasonal changes. Figure 7 shows the increase in settlement, from the monitoring data of the settlement plates, in response to the increase in pore water pressure during the same period. The increase in settlement reduced when the pore water pressure stabilised, and the

rate of settlement became insignificant. Figures 7 & 8 show the settlement monitoring results at the crown (by extensometers) and at the berm (by settlement plates). The total settlement which occurred at the crown of the embankment was about 150mm, while the settlement which occurred at the berm was about 70mm.

Two plots were employed for the interpretation of inclinometer data. The 'cumulative' plot gave a more graphic representation of the actual deformation pattern and was most commonly used. The 'change' plot, which plots the gradient of the 'cumulative' plot, accentuates the location of the deformation zone, which is useful to identify the shear zone (squeezing) and its magnitude. In general, the shear deformation is expressed in degrees. Figure 9 shows typical cumulative and shear deformation plots in the transverse direction for the inclinometer at a typical section. The plane on which the maximum shear strain occurred was at about 2m below the existing ground level. From the drillhole records, this level coincided with the location of the interface between fill and marine deposits. The magnitude of the maximum shear strain was less than 1 degree.

## 6 PERFORMANCE OF EMBANKMENTS

The performance of the embankments has been assessed from the monitored behaviour of the instrumentation. The fill level has reached a full height of approximately 4 metres. The excess pore water pressures within the marine deposits have dissipated satisfactorily, with an undissipated pore water pressure of only about 5-10 kPa. In general, the settlement plates have provided reasonably good information on the compression of the marine deposits. The shallow and deep settlement plates indicated that the

Figure 4. A Typical Instrumentation Section

Figure 5. Fill Level Plot

Figure 7. Settlement Plot

Figure 6. Piezometer Plot

Figure 8. Settlement Plot

Figure 9. Inclinerometer Plots

settlement for the marine deposits at the embankment crown was between 250mm to 350mm, depending on the thickness of marine deposits, which ranged between 4m to 6m. At the berm of the embankment, the settlement measured by using extensometers was between 60mm to 150mm with thickness of the marine deposits ranged from 6m to 8m. In general, the rate of settlement was insignificant 4-6 months after the end of construction. The inclinometer with extensometer was used to monitor the horizontal and vertical deformation of the ground at

selected locations. At this site it was used to monitor the lateral movement of the earth bunds adjacent to fish ponds. It was found that squeezing of the marine deposits underneath the embankment occurred at the interface between the stiffer alluvium and the marine deposits. In general, the cumulative deformation ranged from 30mm to 100mm along the drainage channel. The maximum shear deformation, in general, occurred at the interface of the marine deposits and the alluvium, with a magnitude of between 0.5° to 2°.

## 7 COMPARISON OF PERFORMANCE

To assess the effectiveness of the performance of the embankments, four cases of trial embankments on soft soil foundations, which employed similar reinforcement materials or had similar site conditions as Hong Kong, were

It is suggested that a way forward to improve the economy, efficiency and effectiveness of the design of embankments on soft soil foundations in Hong Kong is to construct a trial embankment, to define the critical conditions, and to conduct back analyses, so that the design parameters can be more accurately determined.

Table 2. Comparison of Embankment Performance

Case	Reinforcement Material	Su(kN/m <sup>2</sup> )	Soft Clay Depth (m)	Berm	Fill Height (m)	Rft. Strain (%)	Rft. Load (%)	PVD
1986 France Test Embankment	Polyester Woven 225/60	30 Const.	24	Yes (4.5m)	7 8.75 (failed)	2.5	50	No
1989 Canadian Test Embankment	Polyester Woven 216	30 Const.	10	Yes (3.5m)	4 8.2 (failed)	2		No
1982 Hong Kong Deep Bay	Polyester Polypropylene Woven 200/200	5-10 Linearly Increase Ratio 0.25	12	Yes (0.8m)	3.5	9		No
1988 Malaysia Trial Embankment	HDPE Geogrid 80	5-10 Linearly Increase Ratio 0.3	14	No	6	5	40	Yes (Not Functioned)
	HDPE Geogrid 110 × 2			Yes (3m)	8.50	2	25 × 2	Yes (Not Functioned)
1995 Hong Kong DSD Contract A	Polyester Woven 800/100		10	Yes (2m)	4			Yes

reviewed (Delmas, Ph. et al (1992), Rowe, R.K. et al (1994), Cowland, J.W. et al (1997) & Malaysian Highway Authority (1989)).

A comparison of the performance of these trial embankments and the Hong Kong embankment are summarised in Table 2. Although the reinforcement load and strain in the Hong Kong embankments have not been measured, the comparison does indicate that the design of the geotextile reinforcement for these flood protection embankment was conservative.

## 8 CONCLUSIONS

The use of vertical drains in combination with basal reinforcement proved to be a cost-effective means to construct embankments over soft ground without removal of the muds.

Both types of polyester woven reinforcement geotextiles and the prefabricated vertical drains that were used performed satisfactorily. They enhanced the short-term stability of the embankments and accelerated the time of consolidation of the muds.

Instrumentation plays a important role during construction to ensure safety of the construction work, allow control of the construction pace, and to provide data for measurement of quantities.

The performance of the embankments was very much better than the calculated performance assumed in design, reflecting the conservatism in the choice of soil parameters.

# Influence of Geometry and Construction Sequence on Reinforced Embankments on Soft Soils

J.L. Borges

Auxiliary Professor, Department of Civil Engineering, Faculty of Engineering, University of Porto, Portugal

A.S. Cardoso

Associate Professor, Department of Civil Engineering, Faculty of Engineering, University of Porto, Portugal

**ABSTRACT:** In order to study the influence of some parameters, namely the embankment geometry and construction sequence, on the geotechnical behaviour of reinforced embankments on soft soils, a numerical model based on the finite element method is used. The settlements, horizontal displacements, stresses in the reinforcement (geosynthetic) and global stability are analysed. Several conclusions are indicated.

**KEYWORDS:** Embankments, Finite Element Analysis, Reinforcement, Settlement Analysis, Soft Soils.

## 1 INTRODUCTION

In this paper, the influence of two parameters - embankment width and construction sequence (Fowler and Haliburton, 1980; Christopher and Holtz, 1985; Haliburton et al., 1982; Koerner and Welsh, 1980; Ingold and Miller, 1988; Holtz, 1990) - is studied.

A numerical model based on the finite element method (Borges, 1995) is used and, basically, its theoretical hypotheses are: a) validity of the plane strain conditions; b) coupled formulation of the flow and equilibrium equations considering the constitutive relations (elasto-plastic models) formulated in effective stresses (extension of Biot's consolidation theory); this formulation is applied at any phase of the problem, either during the embankment construction or in the post-construction period; c) utilisation of the critical states model  $[p,q,\theta]$  (Lewis and Schrefler, 1987; Borges, 1995) to simulate the constitutive behaviour of the foundation and embankment soils; d) utilisation of a hardening elasto-plastic model to simulate the «instantaneous» constitutive behaviour of the reinforcements; e) simulation of the viscous behaviour of the geosynthetics (time-dependent constitutive relations) using a rheological model based on the serial association of Kelvin's units; f) simulation of the constitutive behaviour of the soil-geosynthetic interfaces using a hardening elasto-plastic model.

These studies involve the numerical results of a reference embankment, reinforced and unreinforced (analyses 1A and 1B, respectively). Firstly, the results of these cases are compared to the results of other two cases (analyses 2A and 2B) which are similar to the first ones except to their width, that is smaller. Secondly, having the purpose to verify the influence of the way each embankment layer is constructed (in this case, starting, or not, from its extremities to its middle), the results of other analysis (3A) are introduced.

## 2 DESCRIPTION OF REFERENCE PROBLEM

The analyses 1A and 1B are similar except in the fact that the first one has a reinforcement in the embankment base and the second one does not. They model a 28 days continuous construction of an embankment of 2 m height, symmetric, with a final platform of 10.6 m width and slopes inclined  $V/H=2/3$ . The foundation is a 5 m depth saturated clay that lays on a rigid and permeable soil (lower boundary of the problem). Figure 1 shows the finite elements mesh. Only the 2D elements are represented; the geosynthetic and the soil-geosynthetic interfaces are modulated by one-dimensional elements put between the foundation and the embankment elements.

The embankment construction was simulated activating successively the elements that form the different embankment layers. Four layers of 0.5 m were considered. Total time of construction was 28 days (7 days by layer).

Figure 1. Finite element mesh

The constitutive relations of the embankment and of the foundation were simulated using the critical states model  $[p,q,\theta]$  with the parameters indicated in Table 1. Tables 2 and 3 show other geotechnical properties and the depth variation of the coefficient of earth pressure at rest,  $k_0$ , and of the over-consolidation ratio, OCR, in the foundation.

Figure 2 shows the mechanical behaviour of the geosynthetic and soil-geosynthetic interfaces (elastoplastic

models). The geosynthetic thickness is 2 mm and its elastic modulus is  $1.5 \times 10^6$  kPa. Normal and tangential stiffnesses of the soil-reinforcement interfaces are  $2.0 \times 10^7$  kPa and  $1.6 \times 10^4$  kPa, respectively.

Table 1. Parameters of the critical states model [p,q,θ] for the foundation and the embankment

	$\lambda$	$k$	$\Gamma$	$N$
Foundation	0.22	0.02	3.26	3.40
Embankment	0.03	0.005	1.80	1.817

### 3 INFLUENCE OF EMBANKMENT WIDTH

Because the 2D character of the problem, it is natural that the alteration of the embankment geometry - namely the embankment width - influences the behaviour, either in terms of displacements or in terms of global stability.

To study this question two analyses were done (2A and 2B), which are, as said, similar to the reference analyses (1A and 1B), except to their width, that is smaller (see Figure 3).

Figure 3. Embankment geometry

Relatively to the geosynthetic traction forces, Figure 4 shows that their maximum values are similar (either at the end of construction or at the end of consolidation) in the 1A and 2A analyses, which shows that the maximum value of the traction, as explained by Borges (1995), does not significantly depend on the embankment width. Increasing this parameter, only increases the area of the geosynthetic in which the traction force has approximately a uniform value (similar to the maximum one), in the middle zone of the embankment base.

Relatively to the embankment settlements (Figure 5), one can see that, in terms of decrease of maximum value of the settlements due to the geosynthetic, this decrease can be more effective in larger embankments. However, the influence on the differential settlements under the embankment platform can be observed in both cases. It is interesting verify that the maximum settlement value increases with the embankment width (different geometry of the problem determines different stresses in the foundation and, consequently, different maximum settlement value at the end of the consolidation).

In terms of global stability, it should be noted that the embankment geometry, namely the  $b/h$  relation (see Figure 6), influences the type of failure surface that can occur, i.e., the probability of occurring a failure surface as the one presented in Figure 6a (without cutting the embankment and the reinforcement) is greater when the  $b/h$  parameter has a small value. In this case the geosynthetic does not directly contribute with its strength to the global stability, so the embankment width can determine the role of the reinforcement on failure mechanism.

Using the numerical results and limit equilibrium assumptions, it can be obtained the failure surfaces

Figure 4. Influence of the embankment width on the reinforcement forces: a) at the end of construction; b) at the end of consolidation

Figure 5. Influence of the embankment width on the embankment settlements at the end of consolidation

concerning the four analysed cases. Figure 7 shows those (cylindrical) surfaces and the respective global stability coefficients, at the end of construction. These calculations were done by a computer program that, in each analysed cylindrical surface, compares acting and failure tangential forces (obtained from the results of the numerical model and the strength characteristics of the materials).

The results show that the increase of the global stability due to the reinforcement (comparing 1A to 1B and 2A to 2B) is less effective for small values of  $b/h$  because failure surfaces could be similar to the one represented in Figure 6a. It was the case of 2A analysis.

Figure 6. Influence of embankment width on the type of global failure

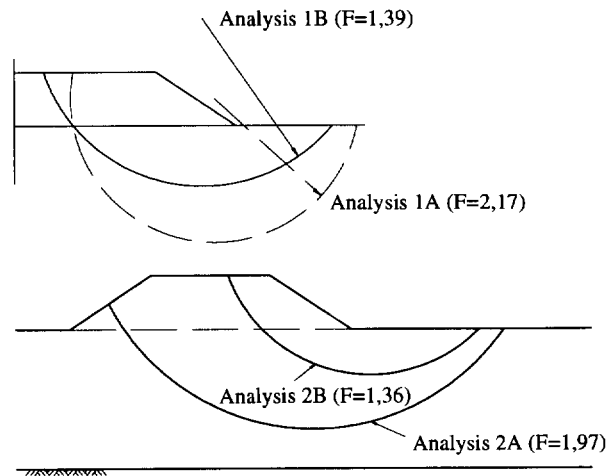

Figure 7. Failure surfaces and respective global stability coefficients (F) at the end of construction.

#### 4 INFLUENCE OF CONSTRUCTION SEQUENCE

To verify the influence of the way each embankment layer is constructed (temporal and spatial evolution), the results

Figure 8. Embankment construction phases: a) analyses 1; b) analyses 3

Figure 9. Influence of construction procedures on the: a) settlements; b) horizontal displacements at the vertical line 3.2 m distant from symmetrical line.

of other analysis (3A) are introduced. This analysis is similar to the reference one, 1A, except in what concerns the construction sequence of each layer (see Figure 8).

From the analysis of the numerical results, it can be concluded that the most important alterations concern the long time settlements (Figure 9a). These settlements are significantly reduce in terms of maximum and differential values.

The reason of that behaviour (Borges, 1995) is related to the fact that, at the end of construction, the distribution of excess pore pressures in the middle of the foundation loaded zone is more uniform. This fact implies a decrease of the shear strains in the foundation, which, consequently, leads to the reduction of settlements (as seen in Figure 9a) and of horizontal displacements, as it can be seen, for example, at the vertical line 3.2 meters distant from symmetry line (Figure 9b).

**ABSTRACT:** Use of marginal, poorly draining backfill to construct reinforced soil structures offers significant advantages for numerous applications. This paper reviews the issues associated with using such soils with an emphasis on the use of permeable inclusions as a design alternative to provide internal drainage of the reinforced zone. Case histories demonstrating the successful use of permeable inclusions for addressing both internal and external seepage problems are presented. Adverse conditions of excessive moisture and pore water pressures within the poorly draining backfill are identified. Finally, preliminary guidance for reinforced soil structures using poorly draining backfills is provided to account for these adverse conditions in their design.

**KEYWORDS:** Reinforcement, Design, Seepage Control, Shear Strength, Drainage.

## 1 INTRODUCTION

Granular soils have been the preferred backfill material for reinforced soil construction due to their high strength and ability to prevent development of pore water pressures. Stringent specifications regarding selection of granular backfill are provided, for example, by the United States FHWA guidelines (Elias and Christopher, 1996). However, if granular fills were not readily available, or if substantial cost benefits resulted from relaxing fill specifications, poorly draining soils (e.g. silty or clayey soils) have been used in practice. In these cases, proper understanding of the conditions leading to wetting of the fill and to the development of pore water pressures is imperative for an adequate design.

Although marginal soils have been successfully reinforced using impermeable reinforcements (e.g. geogrids, woven geotextiles, metallic reinforcements), failures have also been reported. These failures generally occurred if the generation of pore pressures or seepage related conditions were not correctly addressed during design (Mitchell and Zornberg, 1995).

A promising approach for design of reinforced marginal soils is to promote lateral drainage in combination with soil reinforcement. This may be achieved by using geocomposites with in-plane drainage capabilities or thin layers of granular soil in combination with the geosynthetic reinforcements. This design approach may even lead to the elimination of external drainage requirements. The potential use of permeable inclusions to reinforce poorly draining soils is well documented (e.g. Tatsuoka et al.,

1990; Zornberg and Mitchell, 1994; Mitchell and Zornberg, 1995). The focus of this paper is on the implementation of this technology by providing design guidance based on experience gained in recent case histories. Emphasis is placed on the identification of the adverse conditions that may result in wetting and pore water pressure development within the reinforced marginal fill.

This paper initially identifies the problems related to the use of marginal soils and the potential use of permeable inclusions as a design alternative. Next, experiences from the technical literature and by the authors on recent case histories are presented. Finally, preliminary guidance is provided, considering the identified adverse conditions, regarding the design of reinforced soil structure using poorly draining backfills.

## 2 BACKGROUND

### 2.1 Reinforcing Poorly Draining Backfills: Identification of Adverse Conditions

Significant problems are associated with the use of marginal soils in reinforced soil construction. The use of comparatively wet soils leads, for example, to construction problems associated with compaction difficulties during placement. However, the most serious concerns are related to stability problems associated with the potential development of pore water pressures or loss of strength due to wetting within the reinforced fill mass. The following three adverse conditions of pore water pressure generation and/or loss of

strength due to wetting are of concern when reinforcing poorly draining backfills (Fig. 1):

*Condition (a): Generation of pore water pressures within the reinforced fill.* When fine grained, poorly draining soils are used in reinforced soil construction (particularly if placed wet of optimum moisture), excess pore water pressure can develop during compaction, subsequent loading, and surcharging. The designer must then account for these pore water pressures for the evaluations of stability and consolidation-induced settlements.

*Condition (b): Wetting front advancing into the reinforced fill.* This is the case for fills placed comparatively dry (i.e. no pore water pressure generation is expected during construction). However, loss of soil shear strength may occur due to wetting of the backfill soils as a consequence of post-construction infiltration. This loss of strength due to wetting could be expected, even if no positive pore water pressures are generated and no seepage flow configuration is established within the fill.

*Condition (c): Seepage configuration established within the reinforced fill.* Seepage flow may occur within the reinforced soil mass, for example, in the case of sliver fills constructed on existing embankment side slopes and cut slopes in which infiltration occurs from the adjacent ground. Significant seepage forces may occur either during rainy or spring thaw seasons. Water level fluctuations and rapid draw down conditions can also induce seepage forces in structures subjected to flooding or constructed adjacent to or within bodies of water. Seepage forces may also occur during ground wetting, inducing an additional destabilizing effect to the loss in shear strength described by Condition (b).

## 2.2 Reinforcing Poorly Draining Backfills: Permeable Inclusions as Potential Design Alternative

The potential benefits of using marginal soils to construct steepened slopes are significant and include:

- reduced cost of structures that would otherwise be constructed with expensive select backfill;
- improved performance of compacted clay structures that would otherwise be constructed without reinforcements; and
- use of materials, such as nearly saturated cohesive soils and mine wastes, that would otherwise require disposal.

However, the significant benefits of using poorly draining soils as backfill material can be realized only if a proper design accounts for the three adverse conditions listed in Section 2.1. The use of permeable reinforcements is a potential design alternative to properly handle these conditions, as follows:

*Condition (a):* Pore water pressures generated during construction within the reinforced poorly draining fill could be dissipated if the geosynthetic inclusions are used not only as reinforcements, but also as lateral drains. New applications in the use of geosynthetics for stabilization in land reclamation projects could be developed. For example, acceleration of drainage of hydraulically dredged materials could be achieved.

*Condition (b):* A problem frequently reported for embankments of (unreinforced) compacted cohesive soils is the development of surface tension cracks and the subsequent loss of soil strength due to soaking. The wetting front and development of surface tension cracks have been observed by the authors and other investigators (Tatsuoka et al., 1990) to extend only down to the region above the first geosynthetic layer. If the reinforcement is permeable, water that might normally accumulate in the crack can drain when the crack reaches the first layer of reinforcement.

*Condition (c):* Permeable reinforcements can prevent the development of flow configurations with destabilizing seepage forces within the embankment fill. Internal drainage is of particular concern in road widening projects, because of the potential water seepage from cut slopes into the reinforced fill. Although the adverse effect of seepage forces in engineered slopes could be prevented by designing special drainage systems, a more economical design alternative is to combine drainage and reinforcement capabilities by using permeable reinforcement elements.

In addition to addressing stability problems, the use of permeable inclusions may also be of benefit during construction. Wet soils typically must be dried to provide desired compaction levels and associated design strengths. However, it has been verified that permeable inclusions (e.g. nonwoven geotextiles) help in the compaction of the

Fig. 1. Different conditions of concern in reinforced soil slopes using poorly draining backfills.

fill both by allowing better distribution of the compaction effort and by draining excess pore water pressure induced during compaction (Indraratna et al., 1991; Zornberg et al., 1995). On several projects, water has even been observed seeping out of the geotextile during compaction of such soils placed wet of optimum. The most significant improvement in compaction has been reported for low plasticity clayey and silty soils. Although some compaction improvement has been observed in plastic soils, the influence would not be nearly as significant. In either case, drying may still be required to facilitate placement and compaction, especially in very wet soils. Test pads are recommended to determine the actual placement requirements and compaction improvements. The increased rate of settlement would also expedite the construction of structures with a low tolerance for settlement (e.g. roads, bridges and buildings) that may be supported by the reinforced structure.

### 3. EXPERIENCE IN THE USE OF REINFORCED POORLY DRAINING FILLS

Although there are no generally accepted design guidelines for reinforced soil structures using marginal soils, good performance has been observed in cases where the generation of pore water pressures within the fill was mitigated. The observed performance of a 5.6 m high experimental structure built using silt backfill in Rouen, France is a good example (Perrier et al., 1986). Pore water pressures were monitored within the silt backfill. The structure consisted of sections reinforced with woven geotextiles and a section reinforced with a composite nonwoven/geogrid. Fig. 2 shows positive and negative pore water pressures as a function of time recorded at different locations within the fill. The pressure sensor behind the reinforcement region recorded placement excess pore water pressures of as much as 60 kPa at the end of construction. Along the woven geotextile, 3.5 m from the wall face, positive pore water pressures on the order of 20 kPa were registered at the end of construction and dissipated in 350 days. Along the composite geotextile, on the other hand, negative pore water pressures were registered over the entire length of the reinforcement, even at the end of construction. The negative pore water pressure recorded for the geocomposite most likely developed due to the ability of the geosynthetic to maintain partial saturation in the soil or to the unsaturated condition of the geosynthetic itself. Pore water pressures along the composite geotextile were systematically lower than those recorded along the woven textile.

Permeable reinforcements were also used to control pore water pressure during construction and to accelerate post-construction consolidation as part of the reconstruction of an embankment in Pennsylvania (Wayne et al., 1996). A sink hole developed in a section of state

route SR54 due to the collapse of an abandoned railroad tunnel. The traditional repair would have involved the removal and replacement of the 15 m high embankment. However, the native soil (a sandy clay of high moisture content) was deemed unsuitable backfill due to potential stability and settlement problems. Consequently, due to the high cost of granular fill as replacement material (estimated as \$19.60/m<sup>3</sup>), the Pennsylvania DOT decided to use geosynthetics to provide both drainage and reinforcement to the native soil used as fill. The estimated cost savings are \$200,000 (based on an as built cost of \$4/m<sup>3</sup> for the native

Fig. 2. Pore water pressures ( $u$ ) in the Rouen reinforced wall, along a woven and a nonwoven/geogrid composite, within a silty backfill (redrawn after Perrier et al., 1986).

soil plus the geotextile). Based on the results of field tests used to evaluate pore pressure response, a nonwoven geotextile was selected to allow pore pressure dissipation in the native soil. The geotextile, with an ultimate strength of 16 kN/m, also provided reinforcement to the 1.5H:1V side slopes. Placement of geotextiles at each compacted lift (0.3 m spacing, i.e. 0.15 m drainage path), led to full dissipation of pore water pressure within approximately 4 days. Only approximately 25% of the pore water pressures were dissipated during the same time period in zones that did not contain geosynthetics. Piezometers installed at the base and middle of the slope confirmed the test pad results. Fig. 3 shows the development and subsequent dissipation of pore pressure during and following construction of the embankment. Geotextile deformations in the side slope were monitored and found to be less than the precision of the gages ( $\pm 1\%$  strain).

There is also good evidence that permeable geosynthetic reinforcements can reduce the influence of external seepage behind the reinforced soil mass (e.g. in cut slope applications). Recent centrifuge model studies evaluated the performance of unreinforced and reinforced steep slopes constructed with clay (Mahmud, 1997). Seepage was induced into the reinforced clay by maintaining a constant water level at the back of the structure. Measurement of pore pressure across the base of the structure, indicated a lower phreatic surface if the slope was constructed using permeable geosynthetic reinforcements than if the slope was unreinforced (Fig. 4).

The use of permeable reinforcements to reduce external seepage problems was also demonstrated in a recent project which included one of the highest geotextile-reinforced slopes in the U. S. (Zornberg et al., 1995). As part of a highway widening project, the Federal Highway Administration constructed a permanent, 15.3 m high geotextile-reinforced slope. Several characteristics were unique to the design: the structure was higher than usual geotextile-reinforced slopes, it involved the use of both a high modulus composite and a nonwoven geotextile, and it was constructed using indigenous soils (decomposed granite) as backfill material. Internal drainage was a design concern because of the potential seepage from the fractured rock mass into the reinforced fill, and because of the potential crushing of decomposed granite particles that was anticipated to reduce the hydraulic conductivity of the fill. Widening of the original road was achieved by converting the existing 2H:1V unreinforced slope into a 1H:1V reinforced slope. The final design adopted a high strength composite geotextile in the lower half of the slope and a nonwoven geotextile in the upper half. Piezometer measurements indicated that a seepage flow configuration did not develop within the reinforced soil mass even during the spring thaw, when seepage water infiltrated from the backslope fractured rock into the reinforced fill.

Additional evidences that good structure performance is dependent on maintaining a low water pressure in poorly

draining backfills was provided by Tatsuoka et al. (1990) and Mitchell and Zornberg (1995). However, practice has led theory, and a consistent design methodology for design of reinforced soil structures using poorly draining backfills has not been developed yet.

Fig. 4. Centrifuge model results showing the elevation of the phreatic surfaces for unreinforced and reinforced slopes (Mahmud, 1997).

## 4. DESIGN GUIDANCE

### 4.1 General Considerations

Good performance in reinforcing marginal soils depends on accounting for excess pore water pressure development within the fill material. Design criteria involved in the use of reinforcement-drainage geocomposites differ from those developed for conventional soil reinforcement applications. A total stress analysis, considering soil parameters representative of placement conditions, usually has been

adopted in the analysis of impermeable conventional reinforcements. The design generally leads to the use of reinforcements with a comparatively high tensile strength to account for a low soil shear strength and the presence of seepage forces. Reinforcement embedment length is comparatively large to account for reduced pullout resistance. External drainage of the reinforced soil structure has often been considered as part of the design to intercept ground water at the back of the structure.

The general design philosophy for permeable inclusions that is proposed in this paper is that transmissivity of the geosynthetic inclusion should be selected so that the geosynthetic inclusions can carry the full in-plane flow without developing positive pore water pressures along the soil-reinforcement interface. While it is also possible to design for positive pore water pressures at the interface, such a design requires evaluations that are beyond the scope of this paper. Consequently, the design procedure described below is only for reinforced soil structures in which the reinforcement transmissivity is conservatively selected so that flow is not impeded within the geosynthetic. The proposed design methodology assumes no build up of excess pore pressure within the permeable reinforcements.

The analysis should account for the three adverse conditions listed in Section 2.1 in order to determine the tensile strength and pullout requirements. The general design philosophy proposed herein is to consider a two-phase evaluation:

*Analysis (i)* in each adverse condition is performed ignoring the drainage contribution provided by the reinforcements.

This is a total stress analysis which considers that stability is mostly provided by the reinforcements with minimum contribution of the soil shear strength. Due to the conservative nature of this assumption, a relatively low design factor of safety is suggested.

*Analysis (ii)* in each adverse condition is performed accounting fully for the drainage contribution provided by the reinforcements (i.e. zero pore water pressure is considered within the reinforced fill for analysis purposes). Considering that no pore water pressures are assumed to develop, this is an effective stress analysis. Design factors of safety used in conventional engineering practice are considered in this case.

#### 4.2 Designing for Condition (a): Pore water Pressures Generated within the Reinforced Fill

There is good evidence that geosynthetics with adequate transmissivity and vertical spacing on the order of every compaction lift or every other compaction lift (e.g. 200 to 300 mm) can dissipate excess pore pressure along the interface of the permeable inclusions during construction (Bourdillon et al., 1977). However, excess pore water pressures may develop within the soil mass between

geosynthetic layers during construction, especially if highly plastic soils are used as backfill material. Considering the difficulty in accurately evaluating the distribution of pore water pressures generated during construction a two-phase analysis is proposed. These analyses, summarized in Table 1, are as follows:

- i) Total stress analysis ignoring reinforcement lateral drainage. This analysis neglects the dissipation of pore water pressures through the permeable inclusions to provide a conservative estimate of the stability of the structure at the end of construction. Considering the short-term condition and the conservative assumptions in this analysis, a factor of safety of 1.1 is recommended. This analysis determines minimum reinforcement requirements that will preclude collapse during construction of the structure. That is, it provides reinforcement requirements for a short-term situation in which stability is provided mostly by the tensile forces in the reinforcements with only a minor contribution by the undrained shear strength of the backfill. The undrained soil shear strength of the backfill for this analysis should be based on unconsolidated undrained (UU) triaxial tests. The specimens should be prepared at representative field densities and moisture placement conditions, and tested at these placement conditions under project-specific confining pressures. Although the authors consider testing under unsaturated conditions is an adequate approach, testing under fully saturated conditions represents an additional degree of conservatism that the designer may consider on a project-specific basis.
- ii) Effective stress analysis accounting for full lateral drainage by the reinforcement. Full drainage of the reinforced fill is assumed for the long-term conditions. This analysis provides a realistic evaluation of the long-term stability of the structure, because dissipation of pore water pressures generated during construction should have occurred through the permeable inclusions. This analysis determines the minimum reinforcement requirements that will provide adequate stability under long-term conditions following dissipation of pore water pressures generated during construction of the structure. It is emphasized that the transmissivity of the reinforcements should be selected so that generation of pore water pressures is prevented at the soil-reinforcement interface. Typically, the soil shear strength should be based on isotropically consolidated undrained (CIU) triaxial tests performed on saturated samples with pore pressure measurements or on consolidated drained (CD) triaxial tests. The long term design factor of safety typically required for reinforcement of granular fills (e.g. 1.3 to 1.5) should be used in this analysis.

Table 1. Summary of Analyses for Reinforced Soil Structures with Poorly Draining Backfills

<i>Condition</i>	<i>Characteristics</i>	<i>Analysis i: Ignoring lateral drainage</i>	<i>Analysis ii: Accounting for full drainage</i>
<i>a) Generation of pore water pressures within reinforced fill</i>	Type of analysis:	Total Stress	Effective Stress
	Case:	Generation of pore pressures due to short-term loads	Long-term drained condition due to lateral drainage
	Design Criteria:	FS = 1.1	FS = 1.3 to 1.5 (*)
	Reinforcement Transmissivity:	Ignored in analysis	Conveys fully the flow from consolidation process
	Soil shear strength:	$\phi$ and $c$ from UU tests. Specimen condition: as placed	$\phi'$ and $c'$ from CIU or CD tests. Specimen condition: saturated
<i>b) Wetting front advancing into reinforced fill</i>	Type of analysis:	Total Stress	Total Stress
	Case:	Loss of shear strength due to soaking	Unsaturated condition maintained due to permeable reinforcements
	Design Criteria:	FS = 1.1	FS = 1.3 to 1.5 (*)
	Reinforcement Transmissivity:	Ignored in analysis	Prevents advancement of wetting as defined by testing
	Soil shear strength:	$\phi$ and $c$ from CIU tests. Specimen condition: saturated	$\phi$ and $c$ from CIU or CD tests. Specimen condition: highest anticipated moisture
<i>c) Seepage flow configuration established within reinforced fill</i>	Type of analysis:	Total Stress	Effective Stress
	Case:	Development of seepage forces within fill	Saturation of fill, without development of seepage forces due to permeable reinforcements
	Design Criteria:	FS = 1.1	FS = 1.3 to 1.5 (*)
	Reinforcement Transmissivity:	Ignored in analysis	Conveys fully the seepage flowing into the backfill
	Soil shear strength:	$\phi$ and $c$ from CIU tests. Specimen condition: saturated	$\phi'$ and $c'$ from CIU or CD tests. Specimen condition: saturated

(\*) Design criteria for Analysis (ii) should be selected based on design guidelines for reinforced soil structures with granular backfill.

The reinforcement tensile strength eventually selected is the higher value obtained from analyses (i) and (ii). Moreover, the minimum reinforcement length selected for design should be the larger value defined from the two analyses. Note that the analyses described above address internal stability. However, the required length of the reinforcement must also consider external stability of the structure. External stability should consider the undrained soil shear strength for the fill retained behind the reinforced zone if it is to be constructed with similar marginal fill. For cut slopes appropriate pore water pressure assumptions should be made for field conditions.

It should be noted that an effective stress analysis could have been proposed to evaluate the short-term stability of the structure, instead of the total stress Analysis (i). An effective stress analysis would more accurately account for the in-plane drainage capacity of the geosynthetic and the corresponding increase in soil strength. Also, an effective stress analysis would facilitate evaluation of the backfill placement rate that would lead to

an acceptable stability factor of safety during construction. The difficulty in this approach is the accurate determination of the pore water pressures within the fill. They could be estimated from direct measurements in field trials (e.g. test pads) or sealed laboratory specimens (one lift thick with a geosynthetic on the bottom and top connected to drain lines) subjected to stress levels anticipated during construction. Alternatively, pore pressures could be theoretically estimated based on one-dimensional consolidation theory and the assumption of full saturation of the backfill material during construction. An evaluation of this approach is beyond the scope of this paper.

#### 4.3 Designing for Condition (b): Wetting Front Advancing into the Reinforced Fill

As loss of strength may occur because of a wetting front advancing into the reinforced fill. Geosynthetic transmissivity requirements should be established to avoid

advancement of wetting front for expected conditions. A two-phase analysis is also proposed in this case. These analyses, summarized in Table 1, are as follows:

- i) Total stress analysis ignoring the effect of lateral drainage in preventing advancement of a wetting front. This analysis is performed using shear strength properties of the reinforced soil mass defined using saturated specimens. The results of this analysis provide an estimate of the stability of the structure under an advancing wetting front. This analysis is conservative because the backfill is assumed fully saturated, which should not occur in actual practice because the wetting front is intercepted by the permeable reinforcements. Consequently, a factor of safety of 1.1 is recommended in this case. Water pressure that may develop as water fills surface cracks (induced by desiccation, freeze/thaw, or slope movements) should be accounted using boundary water pressures in the analysis.
- ii) Total stress analysis accounting for the effect of lateral drainage in preventing advancement of a wetting front. The total shear strength is defined from unsaturated specimens prepared at the highest moisture anticipated in the fill. Note that the total shear strength defined from unsaturated specimens should be higher than the effective shear strength of the fill. A total stress analysis is considered in this case, instead of an effective stress analysis, in order to account for the beneficial effect of the negative pore water pressures in the unsaturated reinforced fill. The shear strength of the reinforced fill above the top reinforced layer (which may become saturated) should be obtained from saturated specimens. This analysis provides a realistic evaluation of the stability of the structure because it accounts for the lateral drainage of the geosynthetic reinforcements.

#### 4.4 Designing for Condition (c): Seepage Configuration Established within the Reinforced Fill

Post-construction pore water pressures could be generated by a seepage configuration developing within the backfill material. Such a flow configuration may develop seasonally during rainy periods or during spring thaw. A seepage configuration may also develop due to water level fluctuations in structures subjected to flooding or constructed adjacent to or within bodies of water. Finally, seepage forces could be induced by surface water infiltration. The seepage configuration can be determined for an unreinforced embankment using flow nets for seepage analysis. Transmissivity requirements in the geosynthetic inclusions are such that each reinforcement should convey fully the flow quantity it intercepts (as estimated from a flow net defined in an unreinforced

slope). A two-phase analysis is also proposed in this case. These analyses, summarized in Table 1, are as follows:

- i) Total stress analysis ignoring reinforcement lateral drainage. This analysis considers seepage forces defined from a flow configuration that would develop in an unreinforced slope. The results of this analysis provide a conservative estimate of the stability of the structure during a seasonal rapid configuration of seepage flow within the fill. The conservatism of this analysis is because (1) the backfill is assumed as fully saturated, which may not occur in actual practice, and (2) the seepage configuration does not account for the lateral drainage provided by the reinforcements. Therefore, a relatively low factor of safety of 1.1 is recommended in this case (note that seepage forces are considered in the analysis).
- ii) Effective stress analysis accounting for full reinforcement lateral drainage. Full drainage of the reinforced fill is assumed for the typical condition of the structure. This analysis provides a realistic evaluation of the long-term stability of the structure because it accounts for the lateral drainage of the geosynthetic reinforcements. No seepage forces are considered to develop within the reinforced fill if the reinforcements provide adequate internal drainage.

As indicated, the transmissivity and number and location of layers should be selected so that the geosynthetics have in-plane drainage capacity to accommodate the full seepage flowing into the reinforced fill. Otherwise, external groundwater and surface water control systems (e.g. base and back drains and surface collectors) must be incorporated into the design. The soil shear strength in the two analyses (total and effective stresses) should be determined using saturated samples in order to account for the potential loss of shear strength under soaked conditions.

#### 4.5 Reinforcement Requirements

Mechanical and hydraulic properties that must be characterized for alternative reinforcement-drainage geocomposite systems include: tensile strength, pullout resistance, drainage, and filtration. These four characteristics should be carefully evaluated and quantified in order to assess the overall performance of the structures under consideration. The evaluations include at least the following considerations:

- Tensile strength requirements of the geosynthetic, determined as indicated in Table 1, will be typically higher for reinforcement of marginal fills than conventional free draining material. Consideration should be given to soil creep in the determination of long-term design strength.

- Pullout resistance, which require special consideration due to the potential development of pore water pressures at the soil/reinforcement interface and to the creep potential of cohesive soils. For the total stress analyses in Table 1, total stress shear strength properties should be used. For the effective stress analyses, effective shear strength properties should be considered.
- Transmissivity requirements should account for the different conditions indicated in Table 1 (i.e. the total flow induced by consolidation or seepage must be accommodated without inducing positive pore water pressures within the reinforcements). There is good evidence that transmissivity values equivalent to those of needlepunched nonwoven geotextiles are adequate to freely drain cohesive type soil and dissipate excess pore pressure along the interface, provided spacing is on the order of every lift or every other lift of compacted soil (e.g. Bourdillon et al., 1977). They should also be high enough to prevent advancement of a wetting front. Test pads could be used to evaluate the suitability of selected geosynthetics. Increased transmissivity may be required based on flow net analysis of externally induced seepage (Condition c).
- Filtration requirements needed to minimize clogging of the geocomposite should also be evaluated. Design guidance is provided in Holtz et al. (1997) and Koerner (1994).

## 5 CONCLUSIONS

Marginal poorly draining backfill can be used to safely construct reinforced steepened slopes provided internal and external seepage forces have been accounted for in the analysis. Adverse conditions include: (a) the generation of pore water pressures within the reinforced fill (either during construction or subsequent loading); (b) a wetting front advancing into the reinforced fill, which may cause loss of soil shear strength in a fill initially placed in a comparatively dry condition; and (c) a seepage flow configuration established within the reinforced fill due to seepage from the retained soil or fluctuations in the water level for structures constructed adjacent to or within bodies of water.

Reinforcements with in-plane drainage capabilities offer a design alternative for mitigating these adverse conditions. A two-phase analysis is proposed when using permeable reinforcements to account for both short and long-term conditions. Although the design approach is supported by theoretical soil mechanics, it relies heavily on field experience. Therefore, an element of conservatism is inherently included in the proposed methods. Further refinement of this guidance is being developed by the authors in order to provide quantitative transmissivity requirements for the case of pore water pressures developed during construction. Recommendations are

provided herein regarding the selection of soil shear strength properties and design criteria for the analyses.

# Reinforcement of a Saudi Sabkha Soil Using Geotextiles

S.A. Aiban, O.S.B. Al-Amoudi, I. Ahmed, H.I. Al-Abdul Wahhab

Assistant Professor, Assistant Professor, Research Assistant and Associate Professor, respectively, Department of Civil Engineering, King Fahd University of Petroleum and Minerals, Dhahran, Saudi Arabia

**ABSTRACT:** Sabkha soils are well distributed over many parts of the world. Paved roads constructed on sabkha terrains often suffer different classes of damage due to the low load-carrying capacity of sabkha deposits, especially when becoming wet. This calls for the improvement of sabkhas prior to any construction. An experimental program was conducted to assess the performance of a problematic sabkha soil from eastern Saudi Arabia and to improve its strength using different techniques. In this paper, the effects of chemical additive type, dry density, moisture content and exposure conditions on the strength and deformation characteristics of the sabkha are presented. The results indicated that the sabkha had an acute water sensitivity depicted by a complete loss of strength when the samples were compacted at moisture contents other than the optimum value or when the sabkha was inundated with water. The results also showed that cement and lime had a marginal effect on the strength of this sabkha while geotextile significantly enhanced its load-bearing capacity.

**KEYWORDS:** Sabkha, Geotextile, Subgrade, Chemical stabilization, Water sensitivity.

## 1 INTRODUCTION

Sabkha is originally an Arabic expression to describe indefinitely saline flats that are underlain by sand, silt and clay, and often encrusted with salt. It is an equilibrium surface whose level is largely controlled by the prevailing climatic and hydrological conditions (Johnson et al. 1978). These soils are defined as the subaerial evaporite flats that border partially landlocked seas (called coastal sabkhas), or cover a number of continental depressions (called inland or continental sabkhas), both types usually form under hot and arid climates; and are associated with shallow groundwater tables (Al-Amoudi 1995).

Sabkha is widely distributed in the Arabian Peninsula, especially in the well-populated cities along the Arabian Gulf and Red Sea coasts (Al-Amoudi et al. 1992). Along the western and southwestern shores of the Arabian Gulf, these soils are generally viewed as unconsolidated, heterogeneous, layered or unlayered sediments, that are bathed in highly concentrated brines. Their outer surfaces are generally composed of hygroscopic salts which, when dampened, can render the normally stable surface crusts impassable. These characteristics make the sabkha susceptible to collapse upon flooding.

Sabkha soils are not confined to the Arabian Peninsula, but are well distributed over the globe with various nomenclatures, and often highly bewildering (Ellis 1973). Sabkha extends over many parts of the Middle East, including Egypt, Sudan, Libya, Tunisia,

Algeria and Ethiopia. Sabkha also exists in India, Australia, Southern Africa, Mexico as well as in California, Utah and Texas in the USA (Al-Amoudi et al. 1997).

### 1.1 Characteristics of Sabkha Soils

During the last two decades, with the upsurge in oil prices, the Arabian Gulf countries have gone through a spectacular phase of both industrialization and urbanization. Inevitably, some of this construction was located on sabkha flats and, therefore, several problems developed in road construction, such as cracking, ravelling, formation of huge potholes and rutting (Farwana and Majidzadeh 1988), despite the fact that the necessary precaution had been taken. A major contributory factor is the very low bearing capacity of the sabkha soil, which often leads to the formation of depressions and excessive differential settlement (Al-Amoudi et al. 1995). The surficial layers of sabkha deposits are well known for their generally low strength, with SPT N-values of 0 to 8, rarely exceeding 10. In addition, there are three other concerns when dealing with sabkha soils (Al-Amoudi et al. 1995). Firstly, the concentrated nature of sabkha brines, which is often four to six times that of a seawater from the same vicinity, can be drawn into the permeable layers of a construction (such as a road) by capillary action and can recrystallize therein, causing expansion and blistering at the surface. Secondly, the severe climatic conditions, under which

sabkha deposits usually develop, can contribute to the instability of the sabkha soil by phase alteration. Lastly, the mineral grains in the sabkha matrix are bonded together by cements that are somewhat water-soluble, such as halite, gypsum, anhydrite and/or aragonite, thus making the sabkha susceptible to collapse upon wetting.

These characteristics mean that sabkha soils do not comply with routine design requirements, as neither their bearing capacity nor compressibility meet normal constructional practices (Al-Amoudi 1994). Such a situation calls for the improvement of sabkha soil prior to any construction to avoid future problems. A recent search of the literature (Al-Amoudi 1995) indicates that many deep soil densification techniques (i.e. vibroflotation, vibroreplacement, dynamic compaction, etc.) have been implemented for large-scale constructions, with varying degrees of success. Chemical stabilization, using cement, lime and emulsion, did not bring a guaranteed improvement for all types of sabkha (Aiban et al. 1996). Geotextiles have also been used to stabilize sabkha soils in both preliminary laboratory studies and the field. Despite the reported success achieved through the use of geotextiles as a means of reinforcing the sabkha soil and/or drainage control, practicality and durability remain the critical factors (Al-Amoudi 1994). Presently, there is relatively meager information on the usage of geotextile for aggregate bases/subbases constructed over weak soils, such as sabkha. Such applications are of great potential to the construction industry in the Arabian Gulf and elsewhere.

This research program was initiated when lime and cement failed to stabilize a problematic "clayey" sabkha soil. Therefore, geotextiles were proposed to improve the load-bearing capacity of this sabkha. Accordingly, an experimental program was initiated to assess the performance of sabkha soil with and without geotextile. Although there are currently many parameters under investigation, the paper reports the effect of density, moisture content and exposure conditions (i.e. as-molded vs. soaked) on the strength and deformation characteristics of sabkha soils.

## 2 EXPERIMENTAL PROGRAM AND RESULTS

The sabkha sample was retrieved from the gigantic Ar-Riyas sabkha in eastern Saudi Arabia. The characteristics of this sabkha have been described in detail by Al-Amoudi et al. (1997) and Johnson et al. (1978). The soil was collected to embody all the layers up to the water table excluding the salt crust. After being transported to the laboratory, the soil was spread on plastic sheets for air drying and the lumped pieces were broken down using plastic hammers until all the

material passed ASTM # 4 sieve. The soil was thereafter thoroughly mixed, allowed to air dry and stored in plastic drums until testing.

### 2.1 Geomorphology of the Sabkha

The sabkha surface was observed to be covered by non-crystallized, pure halite layer 3 to 4 cm thick. A layer of brownish clay with anhydrite impurities was the second layer in succession and had a thickness of 2 to 3 cm. A band of anhydrite of about 6 to 7 cm thick was encountered followed thereafter by dark brown clay that had an apparent plasticity and contained some cubical crystals of clear halite (sodium chloride). Thereafter, a layer of halite cubes was encountered at a depth of 20 to 22 cm. The water table is shallow and was encountered at the top of the halite layer which is only 20 cm below the ground surface. Some air bubbles were observed after excavation, indicating the presence of artesian flow. The sabkha layering is shown in Figure 1.

Figure 1. Layering characteristics of the sabkha.

### 2.2 Sabkha Classification and Compaction

The USCS and AASHTO systems were used to classify the sabkha soil. In addition to water, the characterization tests were conducted using sabkha brine from the same vicinity. The grain-size distribution curves are shown in Figure 2. The plastic limit values

Figure 2. Grain-size distribution of the sabkha.

were 21% and 28% when distilled water and sabkha brine were used, respectively. The corresponding plasticity indices are 17.1% and 13.4%. Based on the sabkha brine results, the soil is classified as CL and A-6 according to the USCS and AASHTO systems, respectively.

The modified Proctor (i.e. compaction) test (ASTM D 1557) was used to determine the maximum dry density ( $\gamma_{d \max}$ ) and optimum moisture content ( $w_{opt}$ ). The California-bearing ratio (CBR) test (ASTM D 1833) was conducted for samples prepared at different moisture contents to assess the moisture sensitivity of the sabkha. The variation of the dry density and CBR values with the molding moisture content is shown in Figure 3. The CBR results clearly indicate the acute water sensitivity of the sabkha; the as-molded CBR value could reach 64 on the dry side of optimum while on the wet side of optimum, the CBR was as low as 3 only. In addition, the CBR at the  $w_{opt}$  was much lower than those at lower moisture contents. Furthermore, the soaked CBR did not exceed 2 regardless of the molding moisture content.

### 2.3 Chemical Stabilization

The CBR results in Figure 3 indicate a complete loss of strength when the samples were compacted on the wet side of optimum at a moisture content corresponding to 95% of the  $\gamma_{d \max}$ . The complete strength loss calls for stabilization of the sabkha prior to its usage. Different percentages of portland cement and lime were used to increase the strength of the sabkha and improve its water sensitivity, however, the improvements cannot be considered significant. The results in Figure 4 reveal

that only the addition of 10% cement can, at best, double the maximum unsoaked CBR value after 7 days of curing. These additions reduced the water sensitivity of the sabkha, but could not bring out significant improvements as compared with other sabkhas where an increase in the strength in excess of ten times has been reported (Aiban et al. 1996; Al-Amoudi et al. 1995). It was, therefore, decided to use geotextile to improve the bearing capacity of this sabkha.

Figure 3. Variations of dry density and CBR values with molding moisture content for untreated sabkha.

### 2.4 Mold Fabrication

At present, relatively meager information has been developed concerning the use of geotextiles as reinforcement in aggregate bases or under foundations. This is particularly true when using weak and heterogeneous soils, such as sabkhas, as part of a pavement layer system. The only documented laboratory work on the use of geotextiles with sabkha soils is that of Abduljauwad et al. (1994). However, the mold used in their investigation was relatively small and had a diameter of only 320 mm. In this experimental program, a large-scale setup was fabricated at the University central workshop to conduct "representative" tests on sabkha soil reinforced with locally-produced geotextiles. The setup consists of a stainless steel mold having a diameter of 750 mm and a height of 350 mm with a wall thickness of 6.4 mm. The mold rests on a square stainless steel plate having the dimension of 1100 × 1100 mm and 16.5 mm in thickness. Stainless steel material was used in the setup because of the chemical aggressivity of the sabkha. To soak the samples, four

Figure 4. Variation of dry density and unsoaked CBR values with moisture content for sabkha samples treated with 10% cement or lime.

holes were made in the lower portion of the mold which were connected to the top reservoir containing the soaking fluid. The bottom reservoir was provided to maintain a constant water level when testing soaked samples. The setup is schematically shown in Figure 5.

Figure 5. The experimental setup for the sabkha-geotextile system.

## 2.5 Sample Preparation and Testing

The sabkha samples were prepared in the large-scale mold as follows (Figure 5): First, a 20 mm layer of coarse sand filter was laid in the mold, thereafter, a layer of geotextile was spread over the sand, which acted as a separator between the sand filter and sabkha matrix while allowing water to flow in an upward direction when the sabkha samples were soaked. The sabkha soil was mixed with the specific amount of water in a large mixer, then a known weight of soil was placed in the mold and compacted to the required dry density using the static compaction method by means of a large jack which acted against a strong reaction beam. The soil was compacted in three lifts of 70, 60 and 70 mm thicknesses. The reinforcing layer of geotextile was thereafter placed on top of the compacted sabkha soil followed by a 62.5 mm thick layer of fine (0.15 to 4.76 mm in size) steel slag aggregate, which was pluviated to its maximum density. The technical specifications of the geotextile are summarized in Table 1. The geotextile is a locally produced non-woven needle punched fabric manufactured from polyester fibers.

So far, all testings of the geotextile-reinforced sabkha were performed under static loading. A displacement control loading was applied using an electrical motor and the deformation rate was set at 1 mm/min. The load was applied on a stiff circular plate having a diameter of 125 mm and a thickness of 10 mm. The load was measured using a load cell while the deformation was measured using four LVDT's mounted on top of the loading plate.

Table 1. Technical specifications of the geotextile used as reported by the manufacturer.

Property	Standard	Unit	ALYAF-400
Weight	ASTM D5261	gm/cm <sup>2</sup>	400
Thickness under 2 kN/m <sup>2</sup>	ASTM D5199	mm	4.5
Strip tensile strength (Longitudinal/transverse)	DIN 53857	N	925/1650
Grab tensile strength (Longitudinal/transverse)	ASTM D4632	N	1025/1525
Grab elongation (Longitudinal/transverse)	ASTM D4632	%	>80/>80
Cone penetration	BS 6906-6	mm	8.5
Permeability, k	BTTG, UK	cm/s	0.14

The loading plate was selected to be circular for many reasons including: (1) to simulate tire imprints which can be assumed circular for the majority of problems (Yoder and Witczak 1975), (2) to allow direct comparison with the California Bearing Ratio (CBR) results due to the relative similarities in the two systems since the CBR applies the load through a circular piston, and finally (3) to enable future theoretical simulations using both numerical procedures and analytical calculations due to the existence of similar solutions for axisymmetric problems.

The loading plate was chosen to have a diameter of 125 mm so that a clearance of 312 mm (five times the radius of the plate) from the sides of the mold can be maintained. This was intended to avoid any boundary interference from the sides of the mold. In addition, there will be enough distance from the end of the geotextile to provide anchorage of the geotextile and thus prevent failure due to pull out of the geotextile.

Figure 6 depicts the results for the specimens prepared at 90% and 95% of the maximum dry density ( $\gamma_{d \max}$ ) on the dry side of optimum and tested under "soaked" conditions, with and without the geotextile reinforcing layer. The data therein indicates that the strength of the system increased significantly when a geotextile layer was introduced. The ultimate strength of the sample without geotextile layer was 68 and 76 kgf at a deformation of 30 mm for the samples prepared at 90 and 95% of  $\gamma_{d \max}$ , respectively. When a geotextile layer was incorporated in the system, the ultimate strength increased to 248 and 265 kgf for the same deformation. This corresponds to an improvement in the ultimate strength of 365% and 350% compared to that of the corresponding samples without any geotextile layer. With an average improvement of about 357%, the soil-geotextile systems successfully improved the strength of

the present sabkha soil more than the improvement attained using cement or lime at a dosage of 10% by weight of the dry soil.

Figure 6. Load deformation curves for soaked sabkha soil with and without geotextile reinforcement.

It is worth mentioning that the two sets of load-deformation curves for the 90 and 95% relative compaction are almost identical regardless of the sabkha's initial density or moisture content. This is mainly ascribable to the fact that the strength of the sabkha is completely lost upon soaking and, thus, the soaked sabkha samples have the same strength. However, the reinforcing geotextile layer improves the load-carrying capacity of the sabkha significantly irrespective of its initial state. It is believed that the fine slag aggregate and some other factors have an effect on these results. It is the intention of the research team to vary the thickness of the fine slag aggregate and the geotextile (type and properties) and investigate their effects, in order to optimize the design of geotextile-sabkha systems.

### 3 CONCLUSIONS

This experimental program was conducted to compare the influence of chemical additives and geotextile on the load-carrying capacity of a clayey sabkha soil. The results clearly indicated the acute water sensitivity of the sabkha, as evidenced by the complete loss of strength when the samples were prepared at moisture contents other than the optimum value or when the sabkha was soaked. The results also demonstrated the fact that

chemical additives did not improve the strength significantly even when 10% cement or lime was added. However, the use of geotextile improved the load-carrying capacity of the sabkha up to four times that without geotextile. This was the case even for lower degrees of compaction such as 90% of  $\gamma_d$  max. The utilization of problematic sabkha sites seems to be possible with the use of geotextile; a possibility where other stabilization techniques failed.

In addition, the future program will include testing of cement-treated sabkha samples using the 750 mm mold. This will allow a direct comparison between the effectiveness of the chemical stabilization and geotextile. The boundary conditions of the two sets will be identical except for the treatment procedures. It should be clear that the data presented in this paper does not directly compare the chemical stabilization and the improvement using geotextile, nevertheless, the results vividly demonstrated the poor response of sabkha to chemical stabilization. On the other hand, the data clearly indicates the significant improvement of the load-carrying capacity of the sabkha-geotextile system. Both the CBR and loading in the large 750 mm mold simulate a punching problem albeit with some variation in the boundary conditions.

# Long-term Deformation of Reinforced Cohesive Soil Fills and Walls

M. Fukuoka

Dr., Public Works Research Center, Tokyo, Japan

**ABSTRACT:** This paper describes a method of estimating long-term deformation of geosynthetic reinforcing walls or embankments mainly due to percolation of rainwater. The triaxial compression test commonly used for obtaining coefficient of linear deformation and Poisson's ratio cannot be used for gravel-mixed soil or unsaturated soil which change soil constants by percolation of rainwater, under low level stresses and long-term loading tests. Moreover, uniform results are very difficult to obtain, because apparatuses differ from place to place and individual errors in tests are large. It is rather common to construct reinforced walls and embankments in front of original slope, a large unreinforced part is left. Deformation of the total structure is influenced by the deformation of the unreinforced part. Method of calculating deformation by use of coefficient of linear deformation is presented by utilizing an actual example. Finally, the behavior of the surface on the reinforced part, which gets high earth pressure by absorbing much rainwater, is analysed. Shear deformation in the reinforced part is presented.

**KEYWORDS:** Deformation, Testing, Walls, Soil deformation, Design.

## 1 INTRODUCTION

The author presented a paper titled "Well Documented Case Study of a Reinforced Soil Wall", at the 5th International Conference of the IGS In Singapore in 1994 with M. Itoh et al. (Itoh et al. 1992)

The backfill soil was a cohesive soil prevailing in the central region of Japan's mainland, and the reinforcement was a polyethylene geogrid widely used in Japan.

The purpose of this wall was to test applicability of cohesive soils for reinforcing soil structures. The wall was 7.5m high and has a front slope of 1 to 0.3. Geocomposite strips for drainage were inserted in the fill. After completion of the fill, the wet season followed for about 5 months. Total amount of rainfall was about 400mm, which is about 30 percent of the annual rainfall.

Vertical and horizontal deformations at the shoulder were 880mm and 374mm, respectively. Maximum pore water pressure in the fill was 20 kPa. It is clear that the cause of major deformation is due to the percolation of rainwater into the fill. Strain gages, extensometers, pore water pressure meters, earth pressure cells, settlement plates, horizontal displacement rods and deformation plates at the front wall were installed in the test wall. Material tests for both soil and geogrid were conducted in the laboratory. As no such well documented records like these were found, the author asked M. Itoh to translate the full report into English.

It was distributed to the members of the IGS, who came to the meeting room of the IS-Kyushu. The author hoped that this report be used for cooperative research work aiming for forecasting long-term behavior of reinforcing walls and embankments. The author has been studying this report from various angles of investigation. This paper describes in part the results of this studies as such.

## 2 BEHAVIOR OF FILL PART WITH NO REINFORCEMENT

Figure 1 is the reinforced part of the test wall with instrumentation layout. Table 1 is properties of geogrid. Figure 2 illustrates strain versus tension of the geogrid. Table 2 gives soil properties.

Figure 3 illustrates the section of the test wall including both reinforcing and non-reinforcing parts. The area ratio between reinforced and non-reinforced parts is  $46\text{m}^2 : 85\text{m}^2 = 1:1.5$  from Fig.3.

The area of non-reinforced part is very much larger compared with that of reinforced part. Table 3 gives horizontal displacement of the wall face and the boundary plane between reinforced and non-reinforced parts. Horizontal elongation of the non-reinforced part is much larger than that of the reinforced part at the upper portion of the test wall. As stated above, the non-reinforced part of the fill is very important upon discussing displacement of reinforcing walls. But there were no monitoring systems here, because we were not aware of the importance. The author could not help but use case records which he gathered himself for the purpose of analyzing the behavior of this part. The non-reinforced part can be assumed as a backfill supported by a kind of retaining wall. Regarding the reinforced part of the wall as a common retaining wall, the unreinforced part is backfill. As the reinforced part is massive and heavy, it has enough power of retaining backfill. The face between the reinforced and unreinforced parts can be regarded as a front face of the backfill. The inclination of the face is 1:0.3. The author has about 50 well documented case records of earth pressure measurement, some of which are described in the references at the end of this paper. As the results of earth pressure measurements, wall height and inclination of the back side of the retaining wall are more important than other conditions like soil properties and method of compaction. Therefore, the author determines the earth pressure coefficient based on the case records. Some of the selected case records are described here. Finally, the earth pressure coefficient is decided as 0.3. The earth pressure measurement in the soil mass is terribly difficult. The author has several case records now, and is hoping that a chance will come in the near future. Figure 4 is a gravity concrete retaining wall. Three panel type earth pressure gages, 2m in width, were installed to the back of the wall. Figure 5 shows the earth pressure for 3 large concrete block retaining walls. Coefficients of earth pressure  $K$  are described for comparison. Distribution of earth pressure is not triangular. The panel type earth pressure gages are installed not only on the back face of the retaining wall but also on the slope behind the backfill as shown in Fig.6. Precision of the measurement can be checked by using those gages surrounding the backfill. Coefficient of earth pressure is as low as 0.15, which is due to the thickness of the backfill and low energy of compaction. A small-scale laboratory model test was conducted in order to study the effect of backfill width. Sketch of the backfill and test results are given in Fig. 7. The horizontal axis is the coefficient of

earth pressure and vertical axis is the ratio between thickness and height of the backfill (B/H). Inclination of the back face of the retaining wall is 1:0.5. The coefficient of earth pressure decreases remarkably in accordance with the decrease of the B/H, and becomes nearly equal to the final value of the coefficient of earth pressure with the increase of the B/H larger than 0.5. Figure 8 illustrates the external forces acting on the boundaries of the non-reinforced part. The weight of the non-reinforced part is 1.463 MN/m. The earth pressure on the boundary between reinforced and non-reinforced parts is 179 kN/m, assuming the coefficient of earth pressure is 0.3. Reaction from the original ground surface is calculated by the force polygon in the figure. Normal and tangential components of the reaction and mobilized angle of friction are obtained as shown in the figure. Using

cohesion  $c=48$  kPa and friction angle  $\phi=25^\circ$  from the triaxial compression test, safety factor against sliding is computed. The factor of safety is 6.2. As a matter of fact, such soil constants are too large. Even when considering these conditions, such high factor of safety sufficiently verifies that no sliding, deformation shall be caused. Factor of safety against sliding increases with coefficients of earth pressure higher than 0.3. The factor of safety against sliding decreases with lower coefficient of earth pressure, but this part is absolutely safe. Because the inclination of the original ground surface is gentle. If the inclination is  $45^\circ$ , the situation changes entirely. The non-reinforced part moves out horizontally toward the surface of the wall as the fill settles. There is a case example showing such a phenomenon. Distribution of normal and shear stresses along the original ground

Position	May 8			October 7		
	M9	M7	M3	M9	M7	M2
Wall face	23	33	20	242	160	62
Boundary, reinforced & non-reinforced	15	16	4	154	73	17
Elongation of reinforced part parts	8	17	16	88	87	45

Notes: May 8 is date of end of construction.

October 7 is date of end of measurement.

M9, M7, M2 are reinforcing mats in Fig. 3.

Unit: mm

How to read: The wall face at M3 level moved 23mm during construction. It was moving through the rainy season, and finally the amount of movement reached 242mm. Movement of the boundary of reinforced and non-reinforced parts are 15mm (May 8) and 154mm (October 7). Accordingly, elongation of the reinforced part is 23-15=8mm (May 8) and 62-17=45mm (October 7).

surface is not uniform or triangular as shown in Fig. 6. Maximum shear stress is about 2 times larger than the average value for this case. Therefore, it is necessary to maintain a higher factor of safety to prevent sliding movement. Figure 8 illustrates positions of mats M3, M7 and M9. Records of horizontal displacement gages are indicated in Table 3. Displacement of the surface between the reinforcing and non-reinforcing can be inferred by this table. The lengths of the dotted lines in the figure are widths of the non-reinforced part. They are 2.4, 8.2, 12.9 m respectively. Assuming the strains are uniform along those lines, those strains are calculated as shown in Table 4. Comparing these values with strains at the tail ends of the mats measured by strain gages, quite a neat coincidence was recognized. Vertical settlements were measured by the settlement plates. The variation of those thicknesses between two settlement plates are obtained. These variations are calculated in the form of strain and described in Table 4.

Table 4. Variation of vertical and horizontal deformation in the form of strain.

Position	Horizontal strain			Vertical strain		
	~5/8	~10/7	5/8~10/7	~5/8	~10/8	5/8~10/7
M9	0.108	1.19	1.09	S4~S5	0.75	8.80
M7	0.182	0.89	0.71	S3~S4	0.87	5.92
M3	0.167	0.71	0.54	S2~S3	0.46	16.36
				S1~S2	0.42	12.48
(Position)				(Layer)		

As the forces on the boundary and weight of the backfill are obtained, stress distribution is obtained by trial and error method. This rough method of calculation may be sufficient at this stage.

According to the author's case records, earth pressure does not change so much, if the retaining wall moves forward after the completion of it.

Therefore, only horizontal strain in taking into account and the changes of m and E are back-calculated using equations (1) and (2).

$$\epsilon_h = \frac{\sigma_h}{E} - \frac{1}{mE} \left\{ (\sigma_h + \sigma_v) \frac{1}{m} + \sigma_v \right\} \dots \dots \dots (1)$$

$$\epsilon_v = \frac{\sigma_v}{E} - \frac{1}{mE} \left\{ (\sigma_h + \sigma_v) \frac{1}{m} + \sigma_h \right\} \dots \dots \dots (2)$$

The results are described in Table 5. m-values are ranging between 3.08~3.98, E-values between 0.45~7.30 MPa. E-values before May 8 which had ranged between 2.46~7.30 MPa, decreased to 0.49~1.30 MPa at the end of the test on October 7. The reduction caused a drop by 1/10 of original values.

We can realize how the increase of moisture content has a large effect on soil constants. The wide variety of m and E values are mainly due to the non-uniformity of soil kinds and distribution of moisture content.

Table 5. Coefficient of linear deformation E and Poisson's ratio 1/m in the non-reinforcing part.

Period	~5/8			~10/7			5/8~10/7		
	M9	M7	M3	M9	M7	M3	M9	M7	M3

m	3.35	3.08	3.98	3.39	3.32	3.85	3.39	3.37	3.79

There are a lot of monitoring systems set up in the reinforced part of the wall. Twelve conventional earth pressure gages were installed. No. 1 and 12 measure horizontal earth pressure or stress. No. 2, 3, 4 and No. 7, 8, 9 measure two-dimensional earth pressure, namely, horizontal, vertical and shear stresses. No. 5, 6, 10 and 11 measure only vertical stress. These were located behind the wall face. The other 8 gages were located 1.5m behind the wall face. Table 6 describes earth pressure and horizontal strain 1.5m behind the wall face.

 + and - signs of shear stress and counter clockwise and clockwise directions, respectively.  
 Rainy season : 5/16~7/1

Looking at the table, earth pressure changes in wide range with the lapse of time. The strain along the reinforcements are elongated in accordance with the horizontal deformation of the soil. As this soil is not elastic, this elongation is never recovered. Vertical stress  $\sigma_v$  and  $\epsilon_h$  rapidly increase with the start of rainy season. Horizontal stress  $\sigma_h$  of No. 7, 8 and 9 increases gradually with time. Horizontal stress of No. 2, 3 and 4 is large in rainy season. Shear stress is low, and sometimes changes their sign from plus to minus. Shear stress for No. 2, 3 and 4 is high in rainy season.

This paper deals with shear deformation of the fill by use of data from horizontal displacement gages. Figure 9 illustrates distribution of shear strain. Upper figures indicate the shear strains between May 8 and June 20, which is the first part of rainy season, and the lower figures are that between June 20 to October 7, which is the main part of rainy season with much rain. Shear strain in the main part of rainy season is larger than that of the first part.

Legend: ○ : Points measured  
 Upper figure : shear strain before rainy season, | between two points  
 Lower figure : shear strain during rainy season, | marked with ●

Figure 9 Distribution of shear strain, at points marked with ○

1. A large deformation occurred by percolation of rain water, when a geogrid reinforced test wall with cohesive soil backfill was exposed to the wet season. Deformation of the wall is caused by reduction of soil constants with increase of moisture content. The deformation of soil is irreversible, and the elongated reinforcement caused by the soil deformation is left intact. Therefore, a method of soil test for measuring soil constants is needed. It is important to use a simple laboratory test with no individual errors.

2. There are many cases where the triangular unreinforced part comes behind the reinforced part. Effect of deformation on this part is large to estimate total deformation of the wall. Method of estimating such deformation by use of coefficient of linear deformation and Poisson's ratio is described.

3. Front face of a reinforced soil wall was exposed to percolation of rainwater causing marked change in earth pressure.

This then caused major deformation, whereupon colossal permanent deformation is caused in reinforcing material. Decrease of soil constants may also induce this phenomenon and increase strain in the reinforcement.

4. Shear strain in the reinforced part of the test wall increased with amount of percolated rain.

**ABSTRACT:** Reinforced ground structures using cohesive soils are difficult to design due to problems relating to consolidation and poor internal drainage. Due to these inherent drawbacks cohesive soils are seldom used as fill materials in reinforced embankments. However, when a geotextile with good filtration and drainage properties is used as a reinforcement, cohesive soils could be successfully used as back-fills in steep embankments. There are few instances of needle-punched nonwoven fabrics, possessing superior hydraulic conductivity, have been used as reinforcements in embankments with back fills of cohesive soil. Non-woven textiles, however, are inferior in tensile properties when compared with the woven textiles. In reinforcement applications, the primary quality required of the fabric is superior tensile properties. Woven geotextiles, which have the required tensile properties, have not been tried as reinforcement for cohesive soils because of their poor transmissivity. Owing to this draw back in woven geotextiles the amount of research done on the transmissivity of woven geotextiles is minimal. By designing novel and innovative woven fabric structures it is possible to increase the transmissivity of the woven geotextiles without sacrificing the tensile properties. This paper presents a new approach that enables woven geotextiles to be designed with superior tensile properties and adequate transmissivity for use as reinforcement in cohesive soil filled earth structures. A theoretical model, derived from the first principles, which predicts the transmissivity values of woven geotextiles is discussed. Laboratory results from tests conducted on some woven geotextiles substantiate the theoretical models and the data is presented.

## 1 INTRODUCTION

In recent years, use of geosynthetics has become accepted as a technically sound and cost-effective solution in solving many geotechnical and environmental problems. In the construction of reinforced earth filled embankments, when the in-situ soil is not suitable as a fill - cohesive soils such as clay, it is usual to fill the structure with a suitable imported granular material. With ever increasing cost in material handling, use of readily available materials from the site is one of the best cost-effective options available. However, use of cohesive soils as back-fill in steep embankments has gained little acceptance due to their inherent low permeability and excess pore water pressures. Therefore, if geotextiles of adequate draining capacity and tensile characteristics are developed and used with the in-site cohesive materials considerable savings can be achieved.

A few case histories of test embankments with cohesive soil back fills employing needle-punched nonwoven fabrics are reported (Tatsuoka et al. 1986, Ling et al., 1993). Further, when the motorway M25, between Junctions 15 and 16 on the west side of London in the UK, was widened, the embankment was reinforced with a combination of a geogrid and a nonwoven geotextile (Leiper, 1995). The soil

in this case was recompacted London Clay. Fabian (1990) too has successfully used needle-punched nonwoven geotextiles to reinforce test embankments built with cohesive fills. However, there are no reports of woven geotextiles being attempted as reinforcement for cohesive soils. The main limitation of the currently available woven geotextiles is their poor drainage capabilities. According to the United Kingdom's Department of Transport requirements, the design life for steep slopes is not less than 60 years if the slope is regarded as an earthwork or 120 years if the slope is regarded as a structure (Ingold 1994). Strength and creep are vital properties to provide such a long life; woven fabrics are capable of providing these properties better than nonwovens or any other fabric type. Thus, if the draining capacity of woven geotextiles is considerably improved, they would become the most suitable geotextile material to reinforce a cohesive soil-filled structure.

In order to design woven geotextiles which have the capacity to drain the estimated quantity of water a suitable theoretical model is required. This paper presents a geometrical model which can estimate the transmissivity of woven fabrics. The model, which is validated by laboratory results, is then used to engineer novel woven fabric structures which give improved transmissivity.

## 2 ESTIMATES OF REQUIRED DRAINAGE

A clay reinforced slope can act as a frictional fill in terms of the effective critical state angle of shearing resistance, provided any excess pore water pressures are rapidly dissipated. The required drainage is a function of the soil consolidation properties, geometry of the reinforcement layers and excess pore water pressures generated by construction. An estimate of the drainage is made using the following assumptions: the clay is fully saturated, with permeability  $k = 10^{-8}$  m/s, and compressibility  $M_v = 0.25$  m<sup>2</sup>/MN, subjected to a total normal stress increase  $\Delta\sigma = 200$  kN/m<sup>2</sup> (equivalent to a basal layer in a 10 m high fill) with geotextile reinforcement drains at a relatively wide spacing of 0.5 m and of length 7.5 m. The clay layer between the reinforcement is assumed to be in one dimensional consolidation, with the excess pore water pressure isochrones modelled as a parabolic function. The rate of discharge from the clay is given by the hydraulic gradient (slope of the isochrone) at the clay surface.

At any time 't' the total volume of water expelled from the clay is equal to the settlement volume at that time:

$$V = 2 d L_{GT} b_{GT} R M_v \Delta\sigma \quad (1)$$

at time:

$$t = \frac{T_v d^2}{c_v} \quad (2)$$

where, d = maximum drainage distance,  $L_{GT}$  = length of the geotextile,  $b_{GT}$  = width of the geotextile, R = average degree of consolidation,  $M_v$  = coefficient of volume compressibility,  $\Delta\sigma$  = total stress increment,  $T_v$  = time factor and  $c_v$  = coefficient of consolidation.

For the assumed values, the total volume of water discharged per metre width by consolidation is 0.1875 m<sup>3</sup>. Hence, 90% consolidation (0.169 m<sup>3</sup> water) takes 3.7 hours.

The rate of discharge per square metre from the clay fill (above and below the geotextile layer) is given by

$$Q = \frac{4 k \Delta\sigma}{\gamma_w \sqrt{12 c_v t}} \text{ for } T_v < \frac{1}{12} \quad (3)$$

where, Q = rate of discharge and  $\gamma_w$  = unit weight of water. From equation (3), the rate of discharge of water from the soil when the isochrone reaches the centre of the clay layer can be calculated to be less than 10<sup>-7</sup> m<sup>3</sup>/s/m<sup>2</sup>, this occurs approximately one hour after the assumed instant load application. Clays typically have permeability of 10<sup>-7</sup> m/s or less, often about 10<sup>-9</sup> m/s, and if permeable layers with permeability of 10<sup>-4</sup> m/s, or greater, are incorporated, then these will act as effective drains.

The computations involved for calculating the required transmissivity for the geotextiles are lengthy and complex (Giroud, 1981). However, one dimensional consolidation theory provides an indication as to the efficiency of these drains. Accordingly, geotextiles placed at small vertical spacing (0.5 m or less), can rapidly consolidate the clay and dissipate excess pore water pressures. The total volume of water is relatively small and the discharge rate diminishes rapidly with time.

## 3 THEORIES OF FLUID FLOW

Predicting the fluid flow through textile materials has largely been studied with the help of the general theories of fluid flow through porous media. In all of these theories, the fluid flow is given as a function of the total pore space available in the fabric mass and the specific area. However, as the structure of woven fabrics are very different from other porous media, with two distinct drainage paths - within the yarns and between the yarns - a need for a specific theoretical model for woven fabrics was realised.

As a result, a theoretical model which predicts the in-plane fluid flow in woven geotextiles is developed from first principles. This model is found to predict the flow of water in woven fabrics more accurately than the available general models for flow through porous media.

The Poiseuille equation for the average laminar flow velocity through straight parallel capillary tubes of constant circular cross-section is,

$$V = \frac{R_h^2 \Delta p}{8\mu L} \quad (4)$$

and hence

$$Q = \frac{R_h^2 \Delta p}{8\mu L} A \quad (5)$$

where, V is the velocity of the fluid,  $\Delta p$  the pressure difference,  $\mu$  the viscosity of the fluid, L the length of the drainage medium, A the area of cross-section and  $R_h$  the hydraulic radius.

When the Poiseuille's equation is extended to non-circular channels it becomes,

$$Q = \frac{R_h^2 \Delta p}{k \mu L} A' \quad (6)$$

where, A' area of the pore space in the channels and k shape constant which depends on the shape of the channel. However, the cross-sectional area of the pores in the channels is  $A\epsilon$ , where,  $\epsilon$  is the porosity. Therefore, equation (6) can be written as,

$$Q = \frac{R_h^2 \Delta p}{k \mu L} A \epsilon \quad (7)$$

Thus, if the hydraulic radius  $R_h$  of the woven fabric is estimated, from equation (7), the rate of discharge can be calculated.

The hydraulic radius is defined as,

$$R_h = \frac{\text{cross sectional area of the pore}}{\text{wetted perimeter}} \quad (8)$$

When the flow of fluid through a woven fabric is considered, it is clear that there exist pores between the yarns and within the yarns. As the structural parameters of the two porous media are different, it is prudent to treat the two separately. The overall coefficient of in-plane permeability is then obtained by combining the two.

Figure 1. Cross-section of two consecutive yarns in an intersection unit

Figure 1 shows a cross-section of two consecutive yarns of a woven fabric in a plane containing the axis of an intersecting weft yarn. The yarns are considered to have the Kemp's race track sectional geometry (Kemp, 1958). If the major diameter of the warp and weft yarns are ' $a_1$ ' and ' $a_2$ ' respectively, and the minor diameter of the warp and weft yarns are ' $b_1$ ' and ' $b_2$ ' respectively and the distance between the centre of two adjacent warp yarns is ' $p_1$ ', we have,

$$\text{total cross-sectional area between two consecutive yarns} = t \times p_1$$

where,  $t$  is the thickness of the fabric.

However, the area of solid in the cross-section =  
area of the warp yarn + area of the weft yarn.

$$\text{Area of the warp yarn} = \frac{\pi b_1^2}{4} + b_1(a_1 - b_1) \quad (9)$$

$$\text{Area of the weft yarn} = l_2 b_2 \quad (10)$$

where,  $l_2$  is the length of weft yarn between the planes

containing the axes of consecutive warp yarns.

$$\text{However,} \quad l_2 = p_1(1 + c_2) \quad (11)$$

where,  $c_2$  is the crimp in the weft yarn. Therefore,

$$\text{Area of the weft yarn} = b_2 p_1(1 + c_2) \quad (12)$$

Hence, Total area of solid

$$= \left\{ \left[ \frac{\pi b_1^2}{4} + b_1(a_1 - b_1) \right] + [b_2 \cdot p_1(1 + c_2)] \right\} \quad (13)$$

Therefore, Area of void between the yarns

$$= t p_1 - \left\{ \left[ \frac{\pi b_1^2}{4} + b_1(a_1 - b_1) \right] + [b_2 p_1(1 + c_2)] \right\} \quad (14)$$

$$\text{Wetted perimeter of the pore} = 2p_1 + \pi b_1 + 2 l_2' \quad (15)$$

where,  $l_2'$  is the length of yarn in the partial geometry of the Kemp's race track section. Further,

$$l_2' = l_2 - (a_1 - b_1) \quad (16)$$

Therefore, wetted perimeter of the pore

$$= 2p_1 + \pi b_1 + 2[p_1(1 + c_2) - (a_1 - b_1)] \quad (17)$$

Substituting (14) and (17) in (8) we get,

$$R_h = \frac{t p_1 - \left\{ \left[ \frac{\pi b_1^2}{4} + b_1(a_1 - b_1) \right] + [b_2 p_1(1 + c_2)] \right\}}{2p_1 + \pi b_1 + 2[p_1(1 + c_2) - (a_1 - b_1)]} \quad (18)$$

A similar treatment is done to find the rate of discharge within the yarns. Considering circular cross-sectional filaments, if the diameter of a single filament in a multi-filament yarn of race track geometrical shape is  $d_f$ , the hydraulic radius for the flow within the yarn is derived.

The porosity of the yarn,

$$\epsilon_y = 1 - \frac{\text{Volume of filament yarns}}{\text{Total volume of yarn}}$$

Considering racetrack geometry and unit length,

$$\text{Total volume of warp yarn} = \left[ \frac{\pi b_1^2}{4} + b_1(a_1 - b_1) \right]$$

Considering circular filaments,

$$\text{Volume of filaments in warp yarn} = \frac{\pi d_f^2}{4} n_f$$

where  $n_f$  is the number of filaments in the yarn.

Therefore, porosity in yarn

$$\varepsilon_y = \left\{ 1 - \frac{\left[ \frac{\pi b_1^2}{4} + b_1 (a_1 - b_1) \right]}{\left( \frac{\pi d_f^2}{4} n_f \right)} \right\} \quad (19)$$

The total cross sectional area of the yarn, considering the race track sectional geometry,

$$= \left[ \frac{\pi b_1^2}{4} + b_1 (a_1 - b_1) \right] \quad (20)$$

Then the cross-sectional area of the pore

$$= \left[ \frac{\pi b_1^2}{4} + b_1 (a_1 - b_1) \right] \varepsilon_y \quad (21)$$

$$\text{total wetted perimeter} = \pi d_f n_f \quad (22)$$

where,  $n_f$  is the number of filaments in the yarn.

Therefore,

$$R_h = \frac{\left[ \frac{\pi b_1^2}{4} + b_1 (a_1 - b_1) \right] \varepsilon_y}{\pi d_f n_f} \quad (23)$$

If the geometrical parameters of the fabric and the yarn are known, the hydraulic radius of the inter-yarn and the intra-yarn porous media can be calculated using equations (18) and (23) respectively. Thus, the rate of discharge between the yarns and within the yarns can be calculated using equation (7) if the appropriate shape constants and the porosity values are known. It is assumed that the shape of the pore within the yarns is of an equilateral triangle and in-between the yarns a rectangular triangle. Therefore, the respective shape constants are 1.67 and 1.63 (Munson et al, 1990). Once the rate of discharge is known the coefficient of in-plane permeability and subsequently the transmissivity of the fabric can be estimated using the equations (24) and (25).

$$\theta = \frac{Q L}{W H} \quad (24)$$

where,  $\theta$  = hydraulic transmissivity,  $W$  = width of the specimen,  $H$  = difference in total head across the specimen and  $L$  = length of the specimen.

$$k_p = \frac{\theta}{t} \quad (25)$$

where,  $k_p$  = coefficient of in-plane permeability and  $t$  = thickness of the geotextile.

In Figures 2 and 3, results obtained by the developed theoretical model, indicated by the name UMIST, and other general models are compared with the laboratory results obtained at various normal stress levels. The hydraulic transmissivity testing was performed in accordance with ASTM D 4716 - 87 (ASTM, 1987). The distinctive advantage of this model is its capability to predict the flow in any composite structure which has a number of drainage paths. Fabric C1 is commercially available and M2 is a fabric made in the laboratories of the Department of Textiles of UMIST. Two other fabrics, M1 and M3, made in the laboratory and a second commercial fabric C2 were also tested for their transmissivity. In Table 2 is given the specifications of all the five fabrics tested.

Table 2. Specifications of the fabrics tested.

Fabr	Weave	Fabric sett		Yarn count		Area density (g/m <sup>2</sup> )	Thickness ** (mm)
		ends/cm	picks/cm	warp (tex)	weft (tex)		
M1	Plain	4.6	3.33	2200	220	1202	1.70
M2	Matt	4.25	4.27	2200	220	1160	1.66
M3	* Double	4.72	2.36	2200	220	2139	3.60
C1	Twill	4.00	5.14	337	330	297	0.93
C2	Plain	5.91	9.84	228	108	224	0.83

\* The count, and the sett correspond to both face and back fabrics individually. \*\* Thickness at 2 kN/m<sup>2</sup> stress level.

#### 4 A NOVEL WOVEN FABRIC

A novel woven fabric which incorporates porous tubes in its structure is designed to enhance the drainage property of the woven geotextile without sacrificing its tensile properties. In this fabric two sets of fabrics are woven on top of one another with a tubular structure, into which the porous tubes are inter woven. The whole composite fabric is woven on a shuttle loom. The laboratory transmissivity results obtained are presented in Figure 4 along with the results obtained for fabrics M1, M2 and M3 developed at the laboratory of UMIST.

Figure 2. Transmissivity - normal pressure relationship for various theories - Fabric C1

Figure 3. Transmissivity - normal pressure relationship for various theories - Fabric M2

Figure 4. Log transmissivity - normal pressure relationship - Fabrics M1, M2, M3 and M4

## 5 TENSILE PROPERTIES

Tensile behaviour of the fabrics are of great importance when the geotextile is to be used for reinforcement applications. One of the most critical property is the tensile stiffness, which must be as high as possible to avoid any undesirable deformations and movements in the soil structure. Therefore, during the design and manufacturing of the geotextile fabric careful consideration was given to keep the warp crimp to a feasible minimum level. For typical slopes a maximum allowable reinforcement elongation of 5% will result in outward face deflections of no greater than 100 to 150 mm (Jewel, 1996). From the estimated initial load - strain curve shown in Figure 5, it is clear that the maximum strain levels in all the designed fabrics are within the permissible levels.

Figure 5. Estimated initial load - strain relationship of fabrics M1, M2 and M3

## 6 DISCUSSION AND CONCLUSIONS

From Figure 2 and 3 it is apparent that the proposed theoretical model for the flow of water in the plane of the woven fabrics is fairly accurate in predicting the actual flow levels compared to the other general theories of flow in porous media. Although the prediction at lower stress levels is comparatively farther from the actual values, at higher stress levels, which are the stress levels encountered in the field, the predictions are reasonably accurate. Tests done on other three fabrics also follow a similar trend. However, for fabric M3, the predictions at lower levels are comparatively away from the measured values. Nevertheless, at 150 kPa and beyond, the predictions are similar to the other fabrics. Giroud considered a geotextile basal drain to an embankment and calculated that a transmissivity of  $3.1 \times 10^{-7} \text{ m}^2/\text{s}$  allowed the geotextile to effectively work as a

drain for compressive stresses of less than about 1 MPa (equivalent to a 50 m high embankment). From Figure 4, where the transmissivity of the geotextiles at various stress levels are indicated, it is clear that the innovative geotextile M4 possesses a transmissivity value that is 100 - 1000 times higher than the transmissivity value predicted by Giroud. Further, from the results given in Figure 4 it can be deduced that with suitable geotechnical designs even geotextiles M1 and M3 can successfully be used as reinforcement geotextiles functioning as drains in clayey soils. Although the cost of these fabrics are higher than the fabrics available in the market, preliminary cost calculations suggest that the savings obtained by the use of in-site soils over imported material will override the fabric cost.

The theoretical model presented in this paper does not take into consideration the fact that soil particles can partially fill the pores in the fabric structure. It is envisaged to study this effect in future research. However, the transmissivity of the novel fabric M4 is sufficiently high to take into account any partial blockage that may occur.

**ABSTRACT:** The use of geosynthetics in soil reinforcement applications has been increasingly popular in recent years. Geosynthetic reinforced soil walls are commonly backfilled with clean sand. In regions where clean sand is not cheaply and easily available, a cost-effective design of the wall is to use locally available soil, that may not be free draining. As a result, the designs of reinforced slopes and walls have to take into consideration of the probable build-up of excess pore water pressures, especially during rainy seasons. In recent years, effort is focused on the development of geosynthetic material that can perform not only reinforcement functions but act as a drainage medium as well. Such soil-reinforcement material can rapidly drain off excess pore water to maintain the stability of the system. This paper reports a series of large scale pullout tests in locally available residual soil which is poorly draining.

**KEYWORDS:** Geotextile, Reinforcement, Pullout tests, Drainage, Deformation.

## 1 INTRODUCTION

The growth of the petrochemical industries in the recent years has led to the development of numerous synthetic products for various geotechnical engineering purposes. One of the many applications is the use of such materials for reinforcement purposes. This includes using geosynthetic products for slope stabilisation, erosion control, reinforcement of steep slopes as well as construction of vertical earth walls. The use of geosynthetics for soil reinforcement applications, especially, depends on the characteristics of the soil-geosynthetic interface which, in turn, is dependent on the effective stress at the interface. When granular material is used as the backfill material, the effective stress at the interface is more stable due to the unlikelihood of build-up of excess pore water pressure.

Granular backfill, however, may not be easily and cheaply available in many areas, especially in Southeast Asian regions. Under such circumstances, the more cost effective way of constructing reinforced earth walls would be to use the locally available residual soil which is lateritic in nature. Lateritic soils are cohesive-frictional soils but they are not free draining in nature. The soil strength is also dependent on its in-situ water content and soaking may lead to a drastic reduction in the expected strength of such material (Bergado et al. 1993). There is an impending threat of build-up of excess pore water pressure

at the soil-geosynthetic interface during heavy raining seasons, leading to the possibility of instability of the soil mass. Hence, in order to effectively use such material as backfill for reinforced soil system, the geosynthetic used must have the dual function of reinforcing the soil mass and, at the same time, drain away pore water in the soil mass. The essential design criteria for such system were outlined in Chew and Loke (1996).

## 2 PULLOUT TESTS

### 2.1 Test Apparatus

The Department of Civil Engineering at National University of Singapore (NUS) has developed a large scale pullout apparatus capable of performing large scale pullout tests on geosynthetic material of various configurations. Recommendations from Farrag et al. (1993) were studied extensively and used as guidelines in the development of the pullout apparatus at NUS. The apparatus measured 1.5 m in length, 1.5 m in width and provides for 30 cm of soil sample to be placed below and on top of the geosynthetic specimen to be tested. Horizontal sleeve plates are provided at the front wall of the pullout apparatus to eliminate boundary effects due to the front wall. The apparatus performs the pullout process at constant strain rate, driven

by a hydraulic machine. Detail description of this large scale pullout apparatus can be found in Chew et al. (1997).

In the first few series of pullout tests performed, the main objectives were to test the ability of the apparatus to function as desired. The series of pullout tests performed by Ng (1995) showed that the pullout apparatus is able to perform pullout at slow constant rates and that boundary effects were minimal. Subsequently, the apparatus were further modified by Ho (1996) to increase its testing capabilities by incorporating drainage systems into the apparatus. The aims of the improvements and modifications were to enable the apparatus to perform pullout tests in various soils, from granular to lateritic.

## 2.2 Geotextile Material

The geosynthetic material used in the two pullout tests is the PEC-75/25, a high-strength geotextile produced by Polyfelt. Theoretically, this material is a geocomposite as it comprised of a woven geotextile mechanically bonded to a nonwoven geotextile. This geotextile has multi-filament woven polyester yarns in grid-like pattern bonded to thermally bonded nonwoven polypropylene sheet. The maximum tensile strength of the geotextile is 75 kN/m along the longitudinal direction and 25 kN/m along the transverse direction. It derives its strength from the woven polyester yarns while the polypropylene sheet provides a drainage medium.

## 2.3 Soil Sample

The soil sample used is the locally available residual soil from the western part of Singapore. The soil is lateritic in nature and its optimal compaction is at water content of about 20%. However, it turns soggy and loses strength rapidly when soaked in water for long periods of time. The soil is reddish brown in the colour and consists of well-graded silty sand. Dry sieving tests on the soil revealed that the soil contains about 10-14% of silts, with a  $D_{50}$  of 0.24 mm and  $C_u$  of 6.2.

## 2.4 Test Program

A number of series of pullout tests were conducted in the last few years using the NUS Large Scale Pullout apparatus. Various type of geosynthetics has been tested with both sand and with residual soils as backfill material. Tests results were found to be consistent, and with good repeatability. In this paper, the test results of two pullout tests with residual soils will be reported. The first pullout test aimed to study the pullout resistance of the geotextile when embedded in residual soil at its in-situ moisture content. The soil sample in test 1 was prepared and compacted to an average density of 1905 kg/m<sup>3</sup> and an average moisture content of 23.5%. In the second test, the objective was to study the reduction in the pullout resistance

of the geotextile in residual soil when the soil is soaked with water to simulate ponding conditions. In this test, the soil was first compacted to an average density of 1887 kg/m<sup>3</sup> and an average water content of 23.3%. The soil sample in the test 2 was then subjected to 20 cm of water ponding for 4 days continuously in order to soak the soil sample in the pullout apparatus. In both tests, the rate of pulling at the front of apparatus was 0.80 mm per minute and the tests were carried out until total pullout had occurred. There was also no additional surcharge applied to the surface of the soil backfill, i.e. the pullout tests were conducted under low stress conditions.

## 2.5 Instrumentation

Aluminium strips with strain gauges were used to measure the pullout resistance mobilized by the geotextile in the course of the pullout process. The aluminium strips were pre-calibrated and a total of 8 were used for measuring the pullout resistance. These were mounted at the front of the geotextile and connected to the clamping plate in front of the pullout apparatus which was pulled forward at a constant and very slow rate by the hydraulic machine.

Displacements at various locations of the geotextile were measured using thin tell-tale wires, with the help of potentiometers with travel range of 100 mm. A total of 7 tell-tales were used in each of the two tests. In addition, potentiometers were used to measure the displacements at the front end of the geotextile. Each of the potentiometers was connected to the data acquisition system together with the strain gauges for the aluminium strips. Readings were recorded at 30 second intervals.

In test 2 where soaking of the soil sample occurred, there was anticipation of possible build-up of excess pore water pressure during the compaction and pullout test. In this test, miniature pore water pressure transducers were used to measure the pore water pressure at various parts of the soil sample. Two of such transducers were placed near the soil-geotextile interface: one just in front of the sleeve plates and the other, about 60 cm from the front wall.

# 3 PULLOUT RESPONSE OF GEOTEXTILES

## 3.1 Peak pullout resistance

The pullout responses of the geotextile in residual soil under different soil conditions are shown in figures 1. In test 1, where the soil is compacted at its in-situ moisture content, it can be seen that the pullout resistance of the geotextile increased steadily with front displacement until an apparent peak. The peak pullout resistance registered in the first pullout test was 23.2 kN while in the soaked pullout test, the peak pullout strength was measured at 19.4 kN. This indicates a drop of 16.4% in the peak pullout

resistance when the soil is pond with water. What was worthy to note was the change in the strength of the residual soil before and after the soaking process. Cone penetrometer tests on the soil sample showed an average CBR value of 3% in test 1. For test 2, where the soil was thoroughly soaked for 4 days, the CBR value dropped to an average of only about 1.5%, with the soil at the interface having only 0.75% in CBR value. This showed that the pullout resistance of the geotextile fell by only 16.4% when the strength of the soil at the interface dropped by almost 75%.

Figure 1 : Pullout response of geotextile in residual soil in tests 1 and 2.

### 3.2 Displacements during pullout

Figures 2 and 3 show the total displacements measured at various locations of the geotextile for test 1 and test 2 respectively. By total displacements, it meant that the magnitude of displacements recorded consisted of both displacement due to sliding of the geotextile against the soil at the soil-geotextile interface, as well as displacement due to material stretching of the geotextile.

It can be seen that the differential displacement between the front end of the geotextile and a point 30 cm from the front wall was lower for test 2 as compared to test 1. This is expected as the peak pullout resistance that can be mobilised in the second test was lower than the first test, substantiating the fact that the residual soil backfill at the interface was indeed weakened by the soaking process. Note that the first 30 cm of the geotextile was not embedded in soil. Thus this section of the geotextile was undergoing a process similar to the wide-strip tensile test.

Another important observation made in the two pullout tests was that in test 1, the differential displacement between two

consecutive locations along the embedded length of the geotextile was less uniform. Differential displacements were larger at locations nearer to the front wall than locations further from the front wall. This meant that the geotextile developed higher levels of strain nearer to the front wall than at locations further from the front wall. In test 2, however, it was observed that the differential displacement seemed to be quite uniform along the length of the geotextile, showing that the strain development was rather uniform along the length of the geotextile.

Figure 2 : Displacements at various locations of the geotextile during pullout test 1.

Figure 3 : Displacement at various locations of the geotextile during pullout test 2.

### 3.3 Pore water pressure measurements

During test 2, pore water pressure transducers were installed in various locations to measure the pore water pressure during the compaction and the pullout stages. While the hydrostatic pore water pressure is about 1.0 kPa at the location 10 cm below the surface of the soil, as indicated as PPT4. The pore water pressure transducer at this point (PPT4) measured a pore pressure of about 3.5 kPa through the test, indicating that there is a built-up of excess pore water pressure of about 2.5 kPa. However, at the location of the soil-geotextile interface, where the hydrostatic pressure is about 2.5 kPa, the pore pressure transducer PPT2 gave pore water pressure reading of practically zero through out the pulling process. This indicates that the geotextile is capability of draining away the water effectively and functioned not only as reinforcement but also as a drainage medium.

Interesting results were obtained from the pore pressure transducer near the sleeve plate (PPT3). At the location of soil-geotextile interface, the transducer just in front of the sleeve plates (PPT3) registered some development of excess pore water pressure during the pullout process, reaching the peak total pore water pressure of about 6.5 kPa at the elapse time of about 60 minutes, which corresponds to the time when peak pullout force occurred. Subsequently, the pore water pressure dissipated rapidly when the geotextile was undergoing pullout.

Figure 4 : Pore water pressure measurements during test 2.

## 4 CONCLUSIONS

The use of residual soil as backfill material for the construction of geosynthetics steep slopes and earth walls

is feasible only if proper drainage mediums are also provided to rapidly drain off the pore water to prevent potential build-up of excess pore water pressure. Hence, the geosynthetics material not only have to functioned as a reinforcement material but also as a drainage medium. One such material is the composite geotextile which consists of high-strength polyester yarns for reinforcement purposes, and a porous nonwoven polypropylene sheet for drainage function. The two large scale pullout tests reported here indicate that high-strength geotextile, coupled with drainage capability, can provide a rational choice as the reinforcement material. The test results indicates that the pore pressure at the soil-geotextile interface is practically zero, except at location near the sleeve plate, while the soil mass above the geotextile were having some excess pore water pressure. This seems to suggest that the geotextile is capable of dissipating excess pore water pressure rapidly during the pullout test. With the provision of this drainage function, peak pullout force dropped by only 16.4% when the residual soil is subjected to ponding. With the use of such material for reinforcement purposes, the reinforced soil concept can be further extended to regions where granular material is not readily available as backfill material.

Y. Nanbu

Chief Engineer, Obayashi Corporation, Osaka, Japan

**ABSTRACT:** A full-scale test embankment reinforced with geosynthetic horizontal drains (GHDs) was carried out. The GHDs consisted of geocomposite materials and had the functions of reinforcement and drainage. Two kinds of GHDs and slope facing materials were selected, and a soft clay generated from an excavation was used for the filling material. The soft clay embankment, reinforced by GHDs, was designed to be 10 meters high with a steep slope angle. Limit values for the safety of the embankment were selected.

During and after the embankment execution, the settlement and the deformation of the embankment, the induced elongation of the GHDs, the strengths of the filling material, etc. were carefully monitored. The results obtained reveal that the soft clay embankment is stable and that the GHDs provide sufficient reinforcement.

**KEYWORDS:** Embankment, Geocomposites, Reinforcements, Soft Soils, Steep Slope

## 1 INTRODUCTION

Recently, embankments reinforced with geosynthetic materials have been used as one of the general construction methods for stabilizing embankments. The good mechanical properties of geogrid, a typical reinforcing material, are widely recognized for their applicability to reinforced embankments filled with sandy soils. Due to the lack of drainage, inferior quality soil such as surplus soil from construction sites can not be used for filling material in reinforced embankments. When soft clay of a low strength is used as a filling material for embankments, the filling is expected to increase in strength owing to consolidation by the effects of dewatering. Therefore, we have developed GHDs which are not only superior strength but also high permeability (Kamon et al. 1994).

This paper describes the results of a case study involving newly developed GHDs applied to a reinforced embankment filled with a soft clay soil.

## 2 OUTLINE OF THE TEST EMBANKMENT AND BASIC PROPERTIES OF GHDS

Two GHDs were applied to a reinforced embankment 10 meters in height. Plastic cores covered by nonwoven fabric (improved mechanical characteristics) and the reinforced nonwoven fabric (reinforced with high tensile strength yarn) were used. The width of each GHD was 0.3 meters. The basic material properties of the GHDs are summarized in Table 1.

The construction site is in the southern part of Osaka Prefecture, and surplus clay soil from an excavation in

Table 1. Basic properties of geosynthetic horizontal drains

### 3 DESIGN OF THE SOFT CLAY EMBANKMENT REINFORCED BY GHDS

The physical properties of the clay soil are indicated in Table 2. The liquidity index was approximately 63% and the clay soil became very soft after remolding.

Based on the in situ failure test results (Kamon et al. 1996), a highly soft clay embankment reinforced by GHDS was constructed. A section of the embankment is illustrated in Figure 1. GHDS were placed over 50% of the embankment with the staggered arrangement shown in this figure. The design factors of the slope stability are summarized in Table 3, which was modified from the Japanese design manual (1992).

The stability of the embankment was calculated according to the following rotational slip method.

$$F_s = \frac{R \cdot \Sigma (c_i \cdot l_i + (W_i \cdot \cos \theta_i + T_i \cdot \sin \theta_i) \cdot \tan \phi_i + T_i \cdot \cos \theta_i)}{R \cdot \Sigma (W_i \cdot \sin \theta_i)} \quad (1)$$

where  $c_i$  = cohesion of the soil (kPa),  $w_i$  = clod weight,  $\phi_i$  = angle of internal friction (degree), and  $T_i$  = tensile strength of material (kN/m).

Figure 1. Section of the test embankment

As  $T_i$  value, we selected the smaller value between the ultimate tensile strength  $T_a$  and the pull out resistance  $T_{pi}$  of GHDS.  $T_{pi}$  was calculated by Equation (2), namely,

$$T_{pi} = 2 \cdot (0.5c_i + 1.0 \cdot \sigma_v \cdot \tan \phi_i) \cdot L_{ei} \quad (2)$$

where  $\sigma_v$ : vertical earth pressure which works upon the anchorage part of the material at each layer,  $L_{ei}$ : anchorage length of the material at each layer,  $F_s$ : safety factor,  $R$ : radius of the rotational slip surface,  $l_i$ : arch length of the slip surface which was divided into sections, and  $\theta_i$ : sliding angle at the center point of the slip surface which was divided into sections.

The embankment had two different zones reinforced by two different GHDS, each 10 meters high and with a

1:0.6 slope angle. Figures 2 and 3 show the embankment reinforced by the GHDs during and after the filling work. Two types of facing materials were newly developed and applied to zones A and B, the details of which are omitted in this paper.

## 4 MONITORING RESULT

### 4.1 Monitoring System of the Embankment

The filling works were carried out smoothly in both zones. To monitor the slope stability, inclinometers, tensiometers, multi-layer settlement gauges, earth pressure gauges, relative displacement meters, and groundwater monitoring wells were installed in the embankment in order to certify the deformation of the embankment and the status of the GHDs. These monitoring instruments with automatic measuring systems (Figure 4) were mainly installed on the slope and around the predicted sliding circle. The measuring points for each parameter are indicated in Figure 5.

Figure 4 Monitoring system of the embankment

Figure 5. Monitoring points of the embankment

Figure 6. Behavior of the deformation of slope surface

### 4.2 Deformation of the Embankment

Figure 6 indicates horizontal displacements at the 3-meter high slope of the embankment measured by surveying the total stations. A large horizontal outward deformation at the early stage of the filling work includes a lateral movement by the overburden load as well as the self-weight effect of the filling machine. After the completion of the filling work on March 22, 1996, the horizontal deformation was very small and the embankment became stable by the consolidation of the clay soil.

### 4.3 Elongation of the GHDs

The results of measuring the strain of the GHDs are illustrated in Figure 7. Strain gauges were set on the fourth and the tenth GHDs where they would be close to the predicted sliding circle. The extensions of the GHDs as well as the compressions were obtained during the filling work. The maximum strains were relatively small values (0.8 to 1.0 %). After the completion of the embankment, no additional strain was observed in the GHDs. This means that the embankment was quite stable.

The difference in the embankment's deformation behavior between zones A and B depends on the elongation and the friction of the GHDs used, but the difference was very small in this case study.

### 4.4 Physical Properties of the Filled Soft Clay

The shear strength of the filled soil during the filling work was measured by a cone penetration test. Figure 8 shows the results of the distribution of cohesion in the embankment. The results are in zone A and the controlled value was 30 kPa. As the shear strength was less than 30 kPa with a height of 3 - 5 meters, additional filling was carefully performed with the confirmation of the stability analysis. Since the safety of the soft clay embankment is at its lowest in the early stage of the execution, the safety factor of the embankment increased in the drainage function of the GHDs after the completion of the embankment.

The variation in suction for the embankment (zone A) during a rainy season is illustrated in Figure 9. Tensiometers at points A3, 7, and 9 are directly set on the GHDs

Figure 7(a). Behavior of elongation of GHD (Zone A)

Figure 7(b). Behavior of elongation of GHD (Zone B)

Figure 8. Cohesion distribution of the embankment

Figure 9. Behavior of tensiometers with rainfall

and A6 was set in the center of the soft clay. The data show negative porewater pressure because of the Pleistocene clay that was filled. This suction (negative porewater pressure) decreases with rainfall, at the surface of the embankment in particular, and increases with dissipation due to the high permeability of the GHDs. It is seen that the GHDs had a high drainage effect and that the safety of the embankment was maintained even with a heavy rainfall.

## 5 CONCLUSION

The GHDs showed a sufficient tensile reinforcing function and the soft clay embankment with a steep slope was safely constructed using them. The reinforcing and drainage effects of the GHDs can be estimated because of the monitoring results, in particular from the deformation behavior of slope surface and elongation data of the GHDs. Consequently, the GHDs can be used practically in designing reinforced embankments filled with soft clays which are usually disposed of as construction waste.

# Centrifuge Modeling of an Innovative MSES for Marginally Stable Slopes

M. B. Mahmud

Lecturer, Faculty of Civil Engineering, Universiti Teknologi Malaysia, Johor Bahru, Johor, Malaysia

T. F. Zimmie

Professor, Department of Civil Engineering, Rensselaer Polytechnic Institute, Troy, New York, USA

**ABSTRACT:** Centrifuge model tests were performed to study the feasibility of a new installation method for the construction of mechanically stabilized earth structures (MSES) using geotextile reinforcement. The proposed method allows wide strips of geotextile to be driven horizontally and directly into existing and marginally stable slopes, similar to the installation of vertical wick drains. It does not require excavation of the soil behind the slope face, thus offering a rapid and economical solution for slope stabilization. Model geotextile strips simulated high strength non-woven geotextiles, which serve both as horizontal drain and reinforcement. The contribution of each function to the stability of marginally stable slopes in soft soil is presented in this paper. Typical results from centrifuge model studies show good agreement with other numerical analyses.

**KEYWORDS:** centrifuge modeling, geotextile reinforced slopes, soil reinforcing, low cost slope stabilization

## 1 INTRODUCTION

Centrifuge model tests were performed to study the feasibility of a new installation method for the construction of mechanically stabilized earth structures (MSES) using geotextile reinforcement. Conventional geotextile reinforced slopes utilize geosynthetics such as geogrids and geotextiles in the form of continuous sheets. These materials are installed in place after excavation of the slope and successive placement of selected soil as backfill. The proposed method allows wide geotextile strips to be driven horizontally and directly into existing and marginally stable slopes, similar to the installation of vertical wick drains. The geotextile strips perform dual functions, both as horizontal drains and reinforcement. Since excavation of the soil behind the slope face is not required, the method offers a rapid and economical solution to slope stabilization. The advantages of the proposed method over conventional MSES are summarized in Table 1.

Table 1. Conventional MSES versus the proposed method

Conventional MSES	Proposed Method

## 2 SOFT SOIL SLOPES

Various full scale studies have been performed dealing with geotextiles performing multiple functions in the stability of reinforced slopes in soft saturated soil. Tatsuoka and Yamauchi (1986) reported on full scale studies performed on two clay test embankments reinforced with planar sheets of non-woven geotextile. The multiple functions of the geotextile, i.e. drainage, tensile reinforcement and compaction control, were the major considerations in the study. Two embankments were constructed using locally available volcanic ash clay, and were fully instrumented to monitor the performance of the embankments over a period of 1.5 and 3 years. The non-woven geotextiles used served well as pore pressure dissipators and the immediate dissipation of pore water pressure was observed after a period of heavy rainfall. The non-woven geotextile was about 3-4 mm thick with an in-plane permeability of  $2 \times 10^{-1}$  to  $3 \times 10^{-2}$  cm/sec and provided the required drainage and hence stabilized the slopes.

Kamon and Akai (1996) constructed full scale reinforced embankments to study the effect of geosynthetic horizontal drains (GHD) on the stability of the embankments. Various types of newly designed GHDs were used in the study. The GHDs were similar to vertical wick drains. The inner cores were wrapped with woven or non-woven geotextiles. These materials were about 12 mm thick, had maximum tensile strengths of about 74.5 kN/m, and exhibited very high in-plane permeabilities. GHD strips, 30 cm wide, were installed during the construction of the clay embankments. The use of GHDs improved the stability of the slopes, increasing the factors of safety (FOS) to about 1.43 and 1.55, compared to a FOS of 1.163 using only conventional geotextiles. Kamon et al. concluded that GHDs can serve the dual functions of reinforcement and drainage for stabilizing soft clay embankments.

It should be noted that the GHDs were installed in a similar manner to conventional MSES systems, i.e. the slopes were excavated in order to install the GHDs or reinforcement.

Loke et al. (1994) also studies the multi-functioning behavior of geotextile-reinforced embankments on soft clay. The full scale embankments, reinforced and unreinforced, were constructed to failure. High strength and multi-layers

non-woven needle punched geotextiles were used in the study. The use of the high strength non-woven geotextiles provided the required drainage and reinforcement for the embankment. Theoretical analyses, using finite difference methods, were performed to determine the critical height of the embankment. The results from the analyses confirmed the behavior of the full scale slope.

Figure 1 The experimental setup showing various instrumentation used in the study

### 3 CENTRIFUGE TESTING

#### 3.1 Experimental Setup

The geotechnical centrifuge at Rensselaer was used to perform all model tests presented herein. The capability and performance of the centrifuge, and a summary of various research projects that have been performed using the centrifuge is presented by Van Laak et al. 1997. Model slopes with a slope angle of 63° (1H:2V) were constructed in a large centrifuge strong box (60.96 cm wide x 91.44 cm long). Two actuators, Actuator A and Actuator B shown in Figure 1, were used to drive the mandrel and apply surcharge loading, respectively.

Soft clay material was used in the model slopes which were accelerated to marginal g-levels (factor of safety close to one) to simulate near failure conditions of the slopes. Geotextile strips were then inserted into the slopes, using the remotely controlled mandrel driver, at that particular high g-level (while the centrifuge was rotating). The slopes were then loaded to failure.

Various instrumentation used in the models are shown in Figure 1. Details dealing with the instrumentation and calibrations are presented elsewhere (Zimmie and Mahmud, 1996a).

#### 3.2 Testing scheme

Four model tests are presented in this paper. The models are Unre301, Rein301, Unre403 and Rein401 which represent an unreinforced slope with surcharge loading, reinforced slope with surcharge loading, unreinforced slope with seepage and reinforced slope with seepage, respectively.

Models Unre301 and Rein301 were spun up to 8 g in the centrifuge and maintained at this g-level for a few minutes, then the g-level was increased to 16 g and again maintained at that g-level for a few minutes before finally being increased to 25 g. The surcharge loading was introduced at the 25 g-level, and the load was monitored by the load cell attached to the loading plate. For model Rein301, six geotextile strips were inserted at 25g, prior to the application of crest loading. Both Actuator A and Actuator B (Figure 1), were utilized in the model. Actuator A moves horizontally, inserting geotextile strips housed inside the mandrels into the soil. This operation occurs while the centrifuge is in motion and the model is at the specified high acceleration level in order to simulate prototype soil stresses in the slope. Actuator B is used to apply a surcharge loading on the slope after the strip installation process is complete. Load cells are used to continuously monitor the driving force and surcharge loading.

Models Unre403 and Rein401 were spun up to 25 g in increments of 5 g. The models were maintained at that g level for several minutes before introducing the water. Water was fed into a reservoir behind the slope, from a water tank mounted on the shaft of the centrifuge. An automatic shut-off valve with a remote switch located in the centrifuge control room was used to control the flow of water in flight. Two perforated plates were placed at the headwater and tailwater sides to allow flow within the model. For model Rein401, six reinforcing and drainage strips were inserted at 25 g before introducing the water at the back of the slope.

Centrifuge modeling requirements were carefully observed to achieve similitude. Additional details concerning centrifuge modeling laws pertinent to this study are presented in Zimmie and Mahmud (1996b).

#### 4 RESULTS AND DISCUSSIONS

The crest settlements of models Unre301 and Rein301 plus corresponding loads that caused failure are shown in Figures 2 and 3 respectively. The unreinforced slope model resisted an applied crest load of about 27.2 kg (60 lbs) and the reinforced slope a load of 45.4 kg (100 lbs). Both tests showed approximately the same amount of settlement to failure but the reinforced slope resisted a higher load, as expected. Using limit equilibrium analyses, the factor of safety (FOS) for the unreinforced and reinforced slopes were 1.24 and 1.62 respectively, prior to the application of surcharge loading. The FOS at failure was about 0.45 for both models, computed using the maximum applied loads, indicating that failure probably occurred at load values slightly less than the maximum. Details results and the failure mode of these slopes are presented in Mahmud and Zimmie (1997).

Figure 2 Unreinforced slope with surcharge loading

Figure 3. Reinforced slope with surcharge loading

Model Unre403 and Rein401 were performed to emphasize the drainage function of the geotextile strips. The difference in water table between the unreinforced and reinforced slopes plotted from pore pressure transducer data is shown in Figure 4. As shown, the installation of six strips into the slope significantly lowered the phreatic surface and increased the stability of the slope. The FOS of the unreinforced and reinforced slopes computed by limit equilibrium analysis were 0.8 and 1.1 respectively.

Figure 4. Phreatic surfaces for unreinforced and reinforced slopes (dimension in model units- inches)

#### 5 CONCLUSIONS

The use of geosynthetics as reinforcing elements in reinforced walls can result in savings of about 20-50% as

compared to the use of metallic strips [Christopher and Holtz (1985), and Mitchell and Villet (1987)]. The new installation technique proposed herein will even further reduce the overall construction cost of mechanically stabilized earth structures (MSES). Detailed analysis of the cost of the proposed method is presented by Mahmud (1997). A comparison of unit costs between the proposed method and other reinforced soil structures is shown in Figure 5. Unit costs of the other structures were provided by Holtz et al. (1995). The proposed method is very economical compared to other MSES, largely due to the fact that no excavation of the slopes is required.

This method can rapidly stabilize marginally stable slopes or slopes near failure. The practicality, and time and cost saving aspects of this new method will be beneficial in various slope stabilization schemes including marginally stable embankments, existing slopes and cut slopes.

The centrifuge modeling techniques used in this study are quite economical and less time consuming than the alternative of full scale prototype testing. In fact, it would have been economically impractical to conduct full scale testing during this stage of the study. Proper scaling conditions were carefully observed, and the results of the centrifuge model tests should agree well with the results of full scale tests.

Obviously the feasibility and cost effectiveness of the proposed methodology can only be truly verified after full scale slope installations are completed.

Figure 5. The cost comparison between the proposed method and other methods for reinforcing slopes.

# Hydraulic Effects of Using Dual-Function Geosynthetics in the Design of Multi-layer Structures

PH. GOTTELAND,  
Assistant Lecture, L.I.R.I.G.M.laboratory, Grenoble University, France.

**ABSTRACT:** This article presents some works to try to model the behavior of multi-layer structures combining a soil having what would be considered as poor mechanical properties for construction purposes, and Dual-Function (draining-reinforcing) Geosynthetics (DFG). We focus on this paper on the hydraulic modeling of a composite soil geosynthetics. We consider for the DFG geosynthetic only the transmissive capacity of the geosynthetic drain for accelerating the dissipation of uplift pressures. Effect of the geosynthetic transmissivity is shown for two types of soil. Modeling of the effect of a local damage of the drain is presented.

**KEYWORDS:** Drainage, Geocomposites, Modeling, Transmissivity, Installation damage

## 1 INTRODUCTION

One advantage of using flexible geosynthetics for ground reinforcement would seem to be the possibility of using soils of poor quality, with a high percentage of fines, often with high initial water content and highly sensitive to water. The concept involves associating a drainage function and a reinforcing function for the inclusion (Dual-Function Geosynthetics: DFG). Thanks to the high transmissive capacity of the geosynthetic with high permeability draining function, interstitial uplift pressures induced by placing the soil can be quickly dissipated. At the same time, the tensile strength of the reinforcing geosynthetic improves the mechanical stability of the structure provided by the consolidation of the material (Figure 1).

A modeling system was already presented (Gotteland et al. 1996) with some results of the combined draining-reinforcing effect of a dual-function inclusion for the construction of multi-layer structures alternating a layer of soil with a geosynthetic sheet. We focus on this paper on the hydraulic modeling and on numerical results obtained to assess the effect of some parameters.

## 2 EMBANKMENTS CONSIDERED

The types of structure concerned are linear structures with vertical or sloping facing with the length being much greater than the other dimensions: height  $H$  and width  $B$ . Calculations can thus be made in the plane of the structure. The structures could be multi-layer, alternating a layer of soil with a Dual-Function Geosynthetic DFG, of length  $B$ , placed horizontally with a spacing of  $D_h$ .

The soil supplied is the same and homogeneous over the entire height of the embankment.

The embankment facing is considered as a perfect drain; the upstream boundary between the structure and the in situ soil is considered to be either perfectly draining, or perfectly impermeable depending on the type of construction.

Figure 1: increase of the pull-out strength of the DFG (1a), increase of the shear strength of the soil (1b), by lowering of the pore water pressure in the structure

### 2.1 The soils

The soils considered in this study are homogeneous fine soils (clays, silts), with high initial water content and permeability,  $k_s$ , between  $10^{-8}$  and  $10^{-10}$  m/s. A saturated state may be achieved on completion of placing operations. Compacting may give rise to permeability anisotropy (vertical and horizontal permeability may be different).

## 2.2 Dual-Function Geosynthetics (DFG)

The DFG inclusions considered are made up of an association of a draining geosynthetic and a reinforcing geosynthetic, for example by the combination of a non-woven and a woven fabric.

As far as only drainage is concerned (hydraulic function), the functional characteristic is the transmissivity  $\theta g$  [ $m^2/s$ ] with  $\theta g = kg \cdot e$  ( $kg[m/s]$  permeability,  $e[m]$  thickness).

## 2.3 Draining properties of DFG in the presence of soil

Contact with the soil and applied stresses, over time, lead to a reduction in draining properties of geosynthetics as well as a reduction in soil permeability in the surrounding filtration area. This is known as the clogging phenomenon. The laws governing the variation in these properties are still being studied but simplified approaches can be considered.

The more simple modeling is to consider the transmissivities could be reduced all a long the drain compared to the same values on virgin geosynthetics in order to take these phenomena into account ( $\theta g$  initial =  $\theta g$  reduced  $\sim 2 \times 10^{-8} m^2/s$ ).

We present one other possibility : local reducing of the drain transmissivity for example to modelise a localized clogging or problems of water penetration in the drain.

## 3 INTERSTITIAL UPLIFT PRESSURES IN A SOIL-GEOSYNTHETIC DRAINING COMPOSITE.

For the hydraulic study, the multi-layer structures studied are broken down into identical elementary element, either by considering two half draining geosynthetic enveloping a soil layer of thickness  $Dh$ , or two soil half-layers enveloping a geosynthetic (Figures 2).

For modeling purposes, the construction of a element  $j$  is assumed to be instantaneous and completed after time  $T_j$ . The time  $T$  [days] is the time in days since the start of embankment construction (layer  $j=1$ ),  $t=T-T_j$  [days] is the relative time since construction of module  $j$ . The construction time between completion of two successive elements is  $Dt$  [days].

The stress  $\sigma$ , generated by the weight of the soil layers, is applied uniformly to each element and is imposed instantaneously when constructing the next overlayer.

The deadweight of the element  $j$  studied is not taken into account.

The soil has an isotropic, linear elastic behavior; after placing, it is assumed to be saturated in water, a fluid considered to be incompressible. The stress  $s$  created by an instantaneous increase in interstitial uplift pressure  $\bar{u}$ ,  $\bar{u}(x, z, t=T-T_j=0) = \sigma$ .

The transmissivity  $\theta g$  of the geosynthetic is constant with time. Flow in the geosynthetic drain obeys Darcy's law.

The evaluation method for  $\bar{u}(t)$  is based on the theory of consolidation. Two approaches are possible: flow in the soil may be considered to be unidirectional (Auriault et al. 77) or two-directional (Bourdillon 76, Gotteland 91).

We consider here the hypothesis of two directional flow in the soil. The consolidation problem is resolved by a finite-difference numerical method. The system is broken down into discrete elements in space (rectangular mesh) and time (explicit scheme). The degree of error in the evaluation of uplift pressures will depend on the size of the mesh  $dx/dz$  (a smaller mesh giving a more accurate result) and on the time step, which must be less than the critical time step in order to ensure convergence.

Figures 2: elementary element, discrete mesh

## 4 MODELING OF CONSTRUCTION

Each element of the multi-layer structure can be studied separately. For each, the effect of the construction stack of successive element on the change in interstitial uplift pressures must be assessed.

A detailed modeling procedure was proposed (Gotteland 91, Gotteland et al 96) in order to assess the effect of the following main parameters on the dissipation times of interstitial uplift pressures in the elements:

- Construction phasing  $Dt$  [days]
- Initial uplift pressure  $\bar{u}(t=0) = \bar{u}_{comp}$  [kPa] (initial remnant pressure after compacting effect)
- Thickness of modules  $Dh$  [m]
- Transmissivity of the geosynthetic  $\theta g$  [ $m^2/s$ ]
- Horizontal and vertical permeability of the soil  $k_x, k_z$  [m/s]
- etc.

We retain for this paper, the following simplified modeling procedure : Hypothesis of instantaneous construction of the complete structure ( $Dt=0$ ), with combined influence of compacting and total overload generated by the weight of overlying modules on the consolidation ( $\bar{u}(t=0) = \bar{u}_{comp} + (n-1) \cdot \bar{u}_{stat}$ ,  $\bar{u}_{comp}$  is the initial remnant pressure after compacting effect,  $\bar{u}_{stat}$  increasing by the weight of the soil from an additional element, simplified model 2, Figure 3).

This model provide a greater safety margin because it does not make allowance for consolidation during construction.

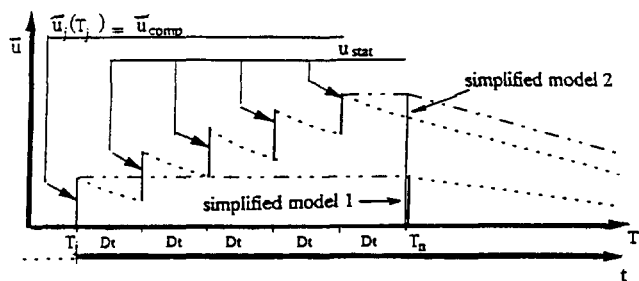

Figure 3: Theoretical modeling of the variation of the uplift pressure during and after construction.

## 5 STUDY

Some characteristic results of a parametric study are presented in order assess the influence of the variation in transmissivity  $\theta_g$  of the DFG. Three soils are considered :

	Soil 1 (clay)	Soil 2 (Silty clay)	Soil 3 (Clayey silt)
$k_s$ [m/s]	$1,7 \cdot 10^{-10}$	$1,6 \cdot 10^{-9}$	$2,6 \cdot 10^{-9}$
$\gamma_s$ [kN/m <sup>3</sup> ]	17,5	17.5	17.5
$Cvs$ [m <sup>2</sup> /s]	$1.47 \cdot 10^{-7}$	$5.4 \cdot 10^{-7}$	$2.8 \cdot 10^{-7}$

$k_s$  [m/s]: permeability,  $\gamma_s$ : soil density [kN/m<sup>3</sup>],  
 $Cvs = k_s \cdot E_{oed} / \gamma_w$  with  $E_{oed}$ : oedometric modules of the soil [kPa],  $\gamma_w$ : water density [kN/m<sup>3</sup>]

Only the uplift pressure distribution in the element at the base is calculated ( height of the structure  $H = 7$  m, length  $B =$  variable , geosynthetic spacing  $D_h = 1$  m) with impermeable upstream boundary.

The instantaneous construction hypothesis is considered:  
 $\bar{u}(t=0) = 105$  [kPa] (simplified model 2, Figure 3)

### 5.1 Influence of the transmissivity $\theta_g$ of the DFG

Figure 4 shows the variation in dissipation time required to obtain 10% maximum residual uplift pressure in the module in the vicinity of the impermeable upstream boundary (time  $t$  such that  $\bar{u}(t)_{max} / \bar{u}(t=0) = 10\%$ ). as a function of DFG transmissivity  $\theta_g$ .

An interesting phenomenon is seen to occur as a result of the modeling calculation: for low transmissivity values, maximum uplift pressures are dissipated faster in soil 1 (clay) than in soil 3 (silt), and even compared to soil 2 for extremely low values, although soil 1 has lower permeability.

For a more important length  $B$  of the drain, the observed phenomena exist for greater value of  $\theta_g$ . In the same way, if the thickness  $D_h$  is smaller ( $D_h = 0.5$  m) the same phenomenon is amplified. Notice, that these values of  $\theta_g$

are similar of real values of  $\theta_g$  for non-woven geotextiles used for D.F.G.

For high transmissivity values ( $\theta_g = 10^{-5}$  m<sup>2</sup>/s), the uplift pressure decreases rapidly in the drains for both soils: drainage occurs mainly through the geosynthetic drains. The soil with the high  $Cvs$  value dissipates the interstitial uplift pressures more quickly.

For a lower transmissivity value ( $\theta_g = 10^{-7}$  m<sup>2</sup>/s), the uplift pressure in the drains takes much longer to decrease. The explanation seems to be that, for soil 1, the ratio  $\theta_g / k_s$  is such that most drainage of the soil takes place through the geosynthetic drains. For soil 3, given the low  $\theta_g$  value, flow is mainly horizontal through the soil; as a result, the drain is subjected to high uplift pressure. Consequently, the draining time being longer, the residual uplift pressure (maximum at the impermeable upstream boundary), is higher for the more permeable soil. Figure 5 shows the uplift pressure distribution for two times  $t = 10$  and  $20$  days for soils 1 and 3 and for  $\theta_g = 10^{-7}$  m<sup>2</sup>/s of the DFG.

The using of a geosynthetic drain seems to be really efficient for low permeability of soil (clay) compared to higher permeability of soil (clayey silt).

The ratio of geosynthetic transmissivity to soil permeability ( $\theta_g / k_s$ ) therefore plays a major role. What can we expect in real life of draining system?

Figure 4: variation in dissipation time ( $\bar{u}(t)_{max} / \bar{u}(t=0) = 10\%$ ) as a function of transmissivity  $\theta_g$  ( $B = 4m, B = 15m$ ).

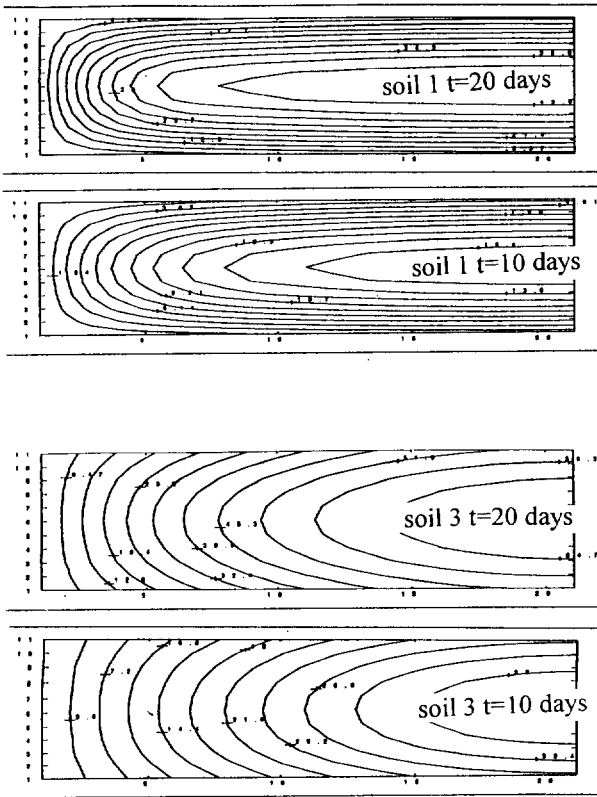

Figure 5: uplift pressure distribution in soil 1 and soil 3 ( $\theta_g = 10^{-7} \text{ m}^2/\text{s}$ ,  $B=4\text{m}$ ,  $d_h=1\text{m}$ , two times 10 and 20 days)

### 5.2 Influence of a localized decrease of $\theta_g$

We show the influence that could have a localized reduce of the DFG transmissivity. This decreasing could be produced: by a local damage of the drain, a decreasing of the thickness of the drain induced by a construction blemish, a water moisture penetration difficulty of the drain. This last phenomena was already observed for non-woven geosynthetics.

We had solved this problem with a numerical method;  $\theta_g$  is locally reduced: ( $\theta_g$  locally reduced =  $\theta_g/100$ ) in the application treated. In function of the place of the damage, we had an uplift pressure discontinuity in the damage DFG: the uplift pressure is increased at the back and is decreased in front of the damage, in comparison with undamaged DFG (Figure 6). This induce an over distribution of the water flow in the soil-DFG composite: the uplift pressure increase in the undamaged DFG and it is more efficient.

## 6 CONCLUSIONS

The use of draining-reinforcing dual-function geosynthetics (DFG) means that it is possible to consider employing poor quality soils to build reinforced-earth structures.

From this first original approach, the effect of the main parameters involved can be judged, although it should be

stressed that this is only the preliminary stage of research on this subject. An instrumented structure will have to be built and monitored to refine the hypotheses considered and modeling procedures in order to establish a necessary validation base.

**ABSTRACT:** This paper focuses on the mobilized strength of prefabricated vertical drains, or PVDs, and is based on the results of theoretical, laboratory and field testing on prototype PVDs. Used herein are PVD simulated units known as load-elongation measuring strips, or LEMS. Results of the paper show that the typical strength of commercially available PVDs are well in excess of the required strength when installed by properly functioning construction equipment.

**KEYWORDS:** Drainage, Wick Drains, Tensile Strength and Survivability

## 1 INTRODUCTION

PVDs have replaced conventional sand drains over the past 20 years, by providing an economical solution to rapidly consolidate fine grained saturated soils. When building on such compressible soils, large settlements are anticipated. As the soil cannot compress at a greater rate than release of the excess pore water pressure, such settlement can continue for a long period of time. PVDs are used to expedite this release of pore water hence they decrease the time for settlement and greatly facilitate the stabilization of such sites.

PVDs are approximately 100 mm wide by 2 to 5 mm thick. They are delivered on site in large rolls. Most PVDs consist of a synthetic drainage core surrounded by a nonwoven heat bonded or mechanically bonded geotextile filter. They are installed vertically in the ground by a pile driving type of construction equipment known as a "wick sticker". Spacings are typically at 1 to 5 m throughout the soil to be stabilized. The length of the drains are site specific but usually extend to the bottom of the soft soil involved.

Once the PVDs are installed over a large area, a surcharge load is placed on the ground surface to mobilize excess pore water pressure in the foundation soil. The expulsion of the water is coincident with consolidation of the soil resulting in settlement at the ground surface. Additional surcharge load is placed in incremental lifts in accordance with the design requirements. The duration of the load depends on the soil characteristics, PVD spacing and type of PVD utilized.

There is a wealth of information available on the technique and a tremendous number of PVDs have been successfully installed around the world. The design method for determining the consolidation time versus PVD spacing as well as the required flow rate has been fully described in the literature. For example, Hansbo [1979]

has developed the relationship usually used to determine the PVD spacing as a function of the desired consolidation time. Holtz, et al. [1991] has given guidance on the flow rate capacity of PVDs in the unkinked and kinked conditions.

Conversely, the mechanical strength requirements of PVDs has seen little quantitative analysis and discussion. The only reference, Kremer, et al. [1983], reports the need for a PVD tensile strength of 500 N at a corresponding minimum strain of 2%. They also suggest a maximum strain of 10%. This upper strain limit is imposed in order to avoid unwanted deformations that might compromise the drain's dimensions and thus flow capacity. The technical background for these tensile strength and strain values is not known. Thus, the pursuit of a more rigorous numerical and experimental treatment of the tensile strength requirements during installation of PVDs is the purpose of this paper.

The tensile strength of PVDs is a consideration both during installation and during consolidation. Installation challenges the drain's strength as it threads through rollers of the wick sticker. The strength of the PVD is also challenged during the mandrel withdrawal process. Both of these situations are exacerbated by high installation speeds. In addition, the tensile strength may also be an issue when the drains are collectively used to resist a circular arc failure of the weak, sensitive soil. A large number of PVDs "sewn into the ground" and working as a unit will intercept and resist such a circular arc failure. This, however, is a design issue and is not addressed in this paper.

The paper will describe theoretical, laboratory and field research aimed at determining the mobilized strength of PVDs. The paper will conclude with generic recommendations on the required strength of PVDs based on the results of this investigation.

## 2 INSTALLATION

Typical equipment used to install PVDs is shown in Figure 1. Lighter trackhoe mounted units are sometimes used when the PVDs are relatively short, e.g., less than 15 m deep. Collectively, we will refer to all PVD installation equipment as "wick stickers". Wick stickers contain a mandrel which encases and carries the PVD while it is being driven. Mandrel designs are product specific. Rhombic mandrels with tapered ends are often used for high speed driving in soft soils. T-shaped mandrels reinforced with a longitudinal steel fin and fitted with harden steel driving tips are used when hard surface layers need to be penetrated. Mandrels are designed to minimize disturbance of the ground and to reduce smear and remolding of the soil adjacent to the PVD.

Figure 1. PVD installation rig, a wick sticker.

At the bottom of the mandrel the PVD is fixed to an end assembly that remains in the ground as the mandrel is withdrawn. The purpose of the end assembly is to keep the PVD fixed at the bottom of the soil layer while at the same time keeping soft soil from entering the mandrel as it is driven.

## 3 THEORETICAL CONSIDERATIONS

PVDs strengths are challenged during installation partly from the drain's self weight and partly from friction between the drain and various parts of the installation equipment. Worst case scenarios are envisioned as maximum forces are developed in the PVD when the mandrel accelerates from a full stop to full speed. Four limiting conditions are identified. These conditions are when the drain is pulled from the roll, as the drain passes through the conveyance system and under the lower roller, as the drain passes over the fixed cylindrical guide roller at the top of the rig, and when the mandrel is retrieved from the penetrated soil leaving the PVD in place.

The first condition investigated is when the drain is initially pulled off the roll. This is a process where the drain is drawn into the mandrel of the installation equipment. This incremental rather than continuous process requires the use of peak rather than average speed for the calculations. By using an angular acceleration of the roll with peak velocity of the wick sticker, a required force of only 14 N is mobilized in the PVD. This occurs at the beginning of each drive when there is a full roll of drain on the reel. The situation is analytically suggested to be as follows:

Velocity of Roll

$$V_{ave} = \frac{L}{D} = \frac{18\text{m}}{18\text{sec}}$$

$$V_{ave} = 1\text{ m / sec}$$

$$2\left(\frac{1}{2}(1)V_{peak}\right) + 16\text{ 1 / peak} = 18$$

$$V_{peak} = 1.06\text{ m / sec}$$

Acceleration of PVD Roll

$$a = \frac{V_{peak}}{t} = \frac{1.06\text{ m / sec}}{1\text{ sec}} = 1.06\text{ m / sec}^2$$

$$\alpha = \frac{a}{r} = \frac{1.06}{0.6} = 1.77\frac{\text{rad}}{\text{sec}^2}$$

Center of Gravity of PVD Roll

$$k^2 = \gamma^2 + r^2$$

$$k = \sqrt{(.1)^2 + .6^2}$$

$$k = 0.61\text{ m}$$

$$\text{mass}_{\text{max}} = m = 25\text{ kg}$$

$$\Sigma M_o = I\alpha$$

$$T_1(0.6) = \frac{1}{2}mk^2\alpha$$

$$T_1 = \frac{1}{0.6} \left[ \frac{1}{2}(25)(0.61)^2(1.77) \right]$$

$$T_1 = 13.6 \text{ N}$$

Note, this is the maximum force due to the fact that  $m$  and  $\alpha$  decrease as the drain is utilized off of the roll.

In the second condition, the drain passes through the conveyance system and under the lower roller. There exists a relationship between the tension in the drain before it enters and after it leaves the roller. This relationship is based on the assumption that the drain is just about to slide into motion. By taking a free body diagram of a small element of the drain the forces acting on the drain are the two forces of tension, the normal component of the reaction of the roller and the friction force. A relationship is obtained knowing that motion is imminent by letting the angular change of the drain approach zero. As seen in the following calculations, only 25 N of strength is required of the PVD in such a condition.

$$\Sigma F_x = 0: (T + \Delta T) \cos \frac{\Delta\theta}{2} - T \cos \frac{\Delta\theta}{2} - \mu_s \Delta N = 0 \quad (1)$$

$$\Sigma F_y = 0: \Delta N - (T + \Delta T) \sin \frac{\Delta\theta}{2} - T \sin \frac{\Delta\theta}{2} = 0 \quad (2)$$

Solving Eq. 2 for  $\Delta N$  and substituting Eq. 1

$$\Delta T \cos \frac{\Delta\theta}{2} - \mu_s (2T + \Delta T) \sin \frac{\Delta\theta}{2} = 0$$

Divide by  $\Delta\theta$

$$\frac{\Delta T}{\Delta\theta} \cos \frac{\Delta\theta}{2} - \mu_s \left( T + \frac{\Delta T}{2} \right) \frac{\sin(\Delta\theta / 2)}{\Delta\theta / 2} = 0$$

Let  $\Delta\theta$  approach zero

$$\frac{dT}{d\theta} = \mu_s T = 0 \quad \frac{dT}{T} = \mu_s d\theta$$

By integration

$$\ln \frac{T_2}{T} = \mu_s \beta \quad \text{or} \quad \frac{T_2}{T} = e^{\mu_s \beta}$$

Given

$$\beta = \pi \text{ rad, and}$$

$$\mu_s = 0.2$$

Since:

$$F = T_1 = 13.6 \text{ N}$$

Therefore the PVD experiences the following after it exits the lower roller

$$T_2 = e^{\mu_s \beta} T_1$$

$$T_2 = e^{(.2)(3.14)} (13.6)$$

$$T_2 = 25 \text{ N}$$

In the third condition, the PVD is considered to be sliding over the roller at the top of the rig. The tensile force in the PVD is calculated by assuming geometric and frictional characteristics of an upper roller for typical construction equipment. The calculations are similar to that of the lower roller. Liberties were taken in estimating the frictional characteristic of the roller. Conservative values were chosen assuming that the roller would seize-up and become partially fixed. Regardless of these conservative assumptions, a relatively low force of 47 N was mobilized in the PVD for this condition.

Upper Roller

$$T_3 = e^{\mu_s \beta} T_2$$

$$T_3 = e^{(.2)(3.14)} (25)$$

$$T_3 = 47 \text{ N}$$

The fourth condition is when the mandrel is withdrawn and pulled out of the soil leaving behind the drain and its end assembly. As stated previously, the end assembly anchors the PVD and keeps soft soil out of the mandrel. It is possible, however, that some soil can enter the bottom of the mandrel. This in turn will impede release of the drain and subject it to a tensile force by snagging the PVD at the tip of the mandrel. Assuming such a condition exists, the end assembly constitutes the resisting force, where the

friction caused by the soil in the end of the mandrel constitutes the driving force. The calculation and assumptions associated with this condition follows. This worst case scenario results in a mobilized strength of approximately 103 N in the PVD.

### 3.1 Friction in the Mandrel

Using Mohr-Coulomb criteria

$$\tau = \sigma_n \tan \phi + c$$

$$\tau = c \text{ assuming } \phi = 0$$

$$\tau = c = 10,000 \text{ Pa for typical soft clay}$$

$$\Sigma F_y = T_4 - 2\tau e A = 0$$

$$T_4 = 2\tau e A$$

$$T_4 = 2(10,000)(30\%)(.1)$$

$$T_4 = 600 \text{ N}$$

However can such a force be mobilized in the drain?

### 3.2 Bearing Capacity of End Rod

$$Q_o = Q_p + Q_s$$

$$Q_o = A_p p_o + 0$$

$$Q_o = A_p (cN_c + 9N_a)$$

$$Q_o = .002(10,000)(5.14)$$

$$Q_o = 103 \text{ N}$$

Since  $Q_o \ll T_4$ ,  $T_4$  will never be mobilized and therefore  $Q_o$  governs

## 4 LABORATORY INVESTIGATION

The purpose of the laboratory investigation was twofold; to verify, or refute, the theoretical values just calculated (wherein many assumptions were required) and to develop a means of determining the mobilized strength of PVDs in the field. To aid us in these pursuits, we constructed a laboratory wick sticker simulator. A schematic diagram of the laboratory wick sticker simulator is shown in Figure 2. The simulator was constructed in the high bay region of GRI's soils laboratory. The high bay allowed for an upper fixed roller height of 10 m above the floor level.

By positioning a load cell at different locations along the PVD path, one could check the mobilized strength of the drain along the path. Results from this exercise showed that the first, second and third conditions resulted in average load cell responses of 10 N, 18 N and 150N

Figure 2 Schematic of laboratory wick sticker simulator.

respectively. To simulate the fourth condition we had to make up a model in the soils lab of an end assembly attached to a PVD being pulled from a freshly remolded column of soft soil. The PVD experienced widely different loads in this simulation depending on the amount of friction imparted in the mock mandrel. Loads in the PVD varied from 25 to 250 N.

These laboratory simulations were interesting, however, it was clear that we could not use the load cell out in the field. It was too cumbersome and fragile to withstand the rigors of field work. Hence we set out on developing a means of determining the mobilized strength of PVDs remotely. Six different techniques were attempted to measure the load elongation response of the PVD. They included:

- Foil strain gages similar to those used by Risseeuw [1986] and Guglielmetti, et al. [1996]
- Load sensitive film which changes color upon being stressed to different levels
- Spray applied coatings which crack to varying degrees after being stressed
- Hole punching to reduce PVD strength
- Side cutting PVD to incrementally reduce its strength
- Development of a simulated PVD unit called "Load-Elongation Measuring Strip" (LEMS)

Of all the techniques attempted, the LEMS showed the most promise. This specially prepared PVD consisting of a polyamide (3 x 3) grid fabric as a core, heat bonded between two 160 g/sq. m. nonwoven PET geotextiles. At 2 m intervals along the LEMS, the geotextile was cut away and specific number of polyamide yarns were cut. This left known numbers of yarns intact which allowed the LEMS to

model progressively weaker PVDs. This procedure was used to develop the curves shown in Figure 3. From this data an average breaking strength of 78 N per yarn was obtained. For comparison purposes, Figure 4 shows the tensile strength behavior of commercially available PVDs. For all tests of Figure 3 and 4 the gage separation was maintained at 100 mm and the strain rate was 10 mm/min.

Figure 3 Load elongation behavior of LEMS.

Figure 4 Commercially available PVD load elongation responses.

With the LEMS now calibrated insofar as its strength per yarn is considered, laboratory trials on the wick sticker simulator were undertaken. In conducting these trials friction in the rolls was increased using a brake and weight assembly to sequentially cause failure of the LEMS. The results of approximately 27 trial runs (with different numbers of uncut yarns) provided the results of Figure 5. The trend is linear resulting in a slope of 75 N per yarn. This roughly agrees with the tension testing in the constant rate of extension machine as noted previously. Equipped with this confirmation, we took the LEMS to the field to try and verify our theoretical and laboratory findings.

Figure 5 Results of LEMS calibration on simulator.

## 5 FIELD INVESTIGATION

Field trials with the LEMS material were conducted at a major soft soil stabilization project at the Philadelphia International Airport. Through the cooperation of Day & Zimmerman Infrastructure, Inc. and Geotechnics America, Inc. (the PVD contractor) a field trial of the LEMS was conducted in October of 1997.

As reported by Koerner [1997], the results of the field work are summarized in Table 1.

Table 1 - Field Behavior of LEMS at the Philadelphia International Airport.

No. of Yarns in LEMS	Resulting Strength of LEMS (N)	No. of Repeat Trials	Result of Each Trial
20	1540 N	2	pass/pass
14	1080 N	2	pass/pass
10	770 N	3	pass/pass/pass
5	390 N	3	pass/pass/pass
3	230 N	2	fail/fail

The results of Table 1 indicate that the mobilized PVD strength for this particular construction equipment and site condition is between 390 and 230 N. It must be clearly stated that it is believed that site conditions and

construction equipment will influence results. However, these limited results are insightful none-the-less.

## 6 SUMMARY AND CONCLUSION

It appears from theoretical calculation, laboratory testing and a limited field investigation that the strength of most commercially available PVDs are greater than required for installation. In addition, it appears that the current trend of increasing the strength requirements of PVDs is unfounded. At present, there does not appear to be any tangible reason for increasing PVD strengths over and above those that are currently being manufactured. For example, Figure 4 indicates that available PVD tensile strengths are from 2000 to 4000 N. Most commercially available PVDs meet or exceed equipment imposed installation stresses as demonstrated in this paper.

In light of the low values of mobilized PVD strengths developed in this study, e.g.,

- theoretically: 14 to 103 N
- experimentally: 10 to 250 N
- field: 230 to 390 N

we are confident in stating that there is an inherent factor of safety for most commercially available PVDs. Of all installation conditions described, it appears that withdrawal of the mandrel is the governing strength condition. Loads during withdrawal of the mandrel are site specific. They depend on the type of anchor plate and will only take place at the tip of the PVD where it connects with the end assembly.

The requirement for discharge of water at this location is limited since it is at the end of the drain. The load in the rest of the drain is probably less than 230 - 390 N. It is interesting to note that this corresponds with an elongation of approximately 2-4% for most PVD.

It is concluded that all commercially available drains have strengths and elongation's at break which are much higher than necessary. Hence, the available factors of safety for mobilized strength is in the range of 4 to 11. We question if the higher factors of safety are warranted in the event that ones construction equipment is functioning properly and geometrically equipped to drive the specific PVD delivered to the specific job site.

## ACKNOWLEDGMENTS

The research project was carried out under the general support of the GSI consortium of member organizations. Appreciation is extended in this regard. The authors would like to specifically thank Mr. Timothy Kruppenbacker, construction manager of Day and Zimmermann, Inc. and Mr. John Case, controller of

Geotechnics America, Inc. for their assistance with our field effort.

**ABSTRACT:** A series of laboratory tests have been conducted to investigate the effects of (a) trapped air bubbles in drainage path, (b) folding (no kinking) of drain, (c) confining drain by clay, and (d) elapsed time (long term), on discharge capacity of prefabricated vertical drain (PVD). The test results indicate that confining the drain by rubber membrane yielded a much higher discharge capacity than that in clay. It suggests that the discharge capacity test of PVD should be conducted by confining the drain in clay. Also, the discharge capacity reduces significantly with elapsed time, and the long term behavior of PVD should be considered in design. For most commercially available PVDs, a long term discharge capacity of less than 100 m<sup>3</sup>/year is tentatively suggested for design. The possible air bubbles trapped in the drainage path of PVD has some effect on discharge capacity, and the test data from this study showed about 20% reduction due to this factor. The folding of the drain does not have obvious influence on discharge capacity because it does not change both length and cross sectional area of drainage path much.

**KEYWORDS:** Prefabricated vertical drain, Laboratory test, Hydraulic conductivity, Drainage.

## 1 INTRODUCTION

Installing the vertical drain into ground can shorten the drainage length of the deposit significantly, and with some surcharge loading, the engineering properties, in terms of the compressibility and undrained shear strength, of the deposit can be substantially improved. The development of prefabricated vertical drain (PVD) has made this method more attractive due to the portability of the material and lower installation cost. During past few decades, vertical drain improvement has been widely used in soft soil engineering.

For a given soil condition, the behavior of vertical drain improved subsoil is controlled by: (a) drain spacing and equivalent drain diameter, (b) smear effect, and (c) discharge capacity of drain (well resistance). The drain spacing is a known factor and the equivalent drain diameter of PVD can be reliably calculated based on the geometry of the PVD. However, smear effect and discharge capacity have to be determined experimentally. At present, the method for determining the discharge capacity of PVD has not been standardized, and the values reported in the literature are not consistent. Most test methods confine the drain by rubber membrane, such as ASTM D4716-87, and determined values are usually high. However, some low values were reported for confining the drain in clay (e.g. Hansbo 1983). An ideal discharge capacity test should simulate the drain installation, confinement of clay on the filter sleeve of drain, and the deformation of drain during consolidation. It is obvious that a full scale test could be expensive if it is possible. For a small scale laboratory test to be valid, it must consider the important influence factors. In order to improve the laboratory test method and advance the prediction ability on the behavior of vertical drain improved

subsoil, there is a need to investigate the main influencing factors on discharge capacity of PVD.

In this paper, the effect of (a) possible air bubbles trapped in the drainage path, (b) folding (no kinking) of drain which most likely will occur in the field due to consolidation of soil, (c) confining the drain by clay, and (d) elapsed time (long term) on discharge capacity of PVD are systematically investigated. First, the unit cell (a drain surrounded by a soil cylinder) consolidation theory is briefly reviewed to indicate the effect of discharge capacity on the rate of consolidation. Then the laboratory test methods as well as results are presented. The suggestions are made on improving the test method on discharge capacity of PVD.

## 2 A BRIEF REVIEW ON UNIT CELL THEORY

The basic theory of vertical drain consolidation is unit cell theory which was first proposed by Barron (1948). Further studies on unit cell behavior were made by Yoshikuni and Nakanodo (1974) and Hansbo (1981). Since Hansbo's theory is relatively simple, it has been widely used. The derivation of the theory is based on equal vertical strain assumption. The resulting equation for average degree of radial consolidation ( $\bar{u}_h$ ) of a unit cell is as follows:

$$\bar{u}_h = 1 - \exp(-8T_h / \mu) \quad (1)$$

$$T_h = \frac{C_h t}{D^2} \quad (2)$$

$$\mu = \ln \frac{n}{s} + \frac{k_h}{k_s} \ln s - \frac{3}{4} + \pi \frac{2l^2 k_h}{3q_w} \quad (3)$$

Where  $C_h$  is the horizontal coefficient of consolidation,  $t$  is time,  $D$  is the diameter of unit cell,  $k_h$  is the horizontal permeability of soil,  $k_s$  is permeability in smear zone,  $l$  is drainage length,  $q_w$  is discharge capacity,  $n=D/d_w$ , and  $s=d_s/d_w$  ( $d_w$  is the diameter of drain, and  $d_s$  is the diameter of smear zone). The last term in Equation 3 represents the well resistance. It can be seen that the larger the discharge capacity,  $q_w$ , the smaller the well resistance, and the higher the rate of consolidation. For example, assuming  $l=15$  m and  $k_h=10^{-8}$  m/sec, if  $q_w$  is less than  $100$  m<sup>3</sup>/year, it will have a considerable influence on consolidation rate of vertical drain improved subsoil.

### 3 APPARATUS AND TEST METHODS

#### 3.1 Apparatus and Test Procedure

The apparatus used is a modified triaxial device as shown in Figure 1. The main cell has a diameter of 200 mm and height of 600 mm. The drain sample is set inside the cell similar to that of setting the triaxial test sample. The lower pedestal is fixed at the bottom of the cell and connected to the inlet water flow system. The upper pedestal is movable (for adjusting the length of drain sample) and connected to the outlet water flow system. The drain length can be

Figure 1. Set-up of discharge capacity test apparatus

tested is 200 mm to 400 mm. The shape of pedestal is made as: one end is cylindrical for fixing the membrane, and rectangular at another end to connect the drain. In this way, when confining the drain by rubber membrane, there will be no gap between membrane and drain. The length of drain inserted into the slot of upper and lower pedestal is about 30 mm each. The diameter of the pedestal is 100 mm. Except the main cell, there are inlet and outlet water containers. The inlet water container is linked with water supply system, and outlet water container is connected to discharge capacity measuring device. After the drain is installed, the cell is filled with water up to about 80% full, and confining pressure is applied by air pressure through an air pressure regulator. For investigating the effect of folding, the drain is folded at one and two point for 10% and 20% vertical strain, respectively. The methods for investigating the possible trapped air bubble effect and confining the drain by clay are described as follows.

#### 3.2 Method for Investigating the Effect of Trapped Air Bubbles

It is considered that installing a drain into ground, the water from soil gradually enters the drain along the whole length of the drain, and there might be some air bubbles trapped into drainage channels. In order to study the possible trapped air bubble effect, a simple air bubble generation device is newly developed. A thin plastic tube is connected to an air tank through an air pressure regulator. Then the tube is placed at the bottom of the drain sample through an inlet hose as shown in Figure 2. The amount of air bubbles generated can be controlled by adjusting the air pressure regulator. The generated air bubbles enter the drain following the water flow. The main test steps are:

- (1) Set-up the drain sample and apply the desired confining pressure as well as hydraulic gradient.

Figure 2. Method for generating air bubbles

- (2) Generate the air bubbles with a diameter of about 1 mm, and a speed of about 100 bubble/min. This process is continued for about 4-6 hours.

- (3) Close the air bubble generation system, and let the water flow continue for more than 2 hours to steady the flow. Then measure the discharge capacity.

### 3.3 Test Procedure for Confining the Drain by Clay

Hansbo (1983) recognized the importance of confining the drain by clay on determining the discharge capacity. However, due to convenience, most discharge capacity tests conducted by manufacturers are confining the drain by rubber membrane. One of the purposes of this investigation is to compare the discharge capacities determined by clay confinement and membrane confinement. The test method proposed in this study for testing the drain in clay is simple and can test the full size of drain. The following main steps are followed during test:

- (1) Connect the drain sample to lower pedestal, fix the membrane to lower pedestal also, and set the mould for preparing the clay sample in position.
- (2) Make clay sample. The remoulded clay with a water content close to the liquid limit is put into the mould layer by layer keeping the drain in the middle. The diameter of the clay sample is 100 mm. After the required height of clay sample is reached, the upper pedestal is installed and the drain is connected to outlet flow system. Care needs to be paid to prevent the contamination of the top of drain by clay.
- (3) Consolidate the clay sample. For removing the mould, a suction of about 10 kPa is applied to the clay sample. After confining pressure is applied, the suction is gradually released and the sample is left for consolidation under lateral pressure.
- (4) Measure discharge capacity. After the consolidation of clay sample is finished, the discharge capacity is measured under desired hydraulic gradient.

Figure 3. Set-up of confining the drain by clay

The set-up of the drain confined by clay is illustrated in Figure 3. With this method, a test with one consolidation pressure and several hydraulic gradients requires 10 days to complete.

### 3.4 Considering the Head Lose in Hose System

Another factor which has been noticed during the investigation is head loss in the hose of the test equipment. Since the discharge capacity of drain confined in membrane is normally high, ignoring the head loss in the hose does not introduce much error. For testing the drain in clay, which is close to field condition, the head loss in the testing system needs to be considered. The calibration of the head loss in the hose system can be made by conducting the test without installing a drain sample.

## 4 TEST RESULTS AND DISCUSSIONS

### 4.1 Materials Used

The PVD adopted in this study is a commercial products and its properties are summarized in Table 1. The soil used is remoulded Ariake clay. Its index properties are: specific gravity,  $\rho_s$ , of 2.60, plastic limit,  $w_p$ , of 42.8%, and liquid limit,  $w_l$ , of 105.0%. The soil consists of 57.0% clay, 41.7% silt, and 1.3% sand particles. The rubber membrane used has a thickness of 1.0 mm.

Table 1. Physical properties of PVD

Size (mm)	Thickness	2.6
	Width	94
Drainage channel	Depth(mm)	1.5
	Width(mm)	1.8
	No. of channel/drain	40
Unit weight (g/m)		90
Material	Filter	Spun bonded polyester
	Core	Polyolefin
Connection condition between filter and core		Fixed
Structure		

### 4.2 Short Term Test Results

For ease in quantifying each influencing factor, the test results of confining a straight drain in a rubber membrane are considered as basic ones and other test results are compared with them. The confining pressures for the basic test were 49 and 392 kPa, and hydraulic gradients were

Figure 4. Results of basic test

about 0.08 and 0.8. The results are plotted in Figure 4. It can be seen that as a general tendency the discharge capacity is reduced with increased confining pressure. It is the same as the results reported in the literature (e.g. Hansbo 1987). If extrapolating the results to unit hydraulic gradient ( $i=1.0$ ), a discharge capacity of 1981  $m^3/year$  and 1307  $m^3/year$  can be obtained for confining pressures of 49 kPa and 392 kPa, respectively. The short term test results are summarized in Figure 5. A discharge capacity ratio is used in the figure, which is defined as the amount of water flow,  $Q$ , divided by the corresponding value of basic test,  $Q_b$  ( $Q/Q_b$ ). Following discussions can be made for short term test results.

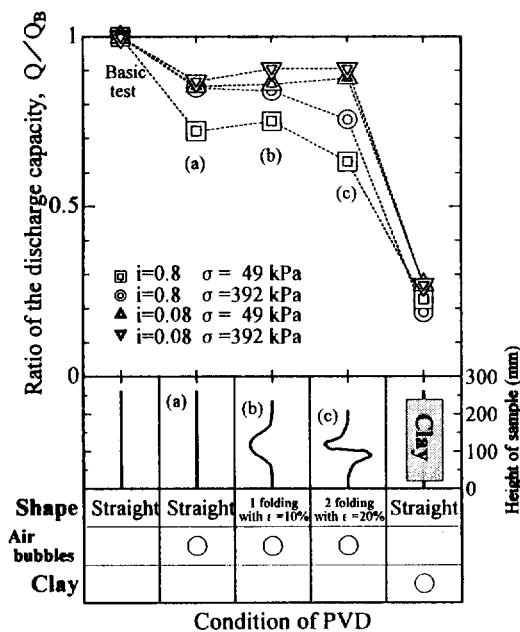

Figure 5. Summary of short term test results

(1) Confining the drain by a rubber membrane can not simulate the actual field condition and the discharge capacity test for determining the design value should confine the drain with clay. When confined by a rubber membrane, it results in a much higher discharge capacity than that in clay. For the case investigated, the clay value is only about 20% of membrane value. Three possible reasons for reduction on discharge capacity of PVD in clay can be considered.

(a) Reducing the cross sectional area of drainage channel due to deformation of filter under pressure. This has been considered as the main reason. After the test, it was observed that the filter was considerably deformed and the cross sectional area of drainage channel was reduced to 70-50% of original value as shown in Figure 6. The left side of Figure 6 was made by stamping the actually used soil sample on paper. Since the amount of reduction on cross-sectional area is a function of stiffness of filter, as a supplementary information, the tension force versus tension strain relationship of the filter was determined by the laboratory wide strip test, with a strain rate of about 1%/min as shown in Figure 7. For the case of confined in rubber membrane, due to the tension stiffness of membrane, filter can not deform as freely as that in clay.

Figure 6. Deformed shape of clay sample adjacent to drain

(b) Reducing the conductivity of filter in longitudinal direction due to soil particles penetrating into the opening of filter. When confining the drain in rubber membrane, the filter may act as a part of vertical water flow path. In the case of confined by clay, the clay particles will enter the opening of the filter and reduce the conductivity of filter. Since the thickness

Figure 7. Tensile force versus tensile strain curve for filter

of the filter is only about 0.2 mm, this effect is a minor one.

(c) Clay particles enter the drainage channel. Although the most of filters commercially used satisfy the filtration criteria, the experimental evidence indicates that some amount of very fine particles entered the drainage path and forming loose flocculated sediments on the wall of drainage path. It is considered that the formation of the flocculated sediments is a function of chemical contents of clay.

(2) It seems that not much air bubbles can remain in the drainage path. The data from this study show that the trapped air bubbles reduced the discharge capacity about 20%.

(3) Considering a vertical strain up to 20%, the folding of the drain has minimal effect on discharge capacity, which supports the conclusion drawn by Hansbo (1983). This factor can be explained as the folding of the drain does not change both the length and cross-sectional area of drainage path much. The kinking was not considered in this study because it rarely occurs in the field.

#### 4.3 Long Term Test Results

Only one test of confining the drain in clay was tested for about 5 months. The conditions were: confining pressure of 49 kPa and hydraulic gradient of 0.08. This confining pressure approximately represents the lateral earth pressure in subsoil under a 5 m high embankment or at 10 to 15 m depth of natural subsoil. A lower hydraulic gradient is adopted because, in the field, the average value during consolidation process may not be high. The long term test results are shown in Figure 8, which indicate that the discharge capacity was continuously reduced with elapsed time except the last measurement point. It has been understood that in the interval between the last two measurements, the inlet hose (about 30 mm in diameter and flexible) had been stepped on several times unexpectedly.

Stepping on the water flow hose is just like applying pressure pulses to water flow system. It was observed that some flocculated fine particles were pressured (due to stepping) out of the drainage channel of drain and deposited on the wall of the outlet hose. Based on these results, it is considered that the reasons for the reduction of discharge capacity with elapsed time are (1) creep behavior of filter which reduces the cross-sectional area of drainage path, and (2) clogging caused by flocculated fine particles. As shown in Figure 8, for the case investigated, the creep effect is evaluated as the difference between last measurement point and the reading at about 1 week of elapsed time, which reduced the discharge capacity about 30%. The most reduction can be attributed to the clogging effect which is a function of soil type and filter type. The chemical analysis about the flocculated fine particles as well as the clay mineral is going on and the results will be reported in the future. The discharge capacity reduction with elapsed time was also reported by Koda et al. (1986) for confining the Geodrain in organic soils. For a drain, it is normally expected to work at least half a year. Therefore, in design, long term behavior of drain should be taken into account.

#### 4.4 Discussions

From this investigation, it shows that the most important factors affecting the discharge capacity of PVD are: (a) confining condition, and (b) the duration of test. Therefore, for determining the design value of discharge capacity, the test should be conducted by confining the drain by clay and tested for a longer period (may be few month). If comparing the results from this study with those reported in the literatures, the following comments can be made.

Figure 8. Long term discharge capacity test results

(1) The values of confining the drain by rubber membrane are comparable with the data reported by manufacturers. Due to the apparent high discharge capacity, it may be considered that the well resistance of PVD can be

ignored in design. However, the results of this study suggest that the high value for confining the drain by rubber membrane may not represent the field condition, and well resistance may be an important design factor, especially for long drains. The discharge capacity of confining the drain by rubber membrane may only be used as a quality control test.

(2) In clay short term (about 1 week) value of discharge capacity is in the lower range of the data summarized by Hansbo (1987). Comparing with the specifications about required discharge capacity as summarized by Bergado et al. (1996), it can be seen that with a discharge capacity of few hundreds  $m^3/year$ , the most specifications can be satisfied. However, the most specifications have no clear requirement about long term behavior.

(3) The long term in clay value (about 5 months) from this study is higher than the data reported by Hansbo (1983) by using the revised CTH (Chalmers University of Technology) method for the similar drain. The revised CTH method also confined the drain in clay with a test duration of less than 1 month. Whether the CTH method considered the head loss in the hose system is not clear, and if not, it might be the reason for the lower value of discharge capacity. The relative lower value of discharge capacity of PVD was also reported by Jamiolkowski et al. (1983). The field discharge capacity may vary with the type of drain, type of clay, and designed consolidation period, but as a rough reference, it is recommended that for most commercial PVD, a design discharge capacity of less than  $100 m^3/year$  can be used.

## 5 CONCLUSIONS

Four influence factors on discharge capacity of PVD are experimentally investigated. These factors are: (a) possible trapped air bubbles in drainage path, (b) folding of drain, (c) confining the drain by clay, and (4) long term behavior. From the test results, following conclusions can be drawn:

1. The discharge capacity of PVD confined in clay is significantly lower than that confined by rubber membrane. It is strongly recommended that for determining the design value, the discharge capacity test should be conducted by confining the drain in clay. The test of confining the drain by rubber membrane not represents the field condition and it might be used for quality control purpose only.
2. The discharge capacity of PVD reduces significantly with elapsed time. For the case investigated, the

long term minimum value is only about 10% of the value at 1 week. This indicates that for design vertical drain improvement, long term behavior of PVD should be considered. For most commercial PVD, a design long term discharge capacity of less than  $100 m^3/year$  is tentatively suggested.

3. The possible air bubbles trapped in drainage channel has an effect on discharge capacity. For the case investigated, it shows that the discharge capacity was reduced by about 20% due to the effect of trapped air bubbles.
4. The folding of drain does not influence discharge capacity significantly because it does not change both the length and cross sectional area of drainage path much.

**ABSTRACT:** During the past few decades, an increasing need has arisen for various types of civil engineering projects on construction sites underlain by thick deposit of soft cohesive soils. Parallel to the development of the sand drains, different types of prefabricated vertical strip drains were developed and were used exclusively in various projects. In this paper, a new cylindrical prefabricated geocomposite drain (environmental friendly coir and jute) has developed and can be used to accelerate the consolidation of soil thereby making the site available for the use in short time. The relatively low cost of manufacture and installation makes this drain quite attractive. A design methodology has been developed and the results are presented in the form of design charts for the handy use.

**KEYWORDS:** Prefabricated vertical drains, Soft soils, Drainage, Filtration, Geocomposite.

## 1 INTRODUCTION

In the recent years many civil engineering projects have been under-taken on the sites which are underlain by thick deposits of soft cohesive soils. In such situations a ground improvement technique is essentially needed to provide adequate soil properties viz., bearing capacity and tolerable post construction total and differential settlements. Preloading and precompression are frequently used in combination with vertical drains, (Hausman, 1990. Holtz, 1987 and Johnston, 1970) especially in areas of very thick deposits of soft soils with high percentage of moisture content. The main purpose of vertical drains is to accelerate the consolidation time by shortening the drainage path. Usually sand drains are used for these purposes (Bergado, et al., 1992). The prefabricated drains were first introduced into the field of geotechnical engineering by Kjellman (1948). Improvement of the Kjellman wick drain included using a grooved plastic core in place of cardboard.

The various types of prefabricated vertical drains, their common installation methods and pertinent characteristics have been documented. (Jamiolkowski et al., 1983 and Koerner, 1994). Most of the prefabricated drains made of natural materials viz., jute and coir has also been studied. (Lee et al., 1989; Ramaswamy, 1994; Dastidar, 1969; Dinesh Mohan, 1977; Sengupta, 1980 and Mandal and Shiv, 1992). As two components of natural geocomposite drains (i.e. jute and coir) are readily available in the Indian subcontinent at low cost, an attempt has been made in the present paper to develop a new design methodology to install geocomposite drains in soft cohesive soils. The design charts are also presented for handy use.

## 2 GEOCOMPOSITE DRAINS

Generally geocomposite drains are made of synthetic materials, yet some geocomposite drains are made of natural fibre extracted from jute and coir. Different configurations of natural geocomposite drains are shown in Figure-1. The schematic diagram of a natural geocomposite drain for which the nomogram is developed is shown in Figure-2.

Fig. 1. Different types of geocomposite drains

Fig. 2 Geocomposites vertical wick drain

Seven coir ropes of diameter 10mm to 60mm are grouped to form one geocomposite drain. These ropes are tied with jute rope at a spacing of 60cm. This group of coir rope is then wrapped with double layer of jute geotextile. The geocomposite drain diameter varies from 50mm to 200mm. The coir ropes provide longitudinal channels to allow percolation where as the filtering quality of the drain is furnished by the two jute burlap layers.

This geocomposite drain can be designed and manufactured to suit the needs of the specific requirements of different soil improvement projects. It is flexible, rugged, resistant to clogging adequately strong in tension and sufficiently durable. The properties of this geocomposite drain and a typical natural soil are given in Table 1. Jute and coir are by nature strong and not easily decomposable under adverse environmental conditions. The geocomposite drain is relatively resistant to chemical action and loses its strength usually after two years of installation in soft marine clay. (Ramaswamy, 1994)

Table 1 Properties of geocomposite drain and soil

a) Material

1) Jute fibre

Thread diameter : 1.5 to 2.0 mm  
weight: 450 g/m<sup>2</sup>  
Tensile strength = 13 KN./m

2) Coir rope

Rope diameter: 10mm to 60mm.  
weight: 350 g/m<sup>2</sup>  
Tensile strength = 11 KN./m

b) Geocomposite drain

- i) Components : seven number of coir ropes of diameter 10mm to 60mm wrapped by double layer jute geotextile.
- ii) Diameter: 100mm to 200mm.
- iii) Filter cover permeability  $> 10^{-3}$  cm/sec.
- iv) Axial permeability :  $> 10$  cm/sec for confining pressure up to 330 KN /sq.m

c) Marine clay

specific gravity = 2.65  
liquid limit = 78%  
plastic limit = 38%  
plasticity index = 40%

2.1 Function of Natural Geocomposite Drain

The function of geocomposite drains are:

1. The jute fiber has the capacity to accept water through the filter jacket and work as water absorbent material.

2. The coir has the capacity to discharge the water quickly out of the consolidation soil strata.

The natural geocomposite drain has a unique structure that enhances the function as a filter fabric has high permeability and restricts the erosion of soil particles. At the same time it allows very fine particles from the soil to flow in and out of the drain without clogging. Removal of very fine sand particles is beneficial as this allow larger particles to form a highly permeable soil network against the fabric.

3 DESIGN CONSIDERATION

The procedure for the design of vertical drains are based on Terzaghi's one dimensional consolidation theory as suggested by (Barron, 1948, Richart, 1959, Kjellman, 1948 and Hansbo, 1979)

3.1 Design Parameters:

The spacing of the vertical drain is governed by

- soil properties
- boundary and drainage conditions
- desired degree of consolidation
- time available for consolidation
- drain installation pattern and
- height of surcharge or fill load.

The degree of consolidation, surcharge intensity, settlement, pore water pressure and drain parameters are interrelated. The degree of improvement of soil properties depends on percentage settlement, dissipation of pore water pressure, increase in effective stress or

increase of shear strength and the drain spacing can be obtained from (Barron, 1948). A more rigorous approach to drain design has been used in Europe and utilizes a combination of Kjellman's, (1948) original work and Hansbo (1979), the relevant design equation follow:

$$t = \frac{D^2}{8Ch} \left[ \frac{l_n \left( \frac{D}{d} \right)}{1 - \left( \frac{d}{D} \right)^2} - \frac{3 - \left( \frac{d}{D} \right)^2}{4} \right] l_n \frac{1}{1-U}$$

which can be simplified, since  $d/D$  is small, to

$$t = \frac{D^2}{8Ch} \left[ l_n \left( \frac{D}{d} \right) - 0.75 \right] l_n \frac{1}{1-U} \quad (1)$$

where :  $t$  = consolidation time

$Ch$  = coefficient of consolidation for horizontal flow

$d$  = equivalent diameter of the wick drain ( $\approx$  circumference /  $\pi$ )

$D$  = sphere of influence of the wick drain (for a triangular pattern use 1.05 times the spacing, for a square pattern use 1.13 times the spacing)

$U$  = average degree of consolidation.

From equation 1 a nomogram has been developed which relate degree of consolidation, coefficient of consolidation  $Ch$ , and the required drain spacing. The results are plotted in a graphical form as shown in Figure-3.

#### 4 CONSTRUCTION PROCEDURE

Geocomposite drains can be lowered into the drill holes made by readily available piling equipment. Koerner (1994) has given varieties of base plates to attach geocomposite drains at bottom of lanes. Similar types of drain plates can be used for lowering the natural geocomposite drain. A coir fabric at the ground surface is proposed for quick drainage of dissipated water beneath the embankment, instead of costly sand blanket. Since geocomposite drain allows faster consolidation the embankment layer thickness may also be increased to complete work at the earliest.

#### 5 CONCLUSIONS

The natural geocomposite vertical drain has been developed to speed up the consolidation process for various types of construction on sites underlain by thick deposits of soft clays. It is flexible, resistant to clogging, resistance to ultraviolet rays, relatively more permeable, strong in tension and sufficiently durable, low cost and environmental superiority over geosynthetics. As with synthetic geocomposite drains the natural geocomposite drain can be designed and manufactured to suit the specific requirements of different soil improvement projects.

#### ACKNOWLEDGMENTS

**ABSTRACT:** The discharge capacity of vertical drains is found to be significantly affected by the testing conditions. This paper presents the drainage performance of prefabricated vertical drains (PVD) under simulated field conditions, using a new drain testing apparatus. This apparatus can simulate realistic field conditions for vertical drains in soft clay deposits. Due to large ground settlement in soft clay, vertical drains may subject to excessive strains and formation of kinks. In general, such drains will have a lower discharge capacity than straight drains. Therefore, in addition to the realistic field properties of soil, critical evaluation of the laboratory determined discharge capacity is needed to understand the field performance of PVD. The testing conditions that can be simulated in this apparatus include varying confinement pressure, kinking of drains and packing in clayey soils. It is seen that different types of prefabricated vertical drains have significantly different discharge capacities under similar testing conditions. A comparative study of the discharge capacity of four drains under various test conditions is also presented in this paper.

**KEYWORDS:** Prefabricated vertical drains, Confining air pressure, Discharge capacity, Kinking, Testing

## 1 INTRODUCTION

Prefabricated vertical drains (PVD) are often used to accelerate consolidation of soft clay soils in ground improvement projects. Many types of prefabricated vertical drains are available in the market. To determine the suitability of a drain for a given project an evaluation of discharge capacity is needed. A new drain testing apparatus for PVD was developed at the National University of Singapore (NUS), to closely simulate the field conditions in such tests. The simulated testing conditions include varying confining pressure, kinking of drains and packing of clay around them. Four types of PVDs were tested under these conditions.

Hansbo (1983) recommended that testing of vertical drains should be carried out by placing it in an impervious soil. Lawrence and Koerner (1988) examined the influence of the kinks on the discharge capacity of drains. Based on these two conditions the discharge capacity of kinked drains that have packed clay around them is an important condition to be specified. The results of such tests with the new apparatus are discussed in this paper.

## 2 NUS DRAIN TESTING APPARATUS

A vertical drain testing apparatus was designed and fabricated to determine the discharge capacity and the transmissivity of prefabricated vertical drains (Loh, 1996). The design of the apparatus adheres closely to the ASTM Standard D4716-87 specifications and the conditions stated in the Hansbo (1983) 'ideal test'. The apparatus consists of three main detachable components: a constant head inlet reservoir, an outlet reservoir and a transparent, cylindrical compressed air chamber as shown in Figure 1.

Figure 1: Schematic diagram of the NUS drain testing apparatus (Loh, 1996)

Table 1: Physical properties of the PVD tested

	VD1	VD	VD3	VD4
Mass/unit area (g/mm <sup>2</sup> ) x10 <sup>-4</sup>	11.81	2.92	4.06	3.4
Core type	Coir	Polypropylene	Polypropylene	Polyester
Core structure		 Continuous channel	 button extrusion	XXXXXXXXXX nylon web
Sleeve filter	Double layer of woven Jute	Polypropylene non-woven	Polypropylene non-woven	Polyester non-woven
Dimensions (W mm x t mm)	100 x 8	100 x 6	100 x 6	100 x 6

The compressed air chamber is designed to be large enough to accommodate a kinking mechanism, which consists of two angle plates. The angle plates can be placed against the drain to form a kink at any desired angle. Hence the discharge capacity of kinked drains can be determined. Remoulded clay can be packed around the drain, which is then encased in a rubber membrane, in order to ensure that the effective lateral pressure of the soil against the drain sleeve is acting as in the field. The liquidity index of the remoulded clay was 0.6 to 0.7. With this layer of clay coming into contact with the drains, there will be a better simulation of the field conditions.

### 3 TYPES OF DRAINS

Four types of prefabricated vertical drains were investigated in this apparatus. VD1 is made of natural fibres of jute and coir. Two layers of jute burlap (Lee et al 1996) envelop four coir strands of 5-6mm in diameter made of coconut fibre. VD2, VD3 and VD4 are geosynthetic drains with different core types and core structures. VD2 has continuous rectangular channels whereas VD3 has button extrusions formed on the polypropylene core. VD4 has a polyester nylon web type of core (Hausmann, 1990). Salient physical properties of the four prefabricated vertical drains are shown in Table 1.

### 4 TEST RESULTS

#### 4.1 Confining Pressure

The four PVDs were tested under a range of confining pressures from 20kPa - 300kPa, which is equivalent to a lateral pressure in 30m-40m thick submerged soft clay. High confining pressure is needed to determine the discharge capacity of such PVD installed at great depths. Figure 2 shows the results for the four drains tested. For all drains, it is noted that with an increase in confining pressure, there is a reduction in discharge capacity. This is to be expected as reported by Hansbo (1993), Kamon et al (1992) and Broms et al (1994). The filter sleeve squeezes

into the core with increased confining pressure and hence the effective cross-sectional area of the core is reduced, leading to a reduction in the discharge capacity.

VD1 has the lowest discharge capacity among the drains tested. VD2 and VD3 have polypropylene non-woven filter sleeves, which were partially squeezed into the channels in the core at large confining pressures. This reduction in core space causes a drastic reduction in the discharge capacity. It is observed that the discharge capacity of VD4 is lower than that of VD2 at low confining pressures, but is the highest among the four at 300 kPa pressure. The relatively high discharge capacity is due to the relative stiffness of the nylon web type of core structure and the filter sleeve. The relatively high stiffness is more effective in preventing the filter sleeve from being squeezed into the core at high confining pressures.

#### 4.2 Type of Confinement

It is very important to have a close simulation of the field conditions of the drains in a study of this type. Besides changing the hydraulic gradient and confining pressure, tests were conducted using different confinement methods for each PVD. These included packing of clay around the PVD, with or without a stiff plate, as prescribed in the ASTM in applying pressure on the PVD.

Hansbo (1983) commented that the determination of the discharge capacity of a drain wrapped in a film of polyethylene and placed between two steel plates is inaccurate in this regard. He recommended that, in order to determine the discharge capacity of a drain, clay should be packed around the drains to ensure that the effective lateral pressure of the soil acting on the drain sleeve is similar to that in the field. The ASTM specification and the testing conditions used by many other workers, for instance Chang et al (1994), are similar without any clay directly around the drain. Hence from the above discussion, it was decided to determine the discharge capacity of PVDs with the placement of a rigid plate, as per ASTM, and to compare the results with those conducted with clay packed PVDs, as

proposed by Hansbo (1983). Two rigid perspex plates placed on either side of the PVD served the purpose.

In Figure 3, the drains lined with rigid (perspex) plates have nearly always a larger discharge capacity than those without rigid plates. The drains with the packed clay around fall in between the discharge capacities measured with and without perspex plates. Hence, clay packing is a closer simulation of the field conditions.

Figure 2: Discharge capacity of different types of PVD

#### 4.3 Kinking of Drains

Another field condition likely to be encountered is the kinking of drains (Lawrence and Koerner, 1988). Two series of kinking tests were conducted. In the first series, an artificial kink with 135° angle was introduced. The second series was a “natural” kink carried out by imposing a 25% axial strain on the drain, similar to the drain deformation in the field. Lawrence and Koerner (1988) observed that with kinks in the PVDs, there is a reduction in discharge capacity.

Figure 4 shows the discharge capacity of straight and kinked drains and Figure 5 shows the percentage reduction of the discharge capacity of kinked drains compared to the straight drains. It is clear that the discharge capacity of straight drains is always higher than that of kinked drains. Although straight VD2 showed much higher discharge capacity than VD3, kinked VD2 showed a greater percentage reduction in discharge capacity than kinked VD3 at 135°. It is apparent that VD3 has a more rigid core structure than VD2. At a confining pressure of 350 kPa, the percentage reduction of discharge capacity for VD4 is the lowest, whereas VD2 has the highest reduction. Tests were also performed with artificial and natural kinks.

Figure 3: Discharge capacity of VD2 under confinement with/without stiff perspex/clay around

Figure 4: Discharge capacity of kinked and straight drains

Figure 6 gives a comparison of results for the two series of tests with artificial and natural kinks. Drains with natural kinks tend to have a higher discharge capacity than drains with artificial kinks. Discharge capacity of kinked drains obtained from natural kink is more realistic as kinks are formed naturally in the field. Figure 7 shows the discharge capacity of drains with natural kinks and clay packing around the drain. The discharge capacity of VD4 is the highest in the kinked condition. This type of drain has a nylon web type of core which is robust and does not collapse much when kinked. Also its filter sleeve is relatively stiff compared to those of VD2 and VD3 and hence it is not squeezed into the core at high confining pressure. In the case of VD1 the discharge remains very low both in the straight and kinked conditions.

Figure 5: Percentage reduction in discharge capacity of kinked drains

Figure 6: Discharge capacity of VD2 with different types of kinks

Figure 7: Discharge capacity of PVD with 25% axial compression

## 5 CONCLUSION

Four types of PVDs were tested in a new apparatus. It is observed that the core structure of the drain plays an important role in the estimation of the discharge capacity. In testing PVDs, the method of confinement of PVDs has a great influence on the discharge capacity. Different confinement modes can yield considerably different results. Other conditions such as kinking of drains are also important when choosing a PVD for a given project. To be more realistic in the measurement of discharge capacity, the confinement pressure on PVD should be applied through a packed layer of clay, where the PVD is to be used, and a natural kink should also be incorporated during the test.

# Geotextiles for the ElDorado International Airport in Colombia

A. Malagón

Civil Engineer, Manager of Ingeniería & Geosintéticos Ltda, Santafé de Bogotá, Colombia, South America

**ABSTRACT:** This document presents the case history of the utilization, between 1996 and 1997, of 1,220,000 m<sup>2</sup> of woven geotextiles, reinforcing the foundation of embankments constructed on soft soils, and 25,000 m<sup>2</sup> of nonwoven geotextiles for filtration, on the second runway of the ElDorado International Airport. In Colombia, geosynthetics have been used since the 1980s; however this is the first job that has been reinforced by high tensile strength geotextiles. The foundation soil at the project site consists of a deep deposit of lacustrine origin, poorly consolidated. The original design was based on improving the characteristics of the soil's resistance through preconsolidation by overload, with the use of wick drains. The building contractor, based on a further investigation of the subsoil, presented and obtained the approval of an alternative, that does not contemplate the preconsolidation nor the wick drains, but rather includes the reinforcement of the foundations of the embankments by woven geotextiles.

**KEY WORDS:** Airport Construction, Soft Soils, Wick Drains, Geotextiles, and Reinforcement

## 1. INTRODUCTION

The use of geosynthetics in Colombia was initiated during the 1980s with the utilization of geotextiles for soil separation and filtration, with the specific purpose of avoiding contamination of structures below pavements and porous mediums in drainage systems. Later, geotextiles were used to reinforce foundations and to construct mechanically stabilized soil retaining walls. In the beginning of the nineties decade, the use of geomembranes started mainly to avoid or diminish leaks in such works as (a) water storage, (b) wastewater treatment and (c) disposition of solid contaminants. Other geosynthetics such as geogrids, geonets, and so on, have been used occasionally in limited quantities.

The development of the geosynthetics market in Colombia, without being very great, has been faster than the diffusion and acquisition of the necessary technical know-how for its correct use and specification. In Colombia, there are no technical norms that regulate the specification, the design and the construction with geosynthetics nor is there an impartial entity that can duly assess the engineer. The industry, along with some universities and engineering firms, has made great efforts to spread the technology but the results are limited and in some case arguable.

On the other hand, Colombia suffers from a lack of runways and transportation infrastructure, which has led some investigators to calculate that Colombia is behind its own necessities by about thirty years. To overcome this problem, the Colombian government has decided recently to grant licenses for the most important construction projects and for the rehabilitation of roads, city streets, airports and seaports. Both national and international firms have been invited. This is the case of the ElDorado International Airport, which handles some of the heaviest air traffic in the world with only one runway. The construction of the second runway has been contracted, by granting a license for a term of seventeen years. The

contractor is a consortium of the Spanish firm Dragados and the Colombian firm Conconcreto.

Figure 1. General plan view of the project

The soil on which the runway is being constructed, is a deposit of some 300 meters deep (for this project about 60 meters have been recognized as soft), consisting of lacustrine origin soils mainly clayey with presence of volcanic ash and also some sand lens. The runway goes in an east-west direction which is 3,800 meters long and crosses the Bogotá river bed which was rectified by means of a canal of some 600 meters long, which made the construction possible (see Figure 1). Figure 2 shows the side view of the runway. As can be observed, the initial 2,600 m of the runway - Sector 1 - rest directly on the top layer of native clays, while the final 1,200 m of the runway - Sector 2 - rest on a embankment with maximum height of 4.0 m.

Figure 2. Side view of the runway

The investigation of the subsoil demonstrated its incapacity to support the loads of the embankments and that the runway would suffer great differential settlements, unless adequate measures were taken to avoid this. The designer specified a process of preconsolidation: induced by an overload caused by an embankment 5 meters high, accelerated by the installation of wick drains placed 1.80 meters apart and 10 meters deep (see Figure 3).

Figure 3. Preconsolidation typical transverse section of the full scale test embankment.

The contractor furthered the investigation of the subsoil through traditional mechanical drilling and through the Cone Penetration Test (CPT), with a continuous measurement of interstitial pressure. In Santafé de Bogotá at that time, there had been no one with the experience required for the project in the use of CPT equipment. When the original design was done, the designer did not have the information that the constructor obtained through his own additional investigation. The results of this investigation made it possible to characterize better the subsoil and led to the conclusion that the treatment of preconsolidation could be avoided. Consequently, the contractor recommended embankment foundation reinforcement in lieu of the acceleration of settlements.

In order to confirm the performance of the original design, a full-scale test embankment has been constructed and monitored.

## 2. ORIGINAL DESIGN : IMPROVEMENT THROUGH PRECONSOLIDATION

### 2.1 Foundation Soil

The soils at the work site are predominantly arguieulous of high plasticity (CH), very soft, and belong to the lacustrine deposit named *Sabana* formation, whose depth beneath the runway is 60 m as a minimum. The water table is 1 or 2 m below the terrain surface. According with the bidding documents, there are two geotechnical zones along the runway: Zone 1, on the Bogotá river valley that presents a layer of fine sands located between 4.0 and 11.0 m below the surface, resting on the typical soils of the *Sabana* formation. Zone 2, located out of the Bogotá river valley where the typical geotechnical profile of the *Sabana* formation is present. The designer specified the use of wick drains in order to improve the resistance of the foundation but mainly to make it uniform. This preconsolidation treatment was designed also to reduce the expected differential long-term settlements between zone 1 and 2, due not only to the geotechnical differences but also taking into account the variable height of the embankment (from 0 to 4.0 m).

The wick drains were specified to have a depth of 10 m; 1.80 m spaced and interconnected on the surface through a granular material layer of high permeability. This layer was designed to capture and evacuate the expelled water from the soil, thanks to the application of the overload of an embankment 5.00 meters in height (Figure 3). The estimated time necessary for the completion of the preconsolidation process was 15 months.

### 2.2 Pavement Structure

In the solicitations, two alternative pavement designs were specified: (a) flexible pavement composed by 13 cm of asphalt carpet, over 38 cm of standard asphalt base and 90 cm of granular material, meeting specifications of subbase course. And (b) rigid pavement composed by 38 cm of concrete slab, over 20 cm of standard asphalt base and 90 cm of granular subbase material.

### 2.3 Embankment Material

Table 1. Embankment material specifications.

CHARACTERISTIC	SPECIFIED	REAL
Maximum Grain Size	75mm	75 mm
% passing No. 200 sieve	<15%	13.5%
Liquid Limit ( $I_L$ )	25%	23%
Plasticity Index ( $I_p$ )	6%	6.7%
CBR	-	38

These specifications correspond to a local material, called "Recebo", with a soil friction angle ( $\phi$ ) that varies between 25° and 30° when compacted, and is composed by a mix of fine and granular soils.

### 3. DEFINITIVE DESIGN : REINFORCEMENT OF THE FOUNDATION WITH GEOTEXTILES

Three typical transversal sections were analyzed: (a) transversal section of the runway, (b) transversal section of the platforms and (c) transversal section of the perimeter roadways for vehicle transit.

This document refers mainly to the runway and platforms reinforcement, though it includes the technical characteristics of low strength geotextiles used to reinforce the perimeter roadways.

Based on the new exploration of the subsoil, the contractor was able to establish more precisely the characteristics of the foundation soil and to analyze, for the embankment material used (see Table 1), the two transversal typical sections of the runway (see Figure 4).

Figure 4. Reinforced Typical Transverse Sections.

Following the design method proposed by Koerner (1990) to determine the required functions of a geotextile in the foundation of embankments on soft soils, the contractor determined the primary and secondary functions of the geotextile. According with the contractor criteria, separation is the primary function for low height embankments, while for high height embankments, depending on the governing mode of failure, reinforcing could be of primary importance (see Figure 5). When Toe or Spreading are the governing failure modes, reinforcement and separation are the geotextile primary functions. When Base failure is governing, separation is the primary geotextile function. For Sector 1, the geotextile was designed for separation. For Sector 2 by means of comparing the embankment height (H), the soft soil depth (D) and the embankment width (B), a toe failure was

determined to be the governing mode and the geotextile was designed for separation and reinforcement.

Figure 5 Mode of Failure

#### 3.1 Geotextile Design for Separation Function

The contractor, considering puncture as the most probable separation geotextile-breaking mode, used the following equation to determine the required geotextile puncture resistance:

$$F_{p_{req}} = (\pi d_i d_a) p' S' \quad (1)$$

Where,

$F_{p_{req}}$  = Required geotextile puncture resistance (kN)

$d_i$  = Geotextile opening size (m)

$d_a$  = Average diameter of the puncturing aggregate (m)

$p'$  = Pressure exerted on the geotextile (kPa)

$S'$  = Shape factor of the aggregate particles

$$S' = (1-S)$$

$S$  = sphericity

$S = 0.4$  for crushed stone

Taking into account that the foundation soils have a passing 200 ASTM sieves > 50%, the contractor decided to specify O95 < 0.3 mm. In consequence for  $d_i = 0.3$  mm,  $p' = 490$  kPa (imposed by the construction trucks) and  $d_a = 70$  mm, we have:

$$F_{p_{req}} = (\pi)(0.3 \times 10^{-3})(70 \times 10^{-3}) 490 (1-0.4)$$

$$F_{p_{req}} = 0.01940 \text{ kN} = 19.40 \text{ N}$$

Using a factor of safety against puncture of 2.0,

$$F_{p_{reqd}} = 38.8 \text{ N}$$

#### 3.2 Geotextile Design for Reinforcement

Using a computer program for geosynthetics design, the contractor determined the required tension at 20% of elongation ( $T_{20}$ ), based on the following parameters:

Table 2. Geotextile for reinforcement design parameters

Design parameter	Symbol	Unity	Value
Embankment Height	H	M	3.50
Elongation at failure	$\epsilon_f$	%	$\leq 20$
Fill material Shear stress	$\tau_f$	kPa	19
Foundation soil Shear stress	$\tau_s$	kPa	17.8
Soft soil depth	D	M	14
Angle of slopes to horizontal	$\beta$	°	26
Fill material Unit weight	$\gamma_f$	kN/m <sup>3</sup>	17.8

Geotextile resin		PP
Uniform surcharge load	$q_a$	kPa 10
Damage during construction partial factor	$f_{m1}$	1.1
Loss of resistance for 20 year partial factor	$f_{m2}$	1.24
Global Factor of Safety	FS	1.5

The computer program calculates the required  $T_{20}$  and minimum anchor length  $L_a$  using the Bishop stability method of analysis. For the runway, the results was:

$$T_{20} = 70 \text{ kN/m}$$

$$L_a = 47 \text{ m}$$

#### 4. PRELIMINARY RESULTS OF THE MONITORING ON THE TEST EMBANKMENT AND ON THE FINAL EMBANKMENT

##### 4.1 Test Embankment

The test embankment, 160 m length by 80 m wide and 5 m high, with slopes 2H:1V (see Figure 6), was constructed near the runway where one can expect the largest velocities of settlement, due to the presence of a sand layer in the stratum. As Figure 6 shows, the test embankment was divided in three zones:

Zone A: on top of foundation soil treated with wick drains installed as defined in the original design (1 wick drain / 2.80 m<sup>2</sup>),

Zone B: on top of foundation soil treated with wick drains installed more closely (1 wick drain / 2.0 m<sup>2</sup>),

Zone C: embankment on top of foundation soil without wick drains.

To monitoring the test embankment performance, the following set of instruments was installed:

Figure 6 Plant View of the Test Embankment

Table 3. Set of instruments installed in the test embankment

Instrument	Quantity
Casagrande's piezometer	11
Settlement plate	18
Extensometer	3 (60 m length)
Continue Settlement line	4

These instruments allow for the measurement of settlements at the foundation level and to evaluate continuously their space variation.

Table 4. Results of settlement plates

Zone	Settlement (mm)	Instrument
A	80	Settlement plate N° 3
B	115	Settlement plate N° 6
C	158	Settlement plate N° 14

Table 5. Maximum excess of pore water pressure (kPa)

Zone	Depth (m)	$\Delta u$ (kPa)	Piezometer
A	10	4.9	N°3
	20	21.6	N°1
	30	15.7	N°2
B	10	9.8	N°6
	20	38.3	N°4
	30	30.4	N°5
C	10	1.9	N°11
	20	29.4	N°10
	30	32.4	N°9

Due to space limitations it is not possible to include in this document more detailed information about these provisional test embankment results, but the initial contractor's conclusions are:

- Measured settlements are smaller than those expected and occur at a velocity near to the expected one,
- The greater part of settlements during the construction occurs in the top 20 m of the stratum,
- Apparently there is not important influence of the wick drains on settlements,
- According with the settlement distribution in the test embankment, differential settlements would occur in the runway (in the order of 5 cm). This magnitude of differential settlements have registered in airports with similar foundation conditions than EIDorado Airport (San Francisco Airport, Mexico City Airport)

##### 4.1 Final Embankment

The final embankment foundation was reinforced by a high strength woven geotextile. During construction, no monitoring instruments were installed. At the moment of this writing the contractor is starting a plan of topography measurements. As the contractor has been able to establish through geotechnical studies and embankment tests, settlements will occur on the runway. However thanks to geotextile reinforcement, abrupt differential settlements will not appear. According to the measurements the magnitude of the general settlement because of consolidation is small and will be compensated by repaving maintenance works, which are normal for this type of construction.

## 5. REQUIRED AND SUPPLIED SPECIFICATIONS FOR THE GEOTEXTILES

### 5.1 Geotextile for the Runway and Platforms

The contractor specified the following necessary characteristics of the woven geotextile to reinforce the runway and platforms:

Property	Un	Value
Ultimate tensile strength	KN/m	70 x 56
Elongation at break	%	< 13
O <sub>95</sub>	µm	< 300

### 5.2 Geotextile for the Perimeter Roadways

The contractor specified the following necessary characteristics of the separation woven geotextile for perimeter roadways:

Property	Un	Value
Ultimate tensile strength	KN/m	25 x 25
Elongation at break	%	50 to 70
O <sub>95</sub>	µm	< 150
Flow Capacity Normal to the plane	L/m <sup>2</sup> .s	0.0319
Thickness	Mm	>3.00
Puncture Strength	N	4000

### 5.3 Geotextiles for Filtration in Drainage System

The pavement drainage system leads infiltrated and ground water, by the open graded asphalt base, to the lateral drainage lines, which are trench drains filled with open graded material including a 100 mm size pipe, wrapped up by nonwoven needle punched geotextile.

Table 6. Characteristics of the geotextiles used.

#### a) Woven geotextile Geotex 4x4 for runway

Property	UN	MARV	Typical
Polymer Type		PP	
Wide Width	KN/m	70x70	81.4x80.5

Permeability	Cm/s	4.8 x 10 <sup>-2</sup>

## 6. METHOD OF CONSTRUCTION

### 6.1 Preparation of the Foundation Soil

Geosynthetics installation guidelines for reinforcement of embankments foundation on soft soils recommend: (a) to install the reinforcement over the terrain, without removing the vegetation and (b) to induce - within adequate limits - the development of the resistance in the reinforcement. However, in this case, the organic soil was removed.

### 6.2 Placement and Joint Systems of the Geotextile

The geotextile was extended in the normal direction along the centerline of the runway, in such a way that the greatest stress was applied in the roll direction.

At first, an instruction was given to sew the geotextile through the interlocking method, recommended by the British Standard Guides 8006 (see Figure 7), in order to guarantee the maximum possible stress transmission. In Colombia neither high strength yarn nor sewing machines to make double chain stitch were available. In consequence, in some spots it was observed that seams could not support the stress due to the extension and compactness of the fill material. To fix that, a new instruction was given to use overlaps whose dimension was adjusted according to the CBR value of the foundation soil in the different zones of the project.

### 6.3 Extension and Compacting of the Fill Material.

This operation was initiated in the zones where the foundation soil was found to have the greatest bearing

capacity. The material was discharged over the geotextile, on firm areas and was distributed in such a way that, when it was spread out a layer of 0.35 m of thickness, before compacting, was obtained. Bulldozers were used on this job of the type CAT D-7 equipped with caterpillars of standard width. Although this kind of equipment exerts high pressure on the soil, the geotextile was able to support those high construction loads. But the seams (see reasons in 6.2) gave way in some places, something which was made evident by observing local failures.

Figure 7. Types of seams.

An initial compacting was applied with the bulldozers and then the final compacting was applied with a vibrator roller until the specified density was achieved.

Some points that showed rutting during construction, due to faults in the subgrade soil, were repaired by adding material, until the geotextile was deformed sufficiently so as to supply the required strength in order to stabilize the filling.

When the adequate bearing capacity was obtained in the first layer, two more layers were added and compacted, until the final projected level was obtained.

On the embankment crest level a hot asphalt spray was applied, on top of which the structure of the pavement was constructed. It was made up of a layer 8 cm of open graded asphalt base, a 30-cm thick standard asphalt base and a carpet layer of 13 cm. The open graded layer was specified for the purpose of improving the drainage conditions of the structure which has a lateral slope of 1.5% and is interconnected with a system of lateral drainage lines, that discharge every 50 m (see Figure 4).

## 7. CONCLUSIONS

The final design of the embankment foundation reinforced with geotextiles has sped up the construction and it is functioning in accordance with what was established by the contractor. This is without the necessity of overload and drainage and has also resulted in being more economical.

This job demonstrates that geosynthetics offer economic alternatives in construction, that are reliable and of great use for modern engineering projects in both developed countries and in those countries found to be in the process of development. In this case, the geotextiles have made it possible:

- (a) to obtain and make uniform the stability conditions of the embankment, which are required by the project, without the necessity of improving the characteristics of the subgrade soil;
- (b) to carry out the work in a shorter period of time and
- (c) To utilize embankment filling material that is available near the construction site, which translates into considerable savings on transport costs.

The construction job represents an important contribution to the development of the specification, design and construction of works carried out with geosynthetics in Colombia, a country where a tremendous academic effort is required in order to ensure that these products are used according to rational criteria.

The relative extensive use of geosynthetics in Colombia is based generally on the intuition of engineers who have seen proof of beneficial effects of these products in their different applications. Only in some cases, such as the second runway at EIDorado International Airport, do the required specifications of the reinforcement correspond to a technically calculated design.

The lack or absence of adequate design has led to partially or totally faulty projects, which have been carried out with geosynthetics in Colombia and this also has meant a lower pace of growth in this market.

The reduced diffusion of rational analytic methods for design with geosynthetics means that only a handful of engineers have the necessary technical information for designing with these products.

As a result, we continue resolving a lot of geotechnical problems by means of traditional technologies that are more costly, not only in terms of money but also in terms of time and the environment.

We hope that the importance and good results of this project will encourage engineers in Colombia, as well as other countries to construct with geosynthetics. To do this we need to utilize sound geotechnical principles to analyze, design and specify geosynthetics and to construct according with the designer and manufacturer recommendations.

## ACKNOWLEDGMENTS

The writer would like to thank Engineers Fernando Bolinaga and Fernando Roman of Dragados and Intecsa, for their help to get the necessary data for this document. The writer also acknowledges the cooperation of the Project Directors, Engineers José Antonio López, Fernando Abadía and José Ignacio Quirós; of the Project Field Director Eng. José Luis Pasión and the Project Technical Director Eng. Pablo Quirós, and of the contractor consortium field engineers, not only because of their cooperation, but especially because of their interest to get the best results in this geosynthetics reinforced job. Finally I would like to thank Engineers Henry Angulo and Rodrigo Arévalo who have made the graphics and Mr. Albert Klein for the translation necessary for this paper.

# Testing and Analysis of Soft Foundation Treatment for Donggang Diking Project

Q. Y. Luo

Senior Engineer, Zhejiang Institute of Water Conservancy and Hydraulic Power, Huajiachi, Hangzhou, China

**ABSTRACT:** A seawall for Donggang diking project is 3635m long and 5.3m to 7.5m high, with a diked area of 2.45km<sup>2</sup>. The foundation consists of silty clay with high water content, high compressibility and low strength. A seawall section having a height of 5.3m to 6.0m was treated with geotextile reinforced foundation mattress; meanwhile, a seawall section having a height of 6.0m to 7.5m was improved using plastic drainage plates. To meet the needs of two treatment schemes the observation instruments had been installed in the seawall, covering observation duration of 830 days and 710 days, respectively. The test results obtained are mainly presented and analysed in this paper. Findings show that the two treatment schemes adopted for this project have achieved excellent effect and the construction of the seawall was smoothly accomplished with faster speed and shorter time. Also, it shows that there is difference in consolidation effect between the two schemes and the popularization and application should be carried out in line with local conditions.

**KEYWORDS:** Seawall, Soft foundation, Plastic drainage plate, Geotextile, Observation result analysis

## 1 INTRODUCTION

Donggang diking project is located in Shenjiamen of Zhoushan City, Zhejiang Province, which is the largest fishing harbour in China, and is close to Putu Island of Zhoushan Archipelago which ranks among the most celebrated Buddhist Meccas in China. The diked area during the first construction period covers 2.45km<sup>2</sup> and has been already completed, in which the development and construction of harbour, industry, commerce and tourism are being conducted.

The seawall for Donggang project involves a total length of 3635m. The beach ground elevation of the seawall line ranges from -1.3m to -3.5m (Huanghai Elevation, the same below). The top elevation of the seawall is 4.0m and the seawall height varies from 5.3m to 7.5m. The design high and low tide levels are 2.84m and -2.8m, respectively. It is a sea area with strong wind, high wave and larger tidal range. The seawall foundation consists of silty soft clay which has high water content and compressibility as well as low strength. The foundation stabilization treatment consists mainly of;

- Geotextile reinforced foundation mattress. The applied area of geotextile included the seawall of less than 6m high. The seawall sections were connected with the land areas at both ends and were 1505m long in total, in which the geotextiles laid were more than 100000m<sup>2</sup>.

- Plastic drainage plate. It was used for the 6m to 7.5m high seawall which was extended into the sea area so as to make the foundation be precompressed, drained and consolidated. The seawall length was 2130m and the plastic drainage plates of 850000m were

driven into the foundation.

In order to verify the stabilization effect of the soft clay foundation, control the construction rate and realize information construction, in accordance with the two treatment schemes a representative seawall with a length of 100m was selected as a test section, respectively. Instruments were embedded to carry out long-term observation. The series of readings which have been obtained started on November 29th, 1992 and ended on March 13th, 1995 and an observation duration lasted eight hundred and thirty days. Now, the test results derived in the course of construction are described as follows.

## 2 FINDINGS FOR GEOTEXTILE SCHEME

The top elevation of the seawall is 4.0m and the seawall is 6.0m high. The cross-section of the seawall is shown in Figure 1. The seawall cross-section was chosen through stability calculation and analysis for several schemes. The cross-section of the seawall treated by geotextile reinforced foundation mattress is more economical than a conventional scheme (natural foundation), in which a counter weight fill of 15m was shortened. The mattress with a thickness of 1.0m, consisted of two layer polypropylene woven fabrics and a crushed stone layer, is an important component part of the seawall. The geotextile utilized was a 60kN/m product and the characteristic indexes are shown in Table 1. The foundation can be divided into four soil strata and the buried elevation and soil characteristic indexes for each layer are listed in Table 2. The observation instruments were installed in November, 1992 and the location is shown in Figure 1. The instruments which were buried in the seawall include five ground

settlement plates(s), four settlement pipes (Fs) in layers, two clinometers(F), fifteen pore water pressure meters(u), six earth pressure cells (P) and two water level pipes (c). Also, the strength measurement was carried out with vanes(Cu). The seawall was filled in five stages starting on November 29th, 1992 and the crest elevation of the dyke reached 4.0m up to September, 1994. Earth material used for closure was placed in four stages. The top elevation of the seawall reached 2.6m up to November, 1994.

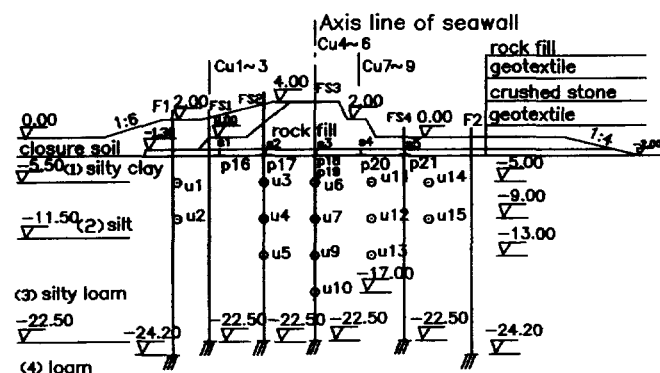

Figure 1. Seawall cross-section and observation instrument layout

Table 1. Main characteristic indexes of geotextile

Mass per unit area	Trapezoidal tearing strength		Ball rupture strength	Strip tensile 10 × 5			
	Longitudinal	Lateral		Tensile strength	Tensile strength rate	Tensile strength	Tensile strength rate
(g/m <sup>2</sup> )	(kN)	(kN)	(kN)	Radial (kN)	Radial (%)	Lateral (kN)	Lateral (%)
285	1.26	0.59	2.13	3.34	31	1.53	22

Table 2. Main characteristics of the foundation soil

Soil type	Water content (%)	Void ratio	Coef. of consolidation (cm/s <sup>2</sup> )	Quick shear	
				Cohesion (kPa)	Angle of inter. friction (°)
Silty clay	44.3	1.24	$2.9 \times 10^{-3}$	11.8	8.5
Silt	54.3	1.47	$1.29 \times 10^{-3}$	8.7	3.5
Silty loam	35.6	0.96	$2.69 \times 10^{-3}$	13.9	13.5
Loam	26.4	0.71	$2.75 \times 10^{-3}$	1.92	12.2

### 2.1 Ground Settlement

The graph of the settlement quantity of  $S_1 \sim S_3$  and time is shown in Figure 2. The settlement curve under the action of each stage loading is presented in Figure 3. Up to the end of March, 1995, the accumulated settlement quantities of  $S_2$  and  $S_3$  at the top of the seawall

were 116.7cm and 115.7cm, respectively. The steady settlement quantity was 152cm based on the calculation of their measured settlement curves.

### 2.2 Stratified Settlement

Taking  $FS_3$  as an example, as can be seen in Figure 4, the settlement quantity of ninety percent occurred in the first and second earth layers having a thickness of 9.5m below the ground surface. The accumulated settlement quantities of  $FS_2$  and  $FS_3$  at the top of the seawall were 114.2cm and 103.2cm, separately, basically identical with that of the corresponding ground settlement plates.

Figure 2. Graph of filling elevation and ground settlement

Figure 3. Settlement curve of each stage loading

### 2.3 Pore Water Pressure

Presenting some measuring points nearby the centre line of the seawall as examples, the graph of the foundation pore water pressure and time in the course of filling the seawall is plotted in Figure 5. It can be seen from Figure 5 that the pore water pressure of  $U_6$  in a shallow layer was more easily dissipated than that of  $U_9$  and  $U_{10}$ . Loading in a thin layer was advantageous to the dissipation of pore water pressure. The pore pressure increment of  $U_6$  was dissipated by twenty percent after one month for the third-stage loading and by thirty-nine percent after four months. It was dissipated by sixty-one percent after one month for the fourth-stage loading and fully dissipated after four months.

Figure 4. Graph of filling elevation and stratified settlement

Figure 5. Graph of filling load and pore water pressure

Figure 6 that, if the elevation of  $-8\text{m}$  was looked upon as a demarcation line, the foundation strength above it would be increased in varying degrees, in which the foundation strength increased greatly near the ground surface; taking the foundation of elevation of  $-5\text{m}$  as an example, the strength had risen to 1 to 1.8 times; it did not almost increase below the elevation of  $-8\text{m}$ .

Figure 6. Test results of vane strength

## 2.4 Horizontal Displacement

The accumulated displacement quantity of  $F_1$  started from December, 1992 and ended in January, 1994 was 110mm. The horizontal displacement quantity was increased and developed to a deeper layer as the height of the seawall was raised and the maximum displacement occurred in the foundation surface layer.

## 2.5 Earth Pressure

Six earth pressure cells were embedded into the foundation below a geotextile reinforced foundation mattress and five of them are functioning normally. The average value of the ratio of the measured earth pressure was raised along with the increase of load, i. e. it was 0.26 for the second - stage loading, 0.43 for the third - stage loading, 0.66 for the fourth - stage loading and 0.73 for the fifth - stage loading.

## 2.6 Foundation Strength

The experimental results of vanes in the natural foundation and during three different construction periods are summarised in Figure 6. It can be known from

## 3 FINDINGS FOR PLASTIC DRAINAGE PLATE SCHEME

The crest elevation of the seawall is 4.0m and the seawall is 7.5m high. The cross - section of the seawall is given in Figure 7. The seawall cross-section was chosen after stability of conventional (natural foundation) and plastic drainage plate schemes had been calculated and analysed according to different water levels and loading. The stability and safety coefficient of the cross-section adopted was only about 0.8 if a conventional (natural foundation) scheme was used. It shows that the effect of plastic drainage plate scheme is excellent. Plastic drainage plates were driven at a range of 36m, with a spacing of 1.4m and a driven depth of 15m. The drainage blanket consisted of crushed stone of less than 10cm in grain diameter was 2.2m in thickness. The plastic drainage plate used is made of polythene cross core bonded with nonwoven fabrics and its performance indexes are listed in Table 3. The beach ground elevation of the seawall was  $-3.5\text{m}$ , in which the foundation is divided into five soil layers. The buried elevation and property indexes for each soil layer are listed in Table 4 and the location of instruments is given in Figure 7.

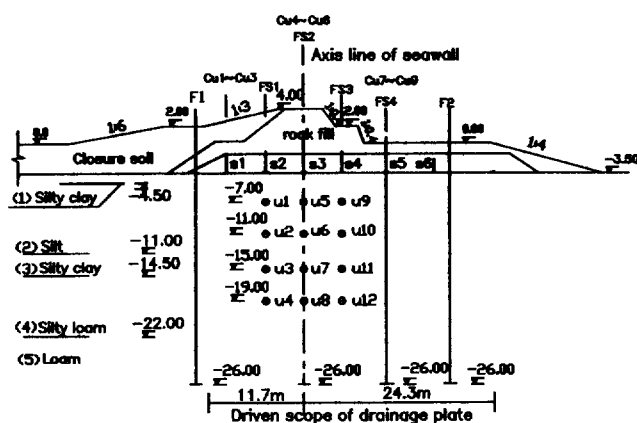

Figure 7. Seawall cross-section and observation instrument layout

Table 3. Main characteristic indexes of plastic drainage plate

Item	Unit	Indexes	Conditions	
Thickness	mm	4		
Wideness	mm	100		
Longitudinal passing water	cm <sup>3</sup> /s	25	Lateral pressure 350kPa	
Filter film permeability coefficient	cm/s	$5 \times 10^{-4}$	Specimen submerged in water for 24h	
Filter film equivalent aperture	mm	0.075	Equal to $O_{80}$	
Composite tensile strength	kN/10cm	1.3	At elongation rate of 10%	
Filter film tensile strength	Longitudinal	N/cm	25	At elongation rate of 10%
	Lateral	N/cm	20	At elongation rate of 10%

Table 4. Main characteristics of the foundation soil

Soil type	Water content (%)	Void ratio	Coef. of consolidation (cm <sup>2</sup> /s <sup>2</sup> )	Quick shear	
				Cohesion (kPa)	Angle of inter. friction (°)
Silty clay	49.3	1.38	$2.53 \times 10^{-3}$	11.7	7
Silt	59.2	1.63	$5.88 \times 10^{-4}$	13.0	2
Silty clay	49.6	1.35	$8.67 \times 10^{-4}$	21.0	2
Silty loam	36.9	1.00	$2.88 \times 10^{-3}$	15.0	17
Loam	32.0	0.88	$1.60 \times 10^{-3}$		

The observation items covered six ground settlement plates (s), four stratified settlement pipes (Fs), two clinometers (F) and twelve pore water pressure meters (u); meanwhile, the strength measurement was conducted with vanes (Cu). The installation of obser-

vation instruments was finished from June 14th to June 25th, 1993. All observation work ended till March 27th, 1995 and it took us seven hundred and ten days.

The construction of the seawall, which was divided into six stages, was accomplished between April 9th, 1993 and October 27th, 1994. The work lasted five hundred and sixty days, including an intermittent period. The construction of earth material for closure was performed in four times and lasted five hundred and four days from October 1st, 1993 to February 28th 1995. The filling graph of the seawall is given in Figure 8.

Figure 8. Graph of filling elevation and ground settlement

### 3.1 Ground Settlement

The graph of the settlement quantity and time is plotted in Figure 8 and the settlement curve of the seawall foundation is shown in Figure 9. As for the first and second stage loading the settlement increment of filling height per metre was larger, about 41cm, respectively; for the third to sixth stage loading the increment was very near, about 28.5cm, respectively. This was because the settlement increment for the first and second stage loading included an instantaneous settlement and an additional settlement induced by disturbed foundation in the course of driving plastic drainage plates. The settlement rate during load stage was all larger, in which the maximum settlement rate amounted to 4.6cm per day. At the end of observation the accumulated settlement quantity of S<sub>3</sub> near the seawall axis line was 260.2cm and the consolidation degree was about ninety percent.

### 3.2 Stratified Settlement

There are numerous data about stratified settlement. Citing FS<sub>2</sub> near the seawall axis line as an example the settlement graph at different measuring points is shown in Figure 10. The total settlement quantity of each soil

layer amounted to 254.8cm, close to 260.2cm for the accumulated settlement quantity of  $S_3$ . The settlement quantity in silty layer (Elevation-3.5m to -11.0m) made up fifty-nine percent of the total, the settlement quantity in silty clay layer (Elevation -11.0m to -14.5m) twenty percent and the settlement quantity in silty loam (Elevation -14.5m to -22.0m) twenty-one percent.

Figure 9. Settlement curve of seawall foundation

Figure 10. Graph of FS2 stratified settlement

### 3.3 Horizontal Displacement

Taking  $F_2$  embedded near the sea side as an example, the distribution curve of the horizontal displacement quantity along the direction of depth in different construction period is presented in Figure 11. The horizontal displacement quantity increased as the addition of load. The maximum horizontal displacement quantity was equal to 203.6mm, which occurred near the elevation of -8.0m and affected the silty loam layer at the elevation of -22m.

### 3.4 Foundation Strength

The vane strength at the elevation of 2.5m increased more obviously than that of the natural foundation

under the action of the fourth-stage loading in May, 1994. At the elevation of -7.25m (half of the seawall height) it was 2.11 times higher than the natural strength. It was 1.78 times at the elevation of -11.0m and it was 1.57 times at the elevation of -14.75m. It was obvious that the foundation strength would further rise with the increase of loading and pre-compression time. The vane tests had not been done afterwards because of the reasons of construction and management.

Figure 11. Curve of horizontal displacement along depth

### 3.5 Pore Water Pressure

According to the statistics of the data obtained from twelve pore pressure cells the pore water pressure rose with filling of the seawall, but it was quickly dissipated. Presenting  $U_1$ ,  $U_3$  and  $U_9$  as examples, the coefficients of pore pressure under the action of second-stage loading were greatest. Its average value equalled 0.79 and surpassed the normal standard limit. However, the coefficients of the pore pressure under the action of other different stage loading were smaller, i.e. 0.49 for the third-stage loading, 0.38 for the fourth-stage loading, 0.34 for the fifth-stage loading and 0.25 for the sixth-stage loading. Practice shows that plastic drainage plates have achieved the excellent effects of drainage and stabilization.

## 4 CONCLUSIONS

Based on the results analysed above, the main conclusions can be concluded as follows:

4.1 The seawall foundation of Donggang diking project is a silty clay with high water content, high

compressibility and low shear strength. For a treatment of this kind of foundation, geotextiles were used as a reinforced foundation mattress and plastic drainage plates as precompression, drainage and stabilization according to the seawall height. The information construction was performed based on the in-situ test results. The seawall was successfully accomplished with faster speed and shorter time and the desired results have been achieved. The methods also have a reference role for a design and construction of similar projects on a soft clay foundation.

4.2 The seawall of 6.0m high which was treated with geotextile reinforced foundation mattress was actually accomplished within twenty-two months. It reveals from the analysis of the test data that the intermittent time of the fourth-stage loading can be reduced from fourteen months to four months. Therefore, if it was not due to untechnical reasons, the seawall would be finished during twelve months. The seawall of 7.5m high, treated with plastic drainage plates, was practically finished during eighteen months. According to the analysis of measured data, the intermittent time for each loading could be shortened except the third-stage loading and it was entirely possible to construct the seawall within twelve months.

4.3 The settlement rate, horizontal displacement rate and pore water pressure coefficient are three main indexes of monitoring the stability of a project and controlling construction rate. As for the seawall treated with two approaches the maximum settlement rate reached 3.2cm to 5.2cm per day, the maximum horizontal displacement rate 4.8mm per day and the pore

water pressure coefficient 0.76 during loading. These three indexes greatly exceed the conventional standard limit and in fact the seawall is always in a stable state.

4.4 The approaches to treating seawall by geotextiles and plastic drainage plates attain the purpose of stabilization foundation. The former exerts a less influence on the stabilization foundation depth, amounting to 6m to 9m, i. e. equivalent to 1 to 1.5 times of the seawall height. The latter's influence scope surpasses the driven depth of plastic drainage plates with a length of 15m; it comes up to the whole silty clay layer, i. e. equivalent to 2.5 times of the seawall height.

## ACKNOWLEDGMENTS

The author wishes to thank Senior Engineers Liao Shude and Hu Henan, as well as Engineers Zhang Mingqiang, Chen Xiuliang, Wu Wenhua and Wu Yunbiao for finishing the study work cooperatively.

**ABSTRACT:** Increasing demands for construction materials, land and the redevelopment of derelict land are leading to the development of new technologies, and the integration of existing ones. It is with the above challenges in mind that the development of electrically conductive geosynthetics (Electrokinetic Geosynthetics EKGs) has come about. EKGs may provide filtration, drainage and reinforcement, which can be enhanced by electrokinetic processes, such as electro-osmosis and ion migration. In addition to the electrokinetic processes, it is possible to incorporate enhanced transmissivity, sorption, wicking, and hydrophilic characteristics into the new geosynthetics. The availability of new materials and production techniques, together with the need for new engineering solutions, to complex environmental and ground engineering situations, have rendered feasible and desirable the inclusion of these properties into a new range of geosynthetics. This paper describes the concepts behind the development of a new generation of geosynthetics, and the laboratory testing of prototype materials and experimental applications.

A series of laboratory experiments have been undertaken which investigated the feasibility of employing EKGs and electro-osmotic consolidation for the improvement of fine grained low permeability fills. These tests showed accelerated dissipation of pore pressures; reduction of moisture contents; and increases in soil strength and adhesion to reinforcement, over and above that from conventional consolidation. Investigations into environmental applications for EKGs have demonstrated that they can be used for integrated electrode and wellpoint installations for electrokinetic remediation of contaminated ground. Investigations have demonstrated the sorption properties of EKGs, in respect of heavy metals.

**KEYWORDS:** Geosynthetics, Reinforcement, Electrokinetic, Drainage, Environmental Engineering.

## 1. INTRODUCTION

The increasing demands for construction materials, land and the redevelopment of derelict land are leading to the development of new technologies, and the integration of existing technologies. The development of *electrically conductive geosynthetics* (EKGs) is an example of this. The concept is to develop a range of geosynthetics which in addition to providing filtration, drainage and reinforcement can be enhanced by electrokinetic techniques for the transport of water and chemical species within fine grained low permeability soils, which are otherwise difficult or impossible to deal with.

The ability of electrokinetic phenomena to move water, charged particles and free ions through fine grained low permeability soil is well established. Electrokinetic phenomena will occur in any soil; however, in medium to coarse grained soils electrokinetic phenomena provide a less effective transport mechanism than hydraulic flows, due to high permeability of the soil.

The first application of electrokinetic phenomena for civil engineering processes was undertaken by Casagrande in 1939 for the dewatering and stabilisation of railway cuttings at Salzgitter, Germany, Casagrande (1952). Since then there have been many other applications of electroosmosis for dewatering and stabilisation of soils, including: (i) The use of electroosmosis for dewatering and strengthening Norwegian quick clays, Bjerrum *et al* (1967); (ii) Electroosmotic stabilisation of West Branch Dam, Fetzer (1967); (iii) Electroosmotic treatment to improve pile friction, Milligan (1994).

## 2. ELECTROKINETIC TRANSPORT PHENOMENA

There are five principle electrokinetic phenomena within soil: Streaming Potential, Migration Potential, Electroosmosis, Ion Migration and Electrophoresis. The first two of these phenomena are concerned with the generation of electrical potential due to the movement of charges and charged particles respectively. The remaining three are concerned with the transport mechanisms developed upon application of an electrical field across a soil mass.

### 2.1 Electroosmosis

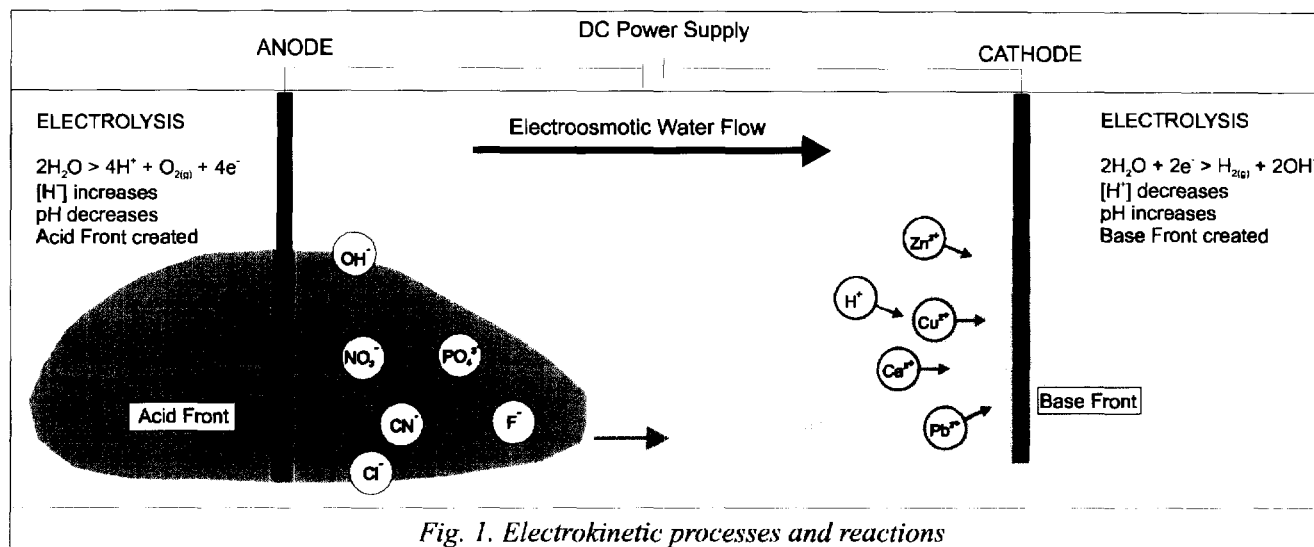

When an electrical field is applied across a fine grained soil mass cations are attracted to the cathode and anions to the anode, Fig. 1. As the ions migrate they carry their hydration water with them, and exert a frictional force on the water around them. Hence, there is a flow of water to both the anode and the cathode. In order to maintain charge neutrality, however, there are more cations than anions in the pore fluid of a soil containing negatively charged clay particles. Therefore, there is a net flow of water to the cathode, Gray & Mitchell (1967).

The electroosmotic flow of water through a soil can be expressed in the form of Darcy's equation for water flow:

$$q_A = k_e i_e A \quad (1)$$

where  $q_A$  is the flow rate,  $i_e$  is the potential gradient  $\Delta V/\Delta L$ ,  $A$  is the cross-sectional area and  $k_e$  is the coefficient of electroosmotic permeability.

The electroosmotic permeability ( $k_e$ ) for most soils lies in the range  $1 \times 10^{-9}$  to  $1 \times 10^{-8}$  m<sup>2</sup>/Vs, Lageman *et al* (1989),

and is independent of pore size, Casagrande (1949).

If both the anode and cathode are open (to water flow) then electroosmosis will “pump” water through a soil. However, if the anode is closed and the cathode open, then electroosmosis will generate negative pore pressures. The magnitude of these is given by:

$$u = \frac{k_e}{k_h} \gamma_w V \quad (2)$$

where  $k_e$  is the electroosmotic permeability,  $k_h$  is the hydraulic permeability,  $\gamma_w$  is the unit weight of water and  $V$  is the applied voltage. If the total stress does not change during electroosmosis then the magnitude of the effective stress is proportional to the negative pore pressure generated at the anode.

### 2.2 Electromigration or Ion Migration

The application of an electrical field across a soil mass causes migration of the free ions and ion complexes, which are present within the pore fluid, to the appropriate electrode, Lageman *et al* (1989) and Hellowell (1994).

Lageman *et al* (1989) report the average mobility of ions in soils as  $5 \times 10^{-8} \text{ m}^2/\text{Vs}$ , which is an order of magnitude greater than the electroosmotic permeability. Hence, anions can usually overcome the electroosmotic flow and migrate towards the anode.

### 2.3 Electrophoresis

When a DC electrical field is applied across a particulate suspension positively charged particles are attracted to the cathode and negatively charged particles are attracted to the anode. Most clay colloids are negatively charged and are therefore, attracted to the anode.

Electrophoretic mobilities reported by Lageman *et al* (1989) and by van Olphen (1977) are in the ranges  $1 \times 10^{-10}$  to  $3 \times 10^{-10} \text{ m}^2/\text{Vs}$  and  $1 \times 10^{-8}$  to  $3 \times 10^{-8} \text{ m}^2/\text{Vs}$  respectively. Hellowell (1994) attributes the discrepancy to differences in the moisture content of the medium. Electrophoresis has found applications in the densification of sludges and mine tailings, Lo *et al* (1991a). Esrig (1968) reports that the process is inconsequential for most naturally occurring soils.

## 3. GROUND IMPROVEMENT AND REINFORCEMENT USING EKGS

Electroosmotic treatment of soils generates negative pore pressures and thereby increases the effective stress, leading to consolidation of the soil. The end result is similar to that gained by the application of a surcharge; however, unlike vertically surcharging a soil mass, there are no stability problems, as the pore pressures generated are negative rather than positive. Electroosmosis may also be used to accelerate the dissipation of positive pore pressures resulting from vertical surcharging. Indeed, once the positive pore pressures have been dissipated electroosmosis can be continued for further consolidation, due to the generation of negative pore pressures. The maximum negative pore pressure due to electroosmotic consolidation will be generated at the anode, Esrig (1968). These processes increase the *strength* of the soil and the *bond* characteristics of the soil and the reinforcement.

Electroosmosis often leads to increases in strength of cohesive soils, due to chemical cementing of the soil fabric, Mitchell (1991).

### 3.1 Laboratory Tests - Consolidation

A number of laboratory tests have been conducted to evaluate the use of conductive geotextiles as electrodes in electroosmotic consolidation. The tests using an electroosmotic cell simulated the reinforcement, electrodes and the drainage configuration expected in reinforced soil applications.

A number of geosynthetic electrodes were considered and compared with a perforated copper disk. The initial type 1 geosynthetic electrode was formed from a non-woven, needle punched geotextile. A copper wire of 300 mm length and 1 mm diameter was inserted at the centre of the geotextile. Copper wire was chosen to inhibit the generation of oxygen at the anode. Any oxygen generated at the anode combined with the copper to form copper oxide, which is a good conductor of electricity.

The samples were prepared from Grade E Kaolinite (SILT) slurry at water contents of 1.5 times the liquid limit to ensure they would be fully saturated. The electroosmotic permeability was  $k_e = 3.4 \times 10^{-9} \text{ cm/sec per volt/cm}$  and hydraulic permeability  $k_h = 6 \times 10^{-7} \text{ cm/sec}$ .

Initially the soil was consolidated with an effective stress of 25 kPa. Electroosmotic tests were conducted with vertical pressures of 50 and 100 kPa to simulate the imposed load of fill material. During the tests, pore pressures, current and voltage variations across the soil sample were recorded. After treatment, tests were carried out to determine the water content and strength of the soil.

**Negative Pore Pressure**

Figure 2 shows the change in pore pressure at the anode during electroosmotic consolidation using type 1 geosynthetic electrodes with different applied voltages.

Fig. 2. Excess pore pressure versus time for normal consolidation and for electroosmotic consolidation.

Initially the back pressure was lowered by 50 kPa to simulate an applied vertical pressure. After the current was switched on the pore pressure at the anode decreased until it equalised the back pressure, signifying full dissipation of the positive pore pressure. As the test continued, the pore pressure at the anode decreased to a value lower than the back pressure, signifying the generation of the negative pore pressure. Upon reaching a maximum negative value, the pore pressure increased before stabilising at a lower negative value. Figure 2 shows that the positive pore pressure generated by the vertical loading was reduced to zero in a shorter time by the application of electroosmosis. The results concur with the theoretical solution by Wan *et al* (1976).

**Vertical Strain**

The vertical strain-time curves are as shown in Figure 3. The electroosmotically induced vertical strain curve was similar to the consolidation due to vertical load. The vertical strain increased from 9.7% for consolidation with a normal load to 13% with the incorporation of electroosmotic consolidation.

**Water Content**

The moisture content profile is as shown in Figure 4. It indicates that moisture content for soil consolidated by a combination of vertical load and electroosmotic consolidation is lower than soil consolidated only with a vertical load.

Fig. 3. Vertical strain versus time for normal consolidation and for electroosmotic consolidation.

The shape of the water content distribution indicates that the lowest water content was at the centre of the specimen. However, the water content at the anode was still significantly reduced. The water content profile agrees with the finding of Lo *et al* (1991b).

Fig. 4. Water content variation across soil specimens consolidated by vertical loading and by electroosmosis, with a closed anode.

Fig. 5. Moisture content profile across electrokinetically treated soil, open anode and cathode conditions.

As a comparison Figure 5 shows the water content profile across a soil sample subjected to electrokinetic treatment, but with an an "open" anode and cathode. This allows water into and out of the soil. The largest degree of dewatering occurs at the cathode, due to a high resistance zone which develops close to the cathode. This high resistance zone causes a localised increase in the voltage gradient and, hence, an increase in electroosmotic flow in this region.

#### Shear Strength

The undrained shear strength of the soil was determined at a depth of 30 mm from the surface. The test showed an increase in the shear strength up to 128% for an applied voltage of 20 volts, Table 1.

Table 1. Increase in shear strength when using electrokinetic geosynthetic reinforcement.

Soil	Shear Strength kPa	% Increase
50 kPa vertical pressure	11	-
50 kPa vertical pressure + 15V	19	72
50 kPa vertical pressure + 20V	26	128

#### 3.2 Laboratory Tests - Soil-Reinforcement Bond

The use of electrically conductive geosynthetic reinforcement can be shown to increase soil-reinforcement bond. A series of pullout tests have been undertaken at Newcastle University to illustrate this concept. The objective of the tests was to study the effect of an electroconductive reinforcement on bond performance under undrained conditions. This represented the most severe case in the use of cohesive fill in a reinforced soil structure.

The tests were performed in a specially designed pullout cell and were conducted on soil strengthened by vertical overburden and also by a combination of overburden and electroosmotic consolidation.

Commercially available grade E kaolin was used for the tests. The soil was mixed at a water content of about 52% which was about 3% below the liquid limit.

A drainage layer which also served as the cathode was first placed at the bottom of the cell. The soil was then placed in the cell and compacted manually. The anode was inserted at mid height of the sample. Another layer of conductive geosynthetic was placed at the top of the soil sample forming a second cathode. Hence a two way drainage configuration was used to accelerate the consolidation process.

The soil was consolidated by the application of vertical pressure or by a combination of vertical pressure and electroosmotic consolidation. The vertical pressure was applied by a hydraulic jack capable of providing a constant vertical pressure. A potential difference of 30 volts was

applied by means of a direct current power supply unit with a maximum output current of 1 ampere.

After the completion of the consolidation process, the cell was turned sideways and bolted to the platen of the frame of the triaxial testing machine. A slit cover was then removed, exposing the geosynthetic reinforcement. The pullout resistance and the vertical displacement were automatically recorded by a load cell and LVDT respectively. After the pullout tests, laboratory vane shear tests were carried out on the soil sample close to the anode. A small portion of the soil sample was also taken for the determination of the water content.

#### Bond Strength

The increase in reinforcement-soil bond due to the use of electrically conductive reinforcement is shown in Table 2. The results show that the increase ranged from 54% to 209% at different overburden pressures.

Table 2. Increase in Shear and Soil Reinforcement Bond strengths using an electrokinetic geosynthetic.

Consolidation Pressure kPa	% Increase in Shear Strength	% Increase in Bond Strength
110	150	209
140	203	113
356	72	54

#### 4. ENVIRONMENTAL APPLICATIONS OF ELECTROKINETIC GEOSYNTHETICS

The electrokinetic processes described in Section 2 can be applied to the remediation and containment of contaminants within the ground. Indeed, electrokinetic remediation is the only technique for the in situ remediation of contaminated fine-grained soils and the groundwater within them (NATO/CCMS 1993). The following are the electrokinetic processes which can be utilised for contaminant remediation and containment:

- Ion migration may be utilised to transport metals and polar contaminants to the relevant electrode, where they may be removed (Lageman *et al* 1989).
- Ion migration may be utilised to transport nutrients to enhance bioremediation (Figure 6).
- Electroosmosis may be utilised to flush contaminants from the soil (Lageman *et al* 1989).
- Electrosorption of contaminants.

In addition because the soil mass acts as a resistor the ground heats up (Lageman *et al* 1989 reports temperature rises of between 20 and 40 °C) and this phenomena may be used to volatilise organic contaminants (Lageman 1995), and to stimulate bioremedial action.

Electrokinetic transport of nutrients has been investigated in a tank containing grade E Kaolinite (Section 3.1). The tank was 400mm long with three wellpoints inserted at 100mm spacings along the length. Nitrate solution (500mg/l) was placed in the electrode reservoirs, an electrical current of 60mA was set across the tank, and porewater samples were taken from the three wells twice a

day. Figure 6 shows the Nitrate breakthrough curves obtained. Well/01 was located 100mm from the anode, well/02 was located at the centre of the tank, and well/03 was located 100mm from the cathode.

Fig. 6. Graph showing transport of Nitrate by ion migration.

## 5. ELECTROKINETIC GEOSYNTHETICS

The new EKGs can take the form of single materials, which are electrically conductive, or composite materials, in which at least one element is electrically conductive. They can be of the same basic form as present day filter, drainage, separator and reinforcement materials, but offer sufficient electrical conduction to allow the application of electrokinetic techniques for ground improvement and remediation.

There are a number of materials which can be used to produce electrically conductive geosynthetics. The principle conductive materials which have been considered and evaluated at Newcastle include:

- Carbon Fibre Materials.
- Conductively Filled Polymers.
- Metallic Fibres (Metal fibres, metallised fibres or metal coated fibres).
- Composites formed from conductive/non conductive elements.

The metallic fibres have been discounted due to corrosion durability problems. Both the carbon fibre and conductively filled polymer materials show great promise as base materials for the new EKGs, and are discussed below.

### 5.1 Conductively Filled Polymers

Organic polymers with all carbon backbones are insulators (eg polyethylene PE, polyvinylchloride PVC, ethylvinylacetate EVA) and can be used for electrical insulation. However, if carbon black, carbon fibres or finely divided metals are used as fillers in such organic polymers, then conductive ( $10^{-5}$  to 1 s/cm) composites may be created, Cowie (1991). In these composites it is the filler which conducts and not the polymer.

If carbon black is used as the conductive filler then a loading of between 20 and 30 wt % will be required to

produce a suitable conductivity. The structure and mixing of the carbon black filler plays an important role in determining the properties of the conductive polymer. There are two main types of carbon structure of interest, the Low structure, which is a jumbled array of carbon spheres, and the High structure, which is a chain of spheres, giving a higher conductivity.

An activated carbon black or carbon fibre filler may also be introduced to increase the sorption characteristics of polymeric materials. Sorption is another potential function of EKGs.

### 5.2 Carbon Fibre Materials

Carbon fibres are representative of graphite materials; they are electrically conductive ( $> 10^2$  s/cm) and chemically stable. High modulus carbon fibres are expensive and their use is limited to specialist applications where high stresses, high temperatures and radiation exposure are expected. The lower modulus carbon fibres are cheaper, their production simpler and the raw materials more abundant, Ermolenko *et al* (1990).

Activated carbon fibres (ACFs) have an open microporous structure which provides sorption sites. They provide similar or higher sorption than activated carbon particles and their shape allows more rapid and greater sorption than is found with carbon particles, Ermolenko *et al* (1990). The low modulus materials have many of the features required for the production of electrically conductive geosynthetics.

### 5.3 EKG functions and design

During electrokinetic treatment utilising EKGs water will flow from the soil and into the EKG at the cathode, and oxygen and hydrogen will be formed and flow into the anode and cathode respectively. The gas and water have to be dissipated to prevent the build up of pore pressures. Hence, the EKG must act as a filter and a drainage material:

- Filtration - to allow the free passage of water from the soil to the drainage system.
- Transmissivity - to transport water and gas out of the system without hindrance.

The EKG must also distribute the electrical current to the pore fluid within the fine grained soil being treated. Any interface resistance to the transfer of current from the electrodes to the soil is a potentially large source of electrical inefficiency for electrokinetic treatment. The higher the interface resistance, the lower will be the effective voltage gradient or current flow for electrokinetic treatment. Factors affecting the pore fluid/electrode interface resistance include:

- Form of the electrodes
- Gas generation during the process
- Current densities - high values lead to electrode polarisation.

Electrode configuration plays an important role in determining the magnitude of interface resistance. An important consideration is the presence of ground water in the porous structure of the geosynthetic. This makes its

whole surface act as an electrode. A major advantage of the use of a geosynthetic electrode is that the surface area can be much larger than traditional electrodes, and the structure is open to the flow of water and gas.

From a study of the electrode requirements for electrokinetic treatment it is clear that a band drain type electrode seems to be the most promising design (Nettleton, 1996). A band drain can be made to act as a local distributor of electrical current by incorporating carbon black fillers into the base polymer for either the geotextile filter or the drainage component of the band drain. Due to the electrical current requirements for electrokinetic treatment a stringer will be required to conduct and distribute the bulk of the current throughout the band drain. The stringer could take the form of a metallic wire coated with a conductive polymer to prevent corrosion due to electrolysis at the electrodes (Nettleton, 1996).

## 6. CONCLUSIONS

The development of electrically conductive geosynthetic materials offers significant new application areas for geosynthetic products, ranging from accelerated consolidation of soft soils to soil decontamination and pollution control. The use of electrically conductive reinforcement in reinforced soil structures is beneficial as the concept is fully compatible with, and has a positive influence on, the parameters controlling the reinforcement mechanisms.

## ACKNOWLEDGEMENTS

The authors would like to express their thanks to the Engineering and Physical Sciences Research Council and the British Council in Japan for their support during this research. In addition the authors would like to thank Mitsui Petrochemical Industrial Products Ltd. and Netlon Ltd. for supplying materials and production facilities.

# A Study of the Behavior of Geogrid Reinforced Stone Column

J.S. Sharma

NTU-PWD Geotechnical Research Centre, Nanyang Technological University, Singapore

**ABSTRACT:** The bearing capacity of a stone column is mainly governed by the bulging failure near its top end. The performance of a stone column can be improved by providing layers of reinforcement in the top region. In this paper, the behavior of geogrid reinforced stone column is explored using the finite element method. Results are presented from a parametric study using a unit cell finite element mesh in which the number, spacing and the stiffness of the geogrid were varied. It was found that increasing the number of geogrid layers results in an increase in the bearing capacity and a reduction in the bulging of the stone column. Decreasing the spacing of geogrid layers also increases the bearing capacity of the stone column. However, decreasing the spacing to less than 0.5 times the diameter of the stone column does not result in appreciable increase in bearing capacity. An inexpensive, low stiffness reinforcement installed at correct spacing is good enough to provide significant increase in the bearing capacity of the stone column.

**KEYWORDS:** Bearing Capacity, Finite Element Analysis, Geogrids, Soft Soils, Stone Columns

## 1 INTRODUCTION

It has become a common practice to install stone columns for improving the bearing capacity of soft clay deposits. When a soft clay layer installed with stone columns is loaded, a redistribution of vertical stress takes place. Most of the vertical stress is carried by the stone column because it is significantly stiffer than the soft clay. As a result, the stone column deforms laterally into the surrounding soil. For stone columns with lengths greater than a certain critical length, it is widely accepted that their load carrying capacity is governed by the bulging failure near their top end irrespective of whether they are end bearing or penetrate partially into a medium stiff soil layer (Madhav and Miura, 1994). The reason for this is the shear strength of the surrounding soft soil near the top end of the stone column is fairly low and therefore, the soil is unable to provide sufficient lateral resistance to the bulging. Experiments on stone columns have indicated that maximum bulging occurs at a depth approximately equal to 1 to 1.5 times the diameter of the stone column (Hughes et al., 1975; Madhav, 1982). The occurrence of bulging failure limits the ultimate load carrying capacity of a stone column regardless of the stiffness of the stone column material.

The magnitude of lateral stresses imposed by the stone column on the surrounding soil can be reduced by reinforcing the stone column near its top end using layers of geogrid. As a result, the bulging of stone column is reduced and its load carrying capacity is increased. The effectiveness of this technique has been demonstrated experimentally by Madhav (1982). Madhav et al. (1994) have proposed a limit equilibrium based method for the design of such stone columns. Their method is simple to use but it does not take into account the effect of slip at the stone column-soil interface and the stiffness of the reinforcement. In this paper, the behavior of geogrid reinforced stone columns is explored using the finite element method. A parametric study was conducted using a

“unit cell” finite element mesh in which the number, the spacing and the stiffness of the geogrid were varied. The finite element code was validated against the results of a field trial on a single stone column (Hughes et al., 1975) prior to its deployment in the parametric study.

## 2 FINITE ELEMENT ANALYSIS

### 2.1 The Mesh

Figure 1. The finite element mesh

Figure 1 shows the details of the finite element mesh used in the present study. It is an axisymmetric unit cell mesh with the central axis of the stone column as the axis of symmetry. The diameter of the stone column is 0.8 m whereas the diameter of the unit cell soil cylinder is 4 m, giving the replacement ratio, i.e. the ratio of the volume of stone column to the volume of the unit cell soil cylinder, equal to 0.04 or 4%. Only top 4 m of the stone column has been

modelled. The justification for this the fact that at depths greater than 2 to 3 diameters, the deformation of the stone column is negligible (Hughes and Withers, 1974).

The stone column has been modelled using 8-noded quadrilateral elements with displacements unknown. The surrounding soil has been modelled using 6-noded triangular and 8-noded quadrilateral elements with displacements and pore pressures unknown. The geogrid has been modelled using very thin (0.01 m thickness) 8-noded quadrilateral elements. The interface between the stone column and the surrounding soil has been modelled using 6-noded slip elements. No slip elements are provided at the geogrid-stone column interface.

## 2.2 Constitutive Modelling of Materials

The stone column has been modelled as Elastic-Perfectly Plastic material with Mohr-Coulomb failure criterion. The surrounding soft clay is considered as normally consolidated and is modelled as an Elastic-Perfectly Plastic material but with Tresca failure criterion. The undrained shear strength of the soft clay increases linearly with depth. The geogrid has been modelled as Linear Elastic material. The slip elements at stone column-soft clay interface have also been modelled as Elastic-Perfectly Plastic material with Mohr-Coulomb failure criterion. Following the experience of Balaam and Poulos (1982), the stone column-soft clay interface is assumed as purely cohesive, i.e. zero angle of friction but a finite value of cohesion. The cohesion at the stone-column-soft clay interface at any level is taken as 80% of the undrained shear strength of soft clay at that level. Table 1 lists all the parameters chosen for the above four types of materials.

Table 1. Parameters for the stone column, soft clay, geogrid and the stone-column-soft clay interface

Parameter	Stone Column	Soft Clay	Geogrid	Inter-face
$c_o$ (kPa)	1.0	1.2	—	1.0
$m_c$ (kPa/m)	0.0	1.94	—	1.55
$\phi$ (Degrees)	40.0	0.0	—	0.0
$E_o$ (kPa)	40,000	720	2,500,000	600
$m_E$ (kPa/m)	9200	1150	0.0	900
$\nu$	0.3	0.49	0.3	—
$\gamma_{bulk}$ (kN/m <sup>3</sup> )	18.0	18.0	18.0	—
$t$ (m)	—	—	0.01	0.04

Notes:  $c_o$  — cohesion at ground level,  $m_c$  — rate of increase of cohesion with depth,  $\phi$  — angle of internal friction,  $E_o$  — Young's modulus at ground level,  $m_E$  — rate of increase of Young's modulus with depth,  $\nu$  — Poisson's ratio,  $\gamma_{bulk}$  — bulk unit weight,  $t$  — thickness.

## 2.3 Stages in a Typical Analysis

A typical finite element analysis in the present study has following stages:

1. In-situ stage: This is the start of the analysis. At this stage of the analysis, the whole mesh contains only the soil elements.
2. Installation of stone column and geogrid layers: In this stage, the soil elements that are occupying stone column space are removed from the mesh and the elements representing stone column and geogrid are added to the mesh.
3. Loading of stone column: In this stage, the stone column is loaded at its top end using displacement control. The displacement is applied in very small increments (0.0002 m per increment) to prevent any divergence from the stress-strain curve.

## 2.4 Validation of the Finite Element Code

Before a finite element mesh is used for a parametric study, it is imperative to validate it against good quality experimental data. The main purposes of the validation are to ensure that the mesh is sufficiently refined and to check that the constitutive models used are satisfactory. For the validation, it was decided to make use of the results of a field trial on a single stone column reported by Hughes et al. (1975). This field trial is supplemented with extensive site investigation data which includes undrained shear strength profile of the soil, in-situ lateral stresses, and the soil modulus obtained from in-situ pressuremeter tests. Almost all the input parameters were taken directly from the site investigation data with the exception of the permeability of the soil which was taken to be  $2 \times 10^{-9}$  m/s in horizontal direction and  $1 \times 10^{-9}$  m/s in the vertical direction. Since the full loading of the stone column was very quick (total time = 0.5 hour), the soil can be assumed to be undrained. Therefore, the finite element simulation can be considered to be insensitive to small differences in permeability of the soil.

Figure 2. Measured and simulated load-settlement curves (after Hughes et al., 1975)

Figure 3. Measured and simulated bulging of stone column (after Hughes et al., 1975).

Detailed account of the finite element simulation can be found in Sharma (1997). Due to lack of space, only two main comparisons are described here. Figure 2 shows the comparison between the measured and the simulated load settlement curves. As seen from Figure 2, there is good agreement between the two curves. The measured and simulated deformation of the stone column at the end of loading are shown in Figure 3. Once again, the agreement between the two curves is satisfactory.

### 3 PARAMETRIC STUDY

As mentioned previously, the main parameters in the present study are: the number, spacing and the stiffness of the geogrid. Table 2 lists these parameters and their range.

Table 2. Range of parameters for the geogrid

Parameter	Range
Number of geogrid layers	0 to 5, in steps of 1
Spacing of geogrid layers	0.5 to 3 times the diameter of stone column
Elastic Modulus of geogrid (kPa)	100,000 to 2,500,000

#### 3.1 Effect of Number of Reinforcement Layers

In this series of finite element runs, the number of geogrid layers was increased from 0 to 5 in steps of 1. The spacing of these layers was kept constant at 0.5 times the diameter of the stone column ( $d_{sc}$ ) and the elastic modulus ( $E_r$ ) of the geogrid was taken equal to  $2.5 \times 10^9$  N/m<sup>2</sup>. Figure 4 shows the load-settlement curves for the stone column.

Figure 4. Effect of number of layers on the load-settlement response of stone column

Figure 5. Variation of normalized bearing capacity of stone column with number of geogrid layers

Figure 5 shows the normalized bearing capacity of the stone column ( $\theta = q_{ur}/q_{up}$ ) plotted against number of geogrid layers. In figure 5 and in subsequent figures,  $q_{ur}$  is the ultimate bearing capacity of a reinforced stone column and  $q_{up}$  is the ultimate bearing capacity of an unreinforced stone column. It is clear from figures 4 and 5 that inclusion of geogrid layers in the stone column results in significant improvement in the load bearing capacity of the stone column. For example, the load bearing capacity of a stone column reinforced with three layers of geogrid is more than

twice that of an unreinforced stone column. The variation between  $\theta$  and the number of geogrid layers is almost linear. However, it does tend to flatten slightly as the number of layers are increased beyond 3 which implies that it may not be economical to put more than 3 layers of reinforcement.

Figure 6. Variation of normalized depth of maximum bulging with normalized bearing capacity of stone column.

Figure 7. Variation of normalized maximum bulging with normalized bearing capacity of stone column

Figure 6 shows normalized depth of maximum bulging ( $\zeta = z_m/d_{sc}$ ) of stone column plotted against  $\theta$ . In this figure,  $z_m$  is the depth at which maximum bulging takes place. It can be seen from figure 6 that the increase in bearing capacity is

achieved by pushing the point of maximum bulging deeper, i.e. the failure mechanism is now benefiting from higher lateral resistance from the surrounding soil.

Increasing number of geogrid layers not only pushes the point of maximum bulging deeper but also reduces the amount of maximum bulging as seen from Figure 7 which shows normalized maximum bulging ( $\beta = b_r/b_p$  where  $b_r$  is maximum bulging for reinforced stone column and  $b_p$  is the maximum bulging for unreinforced stone column) plotted against  $\theta$ . For example, the amount of maximum bulging for a stone column reinforced with 3 geogrid layers is less than 70% of that for an unreinforced stone column. The reduction in amount of maximum bulging is achieved by redistribution of the lateral deformation of stone column over a longer section as shown in Figure 8.

Figure 8. Redistribution of lateral deformation of stone column due to the presence of geogrid layers.

### 3.2 Effect of Spacing of Reinforcement Layers

For this series of finite element runs, the stone column was reinforced with three geogrid layers.  $E_r$  for geogrid was taken equal to  $2.5 \times 10^9 \text{ N/m}^2$ . Figure 9 shows normalized spacing of the geogrid layers ( $\lambda = s_r/d_{sc}$  where  $s_r$  is the spacing of geogrid layers) plotted against  $\theta$ . It can be seen from figure 9 that the maximum benefits of reinforcing the stone column are achieved when the spacing of reinforcement is between 0.5 to 1.5 times the diameter of the stone column. A spacing closer than 0.5 times the diameter would not result in any significant increase in the bearing capacity. Also, the combined action of multiple

layers of reinforcement, i.e. redistribution of lateral deformation of stone column, is not achieved effectively if the spacing of the reinforcement is greater than twice the diameter of the stone column. As a result, the increase in bearing capacity of the stone column is not significant.

Figure 9. Effect of spacing of geogrid on the bearing capacity of the stone column

### 3.3 Effect of Stiffness of Reinforcement

In this series of finite element runs, the stone column was reinforced with three layers of geogrid spaced at 0.5 times the diameter of the stone column. Figure 10 shows elastic modulus of the geogrid ( $E_r$ ) plotted against  $\theta$ . The bearing capacity of a reinforced stone column increases as the stiffness of the reinforcement is increased. The increase is very dramatic when the stiffness is increased from  $E_r = 0$  (unreinforced case) to  $E_r = 1 \times 10^8 \text{ N/m}^2$ . However, beyond a certain stiffness ( $E_r > 10 \times 10^8 \text{ N/m}^2$ ), the increase is not significant. This implies that one need not use an expensive high stiffness reinforcement in order to improve the bearing capacity of stone column. Even a cheap, low stiffness reinforcement installed at correct spacing would provide significant increase in the bearing capacity of the stone column.

Figure 11 shows maximum tension in the geogrid plotted against  $E_r$ . It can be seen from figure 11 that a stiffer reinforcement attracts more tension but does not contribute significantly towards improving the bearing capacity of the stone column. Provision of a low stiffness reinforcement would result in a relatively flexible stone column with low levels of tension in the reinforcement. Such a flexible stone column would deform more uniformly than the one installed with very stiff reinforcement. This would result in the

bulging being distributed over a greater length, thus preventing localised bulging failure and resulting in improved bearing capacity.

Figure 10. Effect of stiffness of geogrid on the bearing capacity of stone column

Figure 11. Effect of the stiffness of the geogrid on the magnitude of maximum tension induced in the geogrid

## 4 CONCLUSIONS

A parametric study of the behavior of geogrid reinforced stone column has been conducted using a finite element unit cell mesh which has been validated against the results of a field trial. The number, the spacing and the stiffness of

geogrid were the main parameters. It was found that increasing number of layers of geogrid increases the bearing capacity of the stone column. It also reduces the bulging of stone column and pushes the point of maximum bulging deeper. The inclusion of geogrid layers results in redistribution of lateral deformation of stone column and therefore, facilitates much more effective transfer of lateral stresses from stone column to the soft clay.

Installing geogrid layers at closer spacing also increases the bearing capacity of the stone column. The optimum spacing of geogrid layers was found to be between 0.5 to 1.5 times the diameter of the stone column. Installation of geogrid layers at spacing closer than 0.5 times the diameter of stone column does not result in appreciable increase in the bearing capacity of the stone column.

The increase in bearing capacity of stone column due to increase in stiffness of geogrid is quite dramatic when the elastic modulus of geogrid is increased from zero (unreinforced) to  $1 \times 10^8$  N/m<sup>2</sup>. However, increasing the elastic modulus beyond  $10 \times 10^8$  N/m<sup>2</sup> does not result in appreciable increase in the bearing capacity. A stiffer reinforcement also tends to attract more tension. Based on these two observations, it can be concluded that it is better to reinforce the stone column using a less stiff reinforcement installed at a spacing between 0.5 and 1.5 times the diameter of the stone column. Such a system would be more flexible and would be able to deform more uniformly than the one installed with stiff reinforcement. This would in turn result in bulging being distributed over a greater length, thus preventing localised bulging failure and improving the bearing capacity of the stone column.

#### ACKNOWLEDGEMENT

The author has benefited greatly from numerous stimulating discussions with Prof. M.R. Madhav of Indian Institute of Technology, Kanpur and would like to take this opportunity to thank him for all his help and encouragement.

# Geosynthetic Reinforced Unpaved Roads on Very Soft Soils: Construction and Maintenance Effects

E.M. Palmeira

Associate Professor, Department of Civil Engineering, University of Brasilia, Brasilia, Brazil

**ABSTRACT:** Geosynthetics can be used in unpaved roads on soft subgrades to increase bearing capacity and reduce fill consumption. When unpaved roads are built on very soft soils and with poor construction techniques excessive deformations of the geosynthetic layer can occur during the construction of the road caused by the traffic of bulldozers and trucks on thin layers of fill. This paper examines the effects of the road construction on the strains in extensible geosynthetic reinforcements. A methodology to estimate geosynthetic strains caused by construction is presented and its results suggest that significant geosynthetic strains can be developed during road construction. The influence of surface maintenance on the bearing capacity of reinforced and unreinforced unpaved roads is also investigated. A methodology to estimate the bearing capacity of this type of road after surface repair is presented. The predictions by this methodology compared well with model tests results available in the literature.

**KEYWORDS:** geosynthetic, reinforcement, unpaved roads, geotextile strains, surface maintenance.

## 1 INTRODUCTION

The construction of embankments on soft soils is generally a problem in routine geotechnical engineering works. In the case of unpaved roads the main load on the embankment is usually due to the weight of the trucks rather than the weight of the fill material itself. High vertical stresses can reach the soft foundation causing excessive deformation or local failures that may lead to interruptions of the traffic and to transportation cost increases. The use of geosynthetics for the reinforcement of unpaved roads on soft subgrades has been a common solution for the increase of road bearing capacity, besides minimizing fill consumption, foundation deformation and road surface rutting.

Several methodologies have been presented so far dealing with the design of reinforced unpaved roads or with the estimate of bearing capacity of this type of structure (Ferreira Jr, 1995). A common feature of these methodologies is to assume the geometrical characteristics of the problem as shown in Figure 1. This assumption does not take into account geosynthetic or subgrade deformations caused by the construction of the road. However, in the case of very soft subgrades (undrained strength at the surface below 15 kPa) large deformations of the subgrade can be caused by construction vehicles such as bulldozers and loaded trucks that bring the fill material for the road construction. In such cases the first deformations on the geosynthetic layer will be caused by these vehicles while spreading and compacting the fill or trafficking on thin layers of fill. In many cases the compaction of the fill material is simply provided by the bulldozer weight and the traffic of the trucks used in the construction of the road.

This paper deals with geosynthetic deformations caused during construction of the road and how they can be

estimated. The behaviour of this type of road after surface maintenance is also approached, particularly for the case of narrow unpaved roads.

Figure 1. Typical approach for reinforced unpaved roads.

## 2 GEOSYNTHETIC DEFORMATIONS CAUSED BY ROAD CONSTRUCTION

The construction of unpaved roads on soft soils usually involves the following steps: cleaning of the ground surface, laying of the geosynthetic layer (if present), spreading of the fill material and fill compaction by appropriate equipments. Because of site conditions or project characteristics some of these steps may not be executed in many cases, such as cleaning of the ground surface and fill compaction by usual compaction equipments. Frequently the compaction of the fill is provided by the bulldozer and the traffic of trucks and at this initial stage the road is continuously repaired until a final height of compacted fill is reached for which further loads can be sustained for a certain period of time until maintenance is required. During spreading of fill on the geosynthetic layer the bulldozer operator can cause severe rutting and geosynthetic deformations due the combination

of the bulldozer weight and thin fill layers. A simple analysis of the mechanics of the problem is shown in Figure 2, where the vertical stress caused by the bulldozer weight is assumed as a uniformly distributed stress (strip load). If the fill strength is neglected, equilibrium along the vertical direction leads to an expression for a conservative estimate of the minimum compacted fill layer below the bulldozer track in order to avoid failure of the fill and excessive rutting:

$$h_0 = \frac{b}{\tan\theta} \left( \frac{p}{N'_c c_0} - 1 \right) \quad [1]$$

where:  $h_0$  is the minimum fill height (when the factor of safety equals to unity),  $p$  is the vertical stress on the surface,  $b$  is half of the track width,  $\theta$  is the load spreading angle,  $N'_c$  is the bearing capacity factor for the foundation and  $c_0$  is the soft soil undrained strength at the surface.

Figure 2. Failure mechanism during spreading of the fill.

A mean value for the subgrade undrained strength can replace the value of  $c_0$  if a less conservative estimate is desired. However, the value of  $c_0$  is chosen at this stage because not all the efforts acting on the system are being considered in expression 1, such as inertia forces and vibrations. For the case of reinforced roads the value of  $N'_c$  to be used is equal to  $\pi + 2$  and for unreinforced roads the value given by the expression below (Houlsby et al, 1989) is suggested:

$$N'_c = 1 + \frac{\pi}{2} + \cos^{-1}\alpha + \sqrt{1 - \alpha^2} \quad [2]$$

where  $\alpha$  is the ratio between the mobilized outward shear stress and the undrained strength at the subgrade surface.

If the bulldozer moves on a fill layer with thickness equal or smaller than the value given by equation 1 a significant vertical displacement at the foundation soil surface will occur. This settlement will reach to a depth where equilibrium is maintained depending on the subgrade undrained strength and on the force mobilized in the reinforcement. This depth can be also estimated considering the vertical equilibrium in Figure 2, which for the reinforced case yields to:

$$S = \frac{pb - T \sin\beta}{\rho N_c (b + h \tan\theta)} - \left( \frac{c_0}{\rho} + 2b \right) \quad [3]$$

where  $S$  is the maximum settlement at the subgrade surface,  $T$  is the geosynthetic tensile force,  $\beta$  is the inclination of  $T$  to the horizontal direction,  $N_c$  is the bearing capacity factor for a foundation with inclined base ( $\lambda$ , in Fig. 2) and  $\theta$  is the load spreading angle in the reinforced case. Due to the assumed trapezoidal shape of the deformed fill below the load (Fig. 2) and assuming no shear stress at the geotextile-subgrade interface the bearing capacity factor in this case ( $N_c$ ) can be obtained by (Houlsby and Wroth, 1983, and Palmeira and Cunha, 1993):

$$N_c = \pi + 2 - 2\lambda \quad [4]$$

where  $\lambda$  is the angle between the fill wedge base and the horizontal (Fig. 2).

Palmeira and Cunha (1993) performed model tests with unpaved roads reinforced with extensible geotextiles subjected to severe rutting caused by successive stages of footing loading and surface repair. Empirical expressions were obtained to estimate  $\beta$ ,  $\lambda$  and the average geosynthetic tensile strain ( $\epsilon$ ) as a function of the maximum vertical displacement at the fill-subgrade interface normalized by the footing width. These expressions were developed for roads with ratios  $h_f/B \leq 0.7$  (Fig. 1) and are presented below:

$$\frac{\beta}{\pi} = 0.237 + 0.191 \log_{10} \frac{S}{B} \quad (\beta \text{ in radians}) \quad [5]$$

$$\frac{\lambda}{\pi} = 0.156 + 0.133 \log_{10} \frac{S}{B} \quad (\lambda \text{ in radians}) \quad [6]$$

$$\epsilon = 0.5 \sqrt{1 + 3.5 \tan^2 \lambda} + \frac{0.27}{\tan \lambda} \ln(1.87 \tan \lambda + \sqrt{1 - 3.5 \tan^2 \lambda}) - 1 \quad [7]$$

Figure 3 presents some comparisons between values of geotextile strain ( $\epsilon$ ) versus  $S/B$  predicted by equation 7 and observed by different researchers (for  $h_f/B \leq 0.7$ ). The results from model tests were inferred from deformed

shapes of the reinforcement layer or obtained by strain measurements in the reinforcement. A good agreement between predicted and observed values can be noted.

Figure 3. Predicted and observed values of geotextile strains.

Laboratory tests on model unpaved roads have also consistently shown that the load spreading angle in the reinforced fill can be significantly greater than in the unreinforced fill (Love, 1984, Palmeira and Cunha, 1993 and Palmeira and Ferreira, 1994). Palmeira and Ferreira (1994) observed load spreading angles between 21 to 34° for reinforced roads and between 6 to 17° for the unreinforced ones.

The value of  $S$  depends on the fill thickness ( $h$  in Fig. 2) below the bulldozer track. This thickness depends on the bulldozer operator experience and is likely to be highly variable in different parts of the road depending on the subgrade undrained strength and stiffness at its surface. If  $h$  is significantly smaller than  $h_0$  (equation 1) and depending on the subgrade strength the rut depth required for equilibrium can be even greater than  $h$  and soft soil may reach the fill surface through fill cracks. This is certainly more critical for the unreinforced case, but depending on the value of  $h$  high geotextile strains can be developed because of this excessive deformation of the system. These strains are not taken into account if the available design methods are applied for unpaved roads on very soft soils or when poor construction techniques are employed.

Assuming a linear relationship between tensile force and tensile strain for the geotextile, expressions 1 and 3 can be combined to obtain the following expression relating maximum vertical displacement at the fill-subgrade interface ( $S$ ) to geotextile strain ( $\epsilon$ ) in dimensionless terms:

$$\frac{S}{B} = \frac{\frac{p}{c_0} - 2 \sin \beta \frac{J}{c_0 B} \epsilon}{N_c \frac{\rho B}{c_0} \{1 + k [\frac{1}{(\pi + 2) c_0} p - 1]\}} - (\frac{c_0}{\rho B} + 1) \quad [8]$$

where  $k$  is the ratio between  $h$  and  $h_0$ .

Figures 4 to 6 show charts obtained from the iterative solution of equations 4 to 8 to estimate the geotextile deformation for  $k = 0.5$  and for different values of the dimensionless terms. The geotextile strain due to road construction may then be taken into account in conjunction with the strains caused by the traffic of vehicles on the road to estimate the total geotextile strain. The associated settlement  $S$  can be estimated by equation 8 and can then be compared with the value of  $h$  ( $h = k h_0$ , with  $h_0$  given by equation 1).

Figure 4. Geotextile strain versus  $p/c_0$  for  $c_0/(\rho B) = 3$ .

Figure 5. Geotextile strain versus  $p/c_0$  for  $c_0/(\rho B) = 6$ .

### 3 BEARING CAPACITY OF UNPAVED ROADS AFTER SURFACE MAINTENANCE

#### 3.1 Theoretical Development

Figure 7 shows the failure mechanism assumed after a repair of the road surface after excessive rutting has occurred under plane strain conditions. This is the case of narrow roads and poor maintenance conditions, where the surface repair is made just by filling the rut and compacting the new material. The region ABCD is inside the compacted material while the block CDEF is composed of the original failed road. It is assumed that failure in the repaired region will develop along vertical planes (plane BC in Fig. 7) due to the punching mechanism of the block underneath. This is consistent with the observation of failure mechanisms in model roads which suffered successive stages of surface repair and loading (Palmeira and Cunha, 1993). For stiff fill materials the block ABCFED is assumed to behave as a rigid mass being pushed into the soft subgrade. A vertical stress distribution throughout the repaired region ABCD similar to the one employed by Terzaghi (1943) for the study of tunnels in soil is adopted (Fig. 8). The yielding base DC controls the failure mechanism of the repaired region and the horizontal stresses along plane BC drops during loading, being assumed that active conditions are reached. This assumption is corroborated by predictions of horizontal stresses in a elastic layer with a yielding base (Poulos and Davis, 1974). Based on these hypotheses the vertical stress at the base of the rut can be derived:

$$\sigma_b = p \cdot e^{-2k_{ap} \tan \phi' \frac{r}{B}} - \frac{2c' - \gamma B}{2k_{ap} \tan \phi'} (1 - e^{-2k_{ap} \tan \phi' \frac{r}{B}}) \quad [9]$$

Figure 7. Failure mechanism after surface repair.

Figure 8. Vertical stress distribution in block ABCD

where  $\gamma$  is the specific weight of the fill,  $k_{ap}$  is the active earth pressure coefficient and  $c'$  and  $\phi'$  are the shear strength parameters of the soil used for the repair (peak values).

According to Figure 9 the study of the equilibrium of block CDEF and the bearing capacity of the subgrade yields to:

$$\sigma_b = \frac{b'}{b} \sigma + \frac{b'}{b} \tan \lambda \tau - \frac{W}{b} + \frac{T \sin \beta}{b} \quad [10]$$

where  $\sigma$  is the foundation bearing capacity,  $\tau$  is the shear stress at the reinforcement-subgrade interface (assumed equal to the undrained strength of the subgrade),  $W$  is the weight of block DCEF and  $T$  is the tensile force in the reinforcement (if present).

The bearing capacity of the foundation soil is given by (Palmeira and Cunha, 1993, Figs. 7 and 9):

$$\sigma = N_c C_u + \gamma h_f + \gamma_s (S - S') \quad [11]$$

where  $\gamma_s$  is the specific weight of the subgrade material and  $h_f$ ,  $S$  and  $S'$  are the dimensions given in Figure 7. The value of  $N_c$  is given by Equation 4, where  $\lambda$  is given by

Figure 9. Failure mechanism of the soft subgrade.

equation 6 for reinforced roads and by the following expression (Palmeira and Cunha, 1993) for the unreinforced case ( $\lambda_{unr}$  in radians):

$$\frac{\lambda_{unr}}{\pi} = 0.247 + 0.236 \log_{10} \frac{S}{B} \quad [12]$$

Rewriting equation 9 yields to:

$$p = \sigma_b \cdot e^{\frac{2k_{ap} \tan \phi' r}{B}} + \frac{2c' - \gamma B}{2k_{ap} \tan \phi'} (e^{\frac{2k_{ap} \tan \phi' r}{B}} - 1) \quad [13]$$

The values of  $\sigma_b$  and  $\sigma$  are calculated by equations 10 and 11, respectively, using appropriate values of  $\lambda$  and  $\theta$  for the reinforced and unreinforced cases.

The case in which a series of repairs are made is schematically presented in Figure 10. The same approach presented above can be used and in this case the load capacity after the second repair can be obtained by:

$$p = \sigma_a \cdot e^{\frac{2k_{ap} \tan \phi' r}{B}} + \frac{2c' - \gamma B}{2k_{ap} \tan \phi'} (e^{\frac{2k_{ap} \tan \phi' r}{B}} - 1) \quad [14]$$

with:

$$\sigma_a = \sigma_b \cdot e^{\frac{2k_{acv} \tan \phi'_{cv} r_0}{B}} + \frac{2c'_{cv} - \gamma B}{2k_{acv} \tan \phi'_{cv}} (e^{\frac{2k_{acv} \tan \phi'_{cv} r_0}{B}} - 1) \quad [15]$$

where  $r_0$  is the depth of the first rut repaired (corresponding to block A'B'CD, in Fig. 10),  $r$  is the depth of the second rut repaired (block ABB'A', in Fig. 10) and  $k_{acv}$ ,  $c'_{cv}$  and  $\phi'_{cv}$  are the fill active earth pressure coefficient and strength parameters under constant volume, which are the relevant ones for the shear strength along the

vertical planes of the first rut (already failed). Similar expressions can be developed for a number of repairs greater than 2 if the subgrade continues to control the failure mechanism. As the fill becomes thicker failure may take place inside the fill material itself (Palmeira and Ferreira Jr., 1994).

Figure 10. Two successive repairs of the road surface.

### 3.2 Comparisons Between Predicted and Observed Values of Road Bearing Capacity After Maintenances

Predictions by the methodology developed above were compared with model test results presented in the literature (Cunha 1991; Palmeira and Cunha 1993; Palmeira and Ferreira Jr. 1994; Ferreira Jr. 1995). These model tests are schematically shown in Figure 11. Different types of soils were used as fill materials ( $\gamma = 16$  to  $18 \text{ kN/m}^3$ , mean particle diameter ( $D_{50}$ ) =  $0.13$  to  $1.20 \text{ mm}$ , coefficient of non uniformity =  $1.6$  to  $36$ ,  $c' = 0$  to  $2.9 \text{ kPa}$ ,  $c'_{cv} = 0$ ,  $\phi' = 35$  to  $50^\circ$  and  $\phi'_{cv} = 31$  to  $38^\circ$ ). Up to three surface repairs were made on the road surface in some cases, as shown in Figure 10. The soft subgrade consisted of a saturated layer of kaolin. A rigid metal footing (plane strain conditions) provided the load on the road surface which was applied at a undrained constant rate of displacement. A model needle-punched nonwoven geotextile ( $75 \text{ g/m}^2$ , thickness =  $0.5 \text{ mm}$ , wide strip tensile strength =  $3.3 \text{ kN/m}$ , tensile strain at failure =  $70\%$  and tensile stiffness =  $4.9 \text{ kN/m}$ ), made of polyester, was used in the reinforced tests. This reinforcement would simulate an extensible geotextile presenting a tensile stiffness of the order of  $60 \text{ kN/m}$  in prototype conditions. Additional information on the materials used and testing methodology can be found in Palmeira and Cunha (1993) and in Palmeira and Ferreira Jr. (1994).

Figure 12 shows comparisons between predicted and observed values of  $p/C_u$  at failure for each loading stage. The value of the undrained strength at a depth equal to  $B$  was used to normalize the values of footing pressure in Figure 12. A reasonably good agreement can be observed

between predicted and observed values of  $p/C_u$  and the scatter can be partially explained by the scatter of the values of undrained strength besides some limitations of the approach.

Figure 11. Schematic view of the model tests performed.

Figure 12. Comparisons between predicted and observed values of  $p/C_u$ .

#### 4 CONCLUSIONS

This paper presents some aspects regarding geotextile deformation during unpaved road construction and bearing capacity of this type of road after surface maintenance. It is observed that significant strains can be mobilized in extensible geotextiles during road construction on very soft subgrades. A methodology is presented for the estimate of these strains. In spite of the limited amount of data available, results from model tests and finite element analyses compared well with predicted values of the variation of geotextile strain ( $\epsilon$ ) with the normalized settlement at the soft soil surface ( $S/B$ ).

The presence of the geosynthetic has a marked effect on the bearing capacity of the unpaved road after maintenances. A proposed methodology has also been presented which improves a similar methodology previously presented in Palmeira and Cunha (1993). Good comparison was observed between predictions by this methodology and model tests results.

# Numerical Analysis of a Pavement Base Reinforced with Geogrid

Mauricio Abramento

IPT- Instituto de Pesquisas Tecnológicas do Estado de São Paulo, Brasil

**ABSTRACT:** This paper presents results of a detailed numerical analysis, using the finite differences software FLAC, comparing the behavior of an unreinforced and geogrid reinforced pavement base. The study was developed for designing a flexible pavement (pavers over crushed stone and sand) to be built in an intermodal yard located in Brazil. Preliminary studies showed that the crushed stone layer collapses under the high imposed loads (transtainers with design wheel load of 35tf), suggesting its reinforcement with geogrids. The results of numerical analysis showed that the pavement performance improved substantially with three layers of geogrid (long-term strength of 50kN/m) evenly spaced in the crushed stone, inhibiting plastification of the materials and reducing the magnitude of plastic displacements at surface.

**KEYWORDS:** Geogrid, Base reinforcement, Pavement, Numerical analysis.

## 1 INTRODUCTION

One of the many applications of geosynthetics is reinforcement of coarse material for sustaining heavy loads. For example, Walls and Galbreath (1987) present a case of ballast reinforcement with geogrid, while Raymond et al. (1993) show the use of a layer of geogrid for reinforcing a sand for gantry cranes tracks. This paper presents results of a detailed numerical analysis, using the finite differences software FLAC, comparing the behavior of an unreinforced and geogrid reinforced pavement base. The study was developed for designing a flexible pavement to be built in an intermodal yard located in Brazil. Very heavy vehicles (transtainers) for handling containers from large ships will circulate in the area. The vehicles have a very high design wheel load of 35tf, corresponding to an unusual applied pressure on the pavement of about 12kgf/cm<sup>2</sup>.

## 2 PAVEMENT LAYERS

Figure 1 shows the pavement system and main soil layers involved in the problem, from top to bottom: a) 15cm thick high strength articulated concrete blocks (pavers); b) crushed stone compacted with high energy (pavement base), with thickness to be determined, ranging from 0.6m (geogrid-reinforced) to 1.2m (unreinforced); c) 3.0m thick dense sand; and d) 8.0m thick compressible clay layer. Geotechnical and pluviometric peculiarities resulted in this system, in particular large differential settlements expected due to consolidation of the soft clay layer. The pavement

Figure 1. Pavement system (not to scale)

system should act as a reservoir, holding large volumes of water from heavy rainfalls. A numerical analysis was carried out to assess the stability and possible reinforcement of the crushed stone layer, considering heavy wheel loads.

## 3 SOIL PARAMETERS

In order to analyze the pavement behavior, it is necessary to estimate the strength (friction angle) and deformability parameters for the sand and the crushed stone layers. The friction angle is the most important parameter, since it indicates the possibility of failure of pavement as well as magnitude of plastic displacements due to the wheel load.

The following equation, proposed Barton and Kjaernsli (1981) was used for determining the crushed stone peak friction angle  $\phi_p$ :

$$\phi_p = R \log (S/\sigma'_n) + \phi_b \quad (1)$$

In this equation, R is a particle shape factor (which depends on the crushed stone porosity after compaction), S is a factor depending on the unconfined compressive strength of the original rock (gneiss),  $\sigma'_n$  is the mean confining stress, and  $\phi_b$  the residual friction angle of crushed stone. Depending on the position of the wheel, two conditions for confining stresses were considered. Far from the wheel, stresses due to compaction prevail in the crushed stone (estimated as 0.1MPa) and immediately under the wheel the static load from the transtainer is dominant (1.0MPa). Stiffness of the crushed stone was estimated from the literature. For the sand, the strength and deformability parameters were determined from triaxial compression tests. Table 1 summarizes the parameters used in the analysis:

Table 1. Parameters used in the numerical analysis.

Condition	Crushed Stone		Sand	
	E (MPa)	$\phi_p$	E (MPa)	$\phi_p$
minimum $\sigma'_n$ (far from wheel)	300	55°	170	37°
maximum $\sigma'_n$ (under wheel)	100	46°	140	33°

In all FLAC analyses, the Mohr-Coulomb constitutive model was used for simulating the behavior of dense sand and crushed stone layers, while elastic model was considered for the reinforcement layers. The effect of dilatancy for the dense sand and crushed stone layers was explicitly included in all analyses. The Poisson's ratio was assumed as 0.33 for both materials.

#### 4 UNREINFORCED CRUSHED STONE BASE

The bearing capacity of the unreinforced crushed stone was initially verified through the classical Terzaghi (1943) formulation, considering a cohesionless soil and rectangular load at the surface. The  $N_y$  factors were determined as proposed by Kumbhojkar (1993) for the range of friction angles assumed in the analysis. The safety factor with respect to general failure for the crushed stone decreases from as high as 7.7 considering small confining pressures (far from the wheel load in Table 1), to as low as 0.96 for high confining pressures, immediately under the wheel. The results suggested that the crushed stone could

be reinforced in order to avoid its plastification due to the heavy loads prevailing in the pavement.

The thickness of the crushed stone layer determines the magnitude of loads on the dense sand layer underneath. This problem was analyzed supposing the stress distribution proposed by Giroud and Noray (1981). The results indicated that the crushed stone layer should be over 80cm thick in order to yield a factor of safety  $FS > 2.0$  with respect to bearing capacity for the sand layer, and over 100cm for  $FS > 3.0$ . If the sand is required to work within elastic conditions, it is generally recommended a high value of factor of safety with respect to bearing capacity. These results motivated the use of reinforcement layers in the crushed stone.

#### 5 GEOGRID REINFORCED CRUSHED STONE BASE

In order to minimize plastic deformations and rutting, and maximize safety factor against failure for the crushed stone and dense sand layer, reinforcement the crushed stone layer is proposed. The use of three layers of geogrid within the crushed stone layer was preferred in order to achieve better stress distribution (Huang and Tatsuoka, 1990). A single layer of reinforcement could also be used in the crushed stone, but the stress redistribution in the layer would not be as much efficient, and the loads carried by the geogrid would be much higher.

Loads in the reinforcement layers were initially quantified using the analytical model proposed by Binquet and Lee (1975). In this model, the loads along the reinforcements are expressed as a function of the depth, number and spacing of reinforcements, width of applied load and bearing capacity of the soil. The crushed stone layer was taken as 60cm, in order to verify the efficiency of the reinforcement on the bearing capacity of the sand layer. Considering three layers of reinforcements evenly spaced in the crushed stone at 20cm, loads in the reinforcements were estimated as varying from 47kN/m for the top layer to 56kN/m for the bottom layer.

Both the unreinforced and reinforced 60cm crushed stone behavior were further analyzed using the finite differences program FLAC (Fast Lagrangian Analysis of Continua). This program, developed by Itasca Consulting Group (USA), allows flexibility in modeling the behavior of the many materials involved (crushed stone, sand, reinforcement layers). Figure 2 shows the grid used in the numerical simulation. Conditions presented in Table 1 were analyzed, each one with and without reinforcement, resulting a total of four cases. The following properties were considered for the reinforcement layers, corresponding to those of commercially available geogrids: Elastic modulus 500MPa, thickness 2.5mm and ultimate tensile strength 100kN/m. These values do not account for installation damage.

Figure 2. Grid for FLAC analysis.

The following additional hypotheses were considered for the problem: plane strain conditions, Mohr-Coulomb plastification criteria for both the sand and crushed stone and elastic behavior for the reinforcements. Only half of the geometry was considered in the grid due to symmetry of the problem (Figure 2).

Results are presented in Figures 3 and 4 for the critical case of minimum strength parameters presented in Table 1 (immediately under the wheel), without and with reinforcement, respectively. Basically, the failure mechanism for the unreinforced crushed stone observed in the analytical model is confirmed in the numerical analysis, as shown in Figure 3. In this case, there are large upward displacements at the surface and downward displacements immediately under the wheel. There is a general plastification in both crushed stone and dense sand layers. The results show that introducing three reinforcements in the crushed stone layer is very efficient, inhibiting almost completely plastification in both crushed stone and dense sand layers, as shown in Figure 4. Displacements at the surface and within the layer are also drastically reduced. The loads in the reinforcement layers vary from 47kN/m for the bottom layer to 24kN/m for the superficial layers. The maximum value for the axial load in the bottom layer compares relatively well with the one determined with the analytical model of Binquet and Lee (1975), while their model overestimates the loads for the more superficial reinforcement layer. Table 2 summarizes the results obtained in the numerical analysis. In general, the results show that reinforcement is generally more efficient in the critical case of minimum peak friction angle, when loads along geogrids and benefits in the system are maximized.

Figure 4. FLAC results, reinforced crushed stone case. Legend: Max. displacement vector=4.5cm. Plastification: \* At yield; X Elastic. Reinforcements load distribution also shown.

Table 2: Summary of numerical analyses and results.

Case	Maximum displacements (cm)	Plastification	Geogrid loads (kN/m)
1: $\phi$ p max unreinf.	1.9	localized	-
2: $\phi$ p max reinf.	1.8	no	5.5 to 9.5
3: $\phi$ p min unreinf.	>30	generalized (failure)	-
4: $\phi$ p min reinf.	4.5	no	24 to 47

## 6 GEOGRID CHARACTERISTICS AND INSTALLATION

In order to choose the correct reinforcement, it is necessary to multiply the maximum loads determined in the numerical analyses by a general factor of safety. One of the most important aspects to be accounted for is the installation damage of reinforcement, since very high energy will be employed for compacting the crushed stone layer. The amount of damage should be assessed by means of large scale laboratory tests. For example, Watts and Brady (1994) carried out a series of high energy compaction tests using crushed stones over geogrids, suggesting factor of safety against damage varying from 1.3 to 1.7. Koerner (1993) also suggests FS values in this range. Creep, chemical and biological damage should also be taken into account for determining the suitable reinforcement. In order to minimize the effects of installation damage, the reinforcement could be placed within two thin layers of grit, avoiding direct contact of the coarse material with the geogrid layers for improved protection.

## 7 CONCLUSIONS

This paper presents results of a numerical analysis with FLAC on the behavior of unreinforced and geogrid reinforced pavement base to be constructed in a intermodal yard. The results show that the unreinforced crushed stone base collapses under the high imposed loads, suggesting its reinforcement with geogrids. The number and position of geogrid layers were initially estimated using simplified closed-form solutions originally developed for reinforcement of shallow foundations, which resulted in a reinforcement configuration consisting of three layers of geogrids with long-term strength of 50kN/m evenly spaced within the crushed stone base. Results of numerical finite difference analyses on this reinforcement configuration showed that the pavement performance improved in the

following ways: a) inhibiting the plastification of the crushed stone base and the dense sand layer; b) reducing the magnitude of plastic and elastic displacements at the pavement surface and within the layers; and c) reducing the thickness of the crushed stone base from 1.2m to 0.6m, without causing collapse of the dense sand layer underneath. The introduction of reinforcement could also drastically reduce maintenance frequency, one of the major aspects related to container terminal management (Meletiou and Knapton, 1987).

**ABSTRACT:** A number of 1g laboratory model footing tests have been carried out to find out which geosynthetics and methods of placement are optimal for giving sufficient bearing capacity for both the trafficability of construction machines and the construction of earth structures on soft soils. To study the effect of sand mat placement, in particular, a numerical simulation was performed using a procedure in which the Sekiguchi-Ohta constitutive model for soft clay was combined with a truss element for the geogrid and Goodman's joint element for interaction between the sand and geogrid. Based on Biot's theory of three-dimensional consolidation, a finite element model was formulated to analyse the deformation and failure mode of the soft clay in the laboratory model tests both with and without the geogrid and sand mat. Typical results from the calculations give a good prediction of the effectiveness of sand mat placement for decreasing settlement, and, therefore, improving the bearing capacity of soft clay. It is concluded that this must be due to an increase in bending stiffness caused by combining the sand mat with the geogrid.

## 1 INTRODUCTION

In previous papers (Hirao et al., 1992; Yasuhara et al., 1994), the authors have emphasized that composite geosynthetics which are non-woven geosynthetics reinforced with woven geosynthetics in-between are best for improving the bearing capacity of soft clay. This composite geosynthetic has a higher tensile strength than the non-woven geosynthetic hitherto used, and in addition has the advantage of giving high friction in soft clay (Hirao et al., 1992). There is no significant improvement in bearing capacity when a geogrid is placed directly over the surface of a soft clay, because the frictional force developed between the geogrid and soft clay is very small (Hirao et al., 1992) and it cannot follow the large deformations of the soft clay.

In order to establish a suitable procedure for the use of geogrids to improve the bearing capacity of soft clay, 1g laboratory model tests were conducted. In particular, a focus was placed on which effect of (i) restraintment, (ii) combination with woven or non-woven geosynthetics and (iii) combination with sand mat contributes most to increasing bearing capacity.

## 2 EXPERIMENTAL PROGRAMME

### 2.1 Outline of Model Tests

A soil tank with 2 m width, 0.5 m length and 1.0 m depth, as illustrated in Fig. 1, was used for the model tests. The properties of the clay were:  $G_s = 2.62$ ,  $w_L = 107\%$ ,  $I_p = 66$ . Details are given in previous papers (Hirao et al., 1992, 1996). Soft clay mixed with water to a moisture content  $w_i$  of 130% was poured into the soil tank to form a 40cm or 80cm thickness clay layer. The average vane shear strength of the model clay layer after

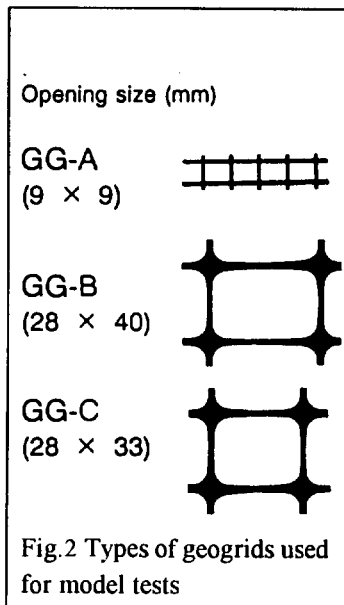

Fig. 1 Testing apparatus for model tests

pouring was 0.5 kPa and was almost constant with depth.

A layer of geogrid was firstly placed directly over whole the surface of the clay layer with a 2m width and 0.5m length. Then a sand mat of 3cm thickness was laid onto the geogrid. To obtain the load versus settlement curves, several kinds of model footing tests were carried out in which step loads were applied to the soft clay reinforced with a geogrid. For comparing the effects of different reinforcements, plate loading tests were also conducted on soft clay without a sand mat and geogrid as well as tests with the combined use of geogrids with non-woven geofabrics.

A vertical load of 1.0 kPa was applied in each step to a plate 10cm wide, 49cm long and 48 Pa in weight until the clay layer failed. The loading duration of each step was 15 min.

A lateral restraint was provided by a tension force developed by a counter weight on the edge of geogrids as is shown in Fig. 1.

## 2.2 Properties of Geogrids Used

Table 1 summarizes the mechanical properties of the three kinds of geogrids used. The differences between the three geogrids illustrated in Fig. 2 were in the size of the opening, tensile strength, frictional force and bending stiffness of which the later two were determined using methods proposed by Hirao et al. (1992, 1996).

Table 1 Mechanical properties of geotextiles used

Material	Symbol	Thickness or Opening (mm)	Bending Stiffness $B_G$ ( $N \cdot cm^2$ )	Stiffness $l$ (cm)	Description
Woven Fabric	WF	0.5	9.3	11.3	-----
Composite Fabric	CF-B	4.0	11.3	16.0	-----
Geogrid	GG-A	9×9	23.1	33.9	-----
	GG-B	28×40	129.4	75.3	-----
	GG-C	28×33	185.2	85.3	-----

As will be mentioned later, the size of the opening is an important factor in the improvement of the bearing capacity of soft clay because of its relation to the magnitude of mobilized friction and the interlocking effect.

## 3 RESULTS FROM EXPERIMENTS

The bearing capacity for reinforced models is defined by the applied load at the yielding point,  $p_{y,n}$  for non-reinforced and  $p_{y,r}$  for reinforced cases in the settlement,  $S$ , versus load,  $p$ , curves. The results relating to the improvement of the bearing capacity of soft clays reinforced with geogrids were taken from the model

Fig. 3 Representative  $p$  vs.  $S$  curves obtained by model tests

Fig. 4 Effect of bending stiffness on increase in bearing capacity of soft clay

tests described in the previous section. Figs. 3 to 6 illustrate the effects of the above-mentioned factors on the settlement,  $S$ , vs. vertical stress,  $p$ , curves.

As can be seen in Fig. 3, the bearing capacity with no reinforcement is very small because the model ground consists of extremely soft clay. A small increase in bearing capacity can be observed in Fig. 3 due to the size of the geogrid's mesh.

The ratio of the bearing capacity,  $p_{yr}$ , of soft clay improved by reinforcement with geogrids to that,  $p_{ym}$ , for no geogrids, is denoted by  $R_p$ . Fig. 4 and Fig. 5 show the effects of both the bending stiffness of geogrids and the stiffness of woven and composite geofabrics, respectively. It can be seen from these results in Figs. 4 and 5 that the placement of a geogrid with a large bending stiffness does not necessarily increase the bearing capacity of soft clay, although the bending stiffness of the geogrid is larger than the composite geofabric. This tendency is irrespective of the thickness of the clay (Hirao et al., 1996). On the other hand, it is also seen from these figures that a combination of sand mat with each geosynthetic markedly increases the bearing capacity, independent of the kind of geosynthetic. The reason for these differences will be discussed later.

Fig. 5 Relation between initial bending stiffness and bearing capacity with and without sand mat

#### 4 EVALUATION OF SAND MAT EFFECT USING FEM ANALYSIS

##### 4.1 Analysis of Laboratory Model Tests

A FEM analysis of the behaviour of an embankment on soft clay with and without geogrids and sand mats was conducted using a model incorporating the effect of the interaction of the geogrid

and soft clay, as summarized in Table 1. The analytical procedure used the elasto-visco-plasticity model developed by Sekiguchi and Ohta (1977) for clay, by using a beam element for modeling the geogrid and a joint element for the interaction between geogrid and soil, respectively. The model also incorporated Biot's theory of three-dimensional consolidation for a coupled analysis. In a previous paper (Tanabashi et al., 1992), the model was successfully applied to the results from model footing tests on soft clay with and without geogrid and sand mat.

The geometry of the model analyzed is shown in Fig. 6 and corresponds to the laboratory model test where the width of the loading plate  $B$  was 10 cm, the depth of the clay layer  $D$  was 40 cm and the thickness of the sand layer was 3 cm. The analysis focused on the effect of the sand mat on the improvement of bearing capacity of a soft clay with and without a geogrid. The embankment on clay was modeled with and without sand mat

Fig. 6 Finite element mesh and boundary condition used for model tests

Fig. 7 Comparison of  $p$  vs.  $S$  curves for model tests with and without sand mat

and geogrid and was divided into 210 nodes and 200 elements for the FEM analysis as is also shown in Fig. 6. The boundary conditions for displacement were complete restraint on the bottom and horizontal restraint on lateral surfaces. In addition, the hydraulic boundary conditions were assumed to be drained at the bottom and surface and undrained on the sides. The parameters necessary for the present analysis were determined indirectly from plasticity indices, as proposed by Iizuka and Ohta (1987). The settlement versus load curves calculated using the FE analysis based on the Sekiguchi and Ohta model (Sekiguchi and Ohta, 1977) were compared in Fig. 7 with those observed in laboratory model tests which includes the results without geogrid and sand mat. Fig. 7 suggests that the method proposed for analyzing the reinforcement effect gives a reasonable prediction of the settlement versus load relations with and without geogrid and sand mat.

The model was also capable of simulating the deformation of the soft clay model both with and without reinforcement. Fig. 8 illustrates a family of results from model tests with and without a sand mat under an applied load,  $q = 8.4$  kPa. It can be seen

Fig. 8 Typical deformation diagrams obtained from numerical simulations

from Fig. 8 that in the case of soft clay alone or with a geogrid the ground deforms as if it is failing, while for soft clay with a geogrid and sand mat the settlements and lateral displacements are clearly restrained. This is due to the composite effect in which the sand mat restricts the movement of the geogrid and thus produces an increase in bearing capacity.

#### 4.2 Numerical Verification for Field Conditions

Numerical experiments using the proposed model were carried out to demonstrate the effect of a sand mat on the improvement of the bearing capacity of soft clay with a geogrid, under in-situ conditions with a typical profile just like as under model footing test condition as illustrated in Fig. 7. For this calculation, the following conditions were assumed: (i) depth of clay layer,  $D$ , 4, 6, 8, 10, 12 m; (ii) depth of clay layer to loaded area ratio,  $D/B$ , 1.33, 2.00, 2.67, 3.33, 4.00, and; (iii) the thickness of sand mat was kept constant equal to 30 cm. The boundary and drainage

Fig. 9 Typical  $p$  vs.  $S$  curves obtained from numerical simulations

Fig. 10 Calculated relationship between  $p_y$  and  $D/B$

Fig. 11 Calculated relationship between maximum upheaval,  $h_{max}$  and  $D/B$

Fig. 12 Relation between normalized critical distance,  $L_1/(B/2)$  and  $D/B$

conditions were the same as those adopted in the analysis of the laboratory model tests. Typical settlement versus load relations for  $D/B = 2.67$  are shown in Fig. 9. The effect of geogrid and geogrid with sand mat on settlement control in soft clay is illustrated in the  $p$  versus  $S$  curves in Fig. 9 by the fact that the settlement increases linearly beyond the yield point with increasing applied loads, but increases abruptly in the case of no reinforcement. However, it is interesting to note that this yielding load becomes larger for reinforced compared with unreinforced models but is independent of the  $D/B$  as shown in Fig. 10. It is also notable that the bearing capacity improvement

due to a sand mat combined with a geogrid is considerable. The applied yielding load, increases by up to 1.8 times compared with no reinforcement. The advantage of a sand mat with geogrids is also observed in the deformation of soft clay under applied load. The amounts of maximum settlement, maximum heave and lateral distance of heave in soft clay are shown in Fig. 11 and Fig. 12 for cases with and without sand mat and geogrid. It is concluded from these comparisons that both settlement and lateral displacement of soft clay reinforced with geogrid and sand mat are not influenced by  $D/B$ .

The results calculated using the proposed model are presented in Fig. 13 in the form of the relation between  $S/D$  and  $d/S$  which is conventionally used for the stability control of soft clay under embankments (Matsuo and Kawamura, 1977). In this representation, it is assumed that soft clay fails when a  $S/D$  versus  $d/S$  path reaches the line for  $1/F = 1$  where  $F$  is a safety factor for stability. When we read off from data in Fig. 13, obtained by calculating for cases with and without a sand mat and  $D/B = 2.67$ , it is clear that the applied load  $p_{pr}$  for  $F = 1$  with sand mat and geogrid is larger than that for no reinforcement.

Fig. 13 Calculated relationship between  $S/D$  and  $d/S$

## 5 CONCLUSIONS

- 1) The direct placement of geogrids on the surface of a soft clay does not improve its bearing capacity.
- 2) There is little increase in the bearing capacity of a soft clay if a tensile force is applied by weighting the edge of a geogrid. The reason for no improvement is due to either the frictional

force or the interlocking effect being not exerted between the geogrid and clay.

3) Combined non-woven geosynthetics with geogrid gives an advantage by increasing bearing capacity.

4) The bearing capacity is markedly improved by an underlying sand mat combined with a geogrid. This effect is caused by an increase in bending stiffness of the composite of geogrid and sand mat as well as the higher frictional force developed between sands and geogrids compared with a geogrid only.

5) The effect of a sand mat on bearing capacity improvement and displacement control in soft clay has been successfully analyzed using a modified model which incorporates the effect of the interaction of the geogrid and sand mat.

#### ACKNOWLEDGEMENT

The authors would like to express their gratitude to Ikegami, M. (the executive director of Mitsui Petrochemical Industrial Products Co., Ltd.) who offered some kinds of geosynthetics and the 1g model footing testing apparatus used in this study.

# The Bearing Capacity of a Reinforced Sand Layer Overlying a Soft Clay Subgrade

M.J. Kenny

Lecturer, Department of Civil Engineering, University of Strathclyde, Glasgow, UK

**ABSTRACT:** Recent interest has developed in the use of geosynthetics for forming a fill layer over soils which have very low bearing capacity. However, the reinforcement mechanism is not clearly understood. A programme of laboratory scale plane-strain bearing capacity tests under monotonic loading has been carried out which considers the reinforcing mechanism of the geosynthetic. Analysis of the test results show that the interpretation of the reinforcing mechanism is highly dependent upon the values assumed for the various model parameters. The results further suggest that in order to function effectively as a reinforcement over very soft clays, the geosynthetic should possess a significant component of in-plane bending stiffness.

**KEYWORDS:** Bearing capacity, Reinforcement, Shallow foundations, Soft soils, Unpaved roads.

## 1 INTRODUCTION

Recent interest has developed in the use of geosynthetics for forming a fill layer over soils which have very low bearing capacity, so that a construction platform can be formed. Although the technique has been successful in practice, there has been considerable disagreement concerning the reinforcement mechanism. After carrying out dimensional analysis of model loading tests, Fakher et al. (1996) concluded that the in-plane bending stiffness is the dominant factor when constructing over very soft soils. However, the current design methods for unpaved roads consider only tensile stiffness in the analysis of the mechanisms of reinforcement.

Many of the design methods have been developed from laboratory scale plane-strain bearing capacity tests under monotonic loading. This paper reports the results of a programme of such model tests carried out at the University of Strathclyde. Although the reinforcement used possessed insignificant bending stiffness, analysis of the reinforcing mechanism has allowed consideration of the relative importance of both tensile and bending stiffness in the bearing capacity of a reinforced sand layer over a soft clay subgrade.

## 2 BACKGROUND

In recent years, two different approaches have been adopted for the design of unpaved roads. The first approach is typified by the design method of Giroud and Noiray (1981). It attributes the improvement in the road performance to the reinforcement acting as a tensioned membrane as rutting develops and an increased subgrade bearing capacity due to subgrade confinement. Burd (1995) further developed membrane theory to produce a model in which the deformed reinforcement shape is obtained from a set of membrane equations. In contrast, the second

approach proposed by Milligan et al. (1989) neglects membrane action but considers that the reinforcement reduces the shear stresses developed at the surface of the subgrade, thus increasing the subgrade bearing capacity. It is thus more appropriate for small deformations. Despite these differences, the two approaches have the following common features :

1. They are derived from a stress distribution model common in the bearing capacity analysis of layered soils (Kenny and Andrawes, 1997). Giroud and Noiray (1981) assume a value of  $\tan^{-1}0.6$  for the stress distribution angle  $\alpha$  (see Figure 5) for both the unreinforced and reinforced road, while Milligan et al. (1989) state that the stress distribution angle should be derived from observation and experience.
2. The allowable subgrade bearing capacity is greater in the reinforced than in the unreinforced case. Both Giroud and Noiray (1981) and Milligan et al. (1989) have proposed modified subgrade bearing capacity factors.
3. The recommended stress distribution angles are the same in both the unreinforced and reinforced cases, although the presence of the reinforcement has been shown to improve the stress distribution.

## 3 EXPERIMENTAL SET UP

A strip footing 0.12 m wide was used in all tests. The test tank has inner dimensions of 2.0 m length, 1.4 m height, and 0.3 m width and parallel glass sides, as shown in Figure 1, and contained a soft clay subgrade overlain by Leighton Buzzard sand. The displacement fields were recorded at intervals of 10 mm footing penetration and analysed using the stereo-photogrammetric technique.

The soft clay subgrade was simulated by an artificial clay known as Glyben (Kenny and Andrawes, 1997), which is manufactured by mixing a sodium-bentonite clay

Figure 1. The experimental set up.

(Fulbent 570) and glycerine, the resulting shear strength depending on the mix proportions. A large number of undrained triaxial tests and vane shear tests were carried out over the period of the study, which demonstrated that Glyben behaved generally as a  $\phi_u = 0$  material under quick undrained loading, with an average  $c_u$  of  $10.6 \text{ kN/m}^2$ . Since Glyben samples are formed by compaction, the material unavoidably contains a small proportion of trapped air (approx. air voids content = 8%). However, the material was completely insensitive to handling and gave excellent repeatability during testing.

The fill material used was a uniformly graded coarse Leighton Buzzard sand placed using an air activated spreader in a dense state, with a mean porosity of 34.5% (porosity limits ; 34.0% - 44.5%). The operational angle of friction  $\phi'$  for the sand placed at this density was found to be  $48.5^\circ$ .

The reinforcement of the upper sand layer was provided by a single layer of geogrid type reinforcement placed at the sand-clay interface. Although no attempt was made to correctly scale all aspects of the problem, the reinforcement used can be considered to be a reduced scale model geogrid. It consists of welded polypropylene filaments of 0.5 mm diameter with grid openings of  $6.1 \text{ mm} \times 7.1 \text{ mm}$  on average. The load-extension properties of the geogrid were investigated using a range of strain rates of relevance to the current investigation.

In the experimental programme, bearing capacity tests were carried out for clay subgrade alone ( $H/B = 0$ ), and with and without the reinforcement layer for  $H/B$  ratios of 0.25, 0.75, 1.0, 1.5 and 2.0.

#### 4 EXPERIMENTAL RESULTS

The stress-settlement relationships for unreinforced and reinforced sand overlying clay shown in Figure 2 are representative of the test programme as a whole. Since

Figure 2. Stress-settlement relationships for unreinforced and reinforced sand over clay.

there is no observable post-peak, strain softening for the clay alone, this stress-settlement behaviour is consistent with a local shear failure of the subgrade due to the compressibility of the material. For unreinforced sand over clay, the ultimate stress can be more readily identified from the peak in the stress-settlement curve, particularly for large  $H/B$  ratios. As for clay alone, there is no clearly defined failure point in the reinforced case. In unpaved road design, a maximum rut depth (i.e. footing settlement) is a more appropriate criteria.

The displacement fields recorded during the later stages of footing penetration are given in Figures 3 and 4 for  $H/B$  ratios of 0.5 and 2.0 respectively. In general it was observed that for small sand depths the deformation of the sand/clay interface was more uniform when reinforcement was present. This indicates improved stress-distribution in the reinforced case. There was also a tendency for the sand beneath the footing to be displaced outwards when no reinforcement was present, particularly for large sand depths and at low footing settlements. This lateral displacement reduced when reinforcement was used. This is consistent with observations of Milligan et al. (1989), but the effect was less pronounced.

Figure 3. Displacement vectors for  $H/B = 0.5$  (Footing settlement,  $S/B = 42-58\%$ ).

Figure 4. Displacement vectors for  $H/B = 2.0$  (Footing settlement,  $S/B = 42-58\%$ ).

Figure 5. Analysis of membrane forces (after Gourc, 1983).

## 5 THE REINFORCEMENT MECHANISM

If we consider a typical stress distribution model with membrane action, as shown in Figure 5, the contribution of the reinforcement tension to the bearing capacity can be

calculated. Since very little subgrade heave was observed during footing penetration, the membrane analysis proposed by Gourc (1983) assuming four circular segments was adopted. This method is sufficient for illustrative purposes, although Burd (1995) gives a more rigorous treatment of reinforcement equilibrium.

From Figure 5 it can be seen that the contribution to the bearing capacity from stress distribution through the upper sand layer,  $q_d$ , is:

$$q_d = q_c \frac{B'}{B} \quad (1)$$

The subgrade reaction  $q_c$  was taken from the clay alone curve in Figure 2 at the same footing settlement. The membrane force which opposes the applied stress is equivalent to the vertical projection of the reinforcement tension at the stationary points. The maximum reinforcement tension is limited by the anchorage capacity.

Denoting the contribution to the bearing capacity due to membrane action by  $q_m$ , it follows that:

$$q_m = 2T \sin \theta / B \quad (2)$$

The angle  $\theta$  and the reinforcement strain depends on the footing settlement,  $S$ . Having determined the strain in the reinforcement and estimating the strain rate from the rate of penetration of the footing, the tension  $T$  was obtained from the load-strain properties of the reinforcement. The bearing capacity of the footing,  $q$ , can be determined by summing the contributions from stress distribution,  $q_d$ , and membrane action,  $q_m$ . The bearing capacities were calculated using a commonly assumed stress distribution angle of  $\alpha = 30^\circ$  and using the actual values measured during the test programme. These are compared with the experimental values,  $q_{exp}$ , in Table 1.

Table 1. Comparison of experimental and predicted bearing capacities for reinforced sand over clay.

Test details			Bearing capacity (kN/m <sup>2</sup> )			
H/B	S/B	B' <sub>r</sub> /B	q <sub>d</sub>	q <sub>m</sub>	q	q <sub>exp</sub>
0.5	0.33	1.58*	78.7	3.7	82.4	71.0
		1.2**	59.9	7.0	66.9	71.0
0.5	0.58	1.58*	78.7	12.2	90.9	92.0
		1.2**	72.7	21.8	94.5	92.0
1.0	0.33	2.16*	107.8	1.8	109.6	81.8
		1.58**	78.6	3.8	82.4	81.8
1.0	0.58	2.16*	130.9	6.0	136.9	103.6
		1.6**	97.0	12.3	109.3	103.6

Note : \* denotes values calculated using  $\alpha = 30^\circ$ ; \*\* denotes values calculated using measured values of  $B'_r$  (distance between points of inflection of sand/clay interface).

It can be seen that by using a stress distribution angle  $\alpha$  of  $30^\circ$ , the calculated membrane forces are approximately 50% of those calculated using the observed values of  $\alpha$ . In addition, the bearing capacity tends to be overpredicted using  $\alpha = 30^\circ$ . A similar analysis of the unreinforced tests gave a larger overprediction, particularly at small displacements when the sand thickness is large, which can be attributed to the lack of lateral restraint of the sand.

## 6 CONCLUSIONS

Based on the experimental results and analysis presented above, the following conclusions can be drawn:

1. In the present investigation, the commonly assumed values of the stress distribution angle were larger than those observed experimentally and resulted in overprediction of the bearing capacity. This seems to oppose the observation of Burd (1995) that the stress distribution angle tends to be greater for soft than firm

clays. This discrepancy could be due to the compressibility of the subgrade.

2. It has often been concluded that the improvements in the load carrying capacity of unpaved roads due to membrane action are insignificant and may therefore be neglected. However, these conclusions appear to be based on the method by which they are calculated rather than on observed behaviour. In the present investigation, the use of a more realistic stress distribution angle rather than the commonly assumed values greatly increased the calculated membrane forces, suggesting that membrane action does make a significant contribution, particularly for small subbase thicknesses. Unpaved road field trials carried out by Sigurdsson and Fannin (1997) confirmed the importance of membrane action for small subbase thicknesses.
3. In reinforcing very soft ground, the contribution to the bearing capacity from the subgrade reaction after load spreading through the fill would be insignificant so that a tensile reinforcement would rely upon membrane action to support the traffic loading. Even assuming that adequate anchorage and subbase-geogrid interlock is maintained, deformation is likely to be excessive under traffic loading. Therefore a geosynthetic with significant in-plane bending stiffness would be beneficial to the performance of the structure.

**ABSTRACT:** Geogrid reinforced sandy soil foundations are often used to improve the supporting capability of soft soil foundations. The vertical load applied on a geogrid reinforced foundation is transmitted to the supporting soil over a wider area, thus, improving the soil's ability to support the foundation load. In order to examine the effect of the vertical load propagation due to geogrid reinforced sandy soils foundation, a series of model loading tests was carried out with different reinforced soil foundation thicknesses and number of geogrids horizontally placed in sandy soils. In addition, a method estimating the effective thickness for geogrid reinforced foundation design is presented based on experimental and theoretical considerations.

**KEYWORDS:** reinforcement, geogrid, soil foundation, vertical load propagation, bearing capacity

## 1 INTRODUCTION

The working platform usually consists of geogrid reinforcement laid within a uniform layer of cohesionless fill on the surface of soft soils. Although a number of methods have been used to construct a fill layer over the soft soil, there seems to be no general agreement with respect to the reinforcement mechanism and load spreading effects.

Reinforced sandy soil foundations with geogrid horizontally placed on soft soil ground are often used to improve the supporting capability of soft soil ground in an economical way. The vertical load applied on the reinforced soil foundations is transmitted to the supporting foundation within a wider area, subsequently, providing the supporting foundation with greater bearing capacity. It is considered that the spreading effects depend on the factors shown in Table 1. It is therefore essential to investigate the properties of vertical load propagation in the reinforced soil foundation with geogrids with reference to the influence factors in

Table 1. Typical factors related to load spreading effects in reinforced sandy soil foundations with geogrid

Term	Influence factors
Reinforced soil ground with geogrid	1. Thickness, 2. Number and position of reinforcement layers, 3. Reinforcement length
Soil property	1. Unit weights of soils, 2. Strength parameters
Geogrid property	1. Tensile strength, 2. Friction property

Table 1. This will develop a rational way of determining the reinforced geogrid soil foundation thickness in practical design. In this paper, the effects of the foundation thickness and the number of reinforcement layers on the spreading effects in reinforced sandy soil foundations with geogrid are investigated using the results of model loading tests and a few theoretical considerations.

## 2 EXPERIMENTAL PROCEDURE

Figure 1 shows the layout of the experiment. On the floor of a 1.08 m wide, 0.4 m deep, 0.8 m high container, twenty-one aluminium blocks (0.05 m wide, 0.4 m long) were lined up.

Figure 1 Experimental setup

Figure 2 Groups of tests

Two elastic springs were fixed under each aluminium block and the vertical deformation of each spring was measured by a dial gauge attached alongside. The elastic springs with an elastic stiffness of  $k=3.14$  (kgf/mm) were used to represent the supporting soil, possessing an elastic modulus of subgrade reaction  $k_g=3077$  kPa/m. The model reinforced soil foundation with geogrid were made of fine gravel. The average dry density was  $16.4$  kN/m<sup>3</sup> and the internal friction angle was 41 degrees (Ochiai et.al.,1994). The tests performed are schematically shown in Figure 2. They consists of the following two cases:

Case 1 aims to study the effects of number of reinforcement layers on the vertical load propagation properties. The spreading effect is also investigated in relation to the thickness of reinforcement layer. Case 2 aims to discuss the spreading effect of vertical load through reinforced gravel foundations with geogrid under different overburden pressures. The tensile strength of geogrid used is 14.7 (kN/m). The size of each model is 1.08 m wide, 0.40 m long and 0.05, 0.1, 0.15 or 0.20 m thick. The loading plate of 0.1 m wide and 0.4 m long is placed on the model reinforced gravel foundation, which is then vertically loaded while controlling displacement. The rate of displacement was 1 mm/min.

Figure 3. Typical vertical stress distribution

Figure 4 Characteristics of load spreading effect related to number of reinforcement layer

### 3 EXPERIMENTAL RESULTS

#### 3.1 Vertical Stress Propagation

Figure 3 shows the vertical stress distribution at the supporting foundation under the reinforced gravel layer with two geogrids (Case 1(b) at  $H/B=1.0$ ) generated by several load intensities  $p$ . It can be seen from this figure that the vertical stress distribution was convex with a maximum vertical stress  $\sigma_{max}$  at the center. It is also obvious that the magnitude of  $\sigma_{max}$  increases with the increasing load intensity  $p$ , and that the magnitude is always smaller than the values of  $p$ .

#### 3.2 Maximum Vertical Stress

Figures 4 and 5 show the effects of number of reinforcement

Figure 6 Definition of effective width BL

Figure 5 Characteristics of load spreading effect related to overburden pressure

## 4 THEORETICAL CONSIDERATIONS

### 4.1 Definition of Effective Width

When loading is applied to a reinforced gravel layer with geogrid, the resulting stress distribution becomes convex with a maximum vertical stress  $\sigma_{max}$  at the center of the base as is schematically shown in Figure 6. Here, in order to reasonably estimate the spreading effects of the reinforced gravel foundation, effective width  $B_L$  is introduced which is defined as an apparent stress distribution width. When considering that  $\sigma_{max}$  is uniformly transmitted to a given supporting subgrade due to a load intensity  $p$ , and then the  $\sigma_{max} B_L$  balances with  $pB$ , the following equation can be given (see Figure 6):

$$pB = \int \sigma dL = \sigma_{max} B_L \quad (1)$$

Eq.(1) can also be rewritten as;

$$\frac{B_L}{B} = \frac{1}{\frac{\sigma_{max}}{p}} \quad (2)$$

As shown in Figures 4 and 5,  $\sigma_{max}/p$  is constant irrespective of load intensity, and it is therefore obvious from Eq.(2) that  $B_L/B$  also becomes constant. In addition, it is important to point out that as the  $\sigma_{max}/p$  becomes smaller and  $B_L/B$  becomes larger, the spreading effect of reinforced gravel layer increases.

When a triangular stress distribution with width  $L_R$  is assumed as shown in Figure 6 which is approximately true (see Figures 4 and 5), the relationship between  $L_R$  and  $B_L$  is represented by

$$L_R = 2B_L \quad (3)$$

layer and overburden pressure on the magnitude of maximum vertical stress  $\sigma_{max}$ . It is found from these figures that 1)  $\sigma_{max}$  decreases with the increasing number of reinforcement layer and overburden pressure (see Figures 4(a) and 5(a)), and that 2) the  $\sigma_{max}$  develops in proportion to the applied vertical stress over a wide load intensity region, irrespective of the two factors mentioned above (see Figures 4(b) and 5(b)), and also that 3) not only the values of  $\sigma_{max}/p$  decrease with the increasing  $H/B$  but also the influence of the two factors on  $\sigma_{max}/p$  gradually decreases with the increasing  $H/B$  (see Figures 4(c) and 5(c)). Similar properties have already been shown in the results of geogrid-mattress loading tests (Ochiai, et. al.,(1994); Yasufuku, et. al.,(1996)).

Figure 7 Schematic view of load spreading effect

#### 4.2 Geogrid Spreading Effects $\Delta B_g$

When a loading plate of width  $B$  is placed on a reinforced gravel layer with geogrid, the applied vertical load is transmitted to the supporting subgrade through the gravel layer. An idea of load spreading is schematically shown in Figure 7. Based on this idea, the total spreading effect  $B_L$  can be divided into two parts: one is geogrid spreading effect  $\Delta B_g$ , which is due to soil-geogrid interaction and the other is  $2H \tan \beta$ , which is due to thickness of gravel layer. Thus, the net spreading effect normalized by  $B$  is given by

$$\frac{B_L - B}{B} = \frac{\Delta B_g}{B} + 2 \frac{H}{B} \tan \beta \quad (4)$$

where,  $\beta$  is defined as spreading angle through a reinforced gravel layer.

The computed relationship between  $(B_L - B)/B$  and  $2H/B$  are shown in Figure 8, together with the experimental data, in which Figure 8(a) indicates the effects of number of reinforcement layers on the net spreading effect, and also Figure 8(b) clarifies the dependence of the effect on the overburden pressure. Here the experimental plots were obtained from Eq.(1) with measured values of  $\sigma_{max}/p$ , and the solid lines are based on Eq.(4), in which spreading angle  $\beta$  was estimated to be 27 degrees, that is  $\tan \beta = 0.5$ , irrespective of number of reinforced layers and overburden pressure. It can be found from these figures that the normalized spreading effect of geogrid  $\Delta B_g/B$ , which is evaluated as the value of  $B_L/B$  at  $H/B = 0$ , increases with the increase in the number of reinforcement layers and overburden pressure, at least in the case of normalized thickness  $H/B$  less than 2. In addition, it can be seen that Eq.(5) can reasonably represent the mechanism of spreading effects in the reinforced gravel layer with geogrid.

Figure 8 Relationship between  $(B_L - B)/B$  and  $2H/B$

#### 4.3 Estimation of Geogrid Reinforced Thickness

In a practical design, it is necessary to properly estimate the thickness of reinforcement layer  $H$  against an allowable bearing capacity  $q_a$  in the supporting soft layer. When  $q_a$  is considered to be  $\sigma_{max}$ , and substituting Eq.(4) into Eq.(1), the following equation is obtained;

$$pB = q_a (B + 2H \tan \beta) + q_a \Delta B_g \quad (5)$$

where  $q_a \Delta B_g$  represents an internal force taken by the reinforcement spreading effect  $\Delta B_g$ . As was discussed by Ochiai et. al., (1986), taking the spreading effect as  $G_e$  and comparing with Eq.(5),  $G_e$  is given by ;

$$\begin{aligned} G_e &= q_a \Delta B_g \\ &= pB - q_a (B + 2H \tan \beta) \end{aligned} \quad (6)$$

Further, considering that  $\tan \beta = 0.5$  ( $\beta = 27^\circ$ ), Eq.(6) is easily rewritten as:

$$\frac{H}{B} = \frac{p}{q_a} \left( 1 - \frac{G_e}{pB} \right) - 1 \quad (7)$$

Figure 9 Chart of determining reinforcement thickness  $H$  against geogrid spreading effect  $G_e$

Figure 10 Idea of load spreading effect

Figure 11 Example of design condition

Figure 9 shows the  $H/B$ - $p/q_a$  relationship calculated from Eq.(7) with various values of  $G_e/pB$ . It is important to note that the estimation of  $G_e$  is needed in order to obtain the thickness of reinforcement layer using Eq.(7). To estimate  $G_e$  in a concrete way, the following assumption can be made; 1) the spreading effects can be produced due to the maximum tensile force  $F_{Tmax}$  in geogrids and the direction is perpendicular to line  $ab$  ( $cd$ ) as shown in Figure 10, that is, the angle between the direction of the force and that of the horizontal plane becomes the load spreading angle  $\beta$  ( $\tan\beta=0.5$ ). 2)  $F_{Tmax}$  can be mobilized by maximum tensile shear stress  $\tau_{max}$  in the range of the load spreading width  $2H\tan\beta$  and 3) the shear stress  $\tau_{max}$  is due to the internal friction between soil and geogrid. A similar idea has been reported by Yang et. al.,(1994).

Base on these assumptions, the tensile force  $F_{Tmax}$  is represented by

$$F_{Tmax} = \tau_{max}(2H \tan \beta) = \sigma_v \tan \delta (2H \tan \beta) = \sigma_v H \tan \delta \quad (8)$$

where,  $\delta$  and  $\sigma_v$  are the friction angle in the soil-geogrid interaction and vertical stress acting on the geogrid respectively. Here, for simplicity  $\sigma_v$  is assumed to be equal to the overburden pressure. Therefore, the spreading effect  $G_e$  in geogrid is estimated by ;

$$G_e = \sum_{i=1}^n F_{Tmax,i} \sin \beta = \sum_{i=1}^n \sigma_{v,i} H \tan \delta \sin \beta \quad (9)$$

where,  $n$  is defined as numbers of reinforcement layer and,

$\sin\beta$  is almost equal to 0.45 from the definition of  $\beta$ . It is easy to understand that when substituting Eq.(9) into Eq.(7), the proper thickness,  $H$ , can be obtained under a certain design condition.

Now, as an application of this model, the following example is considered. The design condition is shown in Figure 11. In this case, the vertical stresses  $\sigma_{v1}$  on geogrid-1 and  $\sigma_{v2}$  on geogrid-2 are evaluated as :

$$\sigma_{v1} = \gamma_1 d_f \quad ; \quad \sigma_{v2} = \gamma_2 (d_f + H) \quad (10)$$

and substituting Eqs.(8), (9) and (10) into Eq.(7), and after some calculation, the thickness  $H$  is computed as follows:

$$H = \frac{-A_2 + \sqrt{A_2^2 - 4A_1A_3}}{2A_1} \quad (11)$$

where,  $A_1 = \gamma_2 \tan \delta \sin \beta$ ,  $A_2 = 2\gamma_1 d_f \tan \delta \sin \beta + q_a$  and  $A_3 = -(p - q_a)B$ . It is important to note that in this case, using this equation, the thickness,  $H$ , is computed as 1.20 m which is about a half compared with the thickness in the case without geogrid ( $G_e=0$ ) which is about 2.18 m calculated using Eq.(7).

## 5 CONCLUSIONS

The vertical load spreading effect of reinforced soil foundation with geogrids is investigated both experimentally and theoretically. The main conclusions obtained are as follows :

1. The vertical load propagation on the surface of subgrade has a convex shape with the maximum vertical stress  $\sigma_{max}$  at the center of applied vertical stress  $p$ .
2. The maximum vertical stress  $\sigma_{max}$  developed is proportional to the applied vertical stress  $p$ . The ratio,  $\sigma_{max}/p$ , is influenced by the thickness of reinforced soil foundations, numbers of geogrids and the overburden pressure.
3. Effective width  $B_e$  is proposed to express the load spreading effect in reinforced soil foundation with geogrid which has two parts: one is geogrid spreading effect and the other is the effect due to the thickness of soil layer.
4. An estimating method is proposed to calculate the thickness of reinforced foundations in design practice using the proposed effective width  $B_e$  and the considered soil-geogrid interaction mechanism.

# Theoretical Solutions for Stress and Strain Fields of a Geosynthetic-Reinforced Foundation Vertically Loaded by a Concentrated Force

Jie Han

Design Engineer, Ph.D., Tensar Earth Technologies, Inc., Atlanta, GA 30328, USA

**ABSTRACT:** Geosynthetics can be used as reinforcements in soils to provide improved bearing capacity and reduced settlement for structural footings or pavement systems. Existence of geosynthetics in a foundation tends to alter the stress and strain fields due to the difference in elastic moduli and strengths between geosynthetics and soils. Geosynthetic-reinforced soil system can be treated as inhomogeneity and inclusion problems as studied in micromechanics of composites. The concept is to represent the inhomogeneities of geosynthetics in soil as the inclusions of eigenstrains in a homogeneous medium. Derivation of the solutions to determine stress and strain fields of the geosynthetic-reinforced foundation vertically loaded by a concentrated load is presented in this paper, in which the Eshelby eigenstrain tensor is introduced.

**KEY WORDS:** Geosynthetic, reinforcement, foundations, inclusion, stress-strain relations.

## 1 INTRODUCTION

Early studies conducted by Binquet and Lee (1975a, b) on geosynthetic-reinforced foundations demonstrated the effectiveness of geosynthetics in increasing bearing capacity of soils. The use of this kind of foundation has attracted more attention in the past few years. A number of model tests have been performed by several researchers (Huang and Tatsuoka 1990; Omar et al. 1994; Yetimoglu et al. 1994). Those tests mainly focused on finding out the optimized configuration of the geosynthetic layers in soil such as the location of the top layer, the spacing between adjacent layers, the width of reinforcement, and the number of layers. However, very few theories have been developed so far to study the mechanisms behind the experimental results. Binquet and Lee (1975b) assumed that the normal and shear stresses along the upper surface of the geosynthetic reinforcement follow Boussinesq's solution. Shukla and Chandra (1994) established a model to analyze the settlement response by treating a geosynthetic layer as an elastic membrane and solving the equilibrium equations under vertical and horizontal loads on the membrane. In those papers, the existence of the geosynthetics was not taken into account in the calculation of applied stresses on the geosynthetics due to the external loads on the upper surface. In reality, the existence of geosynthetics in the foundation disturbs the whole stress and strain fields as indicated by Kurian et al. (1997) using a finite element method.

## 2 THEORIES OF INHOMOGENEITY AND INCLUSION PROBLEMS

A material  $\Omega$  with different elastic moduli from those of a matrix  $D-\Omega$  as shown in Figure 1 is called an inhomogeneity in micromechanics. The existence of the material  $D$  will disturb the applied stresses in the domain  $D-\Omega$  (Mura 1983).

Figure 1 Inhomogeneity and inclusion (Mura 1982)

The disturbed stress field can be simulated by an eigenstress field resulting from a fictitious eigenstrain  $\epsilon_{ij}^*$  in the domain  $\Omega$  in a homogeneous material. The so-called eigenstrain was defined by Mura (1982) as a nonelastic strain such as thermal expansion, phase transformation, initial strains, plastic, and misfit strains, etc. Eigenstress is a self-equilibrated internal stress induced by one or several eigenstrains in a body without any other external force and surface constraint. The domain  $\Omega$  with the eigenstrain  $\epsilon_{ij}^*$  and the same elastic moduli as those in the matrix  $D-\Omega$  is called an inclusion.

Due to applied external forces, the stress-strain relation for the inhomogeneity problem can be expressed as (Mura 1982)

$$\sigma_{ij}^0 + \sigma_{ij} = C_{ijkl}^* (\epsilon_{kl} + \epsilon_{kl}^0) \quad \text{in } \Omega \quad (1)$$

$$\sigma_{ij}^0 + \sigma_{ij} = C_{ijkl} (\epsilon_{kl} + \epsilon_{kl}^0) \quad \text{in } D-\Omega \quad (2)$$

where  $\sigma_{ij}^0$  and  $\epsilon_{kl}^0$  are the stress and the strain induced by external forces without any inhomogeneity, and  $\sigma_{ij}$  and  $\epsilon_{kl}$  are the stress and the strain due to the presence of the inhomogeneity. As pointed out by Eshelby (1957), the

inhomogeneity problem can be treated as an equivalent inclusion problem by including the eigenstrains as follows:

$$\sigma_{ij}^0 + \sigma_{ij} = C_{ijkl}(\varepsilon_{kl} + \varepsilon_{kl}^0 - \varepsilon_{kl}^*) \quad \text{in } \Omega \quad (3)$$

Equalizing Equation (1) and Equation (3) yields

$$C_{ijkl}^*(\varepsilon_{kl} + \varepsilon_{kl}^0) = C_{ijkl}(\varepsilon_{kl} + \varepsilon_{kl}^0 - \varepsilon_{kl}^*) \quad \text{in } \Omega \quad (4)$$

### 3 MODELING OF A GEOSYNTHETIC-REINFORCED FOUNDATION

Figure 2a is a case occurring in geotechnical practice. The geosynthetic layer has two major functions in resisting the applied load  $P$  on the surface: soil confinement and membrane effect. This problem can be modeled as an ellipsoidal inhomogeneity or inclusion in a half space as shown in Figure 2b. This model can be further decomposed into two problems as shown in Figure 3. The problem in Figure 3a is a Boussinesqi problem while the problem in Figure 3b is an inclusion problem. The solutions to the stresses  $\sigma_{ij}^0$  and strains  $\varepsilon_{kl}^0$  for Boussinesqi's problem can be found in many textbooks. Therefore, the aim of this paper is to investigate the inclusion problem.

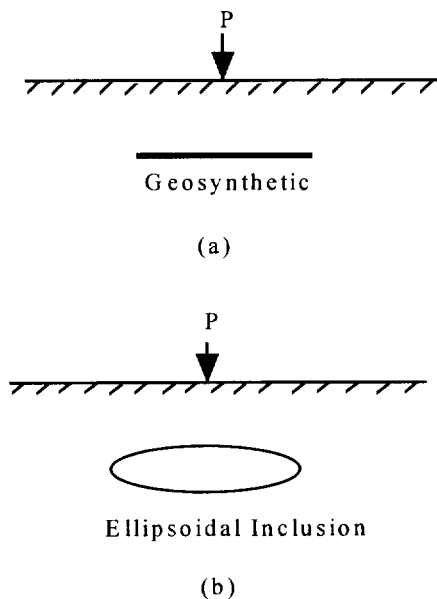

Figure 2 Modeling of a Geosynthetic-Reinforced Foundation

Figure 3 Decomposition of the Problem

### 4 SOLUTION FOR STRESS AND STRAIN FIELDS

The displacement  $u_i(\bar{x})$  induced by the eigenstrain  $\varepsilon_{ij}^*$  in the semi-infinite domain can be expressed by (Seo and Mura 1979)

$$u_i(\bar{x}) = \int_{\Omega} C_{jkmn} \varepsilon_{mn}^*(\bar{x}') \frac{\partial}{\partial x'_k} G_{ij}(\bar{x}, \bar{x}') d\bar{x}' \quad (5)$$

where  $G_{ij}(\bar{x}, \bar{x}')$  are Green's functions and  $C_{jkmn}$  are elastic constants. Green's functions  $G_{ij}(\bar{x}, \bar{x}')$  for the semi-infinite isotropic medium have been obtained by Mindlin (1936) and rewritten by Seo and Mura (1979) in their paper as follows:

$$G_{ij}(\bar{x}, \bar{x}') = \frac{1}{16\pi\mu(1-\nu)} \left\{ \frac{3-4\nu}{R_1} \delta_{ij} + \frac{1}{R_2} \delta_{ij} + \frac{(x_i - x'_i)(x_j - x'_j)}{R_1^3} \right. \\ \left. + \frac{(3-4\nu)(x_i - x'_i)(x_j - x'_j)}{R_2^3} + \frac{2x_3 x'_3}{R_2^3} \left[ \delta_{ij} - \frac{3(x_i - x'_i)(x_j - x'_j)}{R_2^2} \right] \right. \\ \left. + \frac{4(1-\nu)(1-2\nu)}{R_2 + x_3 + x'_3} \left[ \delta_{ij} - \frac{(x_i - x'_i)(x_j - x'_j)}{R_2(R_2 + x_3 + x'_3)} \right] \right\} \\ G_{3j}(\bar{x}, \bar{x}') = \frac{(x_j - x'_j)}{16\pi\mu(1-\nu)} \left[ \frac{(x_3 - x'_3)}{R_1^3} + \frac{(3-4\nu)(x_3 - x'_3)}{R_2^3} \right. \\ \left. - \frac{6x_3 x'_3 (x_3 + x'_3)}{R_2^5} + \frac{4(1-\nu)(1-2\nu)}{R_2(R_2 + x_3 + x'_3)} \right] \\ G_{i3}(\bar{x}, \bar{x}') = \frac{(x_i - x'_i)}{16\pi\mu(1-\nu)} \left[ \frac{(x_3 - x'_3)}{R_1^3} + \frac{(3-4\nu)(x_3 - x'_3)}{R_2^3} \right. \\ \left. + \frac{6x_3 x'_3 (x_3 + x'_3)}{R_2^5} - \frac{4(1-\nu)(1-2\nu)}{R_2(R_2 + x_3 + x'_3)} \right]$$

$$G_{33}(x, x') = \frac{1}{16\pi\mu(1-\nu)} \left[ \frac{3-4\nu}{R_1} + \frac{8(1-\nu)^2 - (3-4\nu)}{R_2} + \frac{(x_3 - x'_3)^2}{R_1^3} + \frac{(3-4\nu)(x_3 + x'_3)^2 - 2x_3x'_3}{R_2^3} + \frac{6x_3x'_3(x_3 + x'_3)^2}{R_2^5} \right] \quad (6)$$

where  $R_1^2 = (x_1 - x'_1)^2 + (x_2 - x'_2)^2 + (x_3 - x'_3)^2$ ;  
 $R_2^2 = (x_1 - x'_1)^2 + (x_2 - x'_2)^2 + (x_3 + x'_3)^2$ ;  
 $\mu =$  shear modulus;  
 $\nu =$  Poisson's ratio.

The effect of the free surface has been included in the above equations by containing the term  $R_2$ .

Figure 4 An Ellipsoidal Inclusion in a Half Space (After Seo and Mura 1979)

Assume a circular geosynthetic sheet with a radius  $R$  horizontally buried in a half space has a constant thickness  $t$  in  $x'_3$  direction, which is much less than the dimensions in  $x'_1$  and  $x'_2$  directions. The vertically applied load  $P$  passes through the center of the geosynthetic sheet. The variation of eigenstrains in the thickness direction is negligible. Due to the geometric symmetry and the location of the applied load, the eigenstrains are symmetric to  $x'_1$  and  $x'_2$  axes.

From Equation (5), the relationship between the strain disturbance and the eigenstrain can be expressed by

$$\epsilon_{kl} = \frac{1}{2} (u_{k,l} + u_{l,k}) = \int_{\Omega} C_{opmn} \epsilon_{mn}^* (\bar{x}') g_{klop}(\bar{x}, \bar{x}') d\bar{x}' \quad (7)$$

$$\text{where } g_{klop}(\bar{x}, \bar{x}') = \frac{1}{2} \left[ \frac{\partial^2 G_{ko}(\bar{x}, \bar{x}')}{\partial x_1 \partial x_p} + \frac{\partial^2 G_{lo}(\bar{x}, \bar{x}')}{\partial x_k \partial x_p} \right].$$

Substituting Equation (7) into Equation (4) yields

$$\epsilon_{kl}^* (\bar{x}) = K \int_{\Omega} C_{opmn} \epsilon_{mn}^* (\bar{x}') g_{klop}(\bar{x}, \bar{x}') d\bar{x}' + F_{kl}(\bar{x}) \text{ in } \Omega \quad (8)$$

where  $K = I - C_{ijkl}^{-1} C_{klij}^*$  and  $F_{kl}(\bar{x}) = K \epsilon_{kl}^0$ .

A variety of numerical methods can be adopted to solve Equation (8). A numerical integration technique is introduced herein. Equation (8) can be expressed as (Wang et al 1977):

$$\epsilon_{kl}^* (\bar{x}_1) = F_{kl}(\bar{x}_1) + KC_{opmn} A_{\Omega} \sum_{j=1}^n w_j \epsilon_{mn}^* (\bar{x}_j) g_{klop}(\bar{x}_1, \bar{x}_j) \quad (9)$$

where  $\bar{x}_1$  and  $\bar{x}_j$  are integral points,  $\bar{x}_1 = (x_1, x_2)$ ,  $\bar{x}_j = (x'_1, x'_2)$ , and  $x_1^2 + x_2^2 \leq R^2$  and  $(x'_1)^2 + (x'_2)^2 \leq R^2$ ;  $w_j =$  weight factor;  $n =$  number of integral point;  $A_{\Omega} =$  integral area, equal to the area of geosynthetic sheet.

Equation (9) can be rewritten in matrix forms as

$$\mathbf{E} = \mathbf{F} + \lambda \mathbf{G} \mathbf{W} \mathbf{E} \quad (10)$$

$$\text{or } \mathbf{H} \mathbf{E} = \mathbf{F} \quad (11)$$

where  $\mathbf{H} = \mathbf{I} - \lambda \mathbf{G} \mathbf{W}$ ;  $\mathbf{I} = n \times n$  unit matrix;  
 $\lambda = K C A_{\Omega} t$ ;  $\mathbf{G} = (G_{ij})$ ;  $\mathbf{E} = (\epsilon_{kl}^* (\bar{x}_1), \epsilon_{kl}^* (\bar{x}_1), \dots, \epsilon_{kl}^* (\bar{x}_n))^T$ ;  
 $\mathbf{F} = (F(\bar{x}_1), F(\bar{x}_1), \dots, F(\bar{x}_n))^T$ ;  $\mathbf{W} = (w_1, w_2, \dots, w_n)$ .

After solving the eigenstrains  $\epsilon_{kl}^*$  at integral points from Equation (11), the strain disturbance  $\epsilon_{kl}$  can be computed by using the numerical integration technique and substituting  $\epsilon_{kl}^*$  into Equation (7). Then, the stress and strain fields can be obtained from Equation (1) and Equation (2).

## 5 FUTURE STUDIES

This paper only focuses on the development of theoretical solutions for stress and strain fields of a geosynthetic-reinforced foundation vertically loaded by a concentrated force. Parametric studies need to be done in the future to investigate influential factors and develop design charts for this problem, which will be very beneficial to researchers and engineers.

## 6 SUMMARY

By mean of the concepts and methodologies in micromechanics, the geosynthetic-reinforced foundation is modeled as an inclusion problem. The stress and strain disturbance due to the presence of a geosynthetic sheet in a half space is simulated by applying an eigenstrain in the region of the geosynthetic sheet. Using the solutions obtained by Mindlin (1936) for a force at a point in the interior of a semi-infinite solid and the stress-strain

relationship proposed by Eshelby (1957) for a general inclusion problem, the eigenstrain for the inclusion is computed. The stress and strain fields for a geosynthetic-reinforced foundation vertically loaded by a concentrated force is formulated.

# Bearing Capacity of Strip Footing on Geogrid-Reinforced Slope

C. S. Yoo

Assistant Professor, Department of Civil Engineering, Sung Kyun Kwan University, Seoul, Korea

D. Y. Lee

Researcher, Geotechnical Engineering Division, Korea Institute of Construction Technology, Seoul, Korea

**ABSTRACT:** This paper presents the results of laboratory model footing tests on the bearing capacity behavior of strip footing on geogrid reinforced slopes. For the model tests, the reinforced slopes were artificially created using the raining technique with sand. A wide range of conditions were analyzed by varying geogrid reinforcing patterns. Furthermore, model tests were simulated using finite element analysis with the aim of investigating the mechanics behavior of the reinforced slope such as failure mechanism and force distribution in geogrid. Based on the results of model tests, both qualitative and quantitative relationships were established between the bearing capacity and the geogrid design parameters such as depth, length, and number of geogrid layers.

**KEYWORDS:** Geogrid, Bearing capacity, Slope, Model test, Strip footing, Finite element analysis.

## 1. INTRODUCTION

Geogrids are often used as slope reinforcement for construction of slopes to angles steeper than those constructed with the fill material being used. When a strip footing is constructed adjacent to such a reinforced slope, the bearing capacity behavior of the footing would be significantly different than that of unreinforced slope. To design such a strip footing on a reinforced slope requires a bearing capacity determination method. Most of the previous studies mentioned above, however, have been focused on horizontally leveled ground, and therefore, no rational method of bearing capacity determination for a shallow foundation on reinforced slope is available up to date. Therefore, much still needs to be investigated in order to develop a generally acceptable design method for shallow foundations on reinforced slope.

This study was undertaken with the aim of investigating the mechanistic behavior of geogrid-reinforced slope under strip load as well as the bearing capacity behavior of strip footings on reinforced ground using experimental and numerical studies.

## 2. LABORATORY MODEL TESTS AND FINITE ELEMENT ANALYSIS

### 2.1 Laboratory Model Tests

The laboratory model tests were conducted in a test box made of 60 mm-thick wood, having an internal dimension of 1.2m (length) x 0.8m (depth) x 0.3m (width). One side of the test box was cleared using a plexiglass for ease of observing failure mechanism during the test. The

inside walls of the test box were greased to minimize the friction with ground and the edges of the foundations as much as possible. Although no slip sheets were attached onto the inside walls, no appreciable friction was observed during the test. Furthermore, a rough base condition of a 80mm-wide model footing made of steel was achieved by attaching a sand paper at the bottom.

Figure 1. A schematic view of model test box with symbols used in this study.

The artificial ground was constructed with fine sands by the raining technique. The effective size( $D_{10}$ ), uniformity coefficient( $C_u$ ), and coefficient of gradation( $C_c$ ) for sand were 0.36 mm, 1.61, and 1.1, respectively. The tests were conducted on a ground with a slope of 1(H):0.67(V) at a relative density of approximately 70%. The slope of the ground was artificially formed by removing the sand with a vacuum after forming horizontally leveled ground. In order to

evaluate the consistency of the placement density during raining, small cans were placed at different locations in the test box. In the test, the Fortrac geogrids by Huesker Synthetic GmbH Co, which has relatively smaller size of apertures, were used in order to reduce a possible size effect. The mechanical properties of the ground and the geogrid are summarized in Table 1. Note that the Young's modulus of the geogrid was back calculated after performing several computer runs.

During the tests, the model footing was loaded using a hydraulic jack at a rate of 1.0 mm/min. The applied footing load and the settlement were measured using a load cell and two LVDTs, respectively. A schematic view of model test box with the symbols used in this study is seen in Fig.1.

Table 1. Mechanical property of the ground and geogrid.

	Ground	Model Footing	Geogrid
Young's modulus E (kN/m <sup>2</sup> )	2500	2.1E08	1700000
Poisson's ratio $\nu$	0.35	0.17	-
Friction angle $\varphi$ (degree)	42	-	-
Cohesion (kN/m <sup>2</sup> )	0	-	-
Unit weight(kN/m <sup>3</sup> )	16	-	-
Tensile strength (kN/m)	-	-	55

## 2.2 Finite Element Analysis

A series of finite element analysis using a commercial code DIANA(1996) were conducted on selected conditions in order to investigate the mechanistic behavior of reinforced slope under strip load. In the finite element modeling, the foundation ground was discretized using isoparametric 8-node elements, while the geogrid using embedded reinforcement element. The embedded reinforcement element is a special type of element provided by DIANA, which can model the grid pattern of reinforcement. The vertical and horizontal boundaries were modeled by placing the y and x direction rollers, respectively, and were placed in accordance with the test configuration.

In the analysis, the footing and geogrid were characterized as a linear elastic material, while the foundation soil being an elasto-plastic material obeying Mohr-Coulomb failure criterion. The mechanical properties tabulated in Table 1 were used as input parameter for analysis. Fig. 2 shows a typical finite element mesh used in the analysis.

Figure 2. Finite element mesh used in the analysis.

## 3. MECHANICAL BEHAVIOR OF REINFORCED SLOPE UNDER STRIP LOAD

### 3.1 Failure Mechanism

The failure mechanism was investigated using the results of model tests and finite element analysis. To observe the failure mechanism during the model tests, horizontal layers of colored sand were placed and photos were taken at various stages of loading to trace the failure surface. The failure patterns for the finite element analysis, on the other hand, were traced using the maximum shear strain ( $\epsilon_1 - \epsilon_3$ ) contours. Figs 3 and 4 show the failure patterns for unreinforced and reinforced slopes, respectively. Note that the results were obtained at the footing settlement level of  $S_v/B=0.15$  ( $S_v$ =footing settlement;  $B$ =footing width), which is beyond its ultimate level for both cases, and that the failure patterns both from the model tests and finite element analysis shown in Figs 3 and 4 are qualitative drawings.

As can be seen in Fig 3 for unreinforced slope, a typical slope failure pattern is observed, which initiates from the footing edge opposite to the slope and progresses toward the slope. The failure pattern for a reinforced slope with three layers of geogrid presented in Fig. 4 demonstrated that due to the reinforcement, the failure surface is not well developed in the reinforced zone, indicating the improved load bearing capacity of the slope. Inspection of the failure pattern reveals that it is desirable to place the geogrids across the potential failure line for unreinforced case so that the geogrid can tie back the potential sliding wedge against outward movement.

Figure 4. Failure patterns for the reinforced slope ( $N=3$ ,  $L/B=5.5$ ,  $u/B=0.33$ ).

### 3.2 Traction Force Distribution in Geogrid

Fig. 5 shows typical examples of the traction force distributions in geogrids obtained from the finite element analysis at different footing settlement levels ( $S_v/B=0.05$  and  $0.1$ ). It is seen that the peak values of tensile force in each layer of geogrid occurs at the points where the slip surface and the geogrid intersect, as one can expect. Furthermore, it is also observed that as the footing load level increases, the traction force in the lower level of geogrid considerably increases while no significant increase is seen in the upper level.

Another finding in this figure is that the traction force distributions are approximately symmetrical from the potential failure surface, and reach nearly zero values at about  $2.0B$  from the peak point. This trend indicates that the geogrid needs to be extended beyond the potential failure surface with at least a length of  $2.0B$  for anchoring effect. Therefore, it seems reasonable to assume in the relevant design calculation a symmetrical triangular reinforcement force distribution at its apex at the intersection point with a potential failure surface for unreinforced case.

Figure 5. Traction force distributions in geogrids

## 4. BEARING CAPACITY BEHAVIOR

Based on the results obtained from the model tests, the bearing capacity behavior of strip footing on reinforced slope was analyzed. In the analysis, the normalized bearing capacity ratio ( $BCR=q_r/q_{ur}$ ) was used, where  $q_r$  and  $q_{ur}$  being bearing capacity values for reinforced and unreinforced slope, respectively.

### 4.1 Effect of length of geogrid

Das et al.(1994) has reported that there exists a critical length of geogrid beyond which the geogrid has no further reinforcing effect. In order to investigate the variation of bearing capacity with the length of geogrid( $L/B$ ), several conditions were tested by varying  $L/B$  for  $N=3.0$  and  $u/B=h/B=0.33$ . Fig. 6 shows the relationship between BCR and  $L/B$  for  $b=1.5B$ , indicating that BCR increases

with increasing  $L/B$  until  $L/B$  reaches its critical value of approximately 5.5 from the slope and becomes almost constant thereafter, indicating  $(L/B)_{cr}=5.5$  in this case.

A similar trend can be observed for  $b=3.0B$  as seen in Fig. 6, showing the critical length of approximately  $7.0B$ . The extended length beyond the failure surface corresponds to approximately  $3.0B$  for both cases( $b=1.5B$  and  $3.0B$ ), implying that the geogrid must be extended approximately  $3.0B$  beyond the potential failure surface to have maximum reinforcing effect. This trend supports the traction force distribution pattern.

Figure 6. Variation of BCR with  $L/B$

### 4.2 Effect of depth of reinforced zone

The variation of bearing capacity with the depth of reinforced zone( $d/B$ ) was investigated by increasing the number of layers( $N$ ) while maintaining  $L/B=(L/B)_{cr}$  and  $u/B=h/B=0.33$ . The relationship between BCR and  $d/B$  for  $b=1.5B$  and  $0B$  is summarized in Fig. 7. As can be seen in this figure, BCR increases almost linearly with  $d/B$  until  $d/B=2.5$  and becomes nearly constant thereafter, indicating  $(d/B)_{cr}=2.5$ . Note that Das et al.(1994) reported  $(d/B)_{cr}$  of 2.0 for horizontally leveled ground for both sand and clay. This discrepancy may be attributed to the fact that the influencing zone is deeper for a sloped ground than a leveled ground.

Figure 7. Variation of BCR with  $d/B$

### 4.3 Effect of $u/B$ and $h/B$

The effects of  $u/B$  and  $h/B$  on the bearing capacity were investigated while keeping  $L/B$  at a constant value of  $(L/B)_{cr} = 5.5$ . Fig. 8 shows the variation of BCR with  $u/B$  for  $N=1, 2$ , and  $3$  cases with  $h/B=0.75$ . As can be seen in this figure, for  $N=1$ , the BCR increases with  $u/B$  up to approximately a maximum value of  $1.0B$  and decreases thereafter, indicating  $(u/B)_{cr}=1.0$ . Note that Das et al.(1994) reported  $(u/B)_{cr}$  of approximately  $0.4$  for horizontally leveled ground. For  $N=2$  and  $3$ , although a similar trend is observed,  $(u/B)_{cr}$  appears to decrease with increasing the number of geogrid layers( $N$ ); i.e.,  $(u/B)_{cr} = 0.8$  for  $N=2$  and  $(u/B)_{cr} = 0.6$  for  $N=3$ . This trend may be explained in terms of deep footing effect suggested by Huang et al.(1994). The deep footing effect is a mechanism that a part of reinforced zone behaves as a part of the footing and transfers a major part of the footing load into a deeper zone. Therefore, as the reinforced zone becomes thicker, the reinforced zone acting as a part of the footing should be located closer to the footing in order to maximize its reinforcing effect.

The variation of BCR with  $h/B$  can be observed in Fig. 9 for  $N=2.0$  and  $3.0$ . The results obtained for the conditions at a fixed value of  $u/B=0.33$ . As noticed, the trend is similar to that for the variation of BCR with  $u/B$ . However, the critical value of  $h/B$  appears to be nearly constant approximately  $(h/B)_{cr}=0.8$  regardless of  $d/B$ .

Figure 8. Variation of BCR with  $u/B$

Figure 9. Variation of BCR with  $h/B$

### 5. CONCLUSIONS

The mechanistic behavior of geogrid-reinforced slope and the bearing capacity behavior of a strip footing on the slope were investigated using both experimental and numerical approaches. A wide range of boundary conditions were tested by varying the reinforcing pattern. The results of model tests and finite element analysis were used to identify the failure mechanism and the traction force distribution in geogrids, and also to establish both qualitative and quantitative relationships between the bearing capacity of a strip footing on reinforced slope and the reinforcing pattern. Based on the results of this study, the following conclusions can be drawn:

1. A symmetrical force distribution with its apex at the intersection point with a potential failure plane can be assumed for traction force distribution in geogrid.
2. The geogrid must be extended at least  $3.0B$  beyond a potential failure surface in order to maximize the reinforcing effect.
3. The reinforced zone must be extended to approximately  $2.5B$  below footing base for maximum reinforcing effect.
4. The critical value of  $u/B$  varies between  $0.6 \sim 1.0$  depending on the number of geogrid layers( $N$ ), while  $(h/B)_{cr}$  being nearly constant value of  $0.8$  regardless of  $N$

# A Study on the Coir Reinforcement for Strengthening Soft Soil Subgrades

Dr. K. Rajagopal  
Associate Professor  
Department of Civil Engineering  
Indian Institute of Technology Madras  
Chennai, India 600 036

Mr. S. Ramakrishna  
Assistant Engineer  
National Highways Department  
Secretariat of Public Works, MS Building  
Bangalore, India 560001

**ABSTRACT:** Coir is a naturally occurring fibre available at relatively low cost in many tropical countries. A number of products can be manufactured from coir fibre for geotechnical applications. The strength and other properties of these products compare favourably with those made of synthetic materials. Through laboratory plate load model tests, this paper examines the suitability of coir geotextiles for construction of unpaved roads over soft soil subgrades. The soft subgrades of 1 m depth (CBR < 0.5) were prepared in a test tank of plan dimensions 1.5 m × 1.5 m. Base course layers of varying thickness values (with and without coir reinforcement) were constructed on top of this subgrade. The results from these tests have clearly illustrated the benefit of using coir reinforcement in such cases.

**Key Words:** geotextiles, coir reinforcement, subgrades, plate load tests, unpaved roads

## 1 INTRODUCTION

The coir is a naturally occurring fibre derived from the husk of coconut fruit. It is abundantly available at very low cost in many tropical countries. A number of products can be manufactured from coir fibre for geotechnical applications, such as geogrids, geotextiles, geomats etc. These products were found to last for as long as four to six years within the soil environment depending on the physical and chemical properties of the soil, Ramakrishna (1996). In many instances, the strength of subgrade soil increases in course of time as the soil undergoes consolidation induced by the traffic loads. For such applications the natural reinforcement products are ideally suitable, Rao and Balan (1994). The current paper describes the results from investigations carried out on coir geotextile reinforced soft soil subgrades.

## 2 MATERIALS USED IN TESTS

### 2.1 Clay Soil

The clay soil used in this investigation had plastic and liquid limits of 15% and 42% respectively. This soil can be classified as CI according to the Indian Standard Classification System, IS 1498-1978. The cohesive strength and friction angle of the clay soil are 21.2 kPa and 1.3° respectively.

### 2.2 Gravel Soil (murum)

The gravel soil (murum) contains 48% gravel size particles, 48% sand size particles and 4% silt and clay size particles. The specific gravity of this soil was found to be

2.75. This soil is classified as A-2-4 (0) as per AASHTO classification system and is rated as a good sub-base material. The cohesive strength and friction angle of this soil are 10 kPa and 44.9° respectively.

### 2.3 Coir Geotextile

The coir geotextiles used in this investigation are commercially available floor mats which are woven from coir fibres. The coir fibres are twisted into a rope form and these ropes are woven in weft and warp directions to form the mat. These mats have approximately the same strength in both the principal directions. The thickness of these mats is dependent on the diameter of the twisted ropes used in forming the mat. The geotextile (coir mat) used in this investigation had a thickness of 7.2 mm at a standard normal pressure of 2 kPa. The mass per unit area of this mat was 1,396 g/m<sup>2</sup> at a room temperature of 30°C.

The ultimate tensile capacity of this mat was found to be 37 kN/m at a strain of 43% from wide-width tensile tests performed according to ASTM D4595 standards. The secant modulus of this material at 10% strain is 110 kN/m. The seam strength, determined according to the suggested ASTM procedures, was found to be 24 kN/m. The seams were stitched using strong nylon thread with 25 mm overlap on both sides of the seam.

The cohesive strength and friction angle of clay-coir geotextile interface were found to be 22.6 kPa and 8.2° respectively. The same properties for gravel-coir interface are 40 kPa and 32.3° respectively. A comparison of these strength properties with those of individual materials shows that coir geotextile has excellent interface strength properties. This may be because of the rough nature of the coir and its natural affinity towards the water and clay because of surface charges.

### 3 LABORATORY PLATE LOAD TESTS

#### 3.1 Test Facility

The plate load tests were performed within a test tank of plan dimensions 1.5 m × 1.5 m and 1.2 m deep. The loading was applied through a 100 kN capacity proving ring using a hydraulic jack. The test tank was centrally located below a reaction frame for applying plate loads. The plate was of 300 mm diameter (D) to simulate the Equivalent Single Wheel Load (ESWL).

#### 3.2 Preparation of Test Bed

The soft clay soil bed was prepared by sedimentation technique under vacuum pressure to simulate the soft natural subgrade. The soil was initially mixed manually using crowbars at 160% water content. This slurry was kept under a low vacuum pressure of 19.6 kPa for three days to drain out the water and remove the entrapped air. Then it was subjected to a consolidation pressure of 98 kPa until the rate of deformation has decreased to less than 0.01 mm per minute. The method of test bed preparation was adapted from the work reported by Kuntiwattanakul et al. (1995). The entire consolidation process took approximately 8 to 10 days for each preparation. This procedure had created soft subgrades with a CBR value of approximately 0.4. The thickness of soft clay layer was maintained at around 900 mm for all the tests.

The gravel sub-base course was prepared directly on top of this clay layer. The gravel layer was compacted at optimum moisture content using a 10 kg drop hammer falling through a height of 500 mm.

The gravel layer was compacted to 80% maximum density in all the tests. The compacted sub-base course was allowed to mature for one day by covering it with a polythene sheet. The coir geotextile reinforcement was introduced during the compaction stage itself.

The above procedure of preparing the clay and gravel layers was repeated for all the tests performed in this present investigation so that the test conditions remain uniform for the entire range of tests.

#### 3.3 Test Programme

The following series of plate load tests were carried out in this investigation with the following four configurations.

- Series 1: soft clay subgrade alone
- Series 2: gravel sub-base course over soft clay subgrade.
- Series 3: gravel sub-base course over soft clay subgrade and one layer of coir geotextile at clay-gravel interface.

- Series 4: gravel sub-base course over soft clay subgrade and two layers of coir geotextile, one at clay-gravel interface and the other at mid-depth of gravel layer.

In Series 2-4, six sub-base layer thickness (h) values of 100, 150, 200, 250, 300 and 350 mm were considered. In subsequent sections, the results from these tests are referred to by these series numbers.

#### 3.4 Test Procedure

The general test procedure for plate load tests as described in *Indian standard IS 1888:1982 (Reaffirmed 1988)* was adopted for all the tests. The loading was applied through a 300 mm diameter plate. The applied load was measured using a pre-calibrated 100 kN capacity proving ring. The settlement of plate and the soil surface were measured using a total of six dial gauges. In the case of tests with reinforcement layers, the coir geotextile was placed at the required levels after wetting.

Each load increment was applied as either 10% of the estimated ultimate load or the load required to produce 1 mm settlement, whichever is lesser. Each load increment was kept constant until the rate of settlement reduces to less than 0.025 mm per minute. The load and the corresponding deformations were recorded after the settlements have stabilised under each load increment, which was typically 6 to 12 hours. The loading was continued until a total plate settlement of 150 mm has occurred which took approximately 6 days.

After each test, the gravel layer was carefully removed. After that, the top 400 mm thick clay soil in the tank bed was replaced with puddled clay having 40% water content. This test bed was once again pre-consolidated under 98 kPa surcharge pressure which took 2 to 3 days to stabilise. This re-formed clay bed had the same properties as the originally prepared clay bed as confirmed by results from in situ vane shear tests. On this, fresh gravel layer of required thickness was laid in the same manner as discussed earlier.

### 4 RESULTS AND DISCUSSIONS

The plate load test carried out on clay bed showed that it is an extremely soft subgrade with an ultimate bearing capacity of 20 kPa. Hence, it can be expected that the provision of gravel sub-base with or without coir reinforcement will significantly improve its load bearing capacity. Typical improvement in the performance obtained with the provision of gravel layer with and without reinforcement layers is illustrated in Figure 1.

Handwritten text at the bottom of the page, possibly a signature or initials.

In general, the performance has improved with the increase in the thickness of gravel layer. The provision of a geotextile layer at the clay-gravel interface has further increased the load bearing capacity of subgrade. When an additional layer of geotextile was placed at the mid-height of the gravel layer, the ultimate capacity and stiffness has tremendously increased.

Figure 1. Performance with 150 mm thick gravel layer

The ultimate pressures developed from various tests are compared in Table 1 which clearly show the improvement in the performance with the provision of coir geotextile reinforcement.

From the results shown in Figure 1 and Table 1, it can be seen that the provision of a single layer reinforcement at the clay-gravel interface does not improve the load bearing capacity very much. The effect of single layer of geotextile is significant when gravel layer is thicker than 200 mm. When a thin layer of gravel is provided, there may not have been an adequate bond with the coir geotextile for the load transfer to take place. In the case of two layers of coir geotextile, the reinforcement layer at the mid-depth of gravel prevents its lateral spread and hence higher loads are mobilised in coir reinforcement which contributes to the increase in ultimate pressures. This can also be explained by the good bond between the coir and the gravel as shown from the interface shear strength properties (Section 2.3).

In the case of unreinforced and single layer reinforcement cases, the ultimate pressures have developed within a settlement of 15 to 40 mm whereas the two layer system had developed ultimate pressures at much higher settlements in the range of 100 mm (Figure 1). This result once again confirms the advantage of placing the additional reinforcement layer within the gravel layer.

In addition to the reinforcement action, the geotextile layer at clay-gravel interface functions as a separator and filtration and drainage medium as it has good compressibility characteristics. On the other hand, the layer within the subbase contributes mainly to the strength and stiffness of subgrade. It is evident from this experimental results that stiffness of the coherent mass is also an important parameter as reported by Douglas and Valsangkar (1992).

Table 1 Ultimate pressures (kPa) from plate load tests

Thickness of gravel layer (h)	unreinforced subbase layer	one layer of reinforcement	two layers of reinforcement
100 mm	100	120	400
150	200	220	550
200	240	250	750
250	300	360	900
300	370	440	1000
350	400	500	1150

From the plate load test data, the pressures developed for different thicknesses of gravel layers at various rut depths (settlement levels) were developed. This data is plotted in a non-dimensional form in Figure 2 for a rut depth of 75 mm. Similar charts were developed for other rut depths also. In these figures the thickness of gravel layer (h) is normalised with respect to the diameter of plate (D) and the plate pressure at any settlement is normalised with respect to the ultimate bearing capacity of soft clay layer (20 kPa) denoted as the Bearing Capacity Ratio (BCR). This term BCR indicates the relative improvement in the bearing capacity of subgrade with the provision of gravel layers with or without reinforcement. These charts can be used for designing the thickness of subbase layer over soft subgrades for a given BCR and the diameter of wheel base.

The above data is presented in a different form in Figure 3 for Indian Road Congress (IRC) standard wheel load of 22.25 kN. Similar curves have also been developed for other standard wheel loads. It is evident from this chart that the thickness of subbase can be substantially reduced with the use of coir geotextile reinforcement. At rut depths less than approximately 10 mm, the gravel layer can not mobilise enough shear strength which results in the requirement of very thick subbases, as is evident from the initial steep slope of curves.

## 5 ILLUSTRATIVE EXAMPLE

Design a subbase course to increase the load bearing capacity to 500 kPa of soft clay subgrade whose ultimate bearing pressure is 25 kPa. Consider the Equivalent

Single Wheel Loads (ESWL) of 28 kN and 48 kN having a tire pressure of 580 kPa. Design the subbase course for allowable rut depths of 25, 50 and 75 mm.

Design: The following step-by-step procedure illustrates the design process using the design charts developed in this investigation.

Step 1: Calculate the Bearing Capacity Ratio (BCR) at the ultimate bearing pressures.

$$BCR = \frac{\text{required ultimate bearing pressure on subbase course}}{\text{ultimate bearing capacity of subgrade}}$$

In the present example,  $BCR = \frac{500}{25} = 20$

Step 2: Calculate the contact area of the wheel as the ratio of ESWL and the tire pressure. From these, the equivalent diameters of contact area are calculated for the two wheel loads as 250 mm and 325 mm respectively.

Step 3: Obtain the required h/D ratios for rut formations of 25, 50 and 75 mm from the design charts. The results are given in Table 2.

Table 2 Design of subbase thickness over soft subgrades

Design Case	Design base course thickness (mm)			Savings in thickness (mm)	
	gravel alone (A)	gravel + one layer reinf. (B)	gravel + two layer reinf. (C)	Savings for B over A	Savings for C over A
i) r = 25 mm P = 28 kN P = 48 kN	300 360	268 321	153 183	32 39	147 177
ii) r = 50 mm P = 28 kN P = 48 kN	288 345	255 310	108 129	33 35	180 216
iii) r = 75 mm P = 28 kN P = 48 kN	275 330	250 300	83 100	25 30	192 230

in which r is the rut depth and P is the wheel load. As can be seen, the single layer reinforcement does not result in much savings in subbase thickness. On the other hand, when an additional layer is provided within the subbase, significant savings are achieved.

## 6 CONCLUSIONS

The use of coir geotextiles for construction of subbase layer over soft subgrades is studied in this paper. Various engineering properties of coir geotextiles have been reported in this paper. These properties are comparable to those of intermediate to high density polypropylene based geotextiles. The plate load tests have clearly indicated the capability of coir geotextiles in improving the stiffness and load bearing capacity of soft subgrades. Hence, the coir geotextiles are suitable for cost-effective field applications.

# Treatment of container stockyard using Stress distribution ability of geonet

Hong Zhu

General Manager, YiChang Netlon Geosynthetics Ltd, Hubei Province, China

Dao hong Ruan

Engineer, YiChang Netlon Geosynthetics Ltd, Hubei Province, China

**ABSTRACT:** This paper presents the technical characteristics of geonet, the effect of stress distribution of geonet was initially observed in eastern China in the winter by a lively trial which can be defined as "NET - ICE TRIAL", The interacting mechanism between geonet and soft soil was analyzed based on lots of laboratory tests, three in - situ plate load tests were carried out on the site which is close to Yangtze River with extensive dredged sand areas of soft soil depth up to 8m. The results showed that bearing capacity of soft soil can be increased about one times undisturbed soil bearing capacity after a layer of geonet was paved horizontally, two layers of geonets lead to four times the bearing capacity of soft soil. The total amount of settlement was reduced by 22% , differential settlement was reduced by 35% . compared with the method of dynamic consolidation, the new technique has advantage of quick speed construction and low cost.

**KEYWORDS:** Container stockyard, Geonet, Stress distribution

## 1 INTRODUCTION OF APPLICATIONS

The use of geonets in China dates back to the early 1980's when the materials were first manufactured in China. The early projects were mainly in soil reinforcement, drainage and filtration. In the late 1980's the applications increased to projects involving embankment foundation consolidation, bridge approach details, reflection cracking of asphalt pavements, slope protection, leachate collection, leakage detection in landfills and coastal erosion protection. The application areas range from highways and railways to hydraulic engineering.

As the applications of geonets increased the construction departments required more information with regard to calculations and theory and this generated large interest in the academic world. A large number of Universities and Research Institutions became involved in studying the principles of geonets in different applications.

The Ministry of Communications considered the setting up of a project to research the mechanism of geonets and then the National Eight - Five Plan research project entitled "Application Research of Geonets in Bridge Abutment and Soft Soil Treatment of High Grade Road" was appraised by them on October 1995. The research into the mechanisms of geonets was promoted very deeply at this stage and this research became a history of the development of geonets in China.

A typical application of geonets is described as "Reinforce-

ment of Soft Soil Container Stockyard Project"

## 2 SELECTION OF GEONET MESH

Geonets have a great number of application areas which can be described as follows:

- 1) Soft soil reinforcement
- 2) Slope protection
- 3) Drainage

Laboratory tests have shown that the mesh shape is very important for stress distribution and that a hexagonal shaped aperture is the best as it is both stable and has low elongation. The order of stability of geonets according to tensile tests is: Hexagonal mesh > diamond mesh > square mesh. Although the tensile strengths are different in the longitudinal and transverse directions this is not important as long as the difference is not too large. If the difference is too large then the reinforcement of soft soil can not be achieved.

The selection of the appropriate mesh is also dependent on the grading of the fill material. In the project described later in this paper, the container stockyard, granular materials (dredged sand) were used and therefore a larger mesh size was selected.

The actual tensile strength of the geonet used, weight 660g/m<sup>2</sup>, tested in the laboratory is greater than the specified value of 5.8 KN/m but it is still not high. Is it possible for this material; to reinforce the soft soil? The answer will be found af-

ter the field tests and laboratory trial are completed.

### 3 THE PHENOMENON OF NET - ICE STRESS DISTRIBUTION

On a container stockyard project where the soft soil foundation was overlain by a geonet reinforced pavement the mesh had been placed on a compacted surface when suddenly the weather became worse. It snowed and the mesh became frozen in ice.

The same load was then imposed on two different ice surfaces, one with the mesh and one without, and the stress distribution of the geonet was observed directly in the two ice surfaces.

photo 1

photo 2

IN photo 1, with the geonet, the thin ice surface cracked but didn't break with white stress circles radiating from the central load. This showed how the load was distributed over a large area with the same geometry as the loaded area. In photo 2 the ice was broken and no distribution occurred.

This was the first time that the phenomenon of "live" stress distribution had been seen on a working site and this was defined as the NET - ICE TRIAL.

now given

R: radius of stress distribution

r: radius of central load

$S_R$ : area of stress distribution

$S_r$ : area of central load

An equation was obtained by measure on the construction site

$$\text{so } R = 5r$$

$$\frac{S_R}{S_r} = \frac{\pi R^2}{\pi r^2} = \frac{(5r)^2}{r^2} = 25 \quad (1)$$

This equation means that the area of stress is increased by 25 times as compared with the loaded area and shows how the bearing capacity of soft soil can be increased. The NETICE TRIAL shows the distribution mechanism in transmitting the load evenly onto a much larger bearing area.

25 times as compared with the loaded area and shows how the bearing capacity of soft soil can be increased. The NETICE TRIAL shows the distribution mechanism in transmitting the load evenly onto a much larger bearing area.

### 4 LABORATORY TEST

In order to illustrate quantitatively the geonet mechanism in improving bearing capacity of soft soil lot of tests have been completed in the past five years.

The trial chooses the mid liquid limit silty clay to do three trial cylinder shape samples.

Sample c is pure clay.

Sample d one layer of geonet is used

sample E three layers of geonets are used c (see fig 1)

Figure 1.

The trial is unconfined compression strength test, test results are as follows (table 1)

Table 1:

Sample mode	C			D			E		
Sample no.	1	2	3	1	2	3	1	2	3
load(kg)	720	722	722	1520	1522	1523	5239	5240	5241
compression strength(kpa)	408.1	409	409	860.6	861.7	862.3	2966.2	2966.7	2967.3
(mean) strength	408.4			861.1			2966.8		

The bearing capacity is increased significantly by geonet, the value of sample D is 2.1 times the value of sample C and sample E is 7.3 times sample C, results show:

- 1) the bearing capacity of soil is improved with the increase of quantity of geonet.
- 2) the bearing capacity is increased by one time when a layer of geonet is paved.

NET - ICE TRIAL and laboratory test of using geonet to increase the bearing capacity of soil provide enough evidences for construction projects, but all the research data in theory need to be confirmed by actual applications.

## 5 CONTAINER STOCKYARD TREATMENT

### 5.1 soil properties

The container stockyard is situated in Jiang Shu province. The harbour area is about two hundred thousand square metres, forty thousand of which will be used as a container stockyard.

The soil profile can be divided into three layers which are described, from top to bottom, as follows:

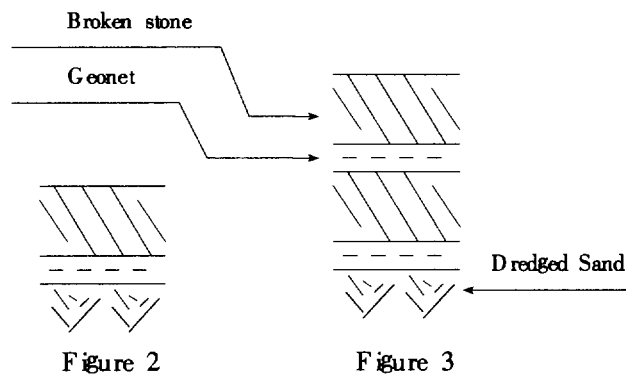

Layer 1: 4 – 5m of pump – dredged yellow fine sand mixed with cohesive soils, saturated and highly compressible. This soil is very susceptible to liquefaction. Particle sizes range from 0.074mm to 0.25mm.

Layer 2: 2 – 3m of mucky clay, brownish yellow and grey in colour, saturated and highly compressible.

Layer 3: Fine sand and intermittent silty clay layers. Moderate to low compressibility with a higher bearing capacity.

The dredged sand was placed two years ago and consolidation of the mucky clay had already occurred due to the overburden load. The groundwater level is not influenced significantly by the water levels of the Yangtze River because of the cofferdam. The only water ingress is due to natural rain water.

The conventional method of treating container stockyard is dynamic consolidation but this method has high cost and slow construction speed, moreover, easily effected by weather. The cross section of new method is shown as follows. (see fig 2):

### 5.2 construction procedure

- 1). Dredged sand is compacted by bulldozer twice times.
- 2). Geonet is unrolled and laid directly over the dredged sand, with an overlap of 150mm between individual sheets, and pinned with "U" shape steel pins at 1.0m spaces.
- 3). Backfill broken stone with 60% clay and 40% granular material.
- 4). Compact backfill, using vibratory roller operating without vi-

bration twice at the beginning and with the vibration for another twice times at one hour interval. The maximum vibrating force is 30 tons.

- 5). Pave the second layer geonet repeat the same procedure.

During the compacting operation in one area in Fig 2 liquefaction occurred. This was assumed to be because the placing and compacting operation had taken place too quickly. It was then suggested that there should be a 1 hour interval between compaction passes and that the fill thickness should be no more than 0.8m – 1m.

### 5.3 bearing capacity test

Three in situ plate load tests were carried out, two of them were finished on the structure of Fig 2 and Fig 3 respectively, another one is for ground which had been treated by dynamic consolidation with 10 tonnes hammer at 10 meters high. The size of plate is 1m by 1m. The results see table 2.

Table 2

load(kn)	measured settlement (mm)		dynamic consolidation
	one layer of geonet	two layers of geonets	
50	7.86	4.42	8.30
100	9.53	5.84	12.23
150	14.38	6.06	16.35
200		6.64	
250	32.58	9.04	
300	39.83		
designed bearing capacity(Mpa)	80	150	150
tested value	125	250	155

Notes: The bearing capacity of undisturbed soil is 60 kpa

Table 2 shows the bearing capacity of two layers of geonets structure is twice times the one layer geonet structure. Interlock between geonet and granular material forms a high density and shear resistant layer which distribute vertical loads also indicate the horizontal elasticity of geonet and granular material is very good, thus the total settlement can be reduced. This concept is confirmed by modulus of resilience test.

Table 3.

Structure mode	one layer of geonet	two layers of geonets
modulus of resilience (Mpa)	711.25	991.89
mean value	706.21	1061.48

Note: The modulus of resilience of undisturbed soil can't be measured.

#### 5.4 Unit weight test (table 4)

Table 4.

Item	Natural soil	one layer of geonet	two layers of geonets	dynamic consolidations
water content %	17.71	13.13	12.56	
unit weight kn/m <sup>3</sup>	16.2	18.3	18.6	18.3

The unit weight of geonet structure changes little. It is increased by 10% to 13%, compared with nature soil the compactness can reach 93.8% to 95.9%.

#### 6 ANALYSIS

It can be seen from Table 2 that the bearing capacity of soft soil has increased significantly. when granular material is compacted over geonet, it partially is penetrates and projects through the apertures creating an interlocking action between granular material and geonet mesh. This interlock enables the mesh to resist horizontal shear from the fill and thereby mobilise the maximum bearing capacity of the soft soil. Mechanical interlock creates a flexurally stiff platform which distributes load evenly and minimizes different settlement, geonet prevents lateral movement of particles at the base of the fill layer, helps the fill to retain its full design strength by preventing contamination by soft soil thus controlling the amount of the more expensive fill.

#### 7 CONCLUSIONS

The following conclusions are drawn:

1. Geonet can increase the bearing capacity of soft soil of dredged sand significantly, reduce the total amount of settlement and control the different settlement.
2. Geonet can distribute vertical load evenly, mechanical interlock between geonet and granular fill plays an important role in reinforcement of soft soil.
3. Tensile strength of geonet is not the main factor in improving soft soil.
4. The further rules of stress distribution of geonet need to be researched.

#### ACKNOWLEDGEMENTS.

**ABSTRACT:** Presented are results from excavations at two edge drain locations adjacent to a freeway pavement (i.e., a limited access divided highway with at least two lanes in each direction). The pavement was built on a high fill of recompacted clayey gravel (GC). Typical Atterberg limits of the fines were  $LL \approx 25$ ;  $PL \approx 16$ ;  $PI \approx 9$ . Directly on the clayey gravel subgrade was a 152 mm cement treated base followed by 229 mm of structural portland cement concrete pavement. Adjacent to the pavement edge was a 3 metre-wide paved shoulder ending in a continuous curb and gutter fitted with catch basins about every 100 m. In 1982 a geotextile-wrapped aggregate pavement edge drainage system was retrofitted through the paved shoulder. The objective of the investigation was to evaluate the performance of the drainage system. From the observations and tests made on the recovered soil samples conclusions and recommendations are stated.

**KEYWORDS:** Drainage, Edge drain, Geotextile, Pavement, Performance evaluation.

## INTRODUCTION

As part of an evaluation of Ontario's highway pavement drainage practice, excavations were made at two edge drain locations adjacent to a freeway pavement on June 4/1992. The pavement was built in 1970 on a high fill of recompacted clayey gravel (GC,  $LL \approx 25$ ;  $PL \approx 16$ ;  $PI \approx 9$ ) and the drains were added in 1982. Figure 1 is a schematic of the pavement edge and edge drain cross section obtained from the construction drawings. Built directly on the clayey gravel subgrade was a 152 mm thick cement treated base followed by 229 mm thick portland cement concrete slab. Adjacent to the pavement edge was a 3 metre wide paved shoulder ending with a continuous curb and gutter and catch basins about every 100 m. The edge drainage system was retrofitted through the paved shoulder as a geotextile-wrapped coarse open graded aggregate (OGA) containing a 100 mm corrugated perforated polyethylene pipe placed 50 mm above the trench base (and base portion of the geotextile). The pipe centre line was to be located 762 mm from the edge of the concrete pavement. The wrapped stone was to be 325 mm thick and its top level with the cement treated base.

## OBJECTIVE

The objective of the investigation was to evaluate the effectiveness of the pavement drainage system some ten years after installation. Also of interest was the condition of the geosynthetics (geotextile and plastic pipe) used in the

**Figure 1. Cross section from construction drawings.**

drainage system.

## GEOSYNTHETICS

The geotextile was a needlepunched staple fibre product with the following properties: filtration opening size = 100  $\mu\text{m}$ ; mass/unit area = 230  $\text{g}/\text{m}^2$ ; grab strength = 550 N at an elongation of 75% at failure. The pipe was a corrugated perforated polyethylene product with a nominal inside diameter of 100 mm, and a nominal outside diameter of 125 mm.

## WEATHER AND STORM DRAINAGE CONDITIONS

The weather the day and night before the excavations had been intermittent rainfall. On the day of the excavations the weather was overcast with intermittent sunshine. The temperature at 7:00 am, which was the start of the excavating, was 14°C. The highway surface drainage was discharged via curb and gutters to catch basins. The catch basins were connected to a deep storm sewer.

## POSITION OF EXCAVATIONS AND OUTLETS

Both excavations were made on the shoulder side of the shoulder/pavement edge area of six contiguous same direction traffic lanes near catch basins which were located at the curb. The longitudinal grade of the Highway was about 2%. The cross-sectional slope of the pavement was about 2.5% and the shoulder about 6%.

## EXCAVATION TP1 (STATION 16+568)

The first excavation (TP1) was made adjacent to a transverse pavement joint at chainage 16+568. The shoulder/pavement surface showed considerable settlement of the shoulder. Figure 2 shows the surface profile measurements taken at both excavations. Figure 3 shows the typical cross section observed at the first excavation TP1. The cross section measurements were taken at both ends of this excavation some 300 mm apart. Little difference was noted between the measurements of the same items. The drainage pipe was not connected to the catch basin at this location. The structural concrete portion of the pavement is about 240 mm thick. The cement treated base was of poor quality either due to deterioration or initial mix. Its thickness was estimated to be 150 mm in accordance with the construction drawing. The geotextile-wrapped aggregate drain was installed adjacent to the edge of the cement treated base. Its centre line was located 780 mm from the edge of the pavement and its width was 420 mm. It extended from the surface elevation of the cement treated base layer into the clayey gravel subgrade for a total thickness of 300 mm. Thus the portion of geotextile forming the base of the drainage system was 540 mm below the pavement surface elevation. Above the upper (top) portion of the geotextile was a thickness of 140 mm of Granular 'A' covered by a thickness of 100 mm of asphalt concrete which formed the shoulder surface.

Figure 4 shows the pipe and the clean condition of the aggregate beside and above the pipe inside the geotextile. Figure 5 shows the fouled cemented condition of the aggregate on the bottom inside of the geotextile wrap. Migration of subgrade fines through the geotextile into the clear stone was visible. Seepage water has washed some of the fines through the clear stone and deposited them on the geotextile. The base portion was wet and once the geotextile was removed a very thin depth of ponded water was evident.

Overall, the top of the drainage pipe was approximately at the same level as the bottom of the cement treated base.

Figure 2. Surface profiles at pavement edge/shoulder.

Figure 3. Cross section at Excavation TP1.

Figure 4. Open graded aggregate and pipe within geotextile.

Once the geotextile had been sampled the excavation was extended back to the pavement edge where a transverse joint existed. It was noted that pumping had eroded a portion of the pavement at this joint. Deposited in the eroded portion was black granular type material. This black material was probably fines from the asphalt pavement shoulder. Sampling

the black soil proved difficult and no representative sample was obtained.

Figure 5. Geotextile condition: side and base.

### EXCAVATION TP2 (CHAINAGE 16+532)

The second excavation (TP2) was made near a catch basin and resulted (prior to enlargement) in much the same findings as the first excavation (TP1). Figure 2 shows the settlement between the pavement edge and the geotextile drain. Figure 6 shows the cross section measurements observed.

Figure 6. Cross section at Excavation TP2.

The curb catch basin was offset about 1.5 metres from the aggregate drain. The excavation was then enlarged to determine if the edge drain was connected, via an outlet pipe, to the catch basin. Indeed it was, and at the outlet chainage, the drainage pipe was turned down slightly. Figure 7 is a plan of the T-junction connecting a non-perforated outlet pipe, running at a right angle to the pavement, to the catch basin. The T-junction was wrapped in geotextile that was bedded on about 150 mm of Granular 'A'. Figure 8 shows a profile view along the perforated pipe highlighting the turned down condition at the T-junction. The slight turndown at the junction of the two pipes (perforated and non-perforated) picked up any water draining along the 50 mm of aggregate located below the perforated pipe in the geotextile-wrapped aggregate drain. Figure 9 shows a profile view along the

outlet non-perforated pipe connection. The connection pipe was cemented into the catch basin wall. Water collecting in the Granular 'A' below the T-junction and below the outlet pipe was trapped by the surrounding clayey gravel since there was no allowance for drainage at the catch basin connection.

Figure 7. Plan view of outlet connection.

Figure 8. Section B-B: Profile of pipe at T-junction.

Figure 9. Section A-A: Connection to catch basin.

## LABORATORY RESULTS

All soil samples recovered from the excavations were subject to grain size analysis. Figure 10 shows the grain size analysis curves from Excavation TP2. The samples from within the geotextile were open graded aggregate with only small amounts of material passing the 75  $\mu\text{m}$  sieve. The material trapped in the geotextile graded from 1 mm down to 50% passing the 75  $\mu\text{m}$  sieve. The Granular 'A' materials graded in accordance with the MTO specification except at the 75  $\mu\text{m}$  limit which was slightly greater than permissible (i.e. 10% to 12 % compared with MTO limits of 2%-8% for Granular 'A'). This quantity of fine sized material within a broad grading granular material indicated the probability of a relatively low permeability of Granular 'A'. Confirmation was obtained by permeability tests on the recovered Granular 'A' samples. The average coefficient of permeability of the as-recovered samples was  $2.8 \times 10^{-5}$  cm/s and after washing on a 75  $\mu\text{m}$  sieve  $2.6 \times 10^{-2}$  cm/s; an increase of nearly 1000 times.

Figure 10. Grading of Excavation TP2 soil samples.

The geotextiles examined in the field and on return to the laboratory showed no sign of obvious damage. There were no holes or severely worn areas that might cause concern that the properties were less than those originally specified in 1982. A good indication of the remaining overall strength was the considerable force needed to remove a small area of the geotextile in the field. This considerable force inflicted no observable damage.

## DISCUSSION

The results of the investigation show that placing a geotextile-wrapped trench drain some distance away from, and separated from, the pavement edge by relatively impermeable Granular 'A' prevented or significantly reduced internal drainage of the area below the structural concrete. The results of this poor drainage were clearly seen at the transverse joint uncovered at the first excavation. At this

joint there was evidence of (a) pumping, (b) erosion of the concrete at the joint base, (c) heave/settlement on the shoulder at the pavement edge (Figure 2) and (d) deterioration of the quality of the cement treated base. Retrofit geotextile-wrapped trench drains should be located adjacent to the pavement edge with the geotextiles against the supporting pavement layers. To prevent subgrade pumping, a filter capping granular material continuously graded down to the 75  $\mu\text{m}$  sieve should be used with any cement treated base.

There was no evidence that the geotextile or the pipe had sustained any damage that would cause concern regarding its ability to continue to function as it has over its ten years in-situ. The sides and top of the geotextile were relatively clean. The main fouling was at and above the base, which is the whole purpose of the clear stone bedding below the pipe. Provision should be made to allow drainage of any granular bedding material placed below any outlet pipes connected to catch basins.

## CONCLUSIONS AND RECOMMENDATIONS

Excavations were made at two granular edge drain locations on the shoulder of a major Ontario freeway. From the observations and tests made on the recovered soil samples, the following conclusions and recommendations are made.

Retrofit geotextile-wrapped trench drains should be located next to the pavement edge.

Geotextiles, if used, should be placed tight against the supporting layers of the concrete pavement.

The need for a 50 mm bedding of open graded aggregate at the base of trench drains was clearly demonstrated at both excavations. The bedding material trapped sediment that otherwise would have accumulated in the drainage pipe reducing the pipe's ability to function effectively.

Evidence of migration of subgrade fines into the open graded aggregate above the cement treated base was observed. Drainage alone does not stop subgrade pumping.

No evidence was noted of loss of ability to function of either the geotextile or pipe.

Evidence of accumulation of fines in the trench drain demonstrated that a geotextile is required.

The T-junction detail illustrated in Figure 8 is recommended.

## ACKNOWLEDGEMENT

Gratefully acknowledged is the considerable cooperation and help provided by Ministry of Transportation of Ontario (MTO) personnel who provided the excavation equipment and manpower. Particular thanks are extended to Ms. P. Marks and Mr. S. Senior of the MTO for their significant contributions to this paper. The views expressed in this paper are those of the authors and not necessarily the MTO.

# Deformations and Damage of Non-Woven Geotextiles in Road Construction

**ABSTRACT:** SINTEF Civil and Environmental Engineering have performed a research project in two phases on non-woven geotextiles in road constructions. The first phase was a large-scale laboratory test aimed to study the effect of non-woven geotextiles on road deformations at cyclic loading. The second phase was a field test aimed to study the resistance against damage of the geotextiles during construction. The project focused on the correspondence between properties from index tests and the observed behaviour. A clear correspondence was found between the initial tension stiffness of a geotextile and the deformation after cyclic loading. Low correlation was found between observed damage during construction and the evaluation criteria used for classification of geotextiles in Norway. To take into account these findings it is recommended a revision of the evaluation criteria. It is also proposed a survivability criterion based on a combination of deformation energy and stress-strain properties to cover the construction and lifetime requirements.

**KEYWORDS:** Geotechnical Engineering, soil, geotextile, damage.

## 1 INTRODUCTION

The criteria for evaluating strength and deformation properties for non-woven geotextiles used in separation and filtration in roads have been discussed for more than twenty years. The first systems for evaluation and classification of geotextiles for separation and filtration in roads were introduced by the Norwegian Road Research Laboratory (NRRL), (Alfheim and Sørli, 1977). Later several systems have been introduced but generally the classification requirements are mainly empirically based, and to some extent dependent on local conditions and experiences (Forschungsgesellschaft für straßen- und Verkehrswesen, 1994, Rathmayer, 1993, AASHTO, 1990). The evaluation criteria and the index test methods which are used, differ between the systems and a possible co-ordination between the systems have been discussed since their introduction.

### 1.1 The Norwegian classification system

Geotextiles for separation and filtration in roads are in Norway divided into four classes dependent on the type of material (maximum grain size) to be used against the geotextile:

Class 1: Generally not used

Class 2: Sand and gravel with max. diameter 50 mm

Class 3: Crushed stone with max. diameter 100 mm

Class 4: Blasted rock with max. diameter 2/3 of the layer thickness

The classification is based on an evaluation of results from the static puncture tests and the cone drop tests. The tested product will achieve points from the results in the tests referring to each criterion and the classification is then dependent on the total sum of points. For the static puncture test (CBR- test, ISO 12236:1996) the measured force and deformation are used to calculate a corresponding tension (force/mm) and strain (%). The classification criterion is based on the derived tension and strain, the maximum tension, the elongation strain at failure and the tension increase from 20 % to 70% strain (or until strain at failure if less than 70%). The average hole diameter is used as evaluation criterion for the cone drop test (Schalin 1995).

### 1.2 Relevant properties and test methods

There is a clear need for establishing a more fundamental understanding of the required characteristics of the geotextile to fulfil its functions (separation and filtration) in the road. The required properties must reflect the environmental loads imposed on the geotextile during the installation, construction and service lifetime. A theoretical sound correlation between the required properties and the corresponding required parameters found from index tests should be established. A combination of index tests, large scale performance tests, full scale field tests and collection of experiences from the field is believed to be the best way to establish such a correlation.

2 RESEARCH PROJECT

SINTEF Civil and Environmental Engineering have performed a research project on non-woven geotextiles in road constructions. The NRRL and has participated with observers and supervisors in the project. The project focused on the correspondence between geotextile properties found in index tests and the observed behaviour in laboratory and the field. The first project phase (SINTEF 1996) included index tests and large scale laboratory load test. This part aimed to study the effect of stress-strain properties on non-woven geotextiles on road deformations at cyclic loading. The second phase was a field test (SINTEF 1997) aiming to study the resistance against damage of the geotextiles during the construction. Non woven geotextiles with different production technology and area weight were used in the research projects.

2.1 Laboratory tests

2.1.1 Index tests

The index tests included cone drop tests, static puncture tests and wide width tensile tests. The tests were performed on virgin samples and on samples extracted after the load test. In addition the effect of thermal cycling and stress strain behaviour under frozen conditions were tested. Six different non-woven geotextiles were tested, three corresponding to class 2 and three corresponding to class 3. The geotextiles used in the laboratory tests corresponding to class 3 are listed in Table 1.

Table 1. Class 3 geotextiles used in the laboratory test.

Reference	Type of product	Nominal area weight (g/m <sup>2</sup> )
SNP 3A	Staple fibre, needle punched, polypropylene	190
CNP 3B	Continuous filament, needle punched, polypropylene	160
CTP 3C	Continuous filament, thermally bonded, polypropylene	190

A summary of the results from the static puncture tests and the falling cone test on virgin samples for class 3 products is presented in Table 2.

Typical load displacement curves from the static puncture test are shown in Figure 2. Observe the differences in initial stiffness between the different geotextiles.

The thermal cycling had no significant effect on the results from the index test measurements.

Table 2 Results from initial index testing of the geotextiles.

Ref	Weight g/mm <sup>2</sup>	Static Puncture test		Falling cone
		Max force, N	Displ.at max. force, mm	Average hole diameter, mm
SNP 3A	197.8	2380	57	14
CNP 3B	171.5	2252	44	24.2
CTP 3C	190.8	1970	50.8	19.1

Figure 1. Typical load displacement curves for the class 3 geotextiles.

2.1.2 Large scale load test

The large scale laboratory testing was performed in a 12.5 m long and 1.8 m wide test bin filled with a 650 mm thick layer of soft clay with 2-3 kPa undrained shear strength. The geotextiles was placed on the clay and covered with 150 mm of crushed stone as shown in Figure 2. The geotextile test samples were 2 x 1.8 m. Cyclic and static load was then applied on a circular plate with diameter 250 mm on the bearing layer. The geotextiles used in the large scale laboratory test are listed in Table 1.

Figure 2. Bearing layer construction.

A cyclic load with frequency 1 Hz and amplitude 0-4 kN was applied on the load plate. A load of 4 kN corresponds to an average applied stress under the load plate of 81.5 kN/m<sup>2</sup>. The gradually developing displacement on the geotextile beneath the load plate was measured during the

test, the resulting deformation profiles after 1000 cycles are presented in Figure 3.

Figure 3. Measured vertical displacement profile of the geotextiles after completed load test.

### 2.1.3 Evaluation of results

There are considerable differences in the measured deformations and strains in the geotextile in the load test. The observed deformations correspond well with the load displacement relations, Figure 2, measured in the static puncture test. The average strain of the geotextiles was measured to be 10.3%, 4.6% and 1.4% for SNP 3A, CNP 3B and CTP 3C, respectively. Converted to displacement in the static puncture test these strains correspond 19 mm, 12 mm, and 7 mm displacement. Figure 4 shows that the load corresponding to the strain levels is approximately 0.08 kN for all the three geotextiles. In the same figure, the area under the load displacement curve, named as the deformation energy, is shaded. Note that the deformation energy based on these results is about the same for all the tested geotextiles, even with large differences in the strain level.

Figure 4. Force-strain relationship related to measured strain for the geotextiles in the load test

This test shows that the strain developing at a typical cyclic loading is strongly dependent of the initial stiffness. A criterion that is aimed to cover the need for remaining

strength after construction should include the effect of initial stiffness.

## 2.2 Full scale field tests

### 2.2.1 Test set up

The test was performed outdoor on frozen uneven ground. The material in the ground consists of fill masses with silt, sand, clay and occasional stones. Due to rainfall just before and under the installation the upper 50-100 mm of the underground was saturated and muddy during the installation. As the temperature was decreasing during the test, this upper layer was frozen at the time of the extraction. Geotextiles used in the field test are listed in table 3.

Table 3. Geotextiles involved in the testing.

Reference	Type of product	Nominal area weight (g/m <sup>2</sup> )
CNP 4A	Continuous filament, needle punched, polypropylene	320
SNP 4B	Staple fibre, needle punched, polypropylene	330
SNP 4C	Staple fibre, needle punched, polypropylene	320
CTP 4D *)	Continuous filament, thermally bonded, polypropylene	350
SNP 4E	Staple fibre, needle punched, calendered on one side, polypropylene	300
CTP 4F **)	Continuous filament, thermally bonded, polypropylene and polyethylene	350

\*) Not previously classified in class 4 in Norway

\*\*\*) Tested in a separate field test

The geotextile CTP 4F was tested in a separate test together with CTP 4D that was also tested together with the other products. The results for CTP 4D are used as reference basis for comparing the results. The field test also included five geotextiles from class 2 not reported in this paper. The results from the index tests on virgin material are presented in Table 4. The load deformation relation curves from the static puncture test are shown in Figure 5.

Table 4. Results from index tests on the class 4 geotextiles.

Ref	Measured area weight $g/m^2$	Strength increase 20 - 70% strain N/mm	Push through tension N/mm	Push through strain %	Hole diameter mm	Number of points acc. to the Norw. classif.	Corresp applic class
CNP 4A	310.7	18.94	34.32	60.86	15.90	35	3
SNP 4B	359.0	23.20	38.28	70.78	12.10	44	4
SNP 4C	314.4	17.17	26.17	87.08	10.10	44	4
CTP 4D	353.1	10.60	33.87	70.12	13.90	41	4
SNP 4E	302.3	19.13	28.44	85.46	13.10	44	4
CTP 4F	345.9	14.3	38.9	51.4	20.9	35	3

Figure 5. Measured force and displacement from the static puncture test.

The principle for the test fill is shown on Figure 6. The geotextiles were placed directly on the ground and then covered with fill material by the use of a pay loader. The covering was done sideways to ensure that each of the geotextiles was treated equally. For the class 4 material, blasted rock with a maximum diameter of 800 mm was used for the fill. The largest rock fragments were flaky shaped thus a fill height 500 mm was possible.

Figure 6. Principle for the test fill.

The fill material was compacted with a heavy vibrating roller with three overpasses along the centre line and on the shoulders on top of each fill. One week after the installation the fill material was removed. The top of the fill material was removed carefully with an excavator. The

geotextile was then tied to the excavator and carefully lifted out.

### 2.2.2 Test results

The amount of damage and deformation of the geotextiles were observed during the extraction. By the visual inspection during extraction some damage in terms of holes could be seen on all the geotextiles. The degree of damage varied. The geotextiles SNP 4B and CTP 4D was less damaged than average, SNP 4C and CNP 4A average damaged while SNP 4E and CTP 4F most damaged. During the extraction it could be observed that the underground was more even under the products having a high initial stiffness compared to the others.

After extraction the samples were brought to the laboratory where the damages (number and size of holes) were counted and measured. The distribution of holes within different diameter ranges is shown in Figure 7.

Figure 7. Distribution of holes.

### 2.2.3 Evaluation of results

In order to correlate the observed damage with index test results the degree of *Damage* on a geotextile is defined as the sum of the measured hole diameters. The *Resistance*

against damage for one product can then be defined as the average damage divided by the damage on each geotextile as shown in Table 5, that is, the higher number the less damage. In the table the measured damage is normalised with respect to the average value for the five geotextiles, that is, a factor of 1.15 means 15 % less damage than the average.

Table 5. Resistance against damage.

Ref	Damage (Sum Of hole diameter)	Resistance against damage (Average damage)/ (damage)
CNP 4A	2793	1.07
SNP 4B	2613	1.15
SNP 4C	3157	0.95
CTP 4D	2655	1.13
SNP 4E	3759	0.80
CTP 4F	-	0.40*)

\*) Based on a scaling of the results

As CTP 4F was tested in a separate test the results can not be compared directly with the others. The additional field test with the geotextiles CTP 4D and CTP 4F used a less heavy compaction equipment resulting in considerably less damage on CTP 4D compared with the first part of the test.

However, by using the results for CTP 4D as a reference basis a possible comparison of the degree of damage can be done. This way of scaling the degree of damage is quite uncertain since it is based on the damages on one geotextile only, but still it illustrates the much higher degree of damage found for CTP 4F compared to the other products tested.

The resistance against damage and the results from the index tests are used to evaluate the requirements in the classification system. The relevancy of an index test parameter for survivability of the geotextile is studied by correlating the parameter with the *resistance against damage* as defined above. The area weights are also included in the correlation. The results of the correlation are shown in Table 7. The test results from geotextile CTP 4F was not included in the correlation.

Table 6. Correlation between index test results and resistance against damage.

Parameter	Correlation
Weight/m <sup>2</sup>	0.81
Strength incr. 20-70%	-0.11
Failure strength	0.84
Strain to failure	-0.77
1/(Cone drop hole diam)	-0.26
Number of points	-0.36

The parameters showing best correlation with the resistance against damage is the *push through strength* and the *area weight*. The criteria for *strength increase*, and the *number of points* shows poor correlation. The *strain to failure* and the *cone drop hole diameter* shows a fair negative correlation. The poor correlation for the number of points is remarkable. The low correlation is mainly caused by the fact that the two geotextiles with the most damage have full score based on the criteria in the index test.

The results from the index test do not point out an obvious candidate among the parameters that may explain why CTP 4F should be so severely damaged. In the primary tests the best correlation with the resistance against damage was found for the unit weight and the failure strength. This was not the case for CTP 4F that gives a high score on both unit weight and failure strength. Geotextile CTP 4F has, however, a relatively low value both for *strain to failure* and the *inverse of the cone drop hole diameter*. These low values may partly explain some of the higher degree of damage for the CTP 4F geotextile.

Both CTP 4D and CTP 4F are thermally bonded geotextiles, having a high initial stiffness. As shown in Figure 5, the force-displacement relations from the static puncture test are relatively similar for these to geotextiles compared to the other geotextiles tested. The large difference in degree of damage between CTP 4D and 4F is not reflected by similar differences in the index test results, with a possible exception for the deformation at failure. The damage on CTP 4F is therefore probably caused by material properties not measured in the index tests. A possible explanation may be the properties on the brittleness in the failure or the tear propagation for the geotextile.

### 3 CONCLUSIONS AND RECOMMENDATIONS

The project has provided useful information for evaluating relevant properties and requirements for geotextiles to be used for separation and filtration in roads. There are considerable differences in stress strain properties of the geotextiles that is also reflected in the behaviour in the field. Noticeable differences are found in the susceptibility for damage during installation. The criteria used in the existing systems for classification and specification do not seem to reflect properly the behaviour in the field. A revision of the criteria is therefore clearly needed.

The deformation of the geotextiles when subjected to loading, that is, in terms of rutting during installation and construction, is clearly linked to the initial stiffness of the geotextile. A criterion for geotextile survivability is clearly relevant, but has to reflect the behaviour during installation, construction and service lifetime. A criterion for geotextile survivability is suggested based on a combi-

nation of requirements for deformation energy and remaining stress and strain till failure. The principle is presented in Figure 8.

The deformation energy related to the installation and construction should be chosen with respect to the type of fill material, construction equipment and type of underground.

Figure 8. Survivability criterion principle.

The requirements for remaining strength and strain to failure should reflect the expected loads and deformations (settlement) for the service lifetime.

The final criteria should be based on a collection of data from laboratory and field tests correlated with long-term experiences from the field. The field experience should include different type of geotextiles, fill materials, subsoil conditions and construction equipment. This should preferably be done as joint project involving several countries, producers, public authorities and research organisations.

#### ACKNOWLEDGEMENT

The authors would like to thank Du Pont de Nemours (Luxembourg) S.A. for funding the work and the purchasers of non-woven geotextiles in Norway for providing free samples for testing. We would also like to thank Ingrid Sødergren from Vägverket, Sweden for participating as observer in the field test and for useful contribution to the discussion.

# Rut Prediction for Roadways with Geosynthetic Separators

Wen-Sen Tsai, Moh and Associates, Inc., Taipei, Taiwan, Republic Of China

Robert D. Holtz

Professor, Department of Civil Engineering, University of Washington, Seattle, Washington, USA

**ABSTRACT:** Laboratory model tests that simulated field loading conditions were conducted to evaluate the performance of geotextiles separators. In the tests, rut depth was determined for various geotextiles, thickness of aggregate, subgrade soils, and the number of loading cycles. A rut prediction formulation for unpaved of roadways was developed, based on the Giroud and Noiray (1981) design procedure for unpaved roads. The prediction formula is verified by the rut measurement in a full scale field test.

**KEY WORDS:** geotextiles, separation, unpaved roads, model tests, rut prediction, design

## 1 INTRODUCTION

That geotextiles can markedly improve the performance of unpaved roadways constructed on soft foundation soils is well established. Although the primary geotextile function is separation, performance of unpaved roads is also significantly enhanced by the filtration, drainage, and reinforcement functions provided by the geotextile.

Ruts in the roadway surface are probably the most important indicator of roadway performance. Excessive or premature rutting is a good indication of either subgrade or aggregate failure, or both. Hence, the influence of geotextiles on the development of ruts can be used to evaluate their performance in unpaved roadway systems. Consequently, in this research, ruts were measured in laboratory scale model tests on subgrade-geotextile-aggregate systems. Cyclic plate load tests were conducted on three different thicknesses of base course aggregate, various types and weights of separator geotextiles, and two soft subgrade soils. The geotextiles investigated included heatbonded nonwovens, needlepunched nonwovens, and a woven silt-film. The results were used to develop a prediction equation for rut depths in unpaved roads. This rut prediction formula considers the base course thickness, subgrade strength, and number of loading cycles. The formula also predicted reasonably well the results of a full scale road test.

## 2 TEST SETUP, SOILS, GEOTEXTILES, AND PROCEDURES

Since the performance of geotextiles has been found to be strongly affected by the loading conditions, e.g. loading level and loading frequency, loading parameters used in this study modeled loading conditions experienced by separation geotextiles in the field. This was done by having stress levels applied to the geotextile due to a

dynamic load in the test the same as in the field.

Furthermore, the boundary of the test apparatus did not interfere with the failure zone in the subgrade, when and if the subgrade experienced a shear failure under a dynamic load.

An 80 kN single axle load, termed the equivalent single axle load (ESAL), is used in the AASHTO pavement design method and a tire pressure of 620 kPa is common for loaded dump trucks. The contact area between the tire and pavement for this loading, expressed as a ratio of wheel load and tire pressure, was 0.0645 m<sup>2</sup>.

A 0.416 m<sup>3</sup> steel drum, (Figure 1) contained layers of soils and was used to simulate a common roadway. The top layer was aggregate, which was underlain by a layer of soft soil 300 mm thick. More details about the setup can be found in Tsai (1995) and Tsai and Holtz (1997).

### 2.1 Subgrade Soils and Aggregate

Two different soils, a silty (ML) soil and a clayey (CL) soil, were used as the subgrades in the study. The silty soil was a tailing material from washed crushed rock. The clayey soil was obtained by mixing the silty soil with 5% bentonite by weight. The crushed stone aggregate (GP) was similar to the base material used by The Washington State Department of Transportation (WSDOT) for pavements. Table 1 shows the basic properties of these three materials.

### 2.2 Geotextiles

Six different separator geotextiles, all polypropylene, were tested. Types and relevant properties and given in Table 2.

Figure 1. Experimental Setup

Table 1. Basic properties of the silty soil, the clayey soil and the aggregate.

Property	Silty Soil	Clayey Soil	Crushed Stone
% passing US No. 200 sieve	81	82	0
Coefficient of Uniformity	25	NA	3.6
Coefficient of Curvature	1	NA	1.3
Plastic Limit, %	27	24	NA
Liquid Limit, %	38	46	NA
Unified Soil Classification System	ML	CL	GP
Permeability, cm/sec	$1.2 \times 10^{-7}$	$2.9 \times 10^{-8}$	NA
Maximum Dry Density, kg/m <sup>3</sup>	1580	1622	1922
Optimum Moisture Content, %	20.5	20.3	NA

### 2.3 Test Procedure

Testing procedure reported by Tsai and Holtz (1994), Tsai (1995) and Tsai and Holtz (1997) was followed in all tests reported in this paper.

Table 2. Nominal physical and mechanical properties of geotextiles used in the study.

Geo-textile	Structure	Thickness	Mass per Unit Area	Grab Strength
		ASTM D 1777 mm	ASTM D 3776 g/m <sup>2</sup>	ASTM D 4632 kN(%)
NP4	Nonwoven	1.3	142	0.511 (50)
NP6	Nonwoven	1.8	204	0.711 (50)
NP8	Nonwoven	2.3	268	0.933 (50)
HB4	Nonwoven	0.4	132	0.578 (100)
HB6	Nonwoven	0.5	197	1.000 (90)
SF4	Woven	NA	136	0.801 (15)

### 3 RUT MEASUREMENTS

In the model tests, the rut depths were determined based on the readings of a built-in LVDT in the MTS actuator that applied load to the circular plate.

A total of 19 tests were conducted in this study. Among the tests, three different aggregate base thicknesses, six different separators, two different subgrade soils, and four different subgrade strengths were used (Tsai, 1995; Tsai and Holtz, 1997).

Figure 2 shows a typical development of rut depth on the aggregate surface in a test where the geotextile was found to have survived. From this figure, we can see that

Figure 2. Typical development of rut depth on aggregate surface.

the rate of rut depth development was high initially, and then decreased with the number of cycles.

A summary of the measured ruts obtained in the tests are shown in Table 3. In this table, the notation of form A-B-C-D-E to identify each test. A is the thickness of the base course in mm; and B represents the type of separator used in the test. If it was a geotextile, then its mass per unit area (in oz/yd<sup>2</sup>) is also given. NP represents a needlepunched nonwoven geotextile; HB is a heatbonded nonwoven, , and SF represents a slit-film woven geotextile. GF represents a graded granular filter separator, while MEM represents an impervious plastic membrane. Null means that no geotextile was used.

The subgrade soil type was represented by C, while D represents the subgrade strength in CBR. E represents the sequence of a test, if the test was repeated.

In some tests, local shear failure of the subgrades was experienced, especially the softer ones (40-NP4-Silt-0.5, 40-NP4-Silt-1, etc.). These tests generally had large ruts, some as deep as 147 mm. The ruts for these tests that failed were not used for rut prediction.

Note that the rut depth of Test 40-MEM-Silt-2 was greater than rut depths in tests with separators of lower moduli, e.g. 40-HB6-Silt-2, 40-NP4-Silt-2, 40-NP8-Silt-2. Similarly, the test with the clayey subgrade (Test 40-NP4-Clay-2) had a deeper rut (63 mm) than test 40-NP4-Silt-2 (45 mm) which had the same experimental parameters except subgrade soil type. This can be explained by the long-persisting high pore pressures in the clay, as discussed by Tsai and Holtz (1997). This high pore pressure reduced the modulus of the subgrade, and thus higher plastic subgrade deformation occurred.

The ruts discussed in this section are not equivalent to the ruts that would occur in the field, since the results are determined from scale model tests. Since a fixed wheel path is simulated in these test, the ruts obtained in laboratory tests are probably greater than in the field.

#### 4 RUT PREDICTION BASED ON LABORATORY TEST RESULTS

Table 3. Ruts and depressions on subgrade surfaces after dynamic loading

Notation	Rut on Aggregate Surface (mm)	Depression Depth on Subgrade Surface (mm)	Depression Diameter on Subgrade Surface (mm)	Ratio of Depression Depth to Rut Depth (%)
110-HB4-Silt-2	18	14	229	78
110-NP4-Silt-2	20	9	152	45
110-SF4-Silt-2	18	6	165	33

40-Np4-Silt-0.5	147	152	330	103
40-NP8-Silt-2	41	41	NA	100
40-SF4-Silt-2	46	64	191	139

a. Depression was very small and it was difficult to determine the depression zone.

b. The shaded rows indicate the tests where geotextiles were found to have failed.

The results from the laboratory model tests reported here can be used to predict the rut depths in the field with various subgrade strengths, base course thicknesses and geotextile separators. Then it may be possible to determine rut depths for given base course thicknesses using projected traffic loads during the road's service life. In 1981 Giroud and Noiray, proposed a design method for unpaved roads, both with and without geotextiles. In their procedure, the geotextile was used to increase the bearing capacity of the subgrade from elastic "bearing capacity", actually the maximum shear stress, or  $N_c = \pi$  to ultimate bearing capacity  $N_c = (\pi + 2)$ , due to the subgrade confinement and stress reduction on the subgrade surface provided by the geotextile. They also considered the effect of traffic load using empirical data presented by Hammit (1970) and Webster and Alford (1978). The design formula proposed by Giroud and Noiray is shown below.

$$h'_o = \frac{119.24 \log N + 470.98 \log P - 279.01r - 2283.34}{c_u^{0.63}} \quad (1)$$

Figure 3. Measured and predicted ruts for Test 40-NP4-Silt-2

Figure 4. Measured and predicted ruts for Test 40-SF4-Silt-2

Figure 5. Measured and predicted ruts for Test 110-Null-silt-2

where

$h'_0$  = aggregate thickness (case without geotextile, when traffic is taken into account), in m

$c_u$  = undrained cohesion of subgrade soil, in Pa

$N$  = number of applications of load  $P$

$P$  = axle load, in N

$r$  = rut depth, in m

Equation 1 can be rearranged to obtain:

$$r = -8.18 + 0.186 \log N - 0.00358 c_u^{0.63} h'_0 + 0.733 \log P \quad (2)$$

This equation is of the form:

$$r = A + B \log N + C c_u^D H + E \left( \frac{k}{H} \right) \quad (3)$$

where  $A$ ,  $B$ ,  $C$ ,  $D$  and  $E$  are parameters, and where  $H$  is aggregate thickness, in meters, for the case with or without geotextile.

The laboratory results (Tsai, 1995) showed that the presence of geotextiles can reduce ruts if the geotextile can survive during its service life. However, the tests also showed that geotextile type did not affect rut depth, probably because of the strength of the subgrade and the types of geotextiles tested. Thus Equation 3 does not include geotextile modulus but instead a term  $E(k/H)$ , where  $k = 1$  if a geotextile is present, and  $k = 0$  if no geotextile is present. Using the laboratory results obtained previously, a regression analysis was conducted. The model tests have a scale of 1:2.75. Therefore, the measured ruts in the laboratory tests were multiplied by 2.75 to reflect field rut depths.

A statistics program, *NLREG*, was used to perform a non-linear regression analysis on the results of the laboratory model tests which did not have a subgrade failure or a failed geotextile. In the regression analysis, the sample size was 330, and from these results, Equation 3 can be expressed as:

$$r = 0.260 + 0.009176 \log N - 0.3935 c_u^{0.1465} H - 0.01689 \left( \frac{k}{H} \right) \quad (4)$$

The proportion of variance explained ( $R^2$ ) and the standard error of estimate were 0.88 and 0.0128, respectively.

Equation 4 is used only with an equivalent single axle load (EASL or 80 kN), and  $N$  is the corresponding number of passages of ESAL. On the other hand, Equation 2 can be used for the design of unpaved roads without geotextiles and also applies for any axle loads besides ESAL. This is why the coefficients of Equation 4

are different from those of Equation 2. Figures 3, 4 and 5 illustrate the development of both measured ruts from some typical laboratory model tests and their predicted values based on Equation 4. These tests represent various loading conditions with respect to base course thickness, subgrade strength, and geotextile separators. From these figures, we can see that Equation 4 provides a reasonable prediction for these three tests. Other results in Tsai (1995) provide similar agreement.

## 5 USE OF THE RUT PREDICTION FORMULA FOR FULL SCALE ROAD TEST RESULTS

The results of the full scale road test described in Tsai et al. (1993) were used to verify the new rut prediction formula. In the full scale road test, ten wheel passes were applied using a loaded dump truck weighing 214 kN. The rear axle of the truck was a tandem axle and supported about two-thirds of the gross weight of the loaded dump truck, i.e. 143 kN. Based on Giroud and Noiray (1981), either single axle of the tandem axle carries an axle load equivalent to:

$$0.6 \times 143 \text{ kN} = 86 \text{ kN} \quad (5)$$

The equivalent number of the passages of the single axle load is:

$$2 \times N = 2 \times 10 = 20 \quad (6)$$

The number of the passages of the tandem axle thus can be expressed in equivalent single axle load (ESAL) and is shown below.

$$N = 20 \times \left( \frac{86 \text{ kN}}{80 \text{ kN}} \right)^{3.95} = 27 \quad (7)$$

Equation 4 was used to calculate the ruts in the full scale road test. Figure 6 shows the values versus the measured values of the rut depths for the sections with 150 and 300 mm thick base courses in the full scale road tests (Tsai et al., 1993). Unfortunately, the subgrade strengths immediately below each location where the ruts were measured were not known. Hence, the mean values of subgrade strengths (shown in Tsai et al., 1993) in each section are used to predict the ruts. Figure 6 shows that many of the predicted values of the ruts are in the range of the measured values, so Equation 4 can be used to reasonably well predict the ruts with 150 and 300 mm base courses. Predictions are not made for the sections with 450 mm thick base course in the full scale road test, because the largest equivalent base course thickness in the laboratory

model tests was only 300 mm. Therefore, some tests with thicker base course are needed to improve this equation for such cases.

## 6 CONCLUSIONS

By modifying Giroud and Noiray's (1981) design equations, a new rut prediction formula based on the results of laboratory tests on scale model subgrade-geotextile-aggregate systems was developed. The formula takes into account base course thickness, subgrade strength, type and weight of geotextile separators, and number of loading cycles. The ruts measured in typical laboratory model test, compared well with their predicted values. The results of full scale road tests were also used to verify the rut prediction formula, up to an equivalent base course thickness of 300 mm. The predicted values tended to be greater than the measured values.

**ABSTRACT:** A field experiment was conducted in which geosynthetics were used at the base/subgrade interface in instrumented sections of a flexible pavement on a rural highway in Bedford County, Virginia. The sections were monitored for two-and-one-half years under local traffic. In this paper, development of a transition layer (intermixing at the base course-subgrade interface) is hypothesized when geosynthetic is absent. An analysis of Falling Weight Deflectometer (FWD) data confirmed the hypothesis in the thinner base (100 mm) sections. The results so far obtained from thicker base sections (150 mm and 200 mm) are inconclusive.

**KEYWORDS:** Geotextiles, Geogrids, Pavements, Separation, Falling Weight Deflectometer.

## 1 INTRODUCTION

To examine the geosynthetic benefits in pavement system and validate an earlier laboratory investigation at Virginia Tech (Al-Qadi et al., 1996, Smith et al., 1995), a section of rural highway in Bedford County, Virginia, was selected in 1994 for an experimental project involving the use and evaluation of geosynthetic functions between a fine-grained subgrade and a granular base course. The experimental section comprised part of a route realignment project undertaken by the Virginia Department of Transportation (VDOT). It was hypothesized that under the action of traffic and environment the subgrade would, in the absence of a separation material, be pumped into the granular base and/or the base course material would penetrate into the subgrade thereby compromising the structural capacity of the pavement.

### 1.1 Site Description

Nine experimental sections, each of approximately 15 m in length, were constructed as part of the realignment of Route 616 in Bedford County, Virginia. The pavement construction comprised a nominal 90 mm hot-mix asphalt (HMA) wearing course surfacing over a granular base. The thickness of the base varied throughout the nine

sections: 100 mm thick in sections 1 through 3, 150 mm in sections 4 through 6, and 200 mm in sections 7 through 9. The subgrade was a weak, reddish brown CH (AASHTO A-7-6) soil, except under sections 5 and 6 where it was identified as ML (AASHTO A-5). These materials were found to have soaked CBR values in the range 6 to 10% at in-situ moisture-density values.

Samples of all construction materials were taken from in-situ and tested in the Materials Laboratory at Virginia Tech. Conventional tests were performed on all recovered materials (HMA: Marshall parameters at 50-blows, asphalt extraction and aggregate gradation; base course: gradation, moisture content, moisture-density and CBR; subgrade: gradation, moisture content, moisture-density and CBR). Extra testing was undertaken on these materials to provide more fundamental material properties (HMA: resilient modulus and creep compliance; base and subgrade: resilient modulus).

The HMA had an asphalt content of about 6.2% by weight of mixture, an average air-void content of 4.6% and an average VMA of 17.9%. The average Marshall Stability and Flow values were 12.3 kN and 10 flow-units. The resilient modulus,  $M_R$ , of field specimens ranged from 3160 MPa at 5°C to 2620 MPa at 40°C. Creep compliance curves were obtained from all field and bulk samples.

The granular base material complied with VDOT specification for a type 21-B base. It classifies as a GW

soil and has an optimum moisture of 6.1% at a density of 22.3 kN/m<sup>3</sup>. Remolded samples were tested for resilient modulus,  $M_R$ , and can be expressed in terms of the bulk stress,  $\theta$ , with an average result of:

$$M_R \text{ (MPa)} = 650\theta^{0.62} \quad (1)$$

Two types of geosynthetic materials were placed at the base/subgrade interface: a woven geotextile and a geogrid. Sections 1, 4, and 7 served as control sections with no geosynthetic at the base/subgrade interface, while the geotextile was placed in sections 2, 5, and 8. The geogrid was likewise installed in sections 3, 6, and 9. The experimental matrix is shown in Table 1. The pre-installation properties of the geosynthetics used are listed in Table 2. The geosynthetics were also tested after three years of field service to determine the installation, construction practice, environmental, and vehicular loading effects on these properties. A 0.6 m x 3.6 m (lane width) piece of each geosynthetic was obtained after excavating the pavement in October 1997. Both geosynthetics were found in excellent condition, and their properties are shown in Table 3. Analysis of changes in the geosynthetic properties and gradation of base and subgrade material after three years of service will be presented in a future publication.

Table 1. Experimental Matrix.

Section Type	Base Thickness		
	100 (mm)	150 (mm)	200 (mm)
Control	1*	4	7
Geosynthetic	2	5	8
Geogrid	3	6	9

\*Denotes section number

Table 2. Characteristics and Properties of Geosynthetics Used (before testing).

Material	Direction	Ultimate	
		Strength (kN/m)	Elong. (%)
Geotextile	Warp	27	23.6
	Fill	25	9.9
Geogrid	Machine	19	8.9
	X-Mach	33	9.3

Construction started in April 1994 and was effectively completed by September 1994. This period included a significant amount of time and effort devoted to installing and checking the various instruments embedded in the pavement. The pavement was opened to traffic in September 1994 (Al-Qadi et al. 1996).

Table 3. Characteristics and Properties of Geosynthetics Used (after testing).

Material	Direction	Ultimate	
		Strength (kN/m)	Elong. (%)
Geotextile	Warp	18	14.8
	Fill	25	12.5
Geogrid	Machine	19	12.4
	X-Mach	32	14.1

## 1.2 Traffic

Traffic volume rates were recorded automatically by the installed instrumentation and varied from 300 vehicles per day in winter to more than 700 vehicles per day in summer.

Three calibration tests were run; a flat-bed truck was used at different axle loads, tire pressures and speeds. This was designed to provide a basis for calibration and validation of the installed instrumentation, and to yield a complete response matrix against which a mechanistic pavement design method, under development, could be validated.

## 1.3 Section Monitoring

Monitoring of the experimental sections was undertaken using two approaches. The first consisted of a series of embedded instrumentation designed to monitor and record traffic, temperature, moisture, pressure, and strains at various points within the pavement sections and on the geosynthetics. A data acquisition system was set up to collect all the appropriate readings from the instrumentation when triggered by the passage of a vehicle. Accumulated data was periodically transmitted electronically to the Materials Laboratory at Virginia Tech for storage and analysis. The second approach relied upon periodic, seasonal visits to the site to measure and record visible distress indicators, although only permanent deformation (rutting) was found to have occurred, to subject the test sections to Falling Weight Deflectometer (FWD) testing for structural evaluation, and, on occasion, to scan the sections using ground penetrating radar (GPR). This paper discusses the rutting and FWD test results

## 2 FIELD MONITORING

The test sections were periodically monitored to provide information relative to surface distresses (rutting) and to perform noninvasive, nondestructive structural evaluations of the different sections.

## 2.1 Rutting

Rutting was measured using a straight-edge method. Two readings were taken on each section during each visit. The magnitude of rutting was defined as the greatest gap between the straight-edge laid upon the pavement transverse to the direction of traffic and the pavement surface. This method would not distinguish between settlement or compaction rutting and plastic flow/heave rutting, however, it is noted that there was no indication of plastic flow/heave distortion of the pavement surfaces. Figures 1 and 2 summarize the development of rut depths during the monitoring period for sections 1 through 3 and 4 through 9, respectively.

From Figures 1 and 2, it is immediately apparent that the rutting histories of sections 1, 2, and 3 stand apart from those in sections 4 through 9, which are statistically identical. In these sections, the magnitude of rutting not only exceeds that in the others, but the rate at which it accumulated is seen to be increasing. Indeed, it has been observed that since about August 1996, the rutting measured in section 1 has exceeded the maximum criterion of acceptability (25 mm), and the rate at which it is accumulating is accelerating.

The rutting that occurred during the first few months of traffic is mainly due to "normal" initial rutting from compaction under traffic. As can be noted, the rutting observed in the first four months is almost the same for all sections. The sharp increase in rutting (in all sections) just before October 1996 is due to the application of two weeks of heavy truck loading to accelerate rutting. The relatively low rutting in sections 4 through 6 was due to the greater wander in the area of the intersection.

Figure 1. Rut Depth for Sections 1 through 3.

## 2.2 Falling Weight Deflectometer (FWD)

The Virginia Department of Transportation (VDOT) FWD was chosen to perform seasonal structural evaluations of the test sections. This device, which drops a calibrated mass onto a circular plate (radius 150 mm) in contact with the pavement surface, records the magnitude of the applied load, and the vertical deformation response of the pavement surface at the center of the loaded plate and a six locations offset from the loaded axis.

Two types of analysis may be performed on FWD data. The simplest and most direct analysis relies on computing a Surface Modulus,  $E_0$ , defined as the applied load divided by the measured axial deformation. This value is analogous to a spring constant (kN/mm), and provides a gross measure of the overall structural value of the pavement system, including the subgrade. A more sophisticated analysis is possible using various techniques of "back-calculation" which seek to match the observed pavement response to that returned by a mathematical model of a layered linear elastic half-space. This technique generally relies upon varying the linear elastic moduli of the component material layers until a satisfactory match to the observed surface deflection is achieved.

Figure 2. Rut Depth for Sections 4 through 9.

### 2.2.1 Surface Modulus ( $E_0$ )

The surface modulus of each section was computed for each of the seasonal site visits. This technique is simple because it requires that no assumptions be made relative to the thickness or elastic response of component layer materials. However, it is subject to modification in HMA surfaced pavement due to the effects of temperature upon the viscoelasticity of the asphalt bound materials, and can be further influenced by the presence of an effective rigid

layer underlying the pavement at some depth. The results of these analyses are shown in Figure 3.

It can be seen from Figure 3 that the overall pavement responses of sections 1, 2, 3, and 9 stand out as being distinct from those in sections 4, 5, 6, 7, and 8 which are remarkably consistent. This apparent difference is ascribed to the details of the design of this road section, which was relocated to transform an intersection into a curve. Consequently, in spite of a significant excavation (mainly in sections 4 through 8), the sections at each end of the new construction are somewhat influenced at some depth by the presence of previously undisturbed and compacted subgrade materials. This will also explain the increased surface moduli observed in these sections; the authors believe that this is due not to stronger pavement sections, but to residual pre-compacted subgrade.

Figure 3. FWD-derived Surface Moduli (MPa).

Nonetheless, if the surface moduli for sections 1, 2 and 3 are closely examined, it will be seen that for all FWD tests, the surface modulus of section 2 (geotextile) exceeds that of section 3 (geogrid), which in turn exceeds that of section 1 (control). This pattern is also observed in sections 4, 5, and 6 (150 mm base) and in sections 7 and 8 (200 mm base), and would tend to indicate that the geotextile may contribute more to the structure than other sections (Al-Qadi et al. 1997).

### 2.2.2 Detailed FWD Analysis

FWD measured deflection profiles were plotted for different periods. The purpose of this exercise was to define any inconsistency, which might occur in the measurements taken by the geophones. Figures 4 and 5 are typical measured deflection basins for different load levels in July 1997 for sections 1 and 2.

The collected FWD field data was further analyzed using proprietary software, MODULUS version 5.0,

developed by the Texas Department of Transportation (TxDOT) and the Texas Transportation Institute (TTI).

This package takes as input pavement responses recorded in the field and the thicknesses of each physical material layer. The elastic parameters ( $E$ ,  $\nu$ ) of any layer except the subgrade may be either fixed or bounded within a range supplied by the user. The program then performs a search algorithm, varying the “slack” variables until an optimal match between the measured and computed deflection basins is found. The output from this program is the “optimal” set of layer moduli consistent with the measured values and the set layer property constraints.

Figure 4. Deflection Basin Profile (July 1997), Section 1.

Figure 5. Deflection Basin Profile (July 1997), Section 2.

MODULUS uses an internal routine to detect the presence and depth of effective rigid layers deep within the pavement. This is important, and has been found to significantly influence the returned moduli. In this project, MODULUS did indeed detect an effective rigid bottom

layer at a varying depth of 0.5-7.5 m (mostly above 2.0 m) below the pavement surface. Further data analysis indicates that the variation in depth to rigid bottom layer did not have any significant effect on the result pattern.

Due to the relatively thin HMA surfacing layer, the elastic properties of this layer were input and fixed by the authors based upon appropriate measured pavement temperatures and the laboratory resilient modulus characterization of specimens obtained from the field. The nominal elastic parameters of the granular base layer were also provided and fixed by the authors based upon laboratory measurements (Al-Qadi et al. 1996). The only parameter returned by MODULUS, therefore, was the subgrade modulus (Figure 6). This analysis confirms the differential response between the different treatments.

For most of the FWD results, the subgrade “apparent” resilient moduli of the sections with geotextile are greater than their corresponding control sections or geogrid stabilized/ reinforced sections. This may be attributed to a weaker base course layer in the latter sections as compared to the corresponding geotextile stabilized sections, which is consistent with the “pumping of subgrade fines into the base course layer and/or intermixing at the base-subgrade interface” hypothesis.

### 2.2.3 Base-Subgrade Interface Intermixing Model

One of the important functions of geosynthetics in pavements is stabilization, which is its ability to isolate and provide a barrier against the base course-subgrade intermixing (Koerner and Koerner 1994, Al-Qadi, et al., 1994, Jorenby and Hicks, 1986; Lair and Brau, 1986). The extent of contamination and the material properties of the intermixing layer are of critical importance in determining the performance of pavements. Although the concept of base course contamination has been realized for sometime (Yoder and Witczak, 1975), an estimate of its contribution to the reduction in pavement service life is still needed to be quantified. The following section details the approach adopted to determine the extent of contamination in this project.

The hypothesis put forth in the study was the development of a transition layer between the subgrade and base layer in the absence of a geotextile. To determine the transition layer thickness developed in control and (may be) geogrid stabilized reinforced sections, an independent layer of resilient modulus value between the base and subgrade was added and the “geotextile subgrade resilient modulus” was considered in the calculations as reference. After adding the transition layer with known properties to the control pavement system, a back-calculation procedure was adopted to determine the subgrade resilient modulus. This is an iterative process where the thickness of the transition layer is changed gradually to yield a subgrade resilient

modulus approximately equal to that of the geotextile stabilized section.

For example, the subgrade resilient modulus, from the data collected in August 1995, for section 1 (100 mm control section) was 105 MPa, where the geotextile stabilized section had a subgrade resilient modulus of 110 MPa. A transition layer thickness of 13 mm at a resilient modulus of 138 MPa was needed to increase the subgrade resilient modulus to 110 MPa. Over the next 8 months the transition layer increased to 64 mm. The thickness further increased to 69 mm by October 1996 indicating asymptotic stabilization of intermixing layer versus time (see Figure 7). Further tests show insensitivity to greater contamination/ intermixing.

For the thicker base course sections (150 mm and 200 mm), the MODULUS program becomes insensitive to changes in transition layer thickness. This implied that the FWD back-calculation procedure could not estimate the contamination layer thickness accurately in the thicker base course sections (150 mm and 200 mm) at this time.

Figure 6. Apparent Subgrade Resilient Modulus Variation over Time.

Figure 8. Development of Transition Layer.

### 3 CONCLUSIONS

The results of this field experiment and analysis of the data derived from non-destructive monitoring (rutting and FWD) suggest a clear difference in performance when geosynthetic is included in the pavement system; specially in the thinner base sections (1 through 3), while the short duration of the project prevent any clear distinctions being made in the thicker base sections (4 through 9) at his time. Within sections 1 through 3, the benefit of the geotextile is noted by comparison with the performance (rutting) of the control to the other sections; equally, a simple analysis of FWD data suggests that the degree of intermixing at the base-subgrade interface is a function of the geosynthetic used - no intermixing in the geotextile section, and delayed or reduced intermixing in the geogrid stabilized/reinforced section. MODOLUS program was used to obtain the extent of intermixing at the base course-subgrade interface in the 100 mm test sections over a period of 17 months (August 1995 to January 1997). It was found that the degree of intermixing can be quantified. However, for the thicker base course sections (150 mm and 200 mm) the back-calculation (so far) turns insensitive and the difference in performance between sections is within the numerical accuracy of the computer model.

### 4 ACKNOWLEDGEMENTS

The authors acknowledge the financial support by the Virginia Center for Innovative Technologies and the Amoco Fabrics and Fibers Company. The authors also acknowledge the VDOT support in providing the FWD testing for this study. The invaluable help by Barney Barnhart and Jeff Kesler of VDOT is greatly appreciated.

**ABSTRACT:** Montana State University (MSU), with support from the Montana Department of Transportation (MDT), has initiated a laboratory and analytical based research program to study and quantify the benefits derived by the addition of geosynthetics to the base course layer of flexible pavements, where the function of the geosynthetic is one of reinforcement. The objectives of the study are to verify previous work showing the positive benefit of using geosynthetics for base course reinforcement, to quantify the stress-strain response of laboratory-scale reinforced pavement test sections such that mechanisms of reinforcement can be more clearly understood and described, and to develop a comprehensive methodology for the design of such pavements. The purpose of this paper is to describe on-going research work at MSU, plans for laboratory testing and analytical modeling, and to present preliminary results from several completed test sections. Details of the test facility and instrumentation used to quantify behavior are presented.

**KEYWORDS:** Pavements, Base Course, Reinforcement, Laboratory Tests, Geogrids, Geotextiles

## 1 INTRODUCTION

Geogrids and geotextiles have been examined and used in practice for reinforcement of the base course layer of flexible pavements for over the past sixteen years, with both successes and failures having been reported. Early attempts using geotextiles (Brown et al., 1982; Ruddock et al., 1982; Halliday and Potter, 1984) indicated very little improvement in rut development characteristics that could be attributed to geotextile reinforcement. For studies involving both geogrids and geotextiles, Anderson and Killeavy (1989), Barksdale et al. (1989) and Cancelli et al. (1996) have demonstrated that geogrids are superior to geotextiles when used as a reinforcement member, while Al-Qadi et al. (1994) showed that superior performance was seen when a geotextile was used.

These studies involving both materials have provided insight into the importance of the roles of separation and filtration and the ensuing effect on reinforcement potential. The only study available where appreciable mixing of the base course and subgrade soils in control sections was noted (Al-Qadi et al., 1994) also corresponds to the one showing superior performance by the geotextile. Other studies exhibiting more moderate amounts of mixing, and indicative of conditions for which separation and filtration functions were not as critical (Anderson and Killeavy, 1989; Barksdale et al., 1989) indicate that improvement due to geogrid reinforcement can still be observed, but perhaps not to the extent had separation and filtration functions been incorporated into the section designs. On the other extreme, studies exhibiting no problems with mixing (Cancelli et al., 1996; Collin et al., 1996; Haas et al., 1988; Mirua et al., 1990; Moghaddas-Nejad and Small, 1996; Webster, 1993) have

demonstrated significant improvement with geogrid reinforcement for properly designed sections.

Improvement in pavement performance has been observed in laboratory-scale experiments involving stationary circular plates to which a cyclic load has been applied (Cancelli et al., 1996; Haas et al., 1988; Miura et al., 1990), test tracks incorporating moving wheel loads (Barksdale et al., 1989; Collin et al., 1996; Moghaddas-Nejad and Small, 1996; Webster, 1993) and full-scale roads constructed with normal construction equipment (Anderson and Killeavy, 1989; Mirua et al., 1990). Improvement has been defined in terms of an extension of the life of the pavement, or the amount by which the base course layer could be reduced such that equivalent performance is seen. Reinforced pavements have been shown to have a life typically 3 to 10 times that of a similar unreinforced section, while a reduction of base thickness ranging from 22 to 50 % has been observed. Performance has typically been measured in terms of accumulated rut depth with increasing load cycle application.

Improvement has been seen for all levels of rut depth below that corresponding to an inoperable condition (25 mm). Measurement of strain on geogrid layers has shown that strain is developed immediately upon the first load application and well before any appreciable rut is developed in the pavement, provided the reinforcement was properly placed in the base layer. Strain measurements have indicated that these materials are engaged in a tensile capacity and that the level to which strain develops is closely related to the amount of improvement observed. These results indicate that this application is well suited for flexible pavements which cannot tolerate significant surface deformations and remain operational. Perkins and Ismeik (1997) have provided a more comprehensive review of studies addressing this application.

Despite the positive successes reported from field and laboratory based studies, this application has not been widely applied in practice and its use has been discouraged by a number of state departments of transportation. The overriding obstacle preventing the use of this application lies in the absence of an accepted design technique which accounts for the variables believed to control pavement performance. MSU, with support from the MDT and Federal Highway Administration, has initiated a laboratory and analytical based research program to study and quantify the benefits derived by the addition of geosynthetics to the base course layer of flexible pavements, where the function of the geosynthetic is one of reinforcement. The objectives of the study are to verify previous work showing the positive benefit of using geosynthetics for base course reinforcement, to quantify the stress-strain response of laboratory-scale reinforced pavement test sections such that mechanisms of reinforcement can be more clearly understood, and to develop a comprehensive methodology for the design of such pavements. The step from the observation of behavior in laboratory experiments to the development of a design solution will be accomplished through the development of a finite element model of a reinforced pavement. Once the model is shown to reasonably match the behavior observed in the laboratory experiments, the model will be used in a parametric study to evaluate the influence of variables thought to impact reinforced pavement performance. The purpose of this paper is to describe the ongoing research work at MSU, the plans for laboratory testing and analytical modeling, and to present preliminary results from several completed laboratory test sections.

## 2 OVERVIEW OF RESEARCH PROGRAM

The MDT faces conditions in the eastern portion of the state where quality gravel sources for road construction are scarce and associated haul costs of such material are high. Subgrade conditions in this region consist of A-6 to A-7 soils, resulting in relatively low subgrade support values and relatively thick base course sections. Faced with these conditions, MDT has been interested in investigating the possible use of geosynthetics as reinforcement in the base course layer. MSU developed an early plan to construct a series of full-scale test sections along an existing or new roadway with these sections containing electronic instrumentation to measure pavement response. To investigate the suitability of proposed instrumentation and installation techniques, a pilot test section was constructed in the Summer of 1995 with results reported by Perkins and Lapeyre (1996, 1997).

The results of this instrumentation study indicated that excessive uncertainty existed in the installation and operation of instrumentation in an outdoor, field-scale test site and that successful completion of the originally planned approach was questionable. An alternate approach was then proposed where similar instrumentation used in the pilot test section would be used along with new devices to monitor the behavior of test

sections constructed in a laboratory setting. This facility is described in this paper and essentially consists of a large reinforced concrete box in which pavement test sections are individually constructed and loaded with a 40 kN load cyclically applied to a 305 mm diameter circular plate resting on the pavement surface. The pavement test sections contain an extensive array of instruments to measure stress, strain, moisture content and temperature. Stress and strain response is measured in the pavement layers both during a dynamic load cycle and between load cycles to monitor the accumulated response with increasing load cycle.

It is anticipated that between 10-15 sections will be constructed and loaded over the course of the study. Geosynthetic type (geogrid versus geotextile), geosynthetic position within the base layer, subgrade type and strength and stiffness characteristics, and base and asphalt concrete (AC) thickness are anticipated as variables to be included in the study. The variables included in these sections are not intended to cover all possible pavement configurations but rather are intended to provide a description of response for a representative cross section of variables. The modeling portion of the study is intended to be used to supplement the experimental data by providing analytical predictions of behavior for those conditions not physically tested.

In conjunction with the experimental portion of the study, a finite element model of the laboratory-scale pavement sections is being developed. The model is being developed to match the stress, strain and deflection response observed in the 10-15 experimental test sections. Once confidence in the model is developed by this step, the model can be used to predict response of a wide range of pavement configurations for which experimental data is not available. Results from this parametric study will then be combined to form a design methodology suitable for use by flexible pavement designers. The form of this design methodology has not been defined at this point, but will most likely consist of simple equations and design charts which account for the variables found to be most influential on reinforced pavement response.

The modeling portion of the study is being accomplished through the use of a commercial finite element program and user defined material constitutive laws. Haas et al. (1988) and Miura et al. (1990) showed that in a similar test arrangement, tensile strains as great as 1.8 % were observed in geogrid reinforcement for surface rut depths less than 25 mm. Cyclic tension tests performed by Bathurst and Cai (1994) and preliminary tests performed by the authors indicate that for strains of this magnitude, simple isotropic linear elastic material models are inadequate. In anticipation of the need to predict strains of this magnitude, a series of monotonic, cyclic and sustained load tests are being performed on the geogrid and geotextile being used in this study. The monotonic load tests are being used to define the orthotropic elastic-plastic properties of the materials, where the in-plane shear modulus is thought to be particularly important in defining pavement response. Sustained load tests will provide intrinsic creep properties of the geosynthetics. Cyclic tension tests will be

used to calibrate a non-linear, combined isotropic/kinematic hardening model which will model the ratchetting effect observed in repeated load tests. Ratchetting refers to the accumulation of plastic strain with increasing load cycle number for cyclic tests performed under constant load amplitude.

Ratchetting effects are also observed under compressive deviatoric loads in soil materials and will be modeled through the use of a bounding surface plasticity model. An interface model will be used between the base soil and the geosynthetics and will consist of a simple elastic-plastic Coulomb type friction law. It is anticipated that the elastic stiffness response will need to be normal stress dependent. The interface model will be calibrated from pull-out tests where the pull-out arrangement will be modeled as a boundary-value problem using the finite element model being developed. A standard viscoelastic model will be used for the asphalt concrete.

The research approach of collecting data from experimental test sections, using a model to match the observed behavior, using the model in a parametric study to examine the influence of a wide range of variables and using these results to establish a design solution to the problem is being applied to laboratory-scale experiments under stationary load conditions. Part of the reason for first exercising this approach in the laboratory is to establish its feasibility. Recognizing that different behavior is to be expected under conditions of a moving wheel load, if this approach is found to be successful, the authors intend to pursue an additional phase to the project where experiments are conducted in a test-track facility where more realistic loads can be applied to the pavement. The same research approach can then be applied, with the resulting design solution reflecting the moving wheel load case.

The remainder of this paper describes the laboratory test facility developed to evaluate reinforced flexible pavements under idealized load conditions. Preliminary results from a geogrid reinforced section and an unreinforced section are presented. These results are preliminary in that the primary function of the sections was to examine the performance of the proposed instrumentation and installation techniques. For this reason, the full array of instruments planned for subsequent sections was not included. While care was taken to make the two sections as comparable as possible, minor differences as noted existed.

### 3 LABORATORY TEST FACILITY

#### 3.1 Test Box and Loading Arrangement

Laboratory-scale pavement test sections are being constructed in a reinforced concrete box having inside dimensions of 2 m by 2 m in plan and 1.5 m in height. The box consists of four sides having an open bottom and with the concrete laboratory floor serving as the bottom face. The front face of the box is removable to facilitate excavation of the test section.

Two I-beams were set into the wall forms prior to the placement of wet concrete. The I-beams were placed parallel to each other along opposite walls perpendicular to the front wall. The upper flanges of each I-beam act as rails for the load frame to move along.

The load frame consists of an additional two I-beams which span between the two I-beams embedded in the concrete wall. The ends of the load frame I-beams are attached to a carriage assembly allowing the load frame to roll from the front to the back of the box. Attached to the two load frame I-beams is a second carriage assembly upon which the load actuator is mounted. This second carriage assembly allows the load actuator to roll along the load frame I-beams, hence allowing the load actuator to move from side to side in the box. The two carriage assemblies allow the load actuator to be positioned at any point along the plan dimensions of the box. Figure 1 shows a photograph of the box and load frame.

Figure 1. Test box and load frame.

The load actuator consists of a 305 mm diameter bore pneumatic cylinder with a 75 mm stroke. The threaded end of the actuator's piston is attached to a load cell having a range of 90 kN. A 55 mm diameter steel rod is attached to the other side of the load cell and extends down to and rests on a 305 mm diameter steel plate having a thickness of 25 mm. The end of the rod resting on the steel plate is rounded and sits inside a similar shaped recess in the plate, thus allowing the plate to rotate during loading. A waffled rubber pad 4 mm in thickness is placed between the steel plate and the AC surface to aid in providing a uniform pressure distribution on the AC surface.

A pneumatic binary regulator is used to control the time-history of air pressure supplied to the load cylinder. The pneumatic regulator is in turn controlled by a computer which sends a series of binary signals to the regulator's four solenoid valves allowing the division of the single inlet pressure into any one of fifteen equally spaced outlet pressures. Control of the binary signals is provided by the same software used for data acquisition.

Inlet pressure to the binary regulator is controlled and monitored by a standard gage and regulator. The binary regulator allows for any shaped load pulse to be specified and approximated by fifteen points for each of the ascending and descending portions of the pulse. Due to the limited number of points available for approximating load pulse curves, a simple triangular pulse with a linear rise time, a hold time at peak load, a linear fall time and a pause time between pulses has been specified. Two pulse durations of 0.5 and 1 Hz have been used, with times for the periods described above being 0.6, 0.3, 0.6 and 0.5 s for the 0.5 Hz pulse and 0.3, 0.2, 0.3 and 0.2 s for the 1 Hz pulse. Inlet pressure to the binary regulator has been set to give a peak load of 40 kN, corresponding to a load plate pressure of 550 kPa.

Two types of loads were applied to the pavement. The first type consisted of the application of a single load pulse at 25 different locations within the box. Application of these loads allowed for the careful examination of response from the different sensors. The second type of load consisted of a series of repeated loads when the load plate was placed at the center of the box. The 1 Hz load pulse was used for the repeated cycle tests for both sections 1 and 2 and the single pulse tests for section 2. The 0.5 Hz pulse was used for the single pulse tests for section 1.

### 3.2 Pavement Layer Materials and Thickness

The preliminary test sections reported in this paper used a slow curing cold mix asphalt concrete. This material was used due to the unavailability of hot mix asphalt during the time period in which the preliminary test sections were constructed. Hot mix asphalt is being used for subsequent test sections. The cold mix was heated in a mobile trailer-mounted oven prior to placement and compaction. Compaction was accomplished by a hand-operated vibratory plate compactor. Compacted thickness of the AC layer for sections 1 and 2 were 70 and 75 mm, with bulk density values of 21 and 22 kN/m<sup>3</sup>, respectively. Results of laboratory tests on the cold mix asphalt are given in Table 1. A grain size distribution of the aggregate used in the mix is given in Figure 2.

A crushed stone base course meeting the MDT specifications for crushed top surfacing, type A, grade 3 is being used for all test sections. The grain size distribution for the material is shown in Figure 2, where it is seen that 100 % of the material passes the 19 mm sieve.

Sections 1 and 2 contained a compacted base section thickness of 200 mm. The material was compacted at a water content ranging between 5 to 6.5 %, resulting in dry density values of 21 kN/m<sup>3</sup>. Measurement of dry density and water content during excavation of the sections indicated that the water content dropped to 4.5 to 5 % with the dry density remaining essentially unchanged.

A fine silty sand consisting of the fines trapped in the baghouse of a hot mix plant were used for the subgrade. The material has 40 % fines with a liquid limit of 18 % and a plastic limit of nearly the same value, classifying the material

Table 1. Cold mix asphalt concrete properties.

Property	Section	
	1	2
Marshall stability, lb (T-245)	9620	9620
Marshall flow (T-245)	15	15
Density, g/cm <sup>3</sup> (T-245)	2.31	2.31
Asphalt content, % (T-164)	5.0	5.0
Rice specific gravity (T-209)	2.48	2.48
Air voids, %	17.9	13.8
Penetration (T-49)	51	51
Kinematic viscosity (T-201)	554	554
Specific gravity of aggregate	2.61	2.61

Note: T designations refer to AASHTO test specifications

Figure 2. Grain size distributions of AC aggregate, base and subgrade.

as a SM or A-4. A grain size distribution of the material is given in Figure 2. Modified Proctor compaction tests indicate that the material has a maximum dry density of 18.2 kN/m<sup>3</sup> occurring at a water content of 11.5 %. The material was compacted in the box at a water content of 14.5 % and at an average dry density of 17.5 kN/m<sup>3</sup>. Laboratory CBR tests on this material at this water content and dry density and in-situ Dynamic Cone Penetration (DCP) tests indicate a CBR of approximately 15. This material was not replaced between sections 1 and 2. Only the asphalt concrete, base and geogrid were removed between sections 1 and 2.

Section 1 contained an extruded, polypropylene, biaxial geogrid placed in the base course at a level of 40 mm above the base course - subgrade interface. The geogrid has a mass per unit area of 215 g/m<sup>2</sup>, an aperture size of 25 by 33 mm in the machine and cross-machine directions, respectively, and

a wide-width ultimate tensile strength of 13 and 20 kN/m in the machine and cross-machine directions, respectively. Section 2 was unreinforced.

The remaining test program will use hot mix asphalt for all sections. A second subgrade consisting of a highly plastic clay will be used for approximately one-half of the program with the silty sand being used for the other half. The clay will be prepared at a water content to produce a weak subgrade having a CBR of approximately 3-4. A woven geotextile will also be incorporated into the test program. Other variables to be included are base course and asphalt concrete thickness, and geosynthetic position.

### 3.3 Instrumentation

The two preliminary test sections described in this paper contained a limited number of instruments compared to sections which are currently being constructed with hot mix asphalt. The primary purpose of these preliminary test sections was to examine the performance and installation procedures of instruments to be used in later sections. The two sections discussed in this paper contained one asphalt concrete strain gage, 12 soil pressure cells, 8 soil strain gages and four foil strain gages mounted to the geogrid specimen in section 1. In addition, 8 LVDT's were used to monitor surface deformation of the asphalt concrete layer and the load cell was used to monitor applied load.

The single AC strain gage was used only in section 2. The strain gage was a H-type gage marketed by Dynatest. The gage was placed at the bottom of the AC layer. The stress cells placed in the base course and subgrade were also marketed by Dynatest and have a diameter of 68 mm and a thickness of 13 mm. Cells having two different ranges of 200 and 825 kPa were used. Four stress cells were placed in the base course layer, two being oriented to measure vertical stress and two to measure stress in the horizontal direction. The centerline of the stress cells was 120 mm below the top of the base course layer and were placed at a radius of 400 mm from the center of the box. The two cells measuring horizontal stress were oriented to measure stress in the radial direction when the load was placed in the middle of the box. Four stress cells were also placed in the upper portion of the subgrade at a distance of 130 mm below the top of the subgrade (level 1) and in a similar configuration as those contained in the base. Two additional cells were placed at levels of 430 mm (level 2) and 705 mm (level 3) below the top of the subgrade. At each level, one cell was placed at a radius of 400 mm to measure vertical stress while the other was placed to measure radial stress at this same radius.

Strain in the base and subgrade soils was measured using a LVDT mounted between rectangular end plates measuring 15 by 50 mm and 5 mm thick. The gage length between the end plates was nominally 80 mm. Four LVDT's were placed in the base course and four in the top layer of the subgrade in a similar configuration to the stress cells placed at these two levels.

On the geogrid used in section 1, four bonded resistance (foil) strain gages were placed on ribs located at a radius of 400 mm from the center of the box. Two gages were placed to measure radial strain in the machine direction of the geogrid while the other two were placed to measure radial strain in the cross-machine direction when the load was placed in the center of the box. The geogrid was placed 40 mm above the bottom of the base.

Data acquisition and control has been established to control the time-history of the load application and to trigger the collection of data. Two types of tests were performed on each section. After the construction of a section, the load frame was moved to 25 different points within the box to apply a single pulse of load. The full time history of each sensor was collected for each of the 25 locations. Once these tests were completed, the load plate was moved to the center of the box where a repeated load was applied. During the application of this repeated load, the peak and baseline reading of each instrument was measured and collected for the majority of the applied load cycles. The baseline reading corresponds to a time when no load was applied to the pavement and represents a permanent response corresponding to that particular load cycle, while the peak reading corresponds to a time when the peak load was applied. In addition to this data, the full time history of each sensor was measured for specified load cycle numbers.

## 4 EXPERIMENTAL RESULTS

### 4.1 Transient Response To A Single Load Pulse

At each of the 25 load locations, three separate single pulse load tests were conducted. Figure 3 illustrates three load traces from one of the 25 load locations for sections 1 and 2, where the shape of the load pulse curve is identical for each of the three applications. The spike on the descending branch of the curve is due to some small feedback in the binary control valve. Figure 4 illustrates the time-history response of stress cells located in the base and subgrade for sections 1 and 2 when the load was applied directly above the sensor. The data shows that in the base the vertical stress was slightly higher in the reinforced section, while in the subgrade the stress was slightly less. Figure 5 shows the time-history of radial stress in the base and subgrade when the load was applied at a radius of 310 mm from the sensor.

The peak response of stress cells located in the base layer and oriented to measure vertical, radial and tangential stress were recorded from various time-history records as the load was applied at different locations. Figure 6 illustrates the variation in these peak measurements with respect to the lateral distance from the load plate to the sensor, where positive stresses correspond to compression. For each stress parameter and at each lateral location, three data points are given corresponding to the three tests performed at that location. Figure 6 illustrates the reproducibility of the results.

Figure 3. Load pulse time-history.

Figure 4. Vertical stress time-history in base and subgrade.

The curves shown in Figure 6 correspond to general trends sketched to match the available data points and were not developed from rigorous analyses. This is also true for the curves shown in Figures 7 and 8.

Figure 7 shows results of vertical, radial and tangential strain in the base in a similar fashion as Figure 6, where positive strain corresponds to contraction. Figure 7 shows more scatter than Figure 6 and is due mainly to the influence of compaction induced during the first and second load applications on the subsequent load applications at that same location.

Figure 8 illustrates radial and tangential strain induced in the geogrid in section 1 due to single load pulses applied at various locations, where positive strains correspond to tension. The results indicate that as much as 0.17 % tensile strain is induced in the geogrid immediately below the centerline the load. Radial tensile strains quickly vanish to zero at a radius of approximately 200 mm, which is 50 mm greater than the radius of the load plate. Beyond this

Figure 5. Radial stress time-history in base and subgrade.

Figure 6. Peak vertical, radial and tangential stress in base.

region strains become compressive, reaching a peak compressive strain at a radius of approximately 300 mm, whereafter they approach zero. In the tangential direction, the strains are seen to be in tension for all points away from the load and approach zero at a radius of 800 mm.

The results shown in Figure 8 have the same trend as the results for radial and tangential strain in the base shown in Figure 7, indicating that in regions where the base experiences extensional strains, the base interacts with the geogrid to transfer tension to the reinforcement. These results indicate that the primary function of the geogrid is in preventing lateral spread of the base course and that anchorage of the geogrid is not needed in such an application.

#### 4.2 Transient and Permanent Response to Multiple Load Cycles

Upon completion of the single pulse tests, the load plate and frame were moved to the center of the box where a repeated load was applied. The mean and standard deviation of the

Figure 7. Peak vertical, radial and tangential strain in base.

Figure 8. Peak radial and tangential strain in geogrid.

applied pressure was 548 and 4.0, and 550 and 4.3 for sections 1 and 2, respectively. Figure 9 shows the plate pressure versus average plate deformation observed during the first load application for sections 1 and 2. Figure 10 shows the development of surface deformation with load cycle number, where for each section three curves provided. The “peak” curve corresponds to the average plate deformation measured at the point in time where the applied load reached a maximum for that cycle. The “permanent” curve corresponds to the deformation immediately prior to when the load was applied. The “transient” curve corresponds to the

Figure 9. Load versus deformation for first cycle.

Figure 10. Deformation versus cycle number.

difference between the “peak” and “permanent” curves and represents the dynamic or transient deformation for each load cycle. Figure 9 indicates that the dynamic stiffness of section 1 is slightly greater than section 2 for the first load cycle. The transient response Figure 10 shows that both sections become slightly more stiff with increasing load cycle, with section 1 experiencing a slightly greater increase in stiffness for load cycle numbers greater than 250,000 as compared to section 2. Section 2 shows a more rapid rate of rut depth than section 1, while section 1 appears to have reached a plateau when the rut depth in section 2 continues to increase linearly with cycle number.

Visual inspection of the asphalt from sections 1 and 2 indicated that the asphalt in section 1 was more stiff and less susceptible to flow than that in section 2 even though the laboratory results, including the Marshall and penetration tests, indicate that the materials were identical and the density and thickness in section 2 were greater than section 1. Temperature of the asphalt prior to compaction was not measured, but it is believed that this is the main difference

between the materials causing the behavior observed. Thus it is not clear if the geogrid in section 1 is responsible for the improvement in behavior observed or if the improvement is due to the difference in asphalt. The additional sections being constructed as part of this project will clarify this point.

## 5 CONCLUSION

Preliminary results from a study designed to examine the reinforcement function of geosynthetics in flexible pavements have indicated the compatibility between extensible strains in the base and the development of tensile strain in the geogrid, indicating the reinforcement function of the material. The comparison of stress and strain measures in the soil layers indicated only slight differences between a reinforced and unreinforced section for the application of a single load pulse. This is to be contrasted against the significant difference observed in rut development for repeated cycle tests, indicating that examination and modeling of repeated load behavior is necessary to understand the mechanisms of reinforcement. Additional work being performed by the authors will help illustrate these mechanisms for pavement variables believed to influence performance.

# Cost Versus Reinforcing Effectiveness of Geotextiles in Pavement Works in Greece

A.G. Kokkalis

Assistant Professor, Democretus University of Thrace, Civil Engineering Department, 67100 Xanthi, Greece

**ABSTRACT:** Geotextile reinforced pavements might be both economically and technically advantageous over their conventional counterparts, especially under poor subgrade conditions. In this paper a systematic method of estimating possible cost implications of including a geotextile in the subgrade-subbase interface are discussed. The cost evaluations are obtained on the basis of the thickness of the aggregate layer which can be replaced by the geotextile been laid in the pavement-subgrade interface, so that the two structure have identical load-deformation behavior. The load-deformation behavior is evaluated by regression formulas, which have been derived from pavement finite element analysis and verified through field experiments. Reinforced pavements might provide numerous others indirect savings and conveniences, such as a more solid roadbed, a shorter construction time, ease in construction methods, savings in maintenance costs, higher factors of safety, acceptability of marginal materials etc. These factors were not included in this economic evaluation and all promote the reinforced alternative. The results obtained have been verified in several case studies.

**KEYWORDS:** Geotextiles, Reinforcement, Pavements, Unpaved roads, Road construction

## 1 INTRODUCTION

Geotextiles have already a 25-years history of successful applications in many fields of geotechnical engineering. A field of particular interest is that of highway and pavement works. In Greece the first relevant application of geotextiles took place in a highway in Peloponnese in 1977. Since then geotextiles established a widespread use in pavement engineering works. Nowadays, they are systematically used in most major highway schemes, like the Patra-Athens-Thessaloniki-Border and the Egnatia motorways. This constantly increasing application rate urged for a systematic analysis of the effectiveness of geotextile inclusion in a pavement system and the cost implications this involves.

A research activity concerning the reinforcing and other beneficial actions of geotextiles been laid in the pavement-subgrade interface was run at the Aristotle University of Thessaloniki since 1985 and at the Democretus University of Thrace lately.

## 2 REINFORCING ACTION OF GEOTEXTILES

A geotextile been laid at the subgrade-subbase interface fulfills any one of the actions of reinforcement, separation, filtration and in few cases drainage. It should be mentioned that in most cases more than one of the above functions act simultaneously. Of interest for this paper is the reinforcement function. This function is expressed, as a rule, in a dual manner, i.e. lateral restraint and membrane action. Membrane action is the most obvious one: as the pavement is deformed by the loads, the geotextile been laid on the top of the subgrade is also deformed. Assuming that no slip occurs the geotextile is strained. The vertical constituent of the stresses developed balance part of the applied load. At the cost of substantial displacement and

ignoring the parameter of creep relaxation, the ultimate loading of the system can markedly increase (Sellmeijer 1993; Espinoza 1994). However, it has become obvious that the membrane effect mechanism fails to accurately predict the benefits that can be obtained from the inclusion of geotextiles at low deformations (Little 1992; Milligan et al. 1989). Non-woven products with relatively low stiffness is unlikely to produce any benefit at all if included in any membrane effect analysis. Nevertheless, experience has shown that there is a clear improvement to the performance of the pavement with the inclusion of low stiffness geotextiles. This improvement is mainly attributed to lateral restraint i.e. the stretched geotextile inhibits the lateral displacements of the aggregates. Another positive effect is that the subgrade just outside the traffic loading area is also loaded more or less vertically, through the stressed geotextile, which ensures maximum bearing capacity of the system. Furthermore, the aggregate layer acts like a beam spreading the load over a larger area. (Sellmeijer 1990, 1993). Finally, the separation and filtration functions, which the geotextile simultaneously performs, ensure the integrity, purity and stiffens of the aggregate layer which mobilize a plastic stress-strain state with higher factors of safety (Little 1992). The exact value of all these mechanisms is hard to evaluate analytically.

There are a profusion of methods for estimating the reinforcing effectiveness of geotextiles in pavements, ranging from the purely empirical to the use of finite elements models. It is the author's opinion that the latter methods, through calibration by full-scale experiments, permit any type of reinforcing action to be evaluated and included.

A finite element program was used herein to calculate the stress-strain fields in a great variety of weak pavements (which can also be considered as subbases of typical pavements) either reinforced or not with geotextiles. The

program analyses the pavement-subgrade system as a three-dimensional axially symmetric multi-layered problem (Snaith et al. 1980). The wheel load is specified as a uniformly distributed pressure over a circular contact area. The boundary conditions of the system are: horizontal restraint at the lateral boundaries and both horizontal and vertical restraint at the base boundary. Material properties are specified for each layer of the system. The resilient modulus of each layer may be either linear or dependent on any number of stress regimes. The elastic analysis employs a successive over-relaxation technique to obtain the stress in each element of the finite element grid. When the elastic analysis is completed a non-iterative procedure makes use of the computed stress values and suitable creep equations to calculate the vertical permanent strain for each element. The strains are then converted to deformations and summed for each column of the grid to yield the overall surface permanent deformation profile.

The fabric has been modeled using a layer of its approximate thickness (for typical non-woven heat-bonded geotextiles their typical thickness has been taken as 1 mm). Since in practice local reinforcement of the soil structure occurs in the vicinity of the fabric, two transitional layers have been introduced, one above and one below the fabric layer having similar thickness as the geotextile itself. Thus, the abrupt change in resilient modulus between the fabric and its adjacent layers has been reduced, since these transition layers have intermediate characteristics between the fabric and the adjacent layers themselves.

A large number of the independent variables i.e. resilient modulus of geotextile, resilient modulus of subgrade and thickness of aggregate layer are then combined. Not taking into account the various numbers of load repetitions, 567 combinations as a total have been solved.

Characteristic permanent deformation profiles obtained from these pavement models are compared with those measured in the field from full scale experiments made in similar pavements. Although the deformation predicted were consistent with those measured, weighting factors were, as a rule, necessary, so that the computed values coincide with those observed in the field experiments. These calibration factors were specified for each layer.

The purpose of the field experiments involved was the determination of the load-deformation characteristics of subbases, either reinforced or not with geotextiles. Cycled plate bearing tests were carried out on the various model pavements. Model pavements were 4 by 4 meters in plan and founded on generally weak subgrades. Loads were applied through a rigid 0.3 meters diameter plate to approximate wheel load contact area. Loads also have magnitudes approximating standard wheel load and were applied on variable thickness granular pavements either reinforced or not with geotextiles. The geotextile anchorage was sufficient to ensure that no lateral slip would occur.

The results were subsequently statistically analyzed so that prediction formulas were developed through which the

thickness of the granular layer could be obtained. This procedure, although it introduces inevitable inaccuracies, is preferable, since applying a prediction formula is considerably simpler than formulating and solving the finite element program for any new set of data. Additionally, it helps the study of the economic consequences of pavement geotextile reinforcement. However, it should be constantly kept in mind, (Palmeira and Cunha 1993; Douglas and Valsangar 1991) that it is difficult to predict geotextile reinforced pavement deformation by simple relationships. More detailed information for the whole procedure is given in Kokkalis, (1990).

The regression formulas obtained are, for pavements without geotextile reinforcement:

$$e_{pl} = 13.0 \frac{1}{E_{SG}^{0.70}} + 18.5 \frac{1}{H_{ag}^{0.63}} + 1.1(\log N)^{0.88} + 2.2 \frac{(\log N)^{1.21}}{E_{ag}^{0.88}} - 3.4, (R = 0.991) \quad (1)$$

$$\text{where: } E_{ag} = 0.19H_{ag}^{0.45}E_{SG} \quad (2)$$

and in the case of geotextile reinforced pavements:

$$e_{pl} = 13.0 \frac{1}{E_{SG}^{0.70}} + 18.5 \frac{1}{H_{ag}^{0.63}} + 1.1(\log N)^{0.88} + 5.1 \frac{1}{E_g^{0.21}} + 2.2 \frac{(\log N)^{1.21}}{E_{ag}^{0.88}} - 6.2, (R = 0.978) \quad (3)$$

$$\text{where: } E_{ag} = 0.12(\log E_g)H_{ag}^{0.45}E_{SG} \quad (4)$$

where:  $e_{pl}$  is the permanent deformation of the whole structure measured in mm,  $E_{SG}$  and  $E_{ag}$  are the resilient modulus of the subgrade and the aggregate layer respectively measured in MPa and  $E_g$  is the resilient modulus of the geotextile measured in KPa,  $H_{ag}$  is the thickness of the aggregate layer expressed in cm for equations (1) and (3) and in mm for equations (2) and (4) and  $N$  is the number of standard load repetitions applied to the pavement.

Care has been taken so that equations (1) and (3) yield consistent results.

The limitations of the formulas obtained are:  $E_{SG} < 50$  MPa and  $H_{ag} < 60$  cm.

A sensitivity analysis conducted on the derived formulas showed, as expected, that the single most important parameter affecting the required pavement thickness is the deformation behavior of the subgrade. Of most interest for this research is the sensitivity of the design equation to the thickness of the granular layer of the pavement and to the resilient modulus of the geotextile: permanent deformation is four times more sensitive to the parameter "thickness of aggregate layer" than to the parameter "modulus of the geotextile".

Apart from the field experiments, the whole procedure involved laboratory experiments for the determination of the interactional characteristics between the geotextile and the surrounding material, the determination of the stress-strain relationship of geotextiles when acting in isolation and when they are confined in the soil-aggregate environment of the project. It is this confined resilient modulus ( $E_g$ ) that has been used in the analysis. To obtain  $E_g$  a large shear box (30 X 30 cm) has been properly modified so that it could include and stress a geotextile specimen. The specimen was kept in contact with representative soil been laid underneath and graded aggregate been laid on top of the specimen. The geotextile specimen in this soil-geotextile-aggregate system was subsequently stressed whilst been compressed by loads equivalent to the traffic and dead loads which really apply to the system. Apart from few difficulties which arose and easily confronted this procedure of determining the confined stress-strain behavior of geotextiles could be regarded as successful (Kokkalis and Papacharisis 1989). From the derived stress-strain diagram, the values of  $E_g$  used were those corresponding to the actual strain the geotextile develops in situ.

### 3 COST IMPLICATIONS OF GEOTEXTILE INCLUSION

Geotextile reinforced pavements, apart from offering certain technical advantages, may consist an economically competent alternative as well. Numerous factors are affecting the relevant economic analysis, so that a generalized solution is unattainable. Each case study has its own prevailing economic parameters. It should be mentioned herein that, from a literature review it can be concluded, that in cases of soft subgrades, geotextile reinforced pavements usually present economic advantages.

The economic analysis of the reinforcing action of geotextile is based on the obvious fact that the stronger the geotextile, the greater the thickness of the subbase layer which could be replaced so that the two structures have identical load-permanent deformation behavior.

Apart from the substitution of part of the aggregate layer, geotextiles been laid on soft subgrades might also indirectly affect certain cost items by:

1. speeding up the construction,
2. creating a more solid working surface,
3. facilitating construction practice,
4. extending working periods,
5. reducing maintenance cost,
6. reducing vehicle operating cost,
7. making marginally rejected soil materials acceptable,
8. attaining higher factors of safety and
9. making the removal of soft surface layers not necessary.

It worth's mentioning for item 5., that maintenance cost for Greek secondary roads amounts up to 60% of the

original construction cost over the whole design life of the road (Nikou 1988).

As it has been previously reported, all the above potential indirect savings are very difficult to be included in an economic analysis. In the analysis presented herein three cost items are taken into account, i.e. purchase cost of geotextiles and aggregate, transport cost and application cost. It should be commented that the application of geotextiles does not demand any specific machinery which should otherwise be included as a cost item. These three cost items have been applied to a number of pavement construction projects in Greece, where there were a geotextile inclusion. It is obvious that the range of unit costs is broad, whilst they are simultaneously critical for the results of the evaluation. Typical unit costs used are (1 ecu = 1.15 U.S. dollars):

1. purchase and transport cost of geotextiles: 1.0 ecu/m<sup>2</sup>,
2. application cost of geotextiles: 0.1 ecu/m<sup>2</sup>,
3. supply cost of aggregates: 0.08 ecu/m<sup>2</sup>/cm of layer thickness,
4. transport cost of aggregates: 0.001 ecu/km/cm of layer thickness,
5. construction cost of aggregate layer: 0.02 ecu/m<sup>2</sup>/cm of layer thickness,

From the above figures and through the equations (1) and (3) it can be derived that, assuming the mean transportation distance of aggregates as being 10 km, the reinforced pavement would be cost-effective if the geotextile could replace more than 10 cm of the thickness of the aggregate layer. This is the case when  $E_{SG} < 40$  Mpa. If  $E_{SG} < 25$  Mpa then the reinforced pavement becomes less expensive even if there is an adjacent source of aggregates. It is obvious that as the subgrade becomes softer, (in which case geotextile inclusion becomes more effective) and as acceptable aggregates can be only obtained from sources being farther away, geotextile reinforcement becomes economically advantageous. The economic influence of the resilient modulus of geotextile can hardly assessed, since it means both higher purchase cost and higher replacement potential. The quotation of the cases where geotextile reinforced pavements are cost effective can not be farther described, since the result depends on each specific data set.

Woven geotextiles possess much higher resilient modulus and are simultaneously more expensive. It would have been interesting to evaluate the cost efficiency of their application on the base that they, obviously, could replace a thicker layer of aggregates. However, the amount of bond that a geotextile can develop with the surrounding soil sets limits to the exploitation of very high modulus. In relevant full scale trials slip surfaces evidently developed for large deformations. It is accepted (Palmeira and Cunha 1993) that, in the long term, the use of a highly frictional medium modulus (like non-woven geotextiles) reinforcements may be capable of producing greater overall cost savings than the use of high modulus geotextiles.

#### 4 CONCLUSIONS

The main conclusion drawn is that the cost implications of geotextile inclusion in pavements depend on the specific conditions of each project. In general, the thickness of the unbound subbase, which the geotextile could replace, costs as much as the supply and application of the geotextile itself, provided that a non-woven product is selected. Woven geotextiles present certain problems which, combined with their higher supply cost, make their application rather expensive.

The most important parameter affecting the economic analysis is the load-deformation behavior of the subgrade. As the subgrade becomes softer the geotextile inclusion solution becomes cost-effective. Availability of acceptable aggregate material is the next important parameter. The economic influence of the resilient modulus of geotextile can be hardly assessed, since it means both higher purchase cost and higher replacement potential.

It should be mentioned that the analysis is limited in the direct construction cost elements of the pavement. If other indirect savings and conveniences, such as providing a more solid roadbed, a shorter construction time, facilitation in construction methods, savings in maintenance and vehicle operating costs, increased factors of safety, acceptability of marginal materials, were included in the analysis, the economic supremacy of geotextile reinforced pavements over weak subgrades is expected to become evident.

#### ACKNOWLEDGEMENTS

The author is indebted to KEDE (Central Laboratory of the Ministry of Public Works) which supported the experimental procedure providing the necessary equipment and personnel. The author also wants to express its gratitude to the Civil Engineering Laboratories of the Aristotle University of Thessaloniki in which a series of experiments have also been performed.

**ABSTRACT:** This paper reports on the achievements in test research of applying needle-punched geotextile to prevent and repair road frost boiling and its application and dissemination in Daqing. The indoor simulated tests and outdoor road repairing tests have been begun since 1990. By these tests and analysis of gained data, the key technical question for preventing and repairing the road frost boiling have been solved and a complete set of design and construction methods also have been summed up. Theory and facts have proved that it is the ideal method by applying geotextile to prevent and repair road frost boiling in the seasonal freezing zone. This method is convenient for construction, excellent effect and notable economic and social benefits.

**KEYWORDS:** Freeze/thaw Behavior, Geotextiles, Geomembranes, Road Construction, Separation

## 1 INTRODUCTION

Daqing Oil Field is situated in the middle of Songnen plain in China, which is a seasonal freezing zone. During spring thawing period, under harmful factors, frost boiling becomes so severe that about 20 km road needs to be repaired in Daqing annually.

Many methods were tried to prevent and repair road frost boiling for many years, but its effects are all unsatisfactory. In 1990, a new way was found for preventing and repairing road frost boiling, which is to employ geotextile. Facts have proved that it is of excellent effect and notable economic benefit to apply geotextile to prevent and repair road frost boiling.

## 2 REASONS AND PREVENTIVE METHOD OF ROAD FROST BOILING

Road frost boiling is a peculiar phenomenon in the seasonal freezing zone. Frost effect increases the water content in subgrade in winter, and the extra water can not be drained off during spring thawing period, which makes subgrade be over-moistured, and reduces its load-bearing capacity. Under the load of running trucks, there appears springing, chapping, bulging and mud pouring, then the whole road is destroyed.

Frost boiling results from the comprehensive effect of 5 factors such as water, soil, temperature, pavement, and the load of running trucks. According to several years experience on repairing road frost boiling, it is believed that water is the major factor of 5 factors. In Daqing the water in the subgrade mainly comes from underground water, so the key of preventing road frost boiling is to cut off the ascent of

capillary underground water. In order to solve this problem, the test research of applying geosynthetics to prevent and repair road frost boiling was carried out.

## 3 INDOOR TESTS

Two kinds of material, geotextile and geomembrane, were used in the indoor tests.

### 3.1 Separating Water and Isolated Heat Tests

The selected soil sample was a clay with medium liquid limit, a typical soil in Daqing. Its water content was 18.5% and its dry density before test was  $1.68 \text{ g/cm}^3$ . The soil sample was put into five round freezing containers (shown in Figure 1). Then the freezing containers were sent into

Figure 1. Sample model type.

freeze room. The samples were froze from the top of freezing containers while supplying enough water to the bottom of samples. Freezing continued 310 hours simulating the soil sample's natural state. At last, the test ended when the

whole samples were frozen. All the measured data is listed in Table 1.

Table 1. The measured data of sample.

Content	Sample for comparison			Geo-memb	Geo-textile
	No.1	No.2	No.3	No.4	No.5
Measured value					
Frost heaving amount (mm)					
Upper 10cm	9.0	11.7	11.6	3.4	1.7
Under 10cm	17.1	12.8	8.1	14.9	12.0
Water content after freezing (%)					
Upper 10cm	26.6	26.6	20.5	13.9	16.7
Under 10cm	29.9	31.6	27.8	34.8	30.8
Temperature in the middle of samples (°C)					
At the beginning	12.7	12.8	13.0	A.M.132 B.M.137	A.T.12.5 B.T.13.6
Temperature at top is -1	1.4	1.4	1.1	A.M.-1.1 B.M.-1.5	A.T.1.1 B.T.2.0
Air temperature is -9	-3.5	-3.2	-2.7	A.M.-2.1 B.M.-0.9	A.T.-2.6 B.T.-1.0
At the end of test	-1.0	-1.7	-1.1	A.M.-1.1 B.M.-0.8	A.T.-1.1 B.T.-0.8

Note: A.M. is the abbreviation for above the membrane; B.M. is the abbreviation for below the membrane; A.T. is the abbreviation for above the textile; B.T. is the abbreviation for below the membrane.

From Table 1 it can be seen that, after freezing under the condition of saturation water, the water content of the upper layer soil sample in container No. 4 and 5 is evidently less than that of the samples for comparison, and the frost heaving amount decreases more than 60%, while the temperature under the geomembrane and the geotextile is clearly higher than that of samples for comparison. Therefore, geomembrane and geotextile are rather effective to separate water, and geotextile can particularly isolate heat to a certain degree.

### 3.2 Freeze-thaw Resistance and Corrosion Resistance Tests

A freeze -thaw test was carried out under the temperature from -20 °C to 10 °C. After dipped into water, polyester geotextile was made to undergo 300 freeze-thaw cycles. Its tensile strength only decreased 21% as much as the original tensile strength, which mean polyester is good at freeze-thaw resistance.

In the corrosion resistance test(resisting acid and alkali), the polyester geotextile was soaked into the water solution of different pH values, and measured its strength which is listed in Table 2. The polyester textile was also dug out, which was buried in soil (pH = 9) for two years, and its

measured strength only decreased 1.9%. The above tests proved that the polyester textile has a certain corrosion resistance .

Table 2. Measured strength of polyester textile in corrosion resistance test.

Soaking time (days)	pH value				
	1.54	4.24	7.00	9.26	11.81
Tensile strength (N/5 cm)					
90	775	877	805	786	723
180	738	795	787	786	649
Strength decrease after 180 days (%)					
	7.8	0.7	1.7	1.9	19.0

Notes: The original tensile strength of geotextile (500 g/m<sup>2</sup>) is 801 N/5 cm.

## 4 TEST ROAD

The test road section is on an Oil Field main line which is 10 m wide in subgrade and 7 m wide on bituminous concrete pavement. Most of the road sections are wet or overwet because of the high underground water level and the water beside the road all the year. Moreover, a busy traffic of heavy trucks can be found on the road. There was always frost boiling since the road was built up in 1984. Up to 1989, the severe frost boiling stopped traffic. It was determined to repair this road thoroughly and to build a test road in the road section where frost boiling was most severe. The test road was began to build in June 1990, and was completed in July. To meet test conditions, there was no drain beside the road, and the height of subgrade embankment was less than the standard so that the road was over-wet.

### 4.1 Test Plans

In view of the reason of road frost boiling, three tests by sealing, separating and replacement were carried out.

#### 4.1.1 Sealing in this plan

Ice gathering zone in subgrade was wrapped with impermeable geomembrane in order to form a water-tight zone for water in the vertical direction, to protect this zone from water on the ground, to cut off the ascent of capillary underground water, to cut down the height of ice gathering zone, to lighten the freeze and subsidence of subgrade, to improve the whole strength of subgrade and prevent frost boiling.

#### 4.1.2 Separation in this plan

Separation, drain filtration and reinforcement characteristics of the geotextile were introduced to prevent road from frost boiling.

During spring thawing period, the water content of the subgrade is high and the strength is low. Under the repeat-

edly load of running trucks, base course material is easily pressed into the subgrade soil, while the mud is easily squeezed upwards. With these two acting together, then there appears frost boiling. After geotextile has being laid, there is no frost boiling. Having dug the road, it can be seen that base course material does not mix with the subgrade soil. It is the geotextile that plays the role of separation.

The test road was dug to be observed the water content of subgrade soil during spring thawing period. The result is there was less ice grains in the soil above geotextile than below it, and the water content in the latter was 1.1 times that of the former. Both indoor test and field observation prove that geotextile can cut off the ascent of capillary underground water from positive temperature zones to negative temperature zones.

Geotextile can drain water away in both vertical and horizontal directions. The measured coefficient of permeability of the soil and the geotextile in the test road were respectively  $1.98 \times 10^{-4}$  cm/s and  $5.5 \times 10^{-1}$  cm/s, the latter being more than 2700 times of the former. Thus water can be drained away along the cross slope through geotextile when the water content of the soil below the geotextile is high. In addition, geotextile laid between structural layers and it can bear load together with road surface and subgrade, and spread stress. Therefore, geotextile reinforces the road.

#### 4.1.3 Replacement method

Replacement method, an usual method, is to replace the frozen subgrade soil with non-freeze or weak freeze material in order to reduce the water content of the subgrade, prevent subgrade from freezing and subsiding, keep the stability of subgrade and protect road from frost boiling.

#### 4.2 Sections of Test Road and Pavement Structure

Based on the severity and contrast condition, the 550 m long test road was equally divided into 11 sections in which 4 sections were for sealing test, 4 sections for separating test and the other for replacement test.

The pavement structure was designed along with the 3<sup>rd</sup> class road standard. The structural composition and thickness were determined referring to the requirement of strength and freeze-thaw resistance, see Table 3.

#### 4.3 The Selection of Geosynthetics

##### 4.3.1 Geomembrane

The geomembrane is made of polyvinyl chloride(PVC), whose density is 200 g/m<sup>2</sup>.

##### 4.3.2 Geotextile

The selection of the geotextile is the key of the separating plan. Geotextile should play roles of separation, drainage, filtration and reinforcement, so its effective opening size(EOS) and strength are very important.

Table 3. Test road pavement structure.

Thickness of the base course	Structural type						
	Sealing		Separation		Replacing embankment		
	I-1 (cm)	I-2 (cm)	II-1 (cm)	II-2 (cm)	III-1 (cm)	III-2 (cm)	III-3 (cm)
Slag lime soil	15	15	20	15	20	20	20
Gravel lime soil	-	-	-	-	15	15	-
Lime soil	15	15	30	15	20	40	30
Soil wrapped by geo-membrane	20	40	-	-	-	-	-
Soil	-	-	-	30	-	-	-
Geotextile	-	-	One layer		-	-	-
Sand and gravel	-	-	-	-	20	-	-

Note: The road surface course is 9 cm thick bituminous concrete; the allowable rebound deflection of pavement is 0.57 mm (The standard axial loading is 60 kN).

The mechanism of separation is similar to filtration mechanism in irrigation works, requiring the effective opening size of geotextile matches the grain diameter of subgrade soil in order to protect soil from capillary rising and drain water off without blocking. Then the following formulation should be satisfied:

$$d_{15} < O_{90} < d_{85} \quad (1)$$

where:  $O_{90}$ , the effective opening size of geotextile;  $d_{15}$  and  $d_{85}$  are respectively diameter of protected soil grain with 85% and 15% passing on standard screen.

Strength according to reference, the tensile strength should satisfy following formulation:

$$0.75 < \frac{\text{transverse tensile strength}}{\text{longitudinal tensile strength}} < 1.25 \quad (2)$$

The selected geotextile should meet strength requirements, and should be durable enough to resist aging and erosion by acid and alkali. Considering the widespread saline soil in Daqing, on the basis of indoor tests, field observation and relevant references on polyester geotextile, the polyester geotextile was selected as working geosynthetics.

#### 4.4 The Determination of Location of Geosynthetics

Another key in both sealing and separating plans is to determine the location of the geomembrane and geotextile in the road cross section. We believe geosynthetics should be laid in the place with the most water content in the subgrade. Referring to the geological reference, the location is 0.6~0.8 m below the road surface, which was also proved by field test. The detailed direction in construction is shown in Figure 2.

Figure 2. Road cross-sectional profile.

## 5 TEST EFFECT AND ECONOMIC BENEFIT

### 5.1 Test Effect

From the completion of the test road up to the end of 1996, most of the sections worked well except some damaged parts of the road surface on a few sections of sealing plan, though the real traffic volume was 45% more than the designed traffic volume. Since this road was built, two year systematic observation and three year detailed observation on road surface strength, evenness, crack, freeze-thaw, subgrade water content and freeze depth at 527 observing places have been carried out, and more than 20,000 data have been obtained. The measured rebound deflection during spring thawing period which is one of the major effect factors on the road, is listed in Table 4.

Table 4. The measured rebound deflection of road surface.

Type	III-1	II-1	I-2
Mileage	250m~300m	300m~350m	350m~400m
	(mm)	(mm)	(mm)
1990 Oct.	0.094	0.129	0.160
1991 Apr.	0.395	0.352	0.481
1992 Apr.	0.391	0.418	0.556
1993 May	0.350	0.378	0.556
1994 Apr.	0.365	0.509	0.793
1995 May	0.409	0.545	0.973
1996 May	0.388	0.494	0.845

The sealing plan resulted in a low road surface strength and a large rebound deflection, which were far from the design requirement. Especially the rebound deflection of type I-1 road section during spring thawing period in 1994 reached 1.1 mm, and a 5 m<sup>2</sup> local part on road surface was damaged. In addition, there were many underground pipelines across road in the Oil Field. The geomembrane will be destroyed when these underground pipelines are dug out. So, the sealing plan is unsuitable for using in Daqing Oil Field.

The replacement method resulted in a thick pavement structure layer and a greater reduction of strength. The rebound deflection during spring thawing period in 1995 was 12.1% more than that in 1994. Moreover, it had a too great amount of work and too much cost (\$18 per square meter)

to be adopted.

The separating plan met the designed strength requirement with a little reduction of strength. For example, the rebound deflection during spring thawing period in 1995 was only 7% more than that in 1994. Besides, it had a thin structural layer, little amount of work, low cost (\$17 per square meter) and an excellent effect. Especially, structure of type II-1 is a structure with advanced technology and better economic benefit for preventing and improving road frost boiling in freeze area.

### 5.2 Economic Result

Referring to the settlement of test road, the separating plan saved \$1 per square meter than the replacement method. Because the test road worked effectively during the first spring thawing period after its completion, this technique was disseminated in the same year, and the construction method was improved, so \$1.3 per square meter was saved.

In the past seven years, more than 640,000 m<sup>2</sup> geotextile have been applied to 45 roads (total length 50 km), and saved \$928,000 (direct expense). Besides, because preventing road from frost boiling and avoiding detours during the construction period, the transport efficiency was improved 54%, and \$600,000 transport expense was saved annually. Therefore, both economic benefit and social benefit are notable.

## 6 CONCLUSION

Facts have proved that this is a new technique with convenient construction, excellent effect and notable economic benefit and social benefit, to apply geotextile to prevent and repair road frost boiling in severe cold area. We believe that the selection of textile and laying elevation are two keys of this technique. In Daqing, the suitable geotextile is polyester geotextile with 500 g/m<sup>2</sup>, effective opening size being 0.08~0.1mm and laying elevation usually being about 0.7 m below the road surface.

**ABSTRACT** : While geosynthetics were considered for pavement reinforcement, the R and CBR properties are no longer sufficient to govern the pavement thickness design. Resilient modulus testing has replaced static penetration testing as it more accurately simulates the in situ conditions on the pavement. Using geogrids of different types, this research studied their reinforcement effects on the subgrade, and the variation in reinforcement effects when geogrids were placed in varied depth during the application of repeated loadings. Repeated load test results show that geogrid reinforcement is highly effective as reflected in factors related to foundation stiffness and the amount of deformation associated with repeated addition of heavy loads. And it was found that improvement of the foundation stiffness is significantly related to the stiffness and initial modulus of the geogrid.

**KEYWORDS**: Bearing Capacity, Geogrids, Pavement, Reinforcement.

## 1 BACKGROUND

The function of geosynthetics in pavement reinforcement is to reduce the amount of deformation when a pavement is subject to loadings. Among various geosynthetics, geogrid is preferable for pavement reinforcement under high loadings. This is principally due to the interlocking between the geogrid and the soil. The fundamental properties of geogrid, such as light weight, resiliency, ease of installation, high modulus to strain resistance, acid resistance, and longer life span, make it an ideal geosynthetic for such applications.

Previously, the capacity of a reinforced pavement structure was determined by static penetration tests. However, the actual loadings by vehicles are dynamic, and such static tests may no longer meet today's requirements. In this study, the effects of geogrids in pavement reinforcement are examined under dynamic loadings. Dynamic tests of this type are not yet in common practice.

## 2 COEFFICIENT OF SUBGRADE REACTION

The coefficient of subgrade reaction was originally defined by Terzaghi (1955) :

$$k_s = \frac{q}{y} \quad (1)$$

in which  $k_s$  = coefficient of subgrade reaction, [KN/m<sup>3</sup>];  $q$  = uniform loadings, Kpa ;  $y$  = deformation under static pressure [m].

Coefficient of subgrade reaction is frequently applied in foundation engineering for the computation of stiffness of subgrade. Upon actual application, this coefficient needs to be calibrated as provided by Terzaghi (1955).

For cohesive soil, then

$$k_s = k_p \times \frac{A_p}{A} \quad (2)$$

For cohesionless soil, then

$$k_s = k_p \left( \frac{A+1}{2A} \right)^2 \quad (3)$$

in which  $k_p$  = coefficient of subgrade reaction derived from the test ;  $A$  = area of foundation. ;  $A_p$  = area of plate ;

When the loading plate is of rectangular shape, then

$$k_s = k_p \left( \frac{m+0.5}{1.5} \right)^2 \quad (4)$$

in which  $m$  = size of the rectangular plate =  $L/B$ .( $B$ : width of foundation)

Many indirect ways and/or empirical formula are available for calculating the coefficient of subgrade reaction. For example, from consolidation tests

$$k_s = \frac{1}{m_v \times H} \quad (5)$$

in which  $m_v$  = coefficient of volumetric compressibility ;  $H$  =  $0.5B \sim 1.0B$ .( $B$ : width of foundation), or by CBR and the like. From the above, it can be seen that size, shape and rigidity of plate, soil properties, and other variables can affect the coefficient of subgrade reaction.

### 3 BEARING CAPACITY RATIO ( BCR )

For more suitable application in pavement reinforcement design , Bearing Capacity Ratio (BCR) is then suggested by Mandal and Sah (1992) as follows :

$$BCR = \frac{q_r}{q_{ur}} \quad (6)$$

in which  $q_r$  = ultimate bearing capacity after reinforcement ;  $q_{ur}$  = ultimate bearing capacity before reinforcement.

Using this ratio, the effect of reinforcement by geosynthetics under static pressure can be determined.

### 4 MATERIALS

In this study, weathered mudstone is used to provide the soft subgrade layer for the testing. General properties of weathered mudstone are shown in Table 1.

Table 1 General properties of weathered mudstone

Properties	Values
Liquid limit, (%)	34.3
Plastic limit, (%)	21.6
Plastic Index	12.7
Maximum dry density, ( g/cm <sup>3</sup> )	1.68
Optimal Moisture Content	
O.M.C. (%)	17.5
Cohesion, (kg/cm <sup>2</sup> )	0.5
Specific Gravity	2.7
Internal friction angle	17°

The specimen was prepared using 95% compaction and a moisture content of O.M.C.+2%, to the in situ condition.

As for geosynthetics, flexible geogrids of two different strength levels are used and are identified as the H-geogrid and the L-geogrid. Their general properties are shown in Table 2 below.

Table 2 General Properties of Geogrids

	H-Geogrid	L-Geogrid
Characteristic	flexible	flexible
Material	polyester	polyester
Size of opening	2cm × 2cm	2cm × 2cm
Elongation at breaking, %	14	17
Ultimate rib strength [kN/m]	232.0	107.9
Tensile modulus [kn/m]	1657.1	634.7

Notes : Rib tensile strength test was based on the method of GRI-GG1.

### 5 TESTING SYSTEM SETUP AND PROCEDURES

(1)Pneumatic system (2)Air tank (3)Valve (4)Pressure gauge (5)Platform (6)Test box (7)Load cell (8)LVD (9)Pressure cylinder (10)Beam (11)Electromagnetic valve (12)Amplifier (13)AD/DA converter (14)Time control card (15)Computer (16)Laser printer (17) Rod (18)Loading Plate

Figure 1. Layout of test system

The testing system used in this study is arranged according to the resilient modulus testing device provided by Chang et al.(1991), and the layout is given in Figure 1. A metal box with a dimension of 0.457 m(length) × 0.457 m(width) × 0.762 m(height) is used for molding soil specimen. Newmark Charts (Newmark, N.M., 1942) were used to compute the transfer of stress below the circular plate. To enable the stress to decrease to the lowest level of 6% underneath the center of circular plate, the thickness of the soft specimen should be at least three times the width of plate. For a plate of 0.1016 m in diameter, the depth of mudstone computed in this test was 0.3 m.

To cope with the pneumatic system used in this test, plates of two different diameters 0.0508 m and 0.1016 m were used. The test was initially performed for each geogrid in four runs at 4 different embedded depths, which are 0.2, 0.4, 0.6 and 1.0 in terms of D/R (embedded depth/radius of plate).The determined best ratio was used for the rest of the tests.

AASHTO T274-82 (1983) method was followed to perform the dynamic loading with levels of 19.6(0.2), 39.2(0.4), 58.8(0.6), 78.4(0.8), 98.0(1.0), 117.6(1.2), 137.2(1.4), and 156.8(1.6) Kpa(kg/cm<sup>2</sup>). As this test is related to the study of pavement reinforcement, the typical M<sub>R</sub> Test details were followed in the selection of frequency of loading, contact interval, and loading waveform. In this case, the frequency is 0.33 Hz, the contact interval is 0.1 sec., and the loading is of triangular waveform.

## 6 RESULTS AND DISCUSSIONS

### 6.1 Effects of Stress Levels, Loading Numbers and Embedded Depth

Typical results are illustrated in Figure 2. A higher dynamic coefficient of subgrade reaction was observed under smaller stress, because smaller deformation resulted under the smaller stress. Under stress at the range between 19.6(0.2) to 117.6(1.2) Kpa(kg/cm<sup>2</sup>), the dynamic coefficient decreased abruptly. When the stress is greater than 117.6(1.2) Kpa(kg/cm<sup>2</sup>), the dynamic coefficient becomes constant. To demonstrate the trend of this curve, more tests have been performed using loading stresses of 29.4(0.3), 58.8(0.6), 88.2(0.9), 117.6(1.2), and 147.0(1.5) Kpa(kg/cm<sup>2</sup>).

Figure 2. Responded dynamic coefficient of subgrade reaction with and without reinforcement

According to Chang et al (1991) study, in the first cycle (the first 200 loadings) of the test, the  $M_R$  values could vary in an irregular way. Several groups of tests have been conducted to verify this phenomenon, and the results are shown in Figure 3. Only H-geogrid, and 5.08cm-plate were used in these tests for determining number of loading for the rest of the program. It can be seen that during the first 200 loadings, the dynamic coefficient of subgrade reaction increases gradually, and after the first 200 loadings, the dynamic coefficient of subgrade reaction becomes stable although slight deviations are still observed. To neutralize these deviations, an averaged value was taken from loading no. 201 to loading no. 500 as the dynamic coefficient of subgrade reaction.

Regardless of whether the loadings are applied by the big plate or the small plate, during the first 200 loadings, the readings of the dynamic coefficient of subgrade reaction

increase gradually. Reasons for this phenomenon could be that: ① the plate was not in complete contact with the mudstone surface, resulting in a larger deformation at the beginning; ② repeated loadings will compact the mudstone, and when the mudstone is compacted to a certain extent, the dynamic loading stress will transfer to a lower elevation in the mudstone. After 150~200 loadings, a certain degree of compaction will result, and the coefficient of subgrade reaction becomes stable accordingly. After 200 loadings, although the coefficient curve still shows some uncertainties, generally speaking, the value is close to a constant. The occurrence of uncertainties is relatively rare in the case of a large plate. This is because the effect of uneven compaction on a large plate is insignificant in comparison to that on a small plate.

Figure 3. Significance of loading numbers for the performance

### 6.2 Effects of Geogrid Strength

Figure 4. indicates that the best reinforcement occurs when  $D/R = 0.2$ . The effects diminish for deeper embedded depth. For  $D/R \geq 0.6$ , the effect of reinforcement becomes negligible. These findings are equivalent to the studies by Mandel and Sah (1992).

A series of tests were carried out at the best embedded depth (i.e.,  $D/R = 0.2$ ), to compare the effect of reinforcement by geogrids of different mesh sizes and plates of different dimensions. Findings indicate that the strength of H-geogrids is two times that of L-geogrids; whereas the dynamic coefficient of subgrade reaction after reinforcement by H-geogrids is more or less the same as that by L-geogrids (Fig.5 and Fig.6). It could be concluded that the effect of reinforcement is not directly related to the strength of geogrids but the tensile modulus (or stiffness) of the geogrid materials.

Figure 4. Effect of different embedded depth for 10.16cm diameter plate

Figure 5. Dynamic coefficient of subgrade reaction with varied loading levels. (5.08cm-plate at D/R=0.2)

Figure 6. Dynamic coefficient of subgrade reaction with varied loading levels. (10.16cm-plate at D/R=0.2)

## 7 CONCLUSIONS

- (1) The effect of geogrids in pavement reinforcement is confirmed.
- (2) The best reinforcement occurs when  $D/R = 0.2$ . The effects diminish for deeper embedded depths. For  $D/R \geq 0.6$ , the effect of reinforcement becomes negligible.
- (3) Both the dynamic coefficient of subgrade reaction and the amount of permanent deformation can be used for the determination of the effect of reinforcement. The effect of reinforcement is not directly related to the strength of geogrids but to the stiffness of the geogrid materials.
- (4) The level of the dynamic coefficient of subgrade reaction is related to the size of the plate, deformation of geogrids, and the interface properties between geogrid and mudstone (such as interlocking, friction).

# Performance prediction model for asphalt overlays with geotextile interlayers on cracked pavements

R. M. Rodrigues

Associate Professor, Geotechnical Department, Instituto Tecnológico de Aeronáutica, São José dos Campos, Brazil

**ABSTRACT:** The paper presents the development of a mechanistic-empirical model for the prediction of reflective cracking on asphalt overlays with the use of a geotextile as interlayer, considering only the effect of traffic loads. The model is based on an interpretation of laboratory experimental data obtained by Majidzadeh et al (1984). The finite element method and concepts of fracture mechanics are used in this process. It is shown that different mechanisms for the reflective cracking process must be considered in function of the temperature and a proposition is made of a general model.

**KEYWORDS:** Reflective crack prevention, Pavements, Geotextiles, Finite element analysis, Asphalt overlay

## 1 INTRODUCTION

Reflective cracking in asphalt concrete overlays placed over cracked or jointed pavements is a major concern for design. The interface between the overlay and the cracked pavement is the best place to apply remedial measures, since it is at this location that the controlling stresses for the reflective cracking process occur. Geotextile-asphalt interlayers are an effective solution but a comprehensive design method is still lacking for cost-benefit evaluations. A model is suggested for practical application and it is the result of a mechanistic interpretation of laboratory test data obtained by Majidzadeh et al (1984).

## 2 EXPERIMENTAL DATA

Majidzadeh et al (1984) conducted repeated load tests on beams supported by elastic foundation (Figure 1) with the purpose of evaluating reflective cracking life of asphalt concrete overlays applied over cracked pavements. They performed tests with and without the presence of an asphalt impregnated geotextile membrane interlayer placed between the overlay and the cracked asphalt concrete (AC) or Portland cement concrete (PCC) layer. Tests were performed at two temperatures (4.4°C and 22.2°C). The asphalt concrete mix was a FAA P-401 with 5.9% in weight of AC-20 asphalt and 3.4% air voids. The existing crack was sawed to a width of 3.2 mm. Several combinations of layer thickness ( $h_1$ ,  $h_2$ ) and applied surface vertical pressure ( $q$ ) were considered for each test configuration. Three geotextiles were considered and designated as being of low, medium and high tensile moduli. The performance of these geotextiles on the increase of reflective cracking life was nearly the same, with a slightly greater beneficial effect with the ones of higher moduli. For this reason, the analysis here performed employed the average of the test results for all geotextiles considered. According to Majidzadeh et al (1984), this result would be a consequence of the asphalt impregnation with different rates (from 0.3 to 0.9 l/m<sup>2</sup>) of the three geotextiles, which tended to saturate them, leading to a more uniform behavior.

Figure 1. The experiment of Majidzadeh et al (1984).

## 3 ANALYSIS OF TEST RESULTS

Two dimensional finite element modeling (plane stress) was employed in the simulation of the test configuration of Figure 1. Only standard constant strain triangle elements were utilized for all materials, with a special mesh refinement at the crack tip. Each analysis had the objective of evaluating the stress state at the critical point in the asphalt concrete overlay. This point is situated immediately above the existing crack, on the underside of the overlay. The parameter chosen for this evaluation was the distortion energy density ( $U_d$ ), which includes only the strain energy due to shear, leaving out the volumetric strains, since these latter strains are not related to fatigue cracking. Besides, this parameter is known to be less susceptible to suffer inaccuracies in the finite element method, when compared to stresses or strains. For these analyses, the asphalt-geotextile membrane interlayer was not included on the finite element mesh. So, even in the tests where the geotextile was present, the calculated values of  $U_d$  referred to a situation where the overlay was placed without the geotextile. The observed number of load cycles to a complete reflection of the crack ( $N_f$ ) was correlated with the calculated values of  $U_d$  by:

$$N_f = A \left( \frac{1}{U_d} \right)^B \quad (1)$$

where A and B are material constants.

It was also analyzed the possible effect of the inclusion on this regression of the overlay thickness ( $h_1$ ), in the form:

$$N_f = A \left( \frac{1}{U_d} \right)^B h_1^C \quad (2)$$

Regression results are shown on Tables 1 and 2, together with the coefficient of determination ( $r^2$ ) and the standard error of estimate (s). It can be seen that parameter  $U_d$  is strongly correlated with reflective cracking, independently of support conditions, applied load and overlay thickness. Besides, for  $T=22.2^\circ\text{C}$  the inclusion of  $h_1$  on the regression was significantly beneficial, while for  $T=4.4^\circ\text{C}$  that is not the case. At  $4.4^\circ\text{C}$  the correlation between  $N_f$  and  $U_d$  is stronger than at  $22.2^\circ\text{C}$  and, for this latter temperature, it is highly desirable to include  $h_1$  on the model. So, while  $U_d$  alone is sufficient to explain reflective cracking at  $4.4^\circ\text{C}$ , there is an effect at  $22.2^\circ\text{C}$  that is controlled by  $h_1$ . A possible interpretation for these results is that there is a stable crack progression through the overlay thickness with load repetitions after the occurrence of fracture at the bottom of layer, for the temperature of  $22.2^\circ\text{C}$ . At  $4.4^\circ\text{C}$  the asphalt concrete mixture would be a fragile material, making the crack progression to be of little importance in relation to the period necessary for fracture beginning at the critical point.

The inclusion of a geotextile-asphalt interlayer significantly increases reflective cracking life, specially for the lower temperature, as indicated by parameter A. At  $4.4^\circ\text{C}$  the influence of  $U_d$  on  $N_f$  is strongly affected by the inclusion of the geotextile interlayer, since the inclination of the  $\log U_d \times \log N_f$  line changes from 1.883 to 0.8589. It is impossible, therefore, to consider geotextile action as of a Stress Absorbing Membrane Interlayer (SAMI) type, since there would not be a well defined reduction factor that could be applied to the calculated values of  $U_d$  for the case of overlay without geotextile in order to predict the greater reflective cracking life with the inclusion of the membrane. A definition of such reduction factor would require, instead, the use of a reduction function (a reduction factor varying with  $U_d$ ), implying in a non linear SAMI action. This hypothesis must, however, be discarded, in light of the excellent correlation observed between  $N_f$  and the  $U_d$  values calculated without the inclusion of the geotextile interlayer on the finite element analyses.

#### 4 OVERLAY WITHOUT GEOTEXTILE

Several studies have shown the validity of Paris' law for fatigue cracking prediction on asphalt concrete (Luther et al 1976). According to this law, crack progression can be predicted by a model of the form:

$$\frac{dc}{dN} = aK_1^b \quad (3)$$

where  $c$  is the crack length,  $N$  is the number of cycles of the stress intensity factor  $K_1$ , and  $a$  and  $b$  are material properties. The stress intensity factor is a parameter that describes the stress field in the vicinity of a crack tip.

The irregular path followed by a crack that goes around aggregate particles puts doubts, however, as to the relevance of stress intensity factors calculations on this so heterogeneous material. The crack progression could be viewed, maybe, as a sequence of discrete ruptures of aggregate particles bonds along this irregular path. Besides, the results on Tables 1 and 2 indicate that reflective cracking life is controlled, to a high degree, by the distortion energy applied at the critical point on the underside of the overlay. Combining these two arguments, one could describe the process of consisting of two stages. During the first one, there would be happening the fracture under repeated loads of the aggregate bonds at the critical location. Conventional fatigue laws under controlled stress would be sufficient to predict duration of this stage. Tensile strength of the asphalt concrete is the major controlling factor in this case. The fracture occurrence would imply in the rupture of bonds of aggregate particles on the critical location and an initial length for this original crack would be on the order of magnitude of the maximum particle diameter ( $\phi_{max}$ ). After this, there begins a new mechanism where the crack thus formed serves as a means to redirection the dissipated energy to the formation of new free surfaces, resulting on the extension of the crack. A low speed for crack progression depends on the ability of the material to dissipate strain energy through plastic distortion rather than through formation of new free surfaces at the crack tip. Therefore, a fragile material will have a faster crack progression than a more ductile one.

These considerations can be expressed by the following model:

$$N_f = N_0 (1 + F_{PT})^\beta \quad (4)$$

$$F_{PT} = \alpha (h_1 - \phi_{max}) \quad (5)$$

$$N_0 = M \left( \frac{1}{U_d} \right)^{n/2} \quad (6)$$

where:  $N_0$  = number of load cycles for the fracture on the critical location of the overlay, where the distortion energy density is equal to  $U_d$ ;  $F_{PT}$  = crack progression factor ( $\geq 0$ );  $\alpha$  = mixture parameter related to crack progression under repeated loads;  $M$  and  $n$  = fatigue parameters of the asphalt concrete mixture.

This model implies in the fact that crack reflection life ( $N_f$ ) is controlled by the fatigue life of the critical region on the underside of the asphalt concrete layer ( $N_0$ ), and that the formed crack must propagate through the entire overlay thickness ( $h_1$ ) from the initial fracture, whose length is of the order of magnitude of  $\phi_{max}$ . Crack speed progression is controlled by parameter  $\alpha$ , which is equal to zero when the material has a fragile behavior and increases from zero as the material becomes of a visco-elasto-plastic nature. If  $\alpha=0$  (crack propagation is unstable) the value of  $\beta$  has not any influence on  $N_f$ , but if  $\alpha > 0$  the value of  $\beta$  will influence crack reflection life. Therefore,  $\beta$  is related to the stable crack progression process and has the meaning of a fracture material parameter, in the same sense as with the fracture parameters of Paris' Law.

Parameters  $M$  and  $n$  of equation (6) must be determined from stress controlled bending fatigue tests, which are well known to represent fracture formation at the critical zone and do not incorporate significant crack propagation effects. From analysis of several tests of this kind, the following relations can be stated:

$$N_0 = K \left( \frac{1}{\varepsilon} \right)^n \quad (7)$$

$$n = 1.813 - 0.1046 \log_e K \quad (8)$$

where  $\varepsilon$  is the maximum tensile strain applied. Parameter  $n$  must be measured in repeated load or creep tests and parameter  $K$  can be calculated by equation (8). In the state of pure bending the following relation is valid:

$$\varepsilon = \left[ \frac{3U_d}{E_R (1 + \nu)} \right]^{1/2} \quad (9)$$

where  $E_R$  is the resilient modulus and  $\nu$  is the Poisson's ratio. For the asphalt concrete employed, values of  $E_R$  are 10545 MPa at 4.4 °C and 3515 MPa at 22.2°C. Poisson's ratio was not measured and a typical value of 0.33 was adopted, as is usual in pavement analysis.

Therefore, the following correspondence can be established between equations (6) and (7):

$$M = K \left[ \frac{E_R (1 + \nu)}{3} \right]^{n/2} \quad (10)$$

Applying this relation to the values of  $M$  determined by regression of data from tests at 4.4°C without geotextile (Table 1, equation 1), results:  $K = 6.8273 \times 10^{-9}$  and  $n=3.77$ . Substituting this value of  $K$  on equation (8) the predicted value for  $n$  is 3.78, which is nearly the same value determined from regression. This implies that  $\alpha = 0$  for  $T=4.4^\circ\text{C}$ . At this temperature the asphalt concrete mixture is, as expected, a fragile material.

Considering now the experimental data for  $T=22.2^\circ\text{C}$  and overlay without geotextile, the fitting of the model was done varying  $\alpha$  as the basic parameter and determining  $M$ ,  $n$  and  $\beta$  by linear regression analysis. For any fixed value of  $\alpha$  the model adjustment to the experimental data is the same ( $r^2=0.957$  and  $s = 0.3095$ ). The absolute error of estimate is the same as for the direct regression of equation (2). Results are shown on Table 3 where it can be seen that exponent  $n$  of the fatigue law is the same for all values of  $\alpha$  and equal to 3.61. Only for  $\alpha = 0.143$  there is agreement between the value of  $M$  predicted by equations (8) and (10) and the value of  $M$  determined by regression to the experimental data, as can be seen at the rightmost column of Table 3. The resulting value of  $\beta$  is equal to 5.246.

Table 3 - Model fitting for  $T = 22.2^\circ\text{C}$ .

$\alpha$	$M$	$n$	$\beta$	$K (\times 10^{-8})$	$K(\text{eq. 8})/K$
0.100	1.544	3.61	6.561	4.0731	1.178
0.120	1.428	3.61	5.833	3.7673	1.089
0.143	1.313	3.61	5.246	3.4587	1.000
0.150	1.278	3.61	5.103	3.3725	0.975
0.200	1.078	3.61	4.373	2.8446	0.822
0.500	0.494	3.61	3.054	1.3036	0.377

## 5 GEOTEXTILE EFFECT

The model for overlay without geotextile can be applied to help in the interpretation of the data for the tests with geotextile. The increase in reflective cracking life due to the geotextile inclusion is given by:

$$\Delta N = N_f - N_{OV} \quad (11)$$

where  $N_f$  is the reflective cracking life with geotextile and  $N_{OV}$  is the predicted reflective cracking life for the overlay without geotextile, as given by equation (4). Figure 2 shows the calculated values of  $\Delta N$  for the tests conducted by Majidzadeh et al (1984), where it can be seen a clear dependence of  $\Delta N$  with  $U_d$ , the distortion energy density at the crack tip on the overlay calculated without the inclusion of the geotextile.

There is a trend for convergence for low values of  $U_d$  of the relations between  $\Delta N$  and  $U_d$  for the two temperatures considered, allowing the proposition of the following model:

$$\Delta N = 5.0 \times 10^5 \left( \frac{U_d}{1 \text{ kPa}} \right)^\xi \quad (12)$$

where:  $\xi = -0.677$  for  $T = 4.4^\circ\text{C}$  (with mean error of 16 %) and  $\xi = -2.10$  for  $T = 22.2^\circ\text{C}$  (with mean error of 27 %).

There are several experimental evidences showing that extension of reflective cracking life with the inclusion of geotextiles is a consequence of a crack arrest process, in which dissipated energy is deviated from the formation of new free surfaces at the critical zone on the overlay to propagation of a horizontal crack at the geotextile-pavement interface (Montestruque 1996). In this way, the possibility of writing equation (12) as an expression of experimental data would be a result from a stable horizontal crack progression, which could be described by a law analogous to Paris' Law:

$$\frac{dl}{dN} = AU_d^B \quad (13)$$

where  $l$  is the horizontal crack length, and  $A$  and  $B$  are fracture parameters for the geotextile-pavement bond. This hypothesis will be valid only if  $B > 0$ , since horizontal crack progression speed must increase with the distortion energy supply on the crack tip region. Integrating equation (13) and considering that  $U_d$  varies only slightly with horizontal crack extension (since this horizontal crack is of small length), one could write:

$$\Delta N = \frac{1}{A} \int_0^{l_{crit}} U_d^{-B} dl = \frac{l_{crit}}{A} U_d^{-B} \quad (14)$$

where  $l_{crit}$  is the critical length reached by horizontal crack, after which dissipated energy goes to the generation of new free surfaces at the crack tip on the overlay.

Comparing equations (12) and (14) one concludes that  $\xi = -B$ . Since  $\xi < 0$  the condition  $B > 0$  is satisfied, giving support to the hypothesis that increase in reflective cracking life can be interpreted as the result of a deviation of dissipated energy from the critical zone of the overlay to the

Figure 2. Increase in reflective cracking life with geotextile.

generation of a small localized rupture between geotextile and overlaid pavement. Parameter  $B$  influences the horizontal cracking process and is temperature dependent. Since the bond and the other materials involved are of asphaltic nature, this dependence is conceivable.

## 6 CONCLUSION

Reflective cracking life of asphalt overlays with the presence of an asphalt-geotextile membrane interlayer can be predicted by first estimating reflective cracking life without the interlayer (equation 4). This number of load cycles is then added to the delay predicted by equation (12). The model should be applied to field data in order to better evaluate its consistency. Material parameters relevant for the model are:  $\alpha$  (degree of fragile behavior in function of temperature),  $n$ ,  $\phi_{max}$  and  $E_R$  for the asphalt concrete, and  $\xi$  for the geotextile-pavement bond, at design temperature.

# EFFECTIVENESS OF SYNTHETIC INTERLAYERS IN BITUMINOUS PAVEMENTS

G. DONDI  
D.I.S.T.A.R.T. DEPARTMENT  
UNIVERSITY OF BOLOGNA, ITALY

## ABSTRACT

The insertion of interlayers in bituminous pavements is quite widespread, although designers tend to use a wide range of synthetic interlayers, from nonwoven low-modulus to high strength polyester geotextiles, not always on the basis of their technical properties. This paper describes the results obtained in an experimental study carried out by our Department, based upon a series of dynamic tests. In order to simulate the road pavement, full-scale square samples were employed: in a steel box, partly filled with rubber, two bituminous concrete layers with different interlayers were placed. In some specimens, deep artificial grooves were made in order to examine a damaged existing pavement. The specimens were dynamically loaded up to failure, with the aim of achieving a simulation of fatigue failure, allowing to better understand sample behaviour. Static tests were carried out at intermediate stages during the dynamic loading. The results of the reinforced specimens, in terms of displacements and rut depths, demonstrated the advantages of interlayers insertion: geosynthetics appear to be able to delay the surface cracking due to reflection of fissures from the underlying layers. Failure cracking patterns can now be reported due to the completion of laboratory experimentation. Such patterns, which may be very different in the case of overlays standing on pre-fissured bases, show the benefits of interposing geosynthetics in pavements.

**KEYWORDS:** Pavements, Fatigue, Reinforcements, Reflection, Cracking, Prevention

## 1. INTRODUCTION

One of the main problems related to the durability of road pavements is represented by surface cracking, induced by fatigue, thermic effects and underlying cracking, i.e. for rehabilitation of cobbled roads (Fig. 1).

Figure 1. Cobbled surface of Via Appia, 2000 years old Roman road.

The interposition of geosynthetics as interlayers in asphalt pavements (often referred to as “reinforcement”), to prevent the mentioned phenomena, is quite widespread and has generally proved to be successful. Nevertheless, an overall accepted design method still does not exist. There are a lot of questions still pending regarding the best and worst type of interlayer (nonwoven geotextiles, geogrids, etc.), the appropriate position of installation and the opportunity of the insertion of interlayers also in new projects.

A reply has not yet been given to all these questions; however, with the laboratory experimentation described in this paper and the information obtained in situ with another experiment underway, an attempt has been made to contribute to the assessment of the behaviour of bituminous pavements containing synthetic interlayers. Only macro-reinforcement we will be considered in this article (Fig. 3); i.e., the interlayers that are well defined in the bituminous mix. This subject has already been studied in the past, from a theoretical point of view by our Department (Dondi and Righi, 1990), (Dondi, 1994) and, more recently, a large number of experiments were carried out. In an initial stage, for a preliminary static evaluation, some “three point bending” tests on asphalt beams: without interlayers (UR), with nonwoven geotextiles (GX) and with polyester (PET) geogrids (GG). Then created 24 specimens (1.4x1.4m) were created, having many different types of interlayers and degrees of disturbance (Fig. 2).

Figure 2. Sample preparation: in some, the longitudinal artificial cuttings can be seen.

It's well known that the reinforcement of asphalt requires high temperature resistant polymers: indeed, with modified binders, during compaction, the mix reaches high temperatures (140-150 °C and higher). For this reason, it was considered that the use of at least PP or PET geosynthetics would be necessary.

Figure 3. Detail of a polypropylene geogrid insertion in a specimen.

The insertion of nonwoven geotextiles in a flexible pavement generally causes a strength decrease, despite a better overall behaviour. For this reason, some stiffer geogrids or composites may be preferred. Furthermore, the latter theoretically appears to provide a better solution since it improves the linking with the upper bituminous layer also without any tack coat upon the interlayer surface.

## 2. PRELIMINARY PHASE

In the preliminary stage of the research, it was verified that, according to Judycki (1990), the best loading methodology

was, for many reasons, the three point bending test since stresses and strains are more realistic. The samples were 100 mm wide, 85 or 100 mm high, and 600 mm long. The interlayer, when present, was placed 35 mm over the bottom of the sample. The rate of loading was approximately 50 mm/min', as also suggested by Kunst e Kirschner (1993) and all the tests were carried out using a bituminous mix, with a 5% of 80/100 penetration grade bituminous binder.

The grain size distribution curve of the aggregate is represented in Fig. 4, with the binder fuse of the Italian National Roads Administration.

As interlayers, we employed two geosynthetics currently used for road pavements: a nonwoven polypropylene geotextile (Grab Test, ASTM D-4632: 18 kN/m,  $\epsilon_f=55\%$ ); and a polyester woven geogrid (Tensile strength: 60 kN/m). The tack coat was obtained with a cationic emulsion containing 70% of 80/100 bitumen, modified with 5 % Styrene-Butadiene-Styrene (SBS-R) modifier with radial structural arrangement.

Results showed that the most important improvement with interlayers was the increased capability of bearing high loads even after failure, i.e. a higher ductility.

Figure 4. Grain size curve of the bituminous mix.

## 3. LABORATORY DYNAMIC TESTS

In a second stage described in this paper, we carried out more specific dynamic tests in order to better simulate traffic loads and boundary conditions (Dondi 1996). The first step of this research project consisted in a comparison of the results obtained with numerical models such as BISAR (De Jong 1973) and F.E.M. non linear models (Fig. 5), such as FENLAP (De Almeida 1993).

FENLAP is a computer program written in FORTRAN 77 language by J.R.de Almeida. This program performs a finite element calculation of an axi-symmetric solid and is designed for the structural analysis of pavements. It can run both on mainframe and on personal computers. FENLAP uses rectangular elements, distributed over a rectangular

grid. A mesh with up to 23 columns and 23 rows, corresponding to a maximum of 484 elements (22 in each direction) may be analysed. The maximum number of layer which can be considered is 5. Due to the axi-symmetry, all nodes on the left side of the mesh are assumed to be on rollers, allowing vertical displacements but preventing radial ones. For the vertical boundary on the right side and for the lower boundary, several boundary conditions may be adopted as options. Nine different material models are given as an option for the stress-strain relationships of each layer; the main models and the corresponding elastic constants follow:

- 1) Linear elastic isotropic (all type of materials): 5 parameters, vertical Young's modulus  $E$  and Poisson's ratio  $\nu$ ;
- 2) Brown's (fine grained soils): 4 parameters, initial Young's modulus  $E_1$ ,  $\nu$ ,  $A$  and  $B$ .

As non-linear models can be used in FENLAP, the program follows an iterative procedure in which the elastic properties are successively adjusted, for they depend on the values of stress computed. At each iterations, an error check is performed by comparing the new elastic moduli with the elastic ones determined in the previous iteration. If failure criteria are considered, the stresses are also compared with the values obtained in the previous iteration. When both errors fall below an admissible tolerance specified by the user, converge is said to be achieved and the iteration procedure is stopped.

In particular, we tried to establish the different behaviour of semi infinite and confined multilayered system with trial moduli. It was discovered that, in order to avoid significative boundary effects, the minimum dimension of square specimens was approximately 1.5x1.5 m.

Consequently, we created a bituminous concrete strip, approximately 36 m long, in two stages (two layers): after completion of the first one, artificial cuttings were also realised in some areas to represent the rehabilitation of a fractured pavement.

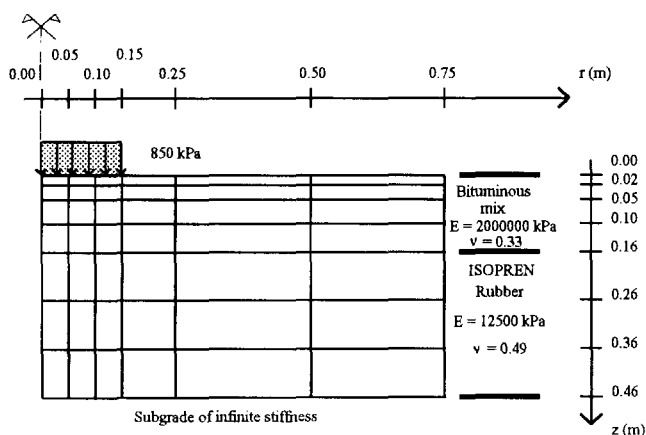

Figure 5. Numerical mesh (of the samples) for numerical analysis.

Various kinds of interlayers were then inserted; these specimens have the characteristics described in Table 1.

A steel box was then built to contain the asphalt specimens and the underlying layers (Fig. 6). The load was applied by means of a circular steel plate, with a diameter of 0.3 m standing on a rubber layer with the function of minimizing stress concentration related to plate stiffness.

To enhance only the behaviour of asphalt, and with the aim of reducing the uncertainties as much as possible, we decided to build the foundation bed with rubber.

This allows to minimise uncertainties related to resilient behaviour of granular materials and increases the reproducibility of the tests (Fig. 6).

Besides the traditional mechanical tests, other experiments were carried out in order to assess the complex modulus ( $E_c$ ) and the phase shift angle ( $\phi$ ) of the asphalt specimens.

From the laboratory results of a simple static creep test, we obtained at a temperature of 25°C:  $E_c = 800$  MPa and  $\phi = 40^\circ$ .

Table 1. Characteristics of specimens tested

a) Non Lesioned bituminous concrete (NL)
a.1) Unreinforced Specimen (UR);
a.2) Specimen with nonwoven geotextile interlayer (GX);
a.3) Specimen with bi-directional woven polyester (PET) geogrid (GG) interlayer;
a.4) Specimen with bi-directional polypropylene (PP) geogrid (RA) interlayer ;
a.5) Specimen with polypropylene (PP) geocomposite (GT=GX+GG) interlayer.
b) Lesioned bituminous concrete(LE)
b.1) Unreinforced Specimen (UR);
b.2) Specimen with nonwoven geotextile interlayer (GX);
b.3) Specimen with bi-directional woven polyester (PET) geogrid (GG) interlayer;
b.4) Specimen with bi-directional polypropylene (PP) geogrid (RA) interlayer;
b.5) Specimen with polypropylene (PP) geocomposite (GT=GX+GG) interlayer.
GX: tensile strength $S_t = 18$ kN/m (long.), 8 kN/m (trans.); yield strain $\epsilon_y = 55\%$ (long.), 40% (trans.).
GG: tensile strength $S_t = 60$ kN/m (long.), 54 kN/m (trans.); yield strain $\epsilon_y = 14\%$ (long.).
RA: tensile strength $S_t = 20$ kN/m (long.), 20 kN/m (trans.); yield strain $\epsilon_y = 13\%$ (long.), 10% (trans.).
GT: tensile strength $S_t = 20$ kN/m (long.), 20 kN/m (trans.); yield strain $\epsilon_y = 13\%$ (long.), 10% (trans.).

All the asphalt specimens, made outside in a single 36 meters long strip as described previously (see also Fig.2), were then cut away, brought in the laboratory, and placed directly on the rubber (settled down)in the steel box. Hence, as far as stiffness is concerned, the rubber represents both the foundation and the subgrade layers. The

asphalt specimens have a total thickness of 160 mm, arranged as follows (Fig. 6):

1. a 60 mm-thick asphalt layer bottom, in some cases fissured (indicated in the text as “LE”, whereas the other non-fissured samples are referred to as “NL”), by cutting it with a steel tool to a depth of 50 mm;
2. the interlayer, when present, fixed with a cationic bituminous emulsion (1000 gr/m<sup>2</sup> approximately ) tack coat;
3. a 100 mm-thick asphalt layer top.

In order to evaluate the minimum thickness of overlays, since some practical applications suggest that such a limit exists, we also realised some “REVERSE” samples (RE) in which the bottom asphalt layer was 100 mm thick (instead of 60 mm) and the overlay 60 mm thick (instead of 100 mm).

The load was applied with a hydraulic jack, controlled by the data acquisition system, at a frequency of 5 Hz. The shape of the loading wave is approximately sinusoidal and has an initial amplitude ( $\Delta V_0$ ) of 60 kN, in the range 5-65 kN. During the tests and in some cases with very high displacements, it was necessary to reduce this amplitude in order to maintain the original frequency.

Two reference grid patterns, 100x100 mm and 50x50 mm in the central portion, were sketched on the surface of the samples previously covered with white paint, to allow reporting the failure pattern vs. number of cycles.

Surface displacements, at different distances from the loading plate, were monitored with inductive transducers connected to an Instron data acquisition system (Fig. 6 )

Figure 6. Sample composition.

In some tests, the acquisition of the temperature gradient to which the specimen is exposed during and after the test, by means of a temperature survey in several points

and at various depths of the specimen, achieved by the installation of thermic probes with automatic data acquisition.

Figure 7. A specimen after  $5 \times 10^5$  loading cycles

## 4. INTERPRETATION OF RESULTS

At the end of the tests (each one is approximately three days long), all the samples showed highly significant permanent displacements (Fig. 7), although the degree of damage was very different. Furthermore, cracks appeared later in specimens and their extension was much smaller than in samples without geosynthetics.

### 4.1 Cracking Pattern

As previously described, it is to be pointed out that the failure behaviour of the various types of samples differs substantially.

In non-lesioned samples (NL), cracking starts in radial directions on the free surface: this behaviour was previously observed by other authors (Kief et al., 1994, and therefore we could assume that this is normal for pavements whose unique factor of degradation is repetitive loading. In lesioned samples (LE), the cracking pattern, as shown in Fig. 9 for  $5 \times 10^5$  cycles, follows the alignment of artificial cuttings.

The estimation of the benefit brought by the interlayers can be made by analysing the tables reported in this paragraph.

#### 4.1.1 Normal Samples

The tables (Tab. 2 and Tab. 3) refer respectively to the specimens NL and LE.

These tables summarize the percentages of damaged surface ( $A_{les}$ ) in comparison to the total area ( $A_t$ ), and the decrease of cracking ( $\Delta A_{les}$ ) in the different situations (UR, GX, GG, GT and RA) in respect to the unreinforced the specimen (UR) at the end of every single test, after  $5 \times 10^5$  loading cycles.

The surface under the loading plate was not included in the calculation of the total area.

Table 2. Percentages of the damaged surface in comparison to the total surface of the specimen (NL specimens).

Sample	NL-UR (%)	NL-GX (%)	NL-GG (%)	NL-GT (%)	NL-RA (%)
$A_{les}/A_t$	43	24	17	23	21
$\Delta A_{les}/A_t$	-	-44	-60	-47	-51

Table 3. Percentages of the damaged surface in comparison to the total surface of the specimen (LE specimens).

Sample	LE-UR (%)	LE-GX (%)	LE-GG (%)	LE-GT (%)	LE-RA (%)
$A_{les}/A_t$	38	13	10	9	17
$\Delta A_{les}/A_t$	-	-66	-74	-76	-55

The benefit had by the interlayer seems extremely high for all the type of interlayers and it is not excessively influenced by its modulus. In particular if we consider the NL specimens, we may observe a maximum improvement of 60 % (GG-PET and GT) while, for the remaining synthetic interlayer, the benefit proves to be quite steady at a range from 45% to 50%.

Figure 8. Cracking after  $5 \times 10^5$  cycles in two samples: one, on the left, has an interlayer (NL -GX) and the other does not (NL -UR).

Instead, with regard to the LE series we obtain an maximum improvement of 74-76% (GT-PP and GG-PET) while, for the remaining materials, the improvement is sufficiently homogeneous with values between the 55% and the 66%.

Therefore, the improvement is more evident for the LE specimens although, also in this case, it is not strictly proportional to the strength of the interlayers.

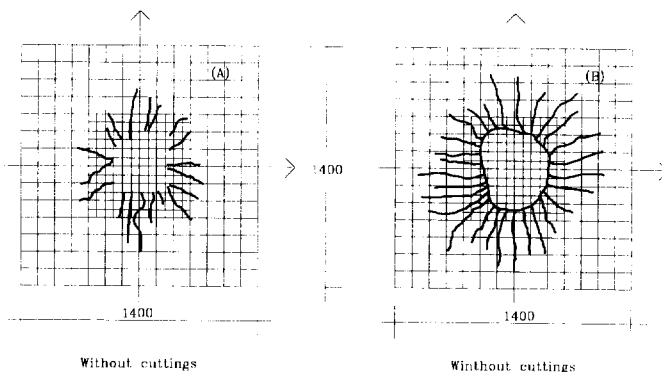

Figure 9. Cracking after  $5 \times 10^5$  cycles in two samples: one, on the left, has an interlayer (LE -GX) and the other does not (LE -UR).

#### 4.1.2 Reverse Samples

Also in these samples, characterised as previously specified by a thin overlay, the insertion of an interlayer reduces the cracking set, although the benefit is much more moderate than in the previous case.

Table 4. Results of "REVERSE" (RE-NL) specimens.

Sample	RE NL-UR (%)	RE NL-GX (%)	RE NL GG (%)	RE NL GT (%)	RE NL RA (%)
$A_{les}/A_t$	43	n.d.	31	28	34
$\Delta A_{les}/A_t$	-	n.d.	-28	-35	-21

The benefit achieved by the interlayer comes to a maximum improvement of 35 % (GT) while, for the remaining materials, the benefit proves to be quite steady at a range from 21% to 28%. Furthermore, with regard to the "reverse" series and unlike specimens with normal section, a very prominent, circular crack appears, at the edge of load mark, from which the previously mentioned radial cracks depart.

This confirms that the insertion of interlayers near the surface, as was foreseeable, must be taken into account with extreme caution.

#### 4.2 Settlements

When analysing deformations settlement of non-fissured samples (NL), it is necessary to point out the difference between permanent deformations (visco-plastic deformation) and reversible ones (visco-elastic deformation).

##### 4.2.1 Visco-plastic settlements

Permanent deformations, in the case there are no artificial cuttings, depend on the presence of interlayers, as is

pointed out by Fig. 10. In this case, it appears evident that their extent is related to the modulus of the interlayer.

Figure 10. Permanent deformations under loading surface vs. N°. of cycles.

#### 4.2.2 Visco-elastic settlements

Instantaneous deformations, with analogy to the previous case and in the same non lesioned condition, are also influenced by the presence of interlayers.

Hence, it's possible to assert that, when there are synthetic interlayers, NL specimens stiffness (not the resistance) increases in strict proportion to the modulus of interlayers. The improvement is made much more evident by increasing the number of loading cycles. This can be explained, order than by the fatigue behaviour, also by taking the specimens temperature into account. In fact, this conspicuously increases while the test is being carried out (Tab.5): this is due to the dissipation of the deformation energy, which is transmitted by the hydraulic jack.

Figure 11 Instantaneous deformations under loading surface vs. N° of cycles.

It's also particular interesting to compare the details of the results obtained on two LE specimens, for which the behaviour appears significantly different in comparison with NL ones.

Table 5. Continuous logging of temperature in the specimen.

Load Cycle x10 <sup>3</sup>	Air Temp. C°	Probe 1 C°	Probe 2 C°	Probe 3 C°	Probe 4 C°
0	22.2	21.7	21.7	21.6	21.3
50	22.4	22.6	22.0	21.7	21.3
100	22.7	23.3	22.4	21.8	21.3
150	22.3	23.9	22.7	21.8	21.2
200	21.9	24.5	23.1	21.9	21.0
250	21.7	25.4	23.6	22.2	21.2
300	21.4	25.8	23.9	22.3	21.1
350	21.1	26.2	24.2	22.4	21.1
400	21.6	26.6	24.5	22.6	21.2
450	22.0	27.0	24.8	22.8	21.3
500	22.5	27.2	25.0	22.9	21.4

We now consider:

1. Lesioned specimen, without interlayers (LE-UR).
2. Lesioned specimen, with a nonwoven geotextile as interlayer (LE-GX).

In this case, maximum deformations (under loading) are surprisingly similar for specimens with (GX) and without interlayers (UR), while pseudo-elastic deformations follow a different behaviour: after  $4 \times 10^5$  cycles, instantaneous settlements significantly increase in LE-UR specimens while they tend to be constant in the LE-GX specimen (see Fig. 12)

When analysing the total settlement of fissured specimens (see Fig. 12), the two curves for UR and GX samples are so close that no differences can be noticed.

So, contrarily to the NL case, we don't record any stiffness increase consequent to the introduction of a nonwoven geotextile in this case.

Figure 12. Settlement under loading surface vs. N° of cycles.

When taking into consideration the elastic fraction of the displacement, we can see that, prior to a certain number

of cycles (i.e. approximately  $4 \times 10^5$ , Fig. 12) the curves are quite similar. After this limit, there is a rapid increase of settlements in UR samples.

We can conclude that with LE specimens there is no reduction of permanent deformation but that the overall behaviour of LE-GX sample is better, considering the increase of pseudo-elastic stiffness.

## 5. IN SITU TESTS

In order to validate laboratory tests, we have created an experimental field by reproducing, in a lane of the Centro Padane Motorway S.p.A., A21 Piacenza-Cremona-Brescia (Fig.13), some sections very similar to those tested in the laboratory.

Figure 13. Experimental field in a motorway lane.

During rehabilitation works of the upper bituminous layer, deep cuttings were made (50-70 mm) in the binder layer (Fig. 14) between the edges of the road, in a 10 m wide and 120 m long area.

Figure 14. Detail of the groove.

These cuttings were regularly spaced at 500 mm to represent existing cracks (Fig. 15).

Figure 15. Detail of the distance between the grooves.

Then interlayers of different types, similar to those previously employed in laboratory tests, were laid down only on some parts of the lesioned field, on a bituminous tack coat (Fig. 16).

Finally, the lane was repaved with a layer of 90-100 mm thick asphalt. In order to evaluate the real traffic volume and composition, we also arranged in the vicinity a digital axles counter and an inductive load-measurement device.

Figure 16. Detail of the reinforcement laying.

The experimental field, after nine months, performs well and there is no evidence of cracking reflection, neither in sections with deep cuttings and without interlayers, but the test is still continuing and we expect the results in next months.

## 6. CONCLUSIONS

The insertion of "high modulus" geosynthetics in upper bituminous layers requires a correct sequence of the following operations:

- thorough cleaning, through blowing and brushing, of the laying plane, or better through hydraulic jetting;
- sealing of the possible cracks through bituminous coat casting;
- laying of a first bituminous emulsion tack coat, possibly with elastomer;
- laying of the interlayer by means of a roller, equipped with clutch, able to provide low pretensioning stress;
- settlement of the surface by means of a clipper shearing machine for removing protrusions, resulting from a not perfectly homogeneous laying;
- laying of a second bituminous emulsion tack coat, possibly elastomer (it is not necessary if geogrids are used);
- laying and compaction of the subsequent asphalt layer.

When summarizing the achievable benefits, we may state that:

- advantages are particularly outstanding with geogrids and composites in critical conditions, such as heavy loads and for overlays of intensely fractured pavements;
- there is a significant improvement of the ductility of bituminous layers;
- with polyester geogrids, there is also a slight increase in ultimate strengths, without interlayer failure;
- in any case, also with nonwovens insertion with a good tack coat, the presence of an interlayer delays the cracking reflection and guarantees the durability for the overlays;
- the pseudo-elastic stiffness of the pavement is slightly increased and the degree of cracking is, in any case, much lower;
- with regard to the reduction of cracking ratio, the benefit brought by the interlayer seems extremely high for all types of interlayers and is not strongly influenced by the strengths and the moduli of this ratio. For the LE specimens and therefore with regard to the reflection of pre-existent cracking, the improvement is much more evident than for the NL specimens;
- it is absolutely unwary to place the interlayers too near the surface: the minimum coverage is 70 – 80 mm thick;
- recycling is allowed.

When designing a reinforcement, the following criteria should be followed.

When the geosynthetic is placed into the bituminous layers, it is necessary to observe some simple, but basic instructions during the laying of the interlayers: the laying

stage is, in fact, fundamental, principally in order to guarantee a monolithic pavement. It's well-tested, in fact that an inadequate link between the layers, especially when geosynthetics with high bitumen absorption capacity are used, i.e. nonwovens and composites, can cause a quick failure of the pavement.

## ACKNOWLEDGEMENTS

The Author wishes to thank Mr. Rimoldi, TENAX S.p.A., for laboratory facilities and Mr. Salvadori (Centro Padane Motorway S.p.A., A21 Piacenza-Cremona-Brescia, Italy) for his help for the realisation of in situ experimental field.

# Geotextile Within Asphalt Overlay on a Brazilian Road: A 13-Year Case Study

P.R. Aguiar  
MULTIGEO Eng. Associados, São Paulo, Brazil

C.E.L. Paiva  
Professor, Geotechnical and Transport Engineering Dept., Faculdade de Engenharia Civil, UNICAMP, São Paulo, Brazil

**ABSTRACT:** This paper examines the use of geotextile within an asphalt overlay on a rural road with medium traffic 13 years after application. Testing was carried out using four 300m long experimental sections of the road. Each one was further divided in two areas: a field test area with geotextile use and a control covered with ordinary asphalt. Different thicknesses of asphalt overlays were used. Data concerning the current pavement surface and structural stages are presented and compared with the original ones. Finally, some conclusions about the four sections are drawn and the concept of the technique employed is evaluated.

**KEYWORDS:** Asphalt overlay, geotextiles, pavements, rehabilitation, reflective crack prevention.

## 1 INTRODUCTION

The SP-52 in São Paulo, Brazil, carries medium traffic from the city of Cruzeiro to the boundary between the states of São Paulo and Minas Gerais. Local temperatures range from 10°C to 38°C.

In 1984 asphalt overlays were laid on the road in order to overcome severe pavement deformations. Four experimental sections with similar pavement structures were chosen for this study and each section was further divided in two areas: one of them received a geotextile reinforced overlay, while the second one was covered with conventional pavement for comparison.

The present work examines the current road surface conditions and compares deflection measurements carried out in 1984, in 1985 and in 1997, 13 years later.

## 2 PREVIOUS PAVEMENT CONDITIONS

The transversal section of the SP-52, built in 1967, consisted of a 0.03m thick asphalt concrete layer over a 0.15m thick wet-mix macadam granular base and a 0.20m thick sub-base reinforced with chosen soil, as shown in figure 1.

In 1981 the Average Daily Traffic (ADT) was 1121 vehicles, 29% of which were commercial (trucks and buses). In 1983 the pavement presented many surface deformations such as longitudinal cracking, alligator cracking, sinking, potholes, holes and localized

patches. To solve these problems the pavement needed improvements in the base course and drainage system as well as repairs to the cracked surface course.

Figure 1: Previous pavement transversal section

Four 300m long sections were chosen for the experimental design. Pavement structural conditions were done by means of Benkelman beam deflection measurements, taken in 1984 (before the overlay), in 1985 (4 months later) and in 1997 (13 years later). Figures 2 and 3 show the internal and external lane deflections, respectively.

**Figure 2: Internal Lanes-Deflections**

**Figure 3: External Lanes-Deflections**

### 3 THE OVERLAY INSTALLATION

Since there were no project criteria considering geotextile reinforcement conditions in Brazil in 1984, the sections were designed according to the usual method based on USACE and thus ignoring the geotextile reinforcement properties.

Each 300m long section was divided in two areas with similar characteristics. The compositions of the pavement sections laid on each of them between May and June, 1984, are shown in figure 4.

A 100 % polyester non-woven continuous filament geotextile called BIDIM OP-20 (RHODIA-STER S/A) was employed (200 g/m<sup>2</sup>, 15 kN/m wide width tensile NF G-38014, 30-35% elongation). In the beginning and at the end of each section the geotextile was attached to the previous pavement with metallic staples in order to avoid sliding.

Table 1 summarises the main occurrences during installation (left and right sides of the road were named considering the São Paulo (Cruzeiro) - Minas Gerais direction), whereas figures 2 and 3 show deflection measurements done in 1985.

Figure 4: Overlays transversal sections

Table 1: Main Occurrences during overlay installation.

#### 4 13 YEARS LATER

In 1995 an analysis made by the Department of Roads of São Paulo State (DER,1995) considered the pavement area to be good, with 14% of cracking, 0.05% of potholes and 0.30% of sinking. The ADT was then 1936 vehicles, 27% of which were commercial.

However, a more recent evaluation carried out in 1997 showed that there was an accelerated pavement damage in the last two years (figures 2 and 3). The current surface conditions were considered regular, with 32% of cracking severity, 5% of potholes and 30% of patches.

Table 2 summarises the observations during the 1997 evaluation.

#### 5 CONCLUSIONS

The last deflection measurements presented in figures 2 and 3 as well as the surface deformations observed (table 2) lead to the conclusion that most of the analysed sections are at the end of their expected lifetime. These

results differ somewhat from the ones obtained in 1995, when the pavement condition was considered good.

Comparing areas 1B to 1A and 2B to 2A one can conclude that the geotextile inlay acted as a reflective cracking barrier, albeit there were no significant differences either between areas 3A and 3B or between 4A and 4B.

Although sections 1 and 4 had the same asphalt concrete thickness, the former is very damaged while the latter is in good conditions. The reason for this disparity may lie on their positions on the road. Section 1 is located on a hill and immediately after a road police station, whereas section 4 presents no obstruction for free flow of commercial vehicles.

An intensive surface damage with alligator cracking was observed in a small segment of area 1A. Some small asphalt concrete pieces could be removed and it turned out that in the damaged area the course thickness was only 0.02m instead of the specified 0.03m. Therefore the asphalt concrete has come apart from the pavement after 10 years in operation.

Table 2: Conditions of the Sections in April 1997

4B	Int	OK	OK	Good state	Good
	Ext	OK	OK		

TB: block cracking TL: longitudinal cracking AI: high intensity BI: low intensity Ext: External lane  
 J: alligator cracking TT: transversal cracking MI: medium intensity Int: Internal lane OK: Good  
 Regular: 25 to 50 % of surface defects; Surface cracking length lower than 3,5 m. PSI between 2,0 and 3,0.  
 Good: 5 to 25 % surface defects. PSI between 3,0 and 3,8.

Residual asphalt for geotextile impregnation was used in much smaller amounts than in the USA, in order to keep the geotextile drainage capacity and avoid the usual exudation that occurs in tropical countries.

There are still few overlays with geotextile in Brazil. A rise in such applications is expected, since some highways are now private and their owners take only high cost-benefit solutions. From our results it is thus possible to advise a 20% increase in the asphalt emulsion for the forthcoming geotextile applications.

#### ACKNOWLEDGMENTS

The authors would like to thank to the DER-Department of Roads of São Paulo, head and local offices, for the equipments and data of pavement system management of SP-52 road, and RHODIA-STER S/A by the data presented.

# Fracture Behaviour of Geosynthetics in Asphalt Layers

R. Lugmayr  
Technical Consultant, Polyfelt Geosynthetics., Linz, Austria

**ABSTRACT:** The fracture behaviour of different overlay systems was determined due to a research from Tschegg et al (1998). Using a new wedge splitting procedure with deep notched drilling cores the fracture properties of the interfaces geosynthetic reinforcement - asphalt layers and the resistance to crack growth of reflection cracks in three different overly systems was determined in this paper. The test was carried out with a polypropylene needle-punched nonwoven geotextile, a flexible geocomposite interlayer consisting of polypropylene needle-punched nonwoven reinforced with high strength glass filaments and a stiff polypropylene geogrid with a nonwoven fixed on the junctions. The result of the research of Tschegg et al (1998) was evaluated and discussed in this paper from the practical engineers point of view.

**KEYWORDS:** Adhesion, Asphalt Overlay, Fractures, Geocomposites, Geogrids

## 1 INTRODUCTION

Formation and propagation of reflection cracks in bituminous pavements are unsolved problems in theory and practical application until today. It is necessary to characterize the fracture behaviour of the basic components in order to be able to calculate, model and simulate cracks. The fracture behaviour and bond strength of bonds between the asphalt layers, has to be determined.

The fracture behaviour of bituminous overlays and the bond strength was basically investigated due to the research at the Technical University in Vienna, Austria (Tschegg et al 1995a,b, 1997). In order to characterize the fracture behaviour of different overlay systems using typical geosynthetic products further research (Tschegg et al. 1998) was also done. The propagation of reflective cracks of the whole system and crack propagation of the interface was investigated. The determined results are of great scientific and practical interest. The results are evaluated and discussed in this paper from the practical engineers point of view. Preliminary a short description of the research procedure (Wedge splitting test and experimental details) Tschegg and Co-worker (1998) is shown.

## 2 PRINCIPLE OF THE TESTING METHOD

In Figure 1 a core specimen of asphalt pavements with mounted loading device and displacement gauge is depicted. Specimens are placed on a narrow linear support in a compression testing machine.

The specimen has a rectangular groove with a starter notch at the bottom of the groove. For interface tests (fracture test of the adhesive bond) , the specimens are oriented in a way, that the interface is aligned in the plane defined by starter notch and linear support. In order to characterize the fracture mechanical properties of the crack propagation the

Geosynthetic Interlayer is placed normal to the plane starter notch and linear support. A deep notch simulates the reflective crack up to the geosynthetic of the wearing course. A crack is forward to (through) the interface into the overlayer of the specimen during the fracture test due to the splitting force (loading condition: bending).

Figure 1: Test arrangement for drill core-specimen (according to Tschegg 1986)

Two load transmission pieces are placed in the groove and a wedge is inserted between them. The wedge transmits a force  $F_M$  from the testing machine to the specimen. The slender wedge exerts a large horizontal force component  $F_H$  and a small vertical force component  $F_V$  on the specimen. The force  $F_M$  is determined with a load cell in the testing machine. More details of the testing method is described in Tschegg et al 1995a and Tschegg 1997.

### 3 EXPERIMENTAL DETAILS

#### 3.1 Material, specimen shape and size

From a bituminous base layer sample, of Austrian standard type BT I 16 (crushed aggregates, maximum grain size 16 mm, binder content 4.8-4.9 % of 100 pen-bitumen), plates of 70 - 80 mm thickness were produced. Compaction was performed with a vibration roller. Thus the asphalt aggregate mixture and production of the layer was similar to that, which is used in road construction. The plate surfaces were treated with a water jet until all binders and fine aggregates were removed from the surface. In this way a road with traffic was simulated.

Further drilling cores with a diameter of 200mm and a height of 120mm with and without interlayer were produced. In order to simulate a reflective crack the wearing course was then cut down of 10mm above the interlayer. Additionally two 50mm deep side notches were cut to eliminate border influences of the specimen. The ligament area has a dimension of 100x55mm and is large enough that the size effect has no influence on the test results. Two stone plates were glued onto the front face of the drilling core parallel to the starter notch. They act as a groove for taking up the loading device. In the case of the stiff geogrid interlayer it was distinguished between specimen with one and two bars (Fig. 2) in order to evaluate the influence of different bar number in the ligament area on the fracture behaviour.

Figure 2 : One and two bar specimen

#### 3.2 Testing conditions and evaluation

The vertical load of the testing machine is transferred into the sample via a wedge ( $\alpha/2=15^\circ$ ) and two load transferring pieces. The load is applied over a roller bearing in order to eliminate any friction forces which would influence the results.

Testing was performed with a mechanical compression testing machine with a load capacity of 5 kN. Unstable crack growth was not observed in any of the tests. The cross-head velocity was 2 mm/min in all tests. Before testing, the specimens were stored in a cooling chamber with a control

accuracy of  $\pm 0,5^\circ\text{C}$  for approximately 24 hours. Testing temperatures were  $-10^\circ\text{C}$ ,  $0^\circ$ , and  $+10^\circ\text{C}$ .

Investigated interlayers were installed according to the producer recommendations. Used interlayer systems were:

- A) Geotextile, flexible polypropylene needle-punched nonwoven ;
- B) Geocomposite, polypropylene needle-punched nonwoven reinforced with flexible high strength glass fibers;
- C) Geogrid, stiff pre-stressed deformation resistant polypropylene grid with nonwoven fixed on the junctions;
- D) Control specimen without interlayer.

The complied load-displacement curves (in the following LDC) are characterizing the fracture behaviour fully, so this curves were used as a basis for the following test evaluation.

The fracture energy (energy which is necessary to split the specimen completely) describe the resistance against crack propagation. The area under the LDC is proportional to the fracture energy. The fracture energy can be obtained simply from the LDC. After dividing the established fracture energy with the area of fracture (projection) the specific fracture energy was obtained. This result is a parameter which is independent of shape and dimension of the specimen.

#### 3.3 Interface fracture behaviour

The different fracture behaviour of the four interface types is best described by the shape of the post-peak section of the LDC in Fig.3. Without interlayer the curve drops very quickly after the maximum values has been reached, compared to geotextile interlayer. This means that with increasing crack mouth opening, without interlayer no more forces are transmitted, whereas with the fibers of the nonwoven geotextile probably bridge the crack and allow a transmission of forces (bridging effect). The surface structure of the geotextil interlayer and the geocomposite interlayer do not differ considerably. Therefore the geotextile shows a more shallow shape of the curve than geocomposite only in the very late post-peak section of the LDC. Due to the included glass fibers of the geocomposite the stiffness increased slightly and reduces insignificantly the bridging effect in the interface crack.

The nonwoven component fixed on the geogrid is extremely stiffened by the geogrid. The fibers are coarser, and the fiber structure is more dense, which results in a smoother and less felted surface of the nonwoven. With the geogrid, the binder cannot guarantee the bonding of the fibers to the base course. The bridging effect is thus small, as the nonwoven can be easily delaminated from the base course. This results in a much lower resistance against crack propagation compared to the other interlayer systems.

The area under the LDC represents the resistance against crack propagation. Figure 3 describe qualitative the high resistance against interface crack elongation of the "Geotextile and the flexible Geocomposite". The low resistance of the "Control and stiff Geogrid" specimen can be also obtained from Fig. 3.

### 3.4 Reflective Cracking Behaviour

The LDC of reflective cracking tests give the best overview of high resistance against crack propagation of interlayer systems. The fracture energy for the crack opening obtained from the LDC are determined till the crack meet the overlay surface.

The obtained specific fracture energies  $G_f$  is direct proportional to resistance against crack propagation. They are drawn up as  $G_f/G_{f0}$ , ( $G_{f0}$ =spec. fracture energy of specimen "Control") in figure 4. The figure point out very clear the excellent performance of geosynthetics to resistance of crack propagation at temperatures  $-10^\circ\text{C}$  to  $+10^\circ\text{C}$ . The "flexible Geocomposite" perform best of all investigated geocomposites.  $G_f$ -values of the "stiff geogrid" are not determined in the investigation Tscheegg et al (1998) due to the low adhesion bonding of the interlayer. At temperatures  $0^\circ\text{C}$  and  $10^\circ\text{C}$  the adhesive bond strength is reduced due to the stiff geogrid. In fact, the specimen were detached during testing and the determination of LDC was not possible (Tscheegg et al 1998).

For the long term behaviour of an asphalt wearing course the energy which is consumed at the beginning of the crack formation is decisive, where the cracked pavement can still fulfill its function. Therefore the specific fracture energies consumed up to a crack opening width of 4 mm at the testing temperature of  $-10^\circ\text{C}$  have been plotted in figure 5. This figure point out very clear the highest values of the consumed energy and the best resistance against crack opening of the flexible Geocomposites. This could be observed from small to large openings of cracks. Under equal conditions of loading the expected lifetime of the system with flexible Geocomposites versus the other tested systems is much longer.

More detailed information of increasing the resistance against crack propagation in asphalt overlayers can be found in the publication Tscheegg et al (1998).

Figure 3 : Load-displacement-curve

Figure 4: Specific fracture energy  $G_f/G_{f0}$

Figure 5: Supplied fracture energy acc. to Crack-opening-displacement

#### 4 DISCUSSION AND CONCLUSION

The fracture mechanical parameters differ considerably for different interlayer systems. A high resistance against crack propagation is achieved by interlayers with flexible (low stiffness) and a good bonding to the asphalt layer by the polymermodified bituminous binder.

Maximum force values ( $F_{max}$ ) from the LDC of the four investigated overlay systems (taken from Figure 3) considerable differences were found at 0°C. The  $F_{max}$  value is comparable with the values of the pull-of-test. Specimen without interlayer ("Control") show the highest values. However the highest resistance against crack propagation in the interface are achieved with Geotextile and flexible Geocomposite. The conclusion is that the adhesion bonding (calculated of max. strength) gives no statement of the fracture behaviour. Only the parameter  $G_f$  and a sound evaluation of the fracture behaviour results in a respectable statement of adhesive bond strength.

The normalized specific fracture energy  $G_f/G_{f0}$  (resistance against reflective crack propagation versus bonding without geosynthetics) shows the different fracture behaviour of overlay systems much more precisely than the strength values (calculated from  $F_{max}$ ) taken from the LDC.

A high resistance against crack propagation was achieved with the flexible geocomposite interlayer with high strength glass fibers at temperatures of -10°C and 0°C. At higher temperatures, the differences were smaller.

The Load-displacement-curves show the consumption of energy during crack propagation as a function of Crack-mouth-opening-displacement and allow the judgement of the crack retarding effect of interlayers. The optimum performance is achieved by interlayers which consume most of the energy in the early post-peak section. If this effect starts at high Crack-mouth-opening-displacement values (i.e. in the late post-peak section) the overlay is already cracked and the interlayer has no significant beneficial effect.

It could be proven by the experiments (Tschegg et al 1998) that interlayers with good bonding to the asphalt show the highest resistance against reflective crack propagation.

#### 5 SUMMARY

On different overlay systems, the fracture behaviour of the interface between interlayer and asphalt layer have been investigated with regard to reflection crack propagation using the wedge splitting method according to Tschegg.

The described wedge splitting method is suitable for the description of interface cracking and reflection cracking in overlay systems. Drill cores can be used as specimens, which are easy to be gained and handled, and need only slight modification. The testing procedure is simple and can be performed in a straight forward an inexpensive way.

For the practical engineer, this fracture test method can help to control and judge the construction quality of pavements with regard to crack formation.

With reference to the maximum splitting force  $F_{max}$  best performance is shown by the conventional homogeneous system without interlayer.

Due to the most inhomogeneous system the largest decrease is given with the stiff geogrid interlayer.

The best resistance against reflective crack propagation is illustrated by the flexible geocomposite interlayer and the geotextile interlayer.

# Response Investigation and Design Guidelines for Asphalt Pavements with an EPS Geofoam Sub-base

M. Duškov

Consultant Pavement Engineering, Oranjewoud BV, Rotterdam, The Netherlands

L.J.M. Houben

Head of Road and Railroad Research Laboratory, Delft University of Technology, Delft, The Netherlands

A. Scarpas

Research Associate, Delft University of Technology, Delft, The Netherlands

**ABSTRACT:** The use of Expanded PolyStyrene (EPS) Geofoam instead of traditional "heavy" sand for pavement sub-base can reduce or even eliminate the additional load on the subsoil, thus decrease or eliminate the settlement of pavement structures on a compressible subsoil. The experiences with EPS geofoam are very promising but a uniform design procedure does not yet exist for this type of structure. Optimisation of the existing EPS pavement design guidelines and their improvement has demanded materials research on EPS, the use of three dimensional finite element pavement models and in situ full-scale measurement. Extensive materials research provided data for the stress-strain response of EPS under representative loading and environmental conditions. 3-D modelling enabled critical evaluation of existing design methodologies by analyzing pavements with different roadbases, different EPS types and different asphalt thicknesses. In situ measurements by means of built-in strain transducers in asphalt provided data for verification of the 3-D modelling.

**KEYWORDS:** Geofoam, Road Construction, Soft Soil, Finite element analysis, Material Tests

## 1 INTRODUCTION

This paper deals with the use of Expanded Polystyrene (EPS) Geofoam as a light-weight sub-base material in pavement structures. In comparison with other sub-base materials EPS has, besides an extremely low density and a low modulus of elasticity, a low water absorption and a low thermal conductivity. Through a substantial reduction of the pavement's weight, EPS as a sub-base material offers a major new solution for reduction of the settlements of new road structures and roads to be widened in areas with soils of poor load-bearing capacity. Such areas are present in the western and northern parts of the Netherlands. The application of EPS however affects the performance of the overlying structure. To investigate, on one hand, to which extent the EPS characteristics influence the overall pavement behaviour and, on the other, the long term durability of EPS in relation to varying environmental conditions, materials research on EPS, in-situ measurements and numerical analyses of the structural behaviour of pavements with an EPS sub-base have been carried out. Based on the research findings the current Dutch design guidelines have been revised and optimized.

## 2 MATERIALS RESEARCH

The extensive testing of the EPS material involved the characterization of the elastic and permanent deformation behavior under both repetitive and static loadings, the water ab-

sorption of EPS, as well as the mechanical properties of EPS15 and EPS20 after water absorption and freeze-thaw cycles (Duškov 1997). Summarizing the experimental results it can be stated that:

- ❑ EPS absorbs water very slowly and to a limited extent. The maximum percentage of water, that EPS20 will absorb, is 2% v/v. The maximum percentage will rapidly increase, however, if EPS is overloaded and its cell structure is damaged.
- ❑ The dynamic E modulus of EPS20 under the loading conditions corresponding to the maximum expected values for pavement sub-base conditions, has the values which are somewhat larger than the value of 5 MPa which is normally used in pavement design procedures.
- ❑ The Poisson's ratio value of EPS20 of 0.10 seems to be appropriate for design purposes.
- ❑ Low temperatures, water absorption level and exposure to freeze-thaw cycles, separately or combined, have no negative influence on the mechanical behaviour of EPS.
- ❑ Under a static stress of about 20 kPa corresponding to the dead weight of the pavement top layers, the creep of EPS20 amounts a few tenths of a percent. The practical consequence is a small additional permanent vertical deformation of the pavement structure caused by creep of the EPS sub-base layer. The main part of this creep however occurs during construction of the overlying layers.
- ❑ The ultrasonic test method has potential to be used on site to determine the elastic modulus at various positions of EPS blocks for quality control purposes. Additional work has to be done, however, to validate the test procedure.

### 3 IN SITU MEASUREMENTS

In order to get an insight into the structural behaviour of flexible pavement structures with an EPS sub-base, asphalt strains and surface deflections have been measured on the Matlingeweg in Rotterdam. The considered pavement structure was of interest for investigation because of its sub-base, which consists of a 1.0 m thick EPS layer, combined with a heavy traffic loading. The measurements were carried out by means of the Falling Weight Deflectometer (FWD) and four strain transducers built-in at the bottom of the asphalt layer. Overlaying of the pavement structure has taken place much earlier than it was originally planned because severe cracking occurred at the pavement's surface within a few weeks after reconstruction.

The temperature dependent behaviour of the asphalt layer disables a direct comparison between the measured strain values. It implicates that those values have to be translated to a reference temperature before comparison. The back-calculated E-values in the pavement structure layers were used to transform the measured asphalt strain values to a reference temperature and to present the trend of the transformed strain values as a function of the pavement structure age.

The following conclusions and recommendations regarding the pavement condition in general (after 3 years in service) and the elasticity moduli of the pavement layers in particular are drawn:

- The back-calculated very low E-values for the sand capping layer (from 40 to 65 MPa) and the crushed masonry/concrete base (from 80 to 85 MPa) before overlaying highlight the inability of the EPS to provide a proper support to the roadbase in the considered pavement structure with a 130 mm thick asphalt layer. Correspondingly insufficient support of the roadbase to the asphalt layer resulted in a critically high asphalt strain of about  $192 \mu\text{m/m}$  ( $T=20^\circ\text{C}$ ). Use of overestimated E-values for the roadbase materials was probably the main reason for the inappropriate pavement design.
- Open joints between the EPS blocks in a sub-base can have very serious consequences for the design life of pavement structures, and thus have to be avoided by all means. The joints between the blocks in various layers should not coincide with each other. Open joints are especially risky in the case of an EPS sub-base which consists of only one EPS layer. The longitudinal joints between the EPS blocks should not be close to a wheel track. An adequate (lateral) support of the blocks is necessary to prevent any movement of the blocks.
- The back-calculated E-value of the EPS sub-base ranges from 10.4 to 19.7 MPa, which is somewhat higher than the elasticity moduli found in literature for the EPS types under consideration (EPS25 and EPS30).
- The back-calculated E-value of the asphaltic concrete layer varied between 5,000 and 25,000 MPa, due to the

temperature range of  $0.2^\circ\text{C}$  to  $31.0^\circ\text{C}$ , during the various FWD measurements. The E-modulus was about 10,500 MPa for the reference temperature  $T=20^\circ\text{C}$ .

- The E-value of the crushed masonry/crushed concrete base ranged from 140 to 600 MPa after overlaying. The modulus found for the sand varied between 70 and 150 MPa. In some measurements the values found for the crushed masonry/concrete base were lower than could be expected for this unbound material. In order to design an appropriate pavement thickness on an EPS sub-base the E-values obtained in this study for the unbound base and sand layer are suggested to be used as input data in calculations of the design life.
- The asphalt strain remained more or less constant in the 3-year period after overlaying. The constant value of the strain is a sign of a good condition of the pavement structure. The maximum horizontal tensile asphalt strain amounts to about  $85 \mu\text{m/m}$  at the reference asphalt temperature of  $20^\circ\text{C}$ .

### 4 3-D FINITE ELEMENT ANALYSIS

#### 4.1 Modelled Pavement Structures

The three-dimensional (3-D) finite element analysis of pavement structures with an EPS sub-base layer is necessary since it allows modelling of the block structure in the EPS sub-base, in contrast with two-dimensional or axial symmetric pavement models. Three separate 3-D analyses were carried out. Firstly, a 3-D pavement structure model was developed with a single vertical interface layer next to the wheel load. Secondly, a polder road was analyzed; in this case a much more complex model was developed to analyze the effects of: *a)* different block patterns, *b)* various EPS types in the sub-base and *c)* a concrete capping layer, on the stress and strain values in the pavement layers. Finally, using experiences from the previous analyses, a model for a motorway pavement structure was designed with a simplified EPS block structure to investigate the consequences of implementation of EPS (instead of sand) on the behaviour of (Dutch) motorway pavement structures.

The analysis of single-joint pavement structure model was performed to investigate whether the existence of an open joint in the sub-base does affect the pavement behaviour. In this particular analysis one interface layer was used to model the vertical joint. The wheel load was placed just adjacent to the joint to enforce maximum shear forces in the layer above the EPS sub-base. Also the effects of using a concrete (capping) layer above the EPS sub-base and a somewhat different EPS type were determined.

The polder road analysis was carried out because in the western part of the Netherlands a great number of polder roads are located in areas with a low bearing capacity subsoil. These polder roads, constructed in the traditional

way on soft, saturated subsoil, are subjected to (uneven) settlements. The use of EPS, particularly in the sub-base of these roads, is likely to offer a solution for the settlement problems by reducing the weight of the pavement structure. Once designed, the 3-D polder road model enabled the analysis of the effects of different block patterns in the sub-base on the pavement structure behaviour. The complexity of the model was defined by the need of modelling different block patterns by means of a single mesh.

The last finite element analysis was performed on a model for a motorway pavement structure with layer thicknesses corresponding to the usual values for Dutch motorways (see Figure 1). 3-D modelling of the heaviest loaded road type was done to determine to which extent building-in of EPS blocks in the sub-base influences its structural behaviour. The reference was an identical structure with a sand sub-base layer. Additionally, the effects of a concrete capping layer above the EPS blocks were investigated. Based upon the results of the previous analyses the motorway model was simplified compared to the polder road model. A single vertical joint was designed in the EPS layer and the axle load was placed next to that joint.

Figure 1. Resulting deformations due to a 100 kN axle load in a motorway pavement structure with an implemented EPS sub-base

All described models and analyses were realized by the means of the three-dimensional version of the finite element program CAPA (Computer Aided Pavement Analysis) (Scarpas 1995). The implemented interface elements allowed a flexible simulation of mechanisms in joint faces making this program one of the best of its kind.

#### 4.2 Concluding Remarks on 3-D Finite Element Analyses

- ❑ Open joints between the EPS blocks in the sub-base significantly affect the behaviour of pavement structures with an unbound roadbase. The wide joints make it impossible to support properly the above-laid unbound base. This results in insufficient support of the roadbase to the asphalt layer. Consequently, higher stress and strain values occur in the asphalt layer under the wheel load with as final result a shorter life of the pavement structure.
- ❑ Implementation of a concrete capping layer above the EPS sub-base neutralizes the (negative) influence of the joints between the EPS blocks on the pavement behaviour. Such a capping layer ensures enough support to the unbound roadbase layers above this layer, also in the case of existing open joints between the EPS blocks.
- ❑ The maximum vertical stress values occurring in the EPS sub-base layers under the 100 kN standard axle load do not exceed the linear-elastic region experimentally determined for this material.
- ❑ Application of a denser (and more costly) EPS type with a somewhat higher elasticity modulus in the sub-base has only a very limited influence on the horizontal strain values at the bottom of the asphalt layer and, therefore, on the overall behaviour of pavement structures with an EPS sub-base.
- ❑ In the case of the polder roads the existence of open vertical joints in the EPS sub-base results into approximately 10% higher horizontal asphalt strains under the 100 kN standard axle load when a wheel load is located above such a joint. Accordingly, if longitudinal open joints coincide with a wheel track it could lead to a reduction of the pavement life with about 40%.
- ❑ EPS sub-bases where the blocks are laid in various patterns deform somewhat different under traffic load. Different sub-base behaviour occurs along the joints between the EPS blocks. However, the absolute deformation differences are so small that the effects on the structural pavement behaviour are of no practical importance.
- ❑ The (negative) influence of the division of the sub-base into two sublayers seems to be very limited. Still, building-in the EPS blocks in at least two sublayers in the sub-base is recommendable to avoid continuous vertical joints. Avoiding open joints between the EPS blocks demands accurate laying and in order to do this it is easier to use less thick blocks because block dimensions always deviate somewhat.
- ❑ In case of the polder road, pavement strengthening by increasing the asphalt layer thickness with 30% (extra 50 mm) or by building-in a 150 mm thick cement treated capping layer above the EPS sub-base appeared to be similarly beneficial with respect to the horizontal asphalt strain. The realized asphalt strain reduction amounts to approximately 30% resulting in a 6 times longer pavement life.

- The horizontal strain values at the bottom of the asphalt layer of the motorway pavement structure with the sand sub-base are approximately 40% lower than the corresponding values above an open joint in the EPS sub-base. As a result of this the reduction of the pavement life would amount to about 12 times if the EPS sub-base has been built-in with a wide joint exactly along the wheel track.
- The implementation of a concrete capping layer above the EPS sub-base enables the design and construction of light-weight pavement structures with an EPS sub-base, suitable for heavily loaded motorways. Its design life is even longer than that of the corresponding traditional structures with a sand sub-base.

## 5 DESIGN GUIDELINES

### 5.1 Current Dutch Design Guidelines

Generally speaking, the current Dutch design procedure for pavement structures with an EPS sub-base includes three steps. In the first step the list of requirements is being established by defining both the boundary conditions and the design starting points. In the next step it is checked whether the implemented light-weight sub-base assures sufficient reduction, if not elimination, of settlements without danger of upward movements due to buoyancy. Repeated calculations for different sub-base thickness values in the assumed pavement structure lead iteratively to the optimum EPS layer thickness. Finally the durability of the considered pavement structure and built-in materials is checked for the expected traffic loading during the design life. Based on these calculations the thickness of the upper pavement layers above the EPS sub-base has to be determined.

The boundary conditions are: in-situ subsoil conditions, groundwater level and traffic intensity. Important subsoil conditions are the geotechnical profile, the density and thickness of the layers, the sensitivity to settlements, the soil mechanical history (settlements in the past) etc. The starting points, i.e. arbitrarily defined preconditions, are: the pavement design life expressed as the number of 100 kN standard axle load repetitions, the street level, and pavement material characteristics of the previously selected type of pavement structure.

This design procedure differs to a certain extent from the Dutch design procedure that is followed in the case of application of a traditional sand sub-base. The differences regard the weight-balance and the buoyancy calculations. Both calculations serve the purpose of determining the proper thickness of the EPS sub-base. With "proper EPS sub-base thickness" is meant such a thickness that subsoil settlements are eliminated or reduced to an acceptable amount; water absorption in the EPS sub-base is taken into account in the subsoil stress calculation by assuming an EPS

density of 100 kg/m<sup>3</sup>. The excavation depth for the EPS material may be restricted by considering the buoyancy forces for the case of highest possible ground water level. Even if areas are flooded the upper pavement layers must be heavy enough to keep the EPS sub-base in position. In the buoyancy calculation the dry density of the EPS sub-base material is used. The minimum safety factor recommended for buoyancy calculations amounts to 1.1 (De Wijs and Hengeveld 1988).

Once the proper EPS layer thickness has been determined the design procedure continues with calculation of the pavement design life based on the Shell Pavement Design Manual (1978). This mechanistic procedure is the main pavement design method used in the Netherlands. The Shell Pavement Design Manual considers the horizontal tensile strain at the bottom of the asphalt layer and the vertical compressive strain at the top of the subgrade to be of critical importance for the design. The asphalt strain value has to be limited in order to prevent asphalt fatigue cracking while the limitation of the vertical strain serves to prevent excessive permanent deformation in the subgrade. In the Manual strain values are given as a function of the allowable number of load applications. So, by knowing the strain values, one is able to determine the pavement design life expressed as 'allowable number of 100 kN axle load repetitions'.

### 5.2 Shortcomings of Current Design Guidelines

The missing part in the discussed current design procedure for pavement structures with an EPS sub-base is a design criterion regarding the EPS material. There is no established maximum value for either strain or stress occurring in the EPS layer due to the traffic load, the limit value which should not be exceeded because of negative effects on the material behaviour.

The strain occurring in the EPS layer is a result of the dead weight of the upper pavement layers, on one hand, and the traffic loading, on the other. Generally speaking, the higher the (static) strain component due to the dead weight, the lower the (dynamic) component due to the traffic loading. The static strain due to the dead weight of a thin pavement structure (where a relatively high dynamic strain can be expected) amounts to about 0.2% (Duškov 1997).

Cyclic loading test results point out that EPS15 does not accumulate permanent deformations under combined static and cyclic stress of 15 kPa and 20 kPa respectively. The related total strain amounted to 0.6%. EPS20 resisted a cyclic stress component of 30 kPa, i.e. undergoing cyclically a total strain of about 0.7%, without permanent deformation.

Based on the results reviewed above it may be stated that as long as the elastic deformation in the EPS sub-base due to repeated (traffic) loads is limited to 0.4%, then permanent deformation of the EPS blocks is negligible and will have no influence on the pavement behaviour. Therefore, the

design criterion for the EPS layer should be a maximum strain value of 0.4%.

In completed pavement structures the strains in the EPS sub-base due to the traffic loads are unlikely to be critical. More problems can be expected in the construction phase before all layers are built-in. If the EPS layer is overstressed by the construction traffic driving on (unbound) base layers, the effective EPS elasticity modulus is reduced and the water absorption increases.

Pavement analyses by means of both multi-layer (Duškov 1991) and finite element models (Duškov 1996) pointed out a negligible influence of the EPS thickness on the structural pavement behaviour. Due to the low elasticity modulus the EPS block layer simply does not contribute to the load distribution and functions only as a fill material.

Since the stress and strain values in the pavement layers are independent of the thickness of the EPS sub-base it is possible to determine the pavement design life before carrying out settlement and buoyancy calculations. As input value an unit EPS thickness, e.g. 0.5 m, could be applied. The advantage of such an approach is that the upper pavement layers can be designed first and their total weight thus is known before carrying out the weight-balance calculation and determining the thickness of the EPS layer.

### 5.3 Revised Design Guidelines

Based on the considerations given in the previous chapters the following guidelines for the design of pavements with an EPS sub-base are given.

- ⇒ In designing the pavement it must be realized that EPS20 blocks in contact with water will absorb about 2% v/v of water. EPS15 blocks will absorb more water, probably about 3% v/v. Although these volume percentages are low it means a considerable increase in weight which has to be taken into account when designing roads with EPS sub-bases. The usually assumed maximum density of saturated EPS of 100 kg/m<sup>3</sup> contains a high safety factor, a density of 50 kg/m<sup>3</sup> seems to be a more realistic value.

Figure 2. Filling up of joints between deviated blocks

- ⇒ During construction much attention should be paid to proper placement of the EPS blocks. All joints should be closed and load transfer across the joints should be promoted. As in the case with concrete block pavements, filling of the joints with jointing sand is strongly recommended. In order to be able to fill the joints a V type joint is recommended (Figure 2). Blocks with such joints can be easily made.
- ⇒ The EPS thickness has a negligible influence on the structural behaviour of the pavement. Therefore, first the upper pavement layers should be designed by using an unit EPS thickness, e.g. 0.5 m, and then, when the exact dead weight of the upper pavement layers is known, the weight-balance calculations should be performed and the proper EPS thickness determined. The revised design procedure, including the  $\epsilon_{EPS}$  criterion, is shown in Figure 3.

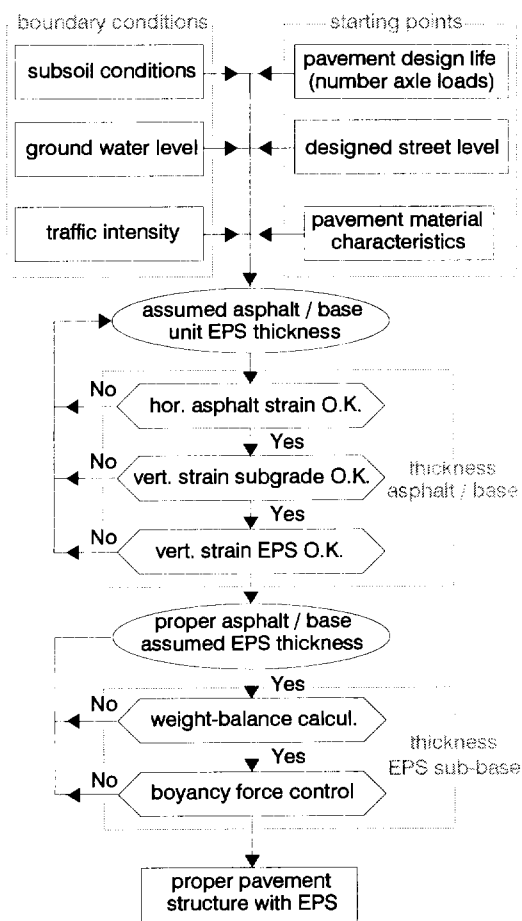

Figure 3. Flowchart of the revised Dutch design procedure (incl. EPS strain criterion) for flexible pavement structures with an EPS sub-base

- ⇨ Longitudinal joints between EPS blocks must not coincide with a wheel track because it will result into a significant reduction of the pavement life. The EPS block pattern should be designed such that longitudinal joints are located between the wheel tracks.
- ⇨ As long as the elastic deformation due to repeated (traffic) loads is limited to 0.4%, then permanent deformation of both EPS15 and EPS20 blocks is negligible and will have no influence on the pavement behaviour. Therefore, the vertical strain value of 0.4% should be used as the design criterion for the EPS layer.
- ⇨ During the construction phase, which is the most critical phase, special measures (such as steel planking) should or could be taken to ensure that the maximum allowable EPS strain value of 0.4% is not exceeded. Overloading EPS results in a lower modulus of elasticity and a higher water absorption.
- ⇨ The presence of an EPS sub-base in a pavement structure has a significant influence on the stress and strain development in the pavement. *If granular materials are placed immediately on top of the EPS layer* then the stiffness of such a layer is low and in fact much lower than is normally expected. Consequently, unbound material modulus values reduced up to 50% should be used as input data for design purposes.  
Unbound base materials that have the potential to develop a high stiffness do not pay off. Also relatively expensive self-cementing materials (e.g. blast furnace slags) seem to be not adequate above an EPS sub-base as cementing does not develop because of a significant amount of movement in the structure caused by the heavy traffic loads.
- ⇨ For design purposes a minimum elastic modulus of 5 MPa can be adopted for EPS20. In the case of EPS15 a minimum modulus of 4 MPa should be used.
- ⇨ Neither the modulus of EPS nor its other characteristics will deteriorate due to environmental influences like repeated wetting and freeze-thaw cycles.
- ⇨ The application of denser (and more expensive) EPS types with a somewhat higher elasticity modulus has no significant effects on the overall pavement behaviour. The use of EPS15, the lightest EPS type, instead of EPS20 can reduce the material costs considerably. However, one has to realize that the vertical strains in EPS15 will be about 1.25 times greater than those in EPS20, while the criterion  $\epsilon_{\text{EPS}} \leq 0.4\%$  is still valid.
- ⇨ Application of a cement treated capping layer on top of the EPS sub-base has a tremendously beneficial effect on the performance of the pavements. Such a capping layer neutralizes the effects of open joints between the EPS blocks, guarantees sufficient support to overlaying unbound base material even under high traffic intensity and eliminates any restriction for use of cheaper low-density EPS types. A cement treated capping layer is therefore strongly recommended.

- ⇨ Although additional work needs to be done to validate the test procedure modulus testing by means of the ultrasonic method is very promising for quality control of the blocks on site.

## 6 ACKNOWLEDGEMENT

Shell Nederland Chemie BV, Road and Hydraulic Engineering Division of the Ministry of Traffic, Public Works and Water Management (DWW-RWS), and Stybenex BV are gratefully acknowledged for sponsoring this research into EPS geofam.

# Particles Washout Associated With The Retention Of Broadly Graded Soils By Geotextiles

Jean Lafleur

Professor, Département de Génie Civil, Géologique et des Mines, Ecole Polytechnique de Montréal, Montréal, QC, Canada

**ABSTRACT:** Engineering sense suggests that the filtration opening size  $O_f$  of a filter does not need to be smaller than the smaller particles of a retained base to fulfill its function. Research on the filtration of broadly graded soils has shown however, that some finer particles are washed out in the process of soil filter bridge formation near the interface zone. The model proposed by Lafleur et al. (1989) relates the mass of washout and the associated settlement to the retention ratio of the combination  $R_R (= O_f/d_f)$  and to the broadness coefficient of the retained soil  $C_b (= O_f/d_o)$ . Compatibility tests between square mesh sieves and three different broadly graded bases were made. The results have confirmed the validity of the existing model.

**KEYWORDS:** Filtration, piping, Gradient Ratio test, woven geotextiles, seepage control.

## 1 INTRODUCTION

The main function of a filter is to retain soil particles without altering the flow of water. Current selection criteria are based on geometric and hydraulic considerations supplemented by experimental evidence from which success or failure has been assessed. Success involves implicitly that there is no washout of soil particles. Giroud (1996) admits however, *that soil retention does not require that the migration of all soil particles be prevented. Soil retention simply requires that the soil behind the filter remains stable.* The amount of washout has been recognized as an important factor in the interpretation of compatibility tests (Austin et al., 1997, Fannin et al., 1994, Honjo et al., 1996, Lafleur et al., 1996, Bhatia et al., 1996). The overall performance of a drainage structure is related to the washout that produces two detrimental effects:

- ▶ formation of voids and caverns near the filter interface, that transmit uneven subsidence at the surface;
- ▶ filling and clogging of downstream water conveyance systems.

The severity of the loading is not the same for every application. For example, a dynamic environment such as beneath roads or erosion control applications is more aggressive on the particles than a static, continuous flow. The consequences of washout may also vary. In dams, concentrated washout and piping lead to the formation of sinkholes at the crest. Austin et al. (1997) have demonstrated that a 150 mm diameter and 100 m. long drainage pipe with a 3% slope can be completely filled at the lowest point in the profile when washout is in the order of 0.25 kg/m<sup>2</sup>.

## 2 PREDICTION OF WASHOUT

Before a filter/base combination attains equilibrium, appreciable washout can occur, especially in broadly graded soils. Lafleur et al. (1996) have shown that for nonwoven geotextiles, the

particles migration is less than 2.5 kg/m<sup>2</sup> provided that for internally stable soils,

$$R_R < 1$$

where:

$R_R$  = retention ratio =  $O_f/d_f$

$O_f$  = filtration opening size obtained from hydrodynamic sieving

$d_f$  = base indicative size

=  $d_{35}$  for uniform soils ( $C_u \leq 6$ )

=  $d_{30}$  for broadly ( $C_u > 6$ ) linearly graded soils

=  $d_{30}$  for broadly concave upward graded soils

=  $d_G$  for broadly gap graded soils ( $d_G$  is the lowest size of the gap)

For internally unstable or suffusive soils, the filtration process is different. Suffusive soils are broadly graded with gradation curves that are markedly concave upward or that show a gap below 30% passing. It has been shown by Kenney and Lau (1985) that for such soils, finer particles can move within the coarser grains skeleton. These movable particles can form a cake near the base/filter interface if  $O_f$  is too small. This phenomenon is called blinding or external clogging. To avoid this risk, the filter must have a minimum opening size. At the other extreme, to avoid piping,  $O_f$  must be less than a given value,  $d_f = d_{30}$  and

$$1 < R_R < 5$$

Lafleur et al. (1989) have studied the self-filtration or bridging that develops near the interface zone separating broadly graded soils from filters. They presented a model to evaluate the amount of base washout  $M_p$  induced in the

process and the associated settlement  $\Delta H$ . Some assumptions had to be made:

- ▶ the combination is compatible i.e. the retention ratio is smaller than 5;

- ▶ the soil near the interface is divided into  $m$  layers, with

$$m = \left\lceil \frac{\log C_B}{\log R'_R} \right\rceil \quad \text{and } C_B = \text{breadth coefficient} = O_p/d_o$$

- ▶ all the fines smaller than the opening size of each upstream layer are washed out. The constriction size of the remaining particles is equal to their minimum grain size divided by the ratio  $R'_R$  taken equal to 9 (Sherard et al., 1984).

The induced settlement is given by

$$\Delta H = d_{100} \sum_{j=1}^m \left( \frac{P_j}{100} \right)$$

$P_j$  = percent in mass finer than  $(O_p/R'_R)^j$  originally present in the  $j$ th layer and  $i = j - 1$

The mass of washout is equal to

$$M_p = \rho_D \cdot \Delta H \quad \text{where } \rho_D = \text{dry density of the base}$$

An extensive testing program was designed to bring some experimental support to the above model and to verify the accuracy of the assumptions.

### 3 TESTING PROGRAM

The program involved broadly graded soils with different gradations filtered by square mesh sieves. The filtrimeter shown on Fig. 1 was used. Its diameter is 197 mm such as to minimize wall effects for samples containing coarse particles. Four lateral piezometers at distances of 55, 90, 130, 180 mm respectively from the filter, allowed the evaluation of the local permeabilities. Water was circulated downward at an overall gradient of 5 through the soils. The downstream part of the filtrimeter was submerged to maintain positive pressure head throughout the samples. The sieve openings were 19.1, 9.52, 4.76 and 2.00 mm and the filters designated 19, 10, 5 and 2 respectively.

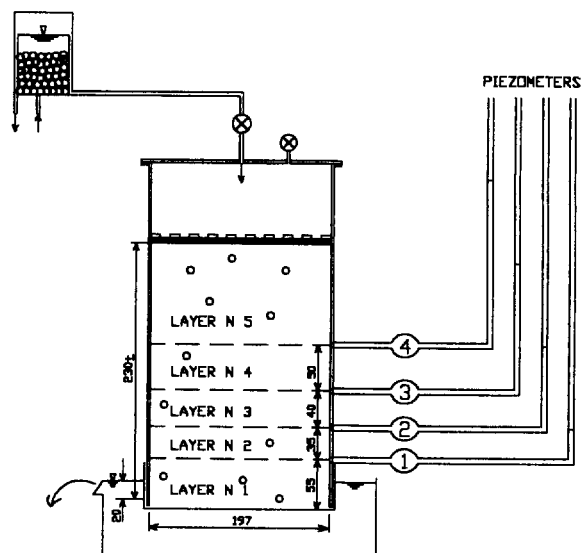

Fig. 1 Filtrimeter for screen tests

The soils were reconstituted either from natural subrounded particles (G) or spherical glass beads (B) comprised between 0.1 and 19 mm in size. Their gradations are described on Fig. 2 and Table 1: rectilinear (R), gap-graded (D) and concave upward (C). They are internally stable and broadly graded. Although their coefficients of uniformity varies between 7 and 21, their coefficients of curvature do not lie between 1 and 3, so they cannot be classified as "well-graded". Their indicative size  $d_i$  (arrows on Fig. 2) varies between 0.7 and 3.0 mm.

Fig. 2 Gradation curves of tested bases

Table 1 Base soil gradation properties

base	$d_{10}$ mm	$d_{85}$ mm	$d_f$ mm	$C_u$	$C_c$
R	0.29	6.6	1.8	6.9	0.77
D	0.22	11.8	0.7	20.0	0.31
C	0.37	13.6	3.0	18.9	3.59

The tests lasted 150 minutes and vibrations were applied by tapping with a rubber hammer on the sides of the permeameter. Equilibrium was interpreted on the basis of the shape of the local permeability curves. At the end of the tests, the mass of passing particles was recorded and the samples were cut for gradation analyses into 5 slices, limited at the top and at the bottom of the sample and at the level of the piezometers.

#### 4 RESULTS

The Table 2 gives an overview of the test results. The retention ratio  $R_R$  of the combinations varies between 0.7 and 27 and those for which the model applies ( $R_R < 5$ ), have been highlighted. One can appreciate the convergency between the model and the measurements, from the computed relative errors  $\Delta$ . It appears that, although the measurements are in the same order of magnitude as the calculations, the model underestimates the amount of washout. The shape of the particles may have played a role since for a given opening size, the washout is nearly the double with the spherical grains (tests B). These are more mobile than the subrounded particles G and thereby, more susceptible to washout.

The Fig. 3 is a logarithmic plot of the mass of washout versus the retention ratio for all the tests of this program:  $M_p$  increases regularly with  $R_R$ . At the critical  $R_R$ -value of one, the plot indicates that  $M_p$  varies between 8 and 50 kg/m<sup>2</sup>, which is more than the previously mentioned limit of 2.5 kg/m<sup>2</sup>. This discrepancy can be related to the structure of the filter. The metallic mesh sieves used in the tests are similar to a woven geotextile and they have a large Percent Open Area (POA), varying between 62 and 75%. This is much more than the current woven geotextiles for which POA ranges between 1 and 20% (Mlynarek and Lombard, 1997). For purpose of comparison, the results of compatibility tests made by these authors (designated ML) have been reported on Fig. 3. They have been classified as low POA ( $\leq 10\%$ ) and high ( $40\% > POA > 10\%$ ). The influence is obvious: for a  $R_R$ -value of one,  $M_p$  is equal to 0.24 kg/m<sup>2</sup> for POA <10 and to 0.92 kg/m<sup>2</sup> for POA > 10.

Physically, when the ratio between the solid retention structure (filaments) and the opening voids is higher, there is relatively more surface to retain particle so that bridging and retention are easily promoted. Giroud (1996) arrived at similar conclusions when he demonstrated that for nonwoven geotextiles with given thickness and fibres diameter, the opening size is smaller with lower porosity.

Fannin et al. (1994) have performed modified Gradient Ratio tests on nonwoven geotextiles and different soils. Their results (FVS) have also been plotted on Fig. 3 separating uniform (U) and well-graded (WG) base soils. The shape of the  $M_p$ - $R_R$  curve is different: for well graded soils it is gradual, for uniform soils, it shows a sharp quasi vertical break around  $R_R = 1$ .

Fig. 3 Mass of washout versus retention ratio

## 5 DISCUSSION AND CONCLUSION

The amount of washout associated with the filtration of broadly graded soils was evaluated from screen tests using square conventional sieve mesh with different opening sizes.

The results have confirmed the validity of the approach suggested by Lafleur et al. (1989). The retention ratio  $R_R$  between the opening size of a filter and the indicative size of the base, is the most important factor intervening in the amount of washout. The experimental relationship between  $M_p$  and  $R_R$  is gradual for broadly graded soils while for uniform soils, it shows a marked bend around  $R_R = 1$ . The success or failure of a filter for broadly graded soils is therefore quite subjective because it depends on the amount of tolerable washout. Finally, the results have disclosed that the Percent Open Area and by extension, the porosity, play a role in the rearrangement of the particles near the interface. The lower the value, the lower the washout.

## ACKNOWLEDGMENT

The author wishes to acknowledge the diligent work of Khaireddine Sakrani, who performed the tests as partial fulfilment for his M.Sc.A. degree and of Sebastien Lopez, who helped in the preparation of this paper.

# Geotextile Characteristic Opening Size: The Influence of Some Test Parameters

Barroso, Madalena C. P.

Research Assistant, National Civil Engineering Laboratory (LNEC), Lisbon, Portugal

Lopes, Maria da Graça D. A.

Senior Research Officer, National Civil Engineering Laboratory (LNEC), Lisbon, Portugal

**ABSTRACT:** Designing a geotextile for filtration applications requires information on the characteristic opening size of the geotextile. Several techniques are available for measuring the characteristic opening size, but there is no one universally accepted. Three test methods are usually used: dry sieving, hydrodynamic sieving and wet sieving. The wet sieving test method was used to study the influence of some test parameters (soil granulometry, water flow rate and vertical amplitude) on the results of opening size measurement. For this purpose six nonwoven geotextiles were used. The results showed that the test conditions can indeed influence results of the measurement of characteristic opening size.

**KEYWORDS:** Geotextile, Wet sieving test method, Characteristic Opening Size

## 1 INTRODUCTION

Where geotextiles are used as filters they must perform two functions simultaneously. One is to retain fine soil particles and the other is to allow the seepage of water from the retained soil. The ability of the geotextile to filter is a function of the size and distribution of the pores and the porosity. However, the distribution of the pores within the geotextile is difficult to determine. As a result, several indirect test methods have been developed. Three techniques are used: dry sieving, standardised in the United States, United Kingdom, Belgium and the Netherlands; hydrodynamic sieving, standardised in Canada, France and Italy; and wet sieving, standardised in Germany, Austria and Switzerland. For a given geotextile the results obtained are dependent on the test method used (Bhatia & Smith, 1995).

In order to obtain a unified standard in Europe, the different existing national standards are being harmonised under the auspices of the European Committee for Standardisation (CEN). An index test has been developed based on the wet sieving technique. A specific parameter, the Characteristic Opening Size (COS also called  $O_{90}$ ), indicates the size of the largest grain size particle that can pass through the geotextile.

A final draft European Standard was authored by Technical Committee 189 and was recently submitted for formal vote to the European countries (prEN ISO 12956). Before becoming a standard the test method was validated. It was necessary to clarify the influence of some specific parameters, in order to determine the best test conditions. During the work on standard harmonisation, intercomparison tests were performed in several countries. The results obtained have shown that  $O_{90}$  can be affected by test conditions, as reported by Faure (1996).

In this context, a test programme has been carried out in Portugal's National Civil Engineering Laboratory (LNEC), to study the influence of some test parameters, namely the soil granulometry, the vertical amplitude and the water flow rate.

## 2 DESCRIPTION OF THE TEST PROCEDURE

The tests were performed based on final draft of the European Standard prEN ISO 12956 (Geotextiles and geotextile related products—Determination of the characteristic opening size).

The principle of the test is to sieve a well graded granular material (usually soil) through a geotextile specimen. The specimens are soaked in water at laboratory temperature and leave it to saturate for at least twelve hours. Then they are placed in the clamping device on the sieving apparatus (figure 1). For each specimen, a soil mass of 7,0 kg per square meter of exposed sieving area is spread on the geotextile and watered by means of a spray nozzle. The water supply is open and it is adjusted by the operator in order to spray uniformly over whole specimen ensuring that all soil particles are wetted, but do not allow the water level to rise above the granular material. The amplitude of sieving is adjusted to a sufficient level to agitate the soil particles. During 10 minutes of sieving all water and soil passing through the specimen are collected. The passed soil is dried and weighed. The particle size distribution is plotted on a semi-logarithmic graph with sieve size on the horizontal axis and the cumulative percentage of the combined passed granular material on the vertical axis. The Characteristic Opening Size corresponds to the  $d_{90}$  of the particle size distribution curve ( $O_{90}=d_{90}$ ).

Figure 1. Example of apparatus.

### 3 MATERIALS TESTED

Six nonwoven geotextiles were used in this work. Table 1 presents the fabrics tested.

Table 1. Geotextiles tested.

Geot.	Manufacturing process	Polymer type	Mass per unit area (g/m <sup>2</sup> )
A	Needlepunched nonwoven	Polyester	133
B	Needlepunched nonwoven	Polypropylene	242
C	Needlepunched nonwoven	Polypropylene	476
D	Heatbonded nonwoven	Polypropylene	139
E	Needlepunched nonwoven	Polyester	134
F	Needlepunched nonwoven	Polyester	293

### 4 TEST PROGRAMME

Before the experimental programme started, the repeatability of the test method was studied. Geotextile B was selected to evaluate the  $O_{90}$  of over forty-eight specimens. The tests were performed with a vertical amplitude of 0,75 mm and with an average water flow rate of 1,4 l/min (at a pressure of 200 kPa). The soil used was the Soil 2 (see figure 2). The  $O_{90}$  obtained was:

- average = 84  $\mu$ m

- standard deviation (s) = 4,5  $\mu$ m
- coefficient of variation = 5,2 %

Based on these values the repeatability of the test method was judged to be good.

During the tests several problems occurred:

- the soil tended to agglomerate on the surface of some specimens, preventing the soil from passing through the geotextile. When this happened, the water flow rate was increased until the agglomerate was broken up;
- water accumulated above some specimens. In these cases, the water flow rate was reduced to avoid soil particle loss.

Following the repeatability tests, the  $O_{90}$  test conditions were studied. Firstly three geotextiles were tested with several soils. Then another three geotextiles were tested with different amplitudes and two water flow rates. Table 2 shows the parameters analysed and the geotextiles used.

### 5 TEST RESULTS AND DISCUSSION

#### 5.1 Influence of Soil Granulometry on $O_{90}$

Three soils were used (figure 2 a). According to the CEN draft test method, the soil used must fulfil the following requirements: it must be cohesionless; the uniformity coefficient ( $C_u$ ) must be greater than 3 and smaller than 20; the soil must not be gap-graded; and the assumed  $O_{90}$  must be between  $d_{20}$  and  $d_{80}$ . Table 3 presents the features of the soils used.

Soil 1 was initially analysed using the ASTM series of sieves, which has fewer sieves than the ISO series. As result, the soil granulometry was not well defined for the particle sizes used to estimate  $O_{90}$ . Therefore, a new soil (Soil 2) was made up. The difference in particle size distribution obtained for Soils 1 and 2 (see figure 2 b) show how important it is to use a higher number of sieves, to define properly the soil granulometry.

(a)

(b)

Figure 2: (a) Particle size distribution of the soils used; (b) detail on difference of Soil 1 and Soil 2.

Table 3. Characteristics of the soils.

Soil 1	Soil 2	Soil 3
$C_u = 6,8$	$C_u = 5,9$	$C_u = 10,3$
$d_{20} = 75 \mu\text{m}$	$d_{20} = 67 \mu\text{m}$	$d_{20} = 25 \mu\text{m}$
$d_{80} = 532 \mu\text{m}$	$d_{80} = 583 \mu\text{m}$	$d_{80} = 218 \mu\text{m}$

The tests were performed with an average water flow rate of 1,8 l/min (at a pressure of 200 kPa). The amplitude selected was 0,75 mm. The results obtained are presented on table 4.

It seems that the  $O_{90}$  values are dependent on the soil used, especially for geotextiles with smaller mass per unit of area, since the one with higher mass per unit area only showed a slight difference in  $O_{90}$ .

Several problems occurred during the tests:

- water accumulated above some specimens of geotextile F when tested with Soil 1, and above some specimens of

geotextiles D, E and F, when tested with Soil 3. The wet sieve pan outlet did not drain the water quickly enough. The solution adopted was to decrease inflow and the amplitude until the water drained;

- it was difficult to keep the amplitude constant for some specimens of geotextiles A, B and C tested with Soils 1 and 2. Changes occurred without any apparent cause. When this occurred, the operator had to adjust the amplitude manually.

Table 4. Variation of  $O_{90}$  with the soil granulometry.

Geotextile	Soil 1	Soil 2	Soil 3
	$O_{90} (\mu\text{m})$	$O_{90} (\mu\text{m})$	$O_{90} (\mu\text{m})$
D	119	125	113
E	118	122	111
F	118	116	110

### 5.2 Influence of Amplitude on $O_{90}$

The tests started with geotextile B carried out with three vertical amplitudes of 0,75 mm, 1 mm, and 1,25 mm, keeping the water flow rate constant (2,4 l/min, at a pressure of approximately 200 kPa). Since the time available to perform the tests was very limited and because the results obtained with geotextile B showed a very small difference in  $O_{90}$  for amplitudes higher than 1 mm, the geotextiles A and C were tested only with amplitudes of 1 mm and 1,25 mm. Nevertheless, it is believed that the results for geotextiles A and C would also follow the same trend, thus producing similar results to those given by geotextile B for amplitudes below 1 mm.

Soil 2 was used in the tests. The overall results are presented in figure 3.

Figure 3. Variation of  $O_{90}$  with the amplitude.

The results showed only a slight variation in  $O_{90}$  with the increasing amplitude for amplitudes above 1 mm.

Several observations were made during the tests:

- the same problem with soil agglomeration on the surface of the geotextiles previously reported also occurred with some specimens of geotextiles A and C, when tested with the amplitude of 1 mm, and with some specimens of geotextile A at an amplitude of 1,25 mm. In these cases, the solution adopted was to increase the water flow rate until the agglomerate was broken up;
- the difficulty with accumulation of water, also occurred with some specimens of geotextile C, when tested with both amplitudes, and with some specimens of geotextile B during the tests performed with an amplitude of 1,25 mm; once more the water flow rate was reduced;
- it was difficult to keep the amplitude constant when some specimens of geotextile A were tested. It decreased without any explanation. When this occurred, the operator had to adjust the amplitude manually.

### 5.3 Influence of Water Flow Rate on $O_{90}$

The tests were performed with two water flow rates: 2,4 l/min (at a pressure of approximately 200 kPa) and 3,0 l/min (at a pressure of approximately 300 kPa), keeping the vertical amplitude constant (1 mm). Soil 2 was used in the tests. The results obtained are presented in figure 4.

Figure 4. Variation of  $O_{90}$  with the water flow rate.

The results showed that there are no significant differences in  $O_{90}$  values obtained when water flow rate is varied, for the soil used.

During the tests several problems occurred:

- the soil tended to agglomerate on the surface of some specimens of the geotextiles A and C, preventing the soil from passing through the geotextiles. When this occurred the water flow was reduced once more. As tests

progressed, soil agglomerates moved freely over the geotextile specimens;

- water accumulated above some specimens of the geotextile C, due to air that was trapped inside the top chamber. When this happened, the test was stopped and the water was allowed to flow through the inlet pipe, before the test was continued.

## 6 CONCLUSIONS

Based on the test results the following was concluded:

- (1) for nonwoven geotextiles, soil granulometry seems only to influence  $O_{90}$  values for geotextiles with small mass per unit area. However, only a few geotextiles were tested, therefore, it is difficult to know if this influence may be attributed to the variability of the nonwoven geotextiles themselves;
- (2) for nonwoven geotextiles, the  $O_{90}$  appeared not to be influenced by amplitude, when the amplitude was higher than 1 mm;
- (3) for nonwoven geotextiles, the  $O_{90}$  seemed not to be affected by the water flow rate.

These conclusions must be seen in the light of the small number of tests that were performed, and the experimental difficulties encountered. The authors suggest that more tests should be carried out using different types of geotextiles.

**ABSTRACT:** Inconsistencies in design of geotextile filters are reported, with reference to current regulatory guidance. Results of laboratory Gradient Ratio tests are then described, and used to illustrate the role of a unified approach to interpretation of soil-geotextile compatibility that accounts for hydraulic gradient, permeability, and excess water head (or porewater pressure) across the filter.

**KEYWORDS:** Filtration; Geotextiles; Gradient Ratio Tests; Permeability; Seepage Control

## 1. INTRODUCTION

Design requirements for a geotextile in filtration applications include soil retention, permeability and strength. The permeability requirements are intended to promote an unimpeded flow of water through the filtration zone. Approaches used in design are derived from empirical relationships comparing the permeability of the geotextile filter ( $k_F$ ) to that of the soil ( $k_S$ ). The USFHWA (Christopher and Holtz, 1985) and Canadian Foundation Engineering Manual (CGS, 1993) require that for filtration of fines in critical or severe applications:

$$k_F > 10 k_S \quad (1)$$

and for filtration of clean medium to coarse sands:

$$k_F > k_S \quad (2)$$

More recently Giroud (1996) has proposed separate design criteria for the pore water pressure, to limiting value of 10% of the compressive stress, and for an excessive reduction in flow rate, to a limit of 10% of that in the soil without a filter. The limit values of 10% in the criteria, which are arbitrary and based on judgement, yield the following relationships:

$$k_F > 10 k_S i_S \quad (\text{excessive pore water pressure}) \quad (3)$$

$$k_F > k_S \quad (\text{excessive flow rate reduction}) \quad (4)$$

In laboratory testing, the relative permeability of the soil and the permeability of the geotextile are evaluated to ensure compatibility. One example is the Gradient Ratio test (ASTM D5101) which allows the permeability of the soil-geotextile composite zone ( $k_{sg}$ ) to be compared with that of the soil ( $k_S$ ). Piping of material adjacent to the geotextile yields a value of  $GR_{ASTM} < 1$ , while in contrast clogging yields a value of  $GR_{ASTM} > 1$ , where ports 3, 5 and 7 define  $GR_{ASTM} = i_{57}/i_{35}$  (see Fig. 1). The basis for a unified interpretation of the GR test was presented (Fannin et al., 1994a), in which the historic limiting criterion of  $GR_{ASTM} < 3$  for compatibility of geotextile and soil was shown, from continuity of flow, to yield an implicit permeability ratio given by:

$$k_{57} > 0.33 k_{35} \quad (5)$$

This criterion for clogging, proposed by Haliburton and Wood (1982) and later adopted by regulatory agencies, differs markedly from the companion empirical criteria for permeability reported above, most notably that of Giroud (1996) for excessive pore water pressure. In this paper, results are presented to illustrate the development of this composite zone with time. The objective is to assess the implications of apparent contradictions in the permeability and clogging criteria advocated for filter design.

## 2. GRADIENT RATIO (GR) TEST RESULTS

A program of tests was performed on selected combinations of 10 soils (4 uniformly graded and 6

Fig. 1. Schematic unified interpretation of the gradient ratio test.

broadly graded) and 4 needle-punched nonwoven geotextiles (Shi, 1993; Fannin et al., 1994a). The GR permeameter was modified to include 3 ports in addition to those specified in the ASTM test method, as follows: port 6 is located only 8 mm above the top surface of the geotextile specimen, port 4 is located midway between ports 3 and 5, and port 2 is located 13 mm above port 3.

Measurements were taken of the water head at each port, and the resulting flow rate, at four values of imposed system hydraulic gradient in the range  $i_{17} = 1$  to 10.

Values of permeability in the soil ( $k_{35}$ ) and in the very thin soil-geotextile composite zone ( $k_{67}$ ) were then deduced, together with a  $GR_{mod}$  given by  $k_{35}/k_{67} (= i_{67}/i_{35})$ . A similar approach has been reported by Austin et al. (1997).

Results are reported for two of the broadly graded soils (BML74 and BML90) with one nonwoven needle punched geotextile, for which material properties are reported in Tables 1 and 2. The variation of permeability with time, see Fig. 2, shows a permeability in the composite zone which is greater than of the soil for BML90 (a silt with trace of sand) but less than that of the soil for BML74 (a sandy silt). The behaviour appears independent of system gradient. The stable response over time is attributed in part to the technique used in sample

Table 1 Properties of the soils

Description	Code	$D_{85}$ ( $\mu\text{m}$ )	$D_{50}$ ( $\mu\text{m}$ )	$D_{15}$ ( $\mu\text{m}$ )	$C_u^a$	$K_{35}^b$ (m/s)

Fig. 2. Permeability of soil and soil-geotextile composite.

preparation, which ensures full saturation of the soil and geotextile (Fannin et al., 1994b).

### 3. EXCESS WATER HEAD LOSS

A relationship for excess water head loss  $\Delta h$  was presented by Shi et al (1996), where with reference to Fig. 1:

$$\Delta h = h_{sg} - h_0 \quad (6)$$

from which it can be shown that:

$$\Delta h = \frac{10i_{17} (GR_{mod} - 1)(\ell_{17} - 10)}{10 (GR_{mod} - 1) + \ell_{17}} \quad (7)$$

and all dimensions are in millimeters.

It is almost independent of the thickness of the upstream soil ( $\ell_{17}$ ) when  $\ell_{17}$  exceeds 1000 mm, see Fig. 3(a), however, it is proportional to  $GR_{mod}$  and  $i_{17}$ , see Figs. 3(b and c).

Typical values of the hydraulic gradient equivalent to  $i_{17}$  are reported after Giroud (1996) and Luettich et al (1992) in Table 3. Assuming that  $\ell_{17} = 1000$  mm, the water head loss is calculated for  $GR_{mod} = 7.4$ ; the losses do not exceed 120 mm for hydraulic gradients less than 2.0. An excess water head loss of 596 mm is predicted for an hydraulic gradient of 10.

Table 3 Typical hydraulic gradients and corresponding excess water head loss ( $\ell_{17} = 1000$  mm,  $GR_{mod} = k_{35}/k_{67} = 7.4$ ).

Application	Typical hydraulic gradient	Excess water head loss $\Delta h$ (mm)
Standard dewatering trench	1.0	60
Inland channel protection	1.0	60
Pavement edge drain	1.0	60
Vertical wall drain	1.5	89
Landfill leachate collection / detection removal system	1.5	89
Landfill leachate collection removal system	1.5	89
Dam toe drains	2	119
Dam clay cores	3 to >10	178 to 596
Shoreline protection	10	596
Liquid impoundment with clay liners	>10	>596

Notes: Typical hydraulic gradients developed after Giroud (1988) and Luettich et al (1992), critical applications may require designing for higher gradients than those given.

Values of  $\Delta h$  determined for the two Gradient Ratio tests described above are reported in Table 4. Given the average gradient ratio ( $GR_{mod}$ ) of 1.7 developed in testing soil BML74 with the geotextile,  $\Delta h$  is found to be in the range 8 to 10 mm, for a system hydraulic gradient ( $i_{17}$ ) of 1.4 and  $\ell_{17}$  varying from 100 to 10,000 mm. The range is 50 to 60 mm when  $i_{17} = 8.6$ . The losses are associated with a partial clogging of the geotextile filter zone.

In contrast, an average gradient ratio ( $GR_{mod}$ ) of 0.8 developed for soil BML90 with the geotextile. A gradient

(a)

(b)

(c)

Fig. 3. Variation of excess water head (from eqn. 7).

ratio less than unity indicates the soil-geotextile composite is more permeable than soil being retained, yielding negative values of  $\Delta h$ .

Table 4 Excess water head loss for soils BML74 and BML90 with TS550 (mm)

$l_{17}$ (mm)	BML74	-TS550	BML90	-TS550
	$i_{17} = 1.4$	$i_{17} = 8.6$	$i_{17} = 1.4$	$i_{17} = 8.6$
100	8.2	50.6	-2.6	-15.8
1000	9.6	59.2	-2.8	-17.1
10,000	9.8	60.1	-2.8	-17.2

#### 4. CONCLUDING REMARKS

1. The gradient ratio test provides a means of evaluating the compatibility of a soil and geotextile with reference to permeability of the soil being retained.
2. The excess head loss ( $\Delta h$ ) in the soil-geotextile composite zone is shown from theoretical analysis to be almost independent of thickness of the upstream soil, but proportional to the system hydraulic gradient ( $i_{17}$ ) and gradient ratio (GR).
3. A series of trial calculations indicates the value of excess water head loss ( $\Delta h$ ) induced by a  $GR > 1$  is relatively small for applications governed by a system hydraulic gradient between 1 and 2, and gradient ratio  $GR_{mod} < 7.4$  and therefore  $GR_{ASTM} < 3$ .
4. There is a need to better link design criteria for  $k_F$  and  $k_S$ , with laboratory performance data from Gradient Ratio tests yielding values of  $k_{sg}$ . It is proposed that excess water head loss ( $\Delta h$ ), which can be used in design assessments of performance and related stability analyses, is the most appropriate parameter.

#### ACKNOWLEDGEMENTS

# Geotextiles Filter Design by Probabilistic Analysis

Urashima, Denise C.

Student, Department of Geotechnique, Aeronautical Institute of Technology, São José dos Campos, São Paulo, Brazil

Vidal, Delma

Professor, Department of Geotechnique, , Aeronautical Institute of Technology, São José dos Campos, São Paulo, Brazil

**ABSTRACT:** A methodology to obtain the parameters to design needle-punched nonwoven geotextiles filters based upon probabilistic analysis and in-suspension filtration tests is proposed. The superposition of theoretical pore size distribution curve and that obtained by in-suspension filtration tests allows one to estimate the distance between confronts, essential to use the probabilistic theory. This paper presents tests results and analysis for thin geotextiles (mass per unit area less than 200 g/m<sup>2</sup>) and a design procedure that shows the versatility of this method.

**KEYWORDS:** Design, Filtration, Geotextiles, Nonwoven Fabrics, Probability

## 1 INTRODUCTION

The good performance of geotextiles in filtration functions has been reported in practical engineering thus becoming one of the most popular geosynthetics applications in the world. In recent years, research has been conducted at several laboratories in order to obtain a better knowledge of mechanisms and parameters associated with filtration problems.

Filter design is usually based on Terzaghi's proposition, empirically or semi-empirically adapted by different authors. However, these design procedures don't allow a complete understanding of the filtration phenomena. It is impossible to estimate the filter thickness needed to retain the soil particles.

Silveira(1965) proposed a probabilistic analysis to study the carrying of soil particles in a filter. This analysis gives us the filter thickness needed to retain the soil particles, if the filter pore size distribution curve and the average distance between confrontation particle/filter voids are known.

This paper presents a procedure to obtain the necessary parameters to design thin needle-punched nonwoven geotextiles filter (mass per unit area less than 200 g/m<sup>2</sup>), combining Gourc's(1982) and Silveira's(1965,1993) propositions, to estimate the distance between confronts. Some results are presented and examples discussed to show the relevance of the adopted procedure.

## 2 THEORETICAL ANALYSIS

From a probabilistic analysis of carrying spherical particles through a protective filter, Silveira(1965) proposes to establish the necessary filter thickness to retain a determined diameter soil particle.

This proposition analyses the particle path through the filter. Taking the confidence level as P', the probability, P,

of a defined diameter particle, d, to be retained by a pore size smaller than it, before a number N of voids confronts, assuming that each confrontation is a independent event, necessary to satisfy the condition:

$$P' \equiv 1 - P^N \quad (1)$$

In other words, it is possible to determine the number of pore confronts necessary to warrant the particle retention when it tries to cross the filter thickness by:

$$N \equiv \log(1 - P') / \log P \quad (2)$$

Considering the average distance between confronts as s, the total filter thickness,  $t_{GT}$ , necessary to retain a defined particle diameter is given by:

$$t_{GT} = s N \quad (3)$$

Therefore, to carry out this analysis it is necessary to know the average distance between confronts and the probability of the particle finding a pore size smaller than itself, represented by the pore size distribution curve. Both these parameters are difficult to obtain.

The filter pore size distribution curve has been evaluated by several experimental methods. Several of them are discussed by Bathia et al.(1994) and Fisher et al.(1993). Some are very complex, others are not compatible with geotextiles.

Silveira(1993) proposed to realise in-suspension filtration tests with different filters thickness and to evaluate the pore size distribution curve by retro-analysis using his probabilistic theory. In this case, it is necessary to estimate the average distance between confronts.

For the granular filters, the average distance between confronts can be evaluated in function of granular filter particle diameters. In the case of geotextiles, this supposition can not be used because the geotextiles fibres

are not necessarily in contact, and the Silveira(1993) proposition can not be directly applied.

To solve this problem, the Silveira's proposition was combined with a theoretical analysis to obtain the filter pore size distribution curve for needle-punched nonwoven geotextiles, proposed by Gourc(1982) in which case the accumulated probability, Q, of finding a pore size smaller than a defined diameter, d, is obtained by the expression:

$$Q = 1 - \exp [ - ( \eta \pi d^2 / 4 + \lambda d / 2 ) / n_{GT} ] \quad (4)$$

where  $n_{GT}$  is the geotextile porosity and the parameters  $\eta$  and  $\lambda$  can be calculated from the fibre diameter,  $d_f$ , by:

$$\eta = 8 ( 1 - n_{GT} ) / ( \pi^2 d_f^2 ) \quad (5)$$

$$\lambda = ( 2 + 4 / \pi ) ( 1 - n_{GT} ) / d_f \quad (6)$$

### 3 TESTS AND MATERIALS

To carry out this work the authors analysed several fabrics available in Brazil. This paper presents results obtained with thin fabrics, usually employed in filtration functions, and separated into three groups, each one having the same production characteristics, as shown in Table 1.

Table 1. Needle-punched nonwoven geotextiles group characteristics

product	filament	polymer	$d_f$ (mm)
A	continuous	PET	0.022
B	staple	PP	0.030
C	staple	PP	0.026

All fabrics were analysed for their physical characteristics: thickness, mass per unit area, and fibre diameter. Specimens with 150 mm diameter and having physical characteristics close to the average value were selected and submitted to a special in-suspension filtration tests described in Urashima and Vidal(1997).

These tests, illustrated on Figure 1, were conducted to evaluate the bigger particle passing across the filter on the first one seepage front, under severe flow conditions (the particles are been transported by flow). These results can be compared to the hydrodynamic opening size tests results, where the particles are submitted to several seepage front (2000 cycles).

The soil particle used in these tests were obtained from a granite powder, selected after analysis in repeated sieving tests, compounded from uniform single fractions (105/88, 88/75, 75/66, 66/53, 53/44, 44/37, <37  $\mu$ m).

### 4 RESULTS

Physical characteristics of the geotextiles are presented in

Table 2. The theoretical pore size distribution curves obtained from Gourc(1982) are presented in Figure 2.

Some results of the in-suspension filtration tests are presented on Figure 3.

Table 3 presents an abstract of experimental and analytical values.  $O_{95, sf}$  is the 95 % opening size measured in suspension filtration tests. The distances between confronts presented were obtained considering a confidence level,  $P' = 98 \%$ , and theoretical pore size distribution curves in Figure 1.

Figure 1. The test apparatus scheme.

Table 2. Geotextiles physical characteristics

geotextile	$M_A$ ( $g/m^2$ )	C.V. (%)	$t_{GT}$ (mm)	C.V. (%)	$n_{GT}$ (%)
AA	158	7.7	1.33	7.4	91.4
AB	181	6.3	1.55	5.3	91.5
BA	167	3.9	1.67	5.4	88.9
BB	198	5.9	1.86	3.7	88.2
CA	129	8.9	0.93	8.3	85.6
CB	135	8.0	1.00	5.8	85.0

Table 3. Experimental and analytical results

geotextile	thickness (mm)	$O_{95, sf}$ (mm)	distance between confronts (mm)
AA	1.33	0.070	0.459
AB	1.55	0.059	0.448
BA	1.67	0.044	0.234
BB	1.86	0.041	0.219
CA	0.93	0.062	0.345
CB	1.00	0.054	0.347

These results show that the adopted methodology provides a very close evaluation of distances between confronts, for fabrics with same production characteristics.

Fabrics with mass per unit area greater than 200  $g/m^2$

present distances between confronts increasing with thickness. For example, to the BC geotextile ( $t_{GT} = 2.28\text{mm}$ ) and CC ( $t_{GT} = 1.74\text{mm}$ ) this distance was 0.367 and 0.518, respectively. Their analysis has been improved to confirm and comprehend this tendency.

## 5 CALCULATIONS

The procedure to specify geotextiles satisfying retention criteria, can take several paths:

- Defining a soil particle diameter to retain (for example,  $d_{85}$  in well graded soil or  $d_{50}$  or an other value in function of soil characteristics), and choosing a geotextile (pore size distribution curve, distance between confronts and thickness known) to obtain the retention confidence level of this diameter;
- Defining a soil particle diameter to retain, to determine the necessary thickness to retain this diameter with a given confidence level, for each geotextile group (for example, A, B or C);
- For a chosen geotextile with pore distribution curve, distance between confronts and thickness known, to verify the soil particle to be retained with a specified confidence level;

With the retention or clogging criteria verified, it is necessary to analyse the permeability and survival criteria to complete the geotextile specification.

A well graded soil with  $d_{85}$  equivalent to 0.11 mm can be used to demonstrate a case of needle-punched nonwoven geotextile filter design, satisfying the retention criteria.

In this case, if it is possible to consider that this soil

particle diameter can retain the soil particles smaller than itself, two attitudes can be adopted:

- to determine the thickness necessary to retain  $d_{85}$  particle diameter for the geotextiles groups analysed,
- to determine the retention confidence level of this particle diameter for a specified geotextile.

From equations 2, 3 and 4:

$$t_{GT} = s \log(1 - P') / \log(1 - Q) \quad (7)$$

for a confidence level  $P'$  equal to 99.9 %,  $Q$  obtained from Figure 1 or equation 4 and  $s$  obtained from Table 3, we have for:

- geotextiles group A:  $t_{GT} > 1.38 \text{ mm}$
- geotextiles group B:  $t_{GT} > 0.84 \text{ mm}$
- geotextiles group C:  $t_{GT} > 0.75 \text{ mm}$

and the geotextiles AB, BA and CA can be adopted.

If the geotextile AA ( $t_{GV} = 1.35 \text{ mm}$ ) is available, the retention confidence level to retain the  $d_{85}$  soil particle, determined from equations 2, 3 and 4 is 99.88%.

Comparing these results with a traditional retention criteria like the one proposed by the French Geotextiles and Geomembranes Committee (CFGG), considering the best soil condition, the geotextile hydrodynamic opening size needs to be lower than 0.138mm. In this case, the geotextiles of the group A can not be adopted (AA -  $O_{95,H} = 0.21 \text{ mm}$ , AB -  $O_{95,H} = 0.17 \text{ mm}$ ).

It is necessary to remember that Silveira's proposition takes into consideration the most critical situation, i.e. the particles are been transported by flow.

Figure 3. Grain size distribution curves of the soil passant mass observed in some in-suspension filtration tests.

## 6 COMMENTS

Although Silveira's (1993) procedure can not allow us to determine directly the pore size distribution curve of geotextiles because the average distance between confronts are not known and we do not have several fabric thicknesses with the same production characteristics (each fabric thickness represents one point of the curve), his proposition is interesting to evaluate the average distance between confrontations, if the pore size distribution curve can be obtained by an other method.

From the results of in-suspension filtration tests, conducted according to the probabilistic theory suppositions, and the theoretical pore size distribution curve proposed by Gourc (1982), it is possible to evaluate the average distance between confronts.

Each geotextile or group of fabrics that presents the same production characteristics can be analysed and have their filtration parameters evaluated.

To define a production line (group of geotextiles presenting the same fabric filtration characteristics) it is necessary to have a good technological control of the production procedure that warrants the same characteristics. The nonwoven geotextiles are very sensitive to a variation of the needle intensity. Anyway, the analysis of in-suspension filtration tests results can detect the fabric variations.

Fabrics with mass per unit area greater than 200 g/m<sup>2</sup> need to be better studied to verify if the observed variation on the average distance between confronts with apparently the same production characteristics is a function of the in-suspension filtration tests methodology adopted, or intrinsic fabric variation. Tests with larger specimens are been carried out to improve our knowledge.

The superposition of the theoretical pore size distribution curve and in-suspension filtration tests results looks to be an applicable proposition for thin geotextiles.

# Filter behaviour of hydraulically and mechanically damaged geotextiles

YH Faure, Y. Kehila

LIRIGM, University Joseph Fourier, Grenoble, France

**ABSTRACT :** In this paper, a geotextile filter is considered hydraulically « damaged » when it is clogged by soft soil and mechanically damaged when it is punched or torn by gravels during installation. Specific tests were performed to damage hydraulically non-woven filters by filtration of fine soil in suspension (critical conditions for clogging). Physical properties and filtration characteristics of filters like filtration opening size are analysed to show their influence on velocity of clogging. Clogging occurs when the filtration opening size is smaller than the  $d_{max}$  of the fine soil and the velocity of clogging is very sensitive to the geotextile density (or porosity). Three levels of damage action were applied to damage filters mechanically. A lot a perforations are necessary to produce variation of filtration opening size when it is determined by sieving method (wet sieving or hydrodynamic sieving). A very deformable geotextile is less damaged than a rigid one.

**KEYWORDS :** Filtration, Degradation, Clogging Tests, Non-woven fabrics

## 1 INTRODUCTION

A lot of studies have been carried out in the past in order to analyse geotextile filter behaviour and, in general, clean undamaged specimens are tested. However, during on-site installation, geotextiles are laid mostly on a soft, saturated fine soil and, as a result, filter pollution (or clogging) occurs when operatives walk on the geotextile. Moreover, when the gravel layers are subsequently placed on the filter, mechanical damage may occur, such as punctures or tears. In both cases, the geotextile filter is considered to be hydraulically or mechanically damaged.

This paper presents the experiments carried out and the results obtained, indicating the filter behaviour of different textile structures.

## 2 HYDRAULIC DAMAGE: FILTRATION OF WATER LOADED WITH SOIL IN SUSPENSION

In order to study the effect of hydraulic damage, a filtration test was performed on a sample of water loaded with soil in suspension. This test, presented in a previous paper by Faure et al. (1993), reproduces the critical conditions encountered when installing the geotextile on site: the soil in the trench is often very muddy and the geotextile must filter the soil carried in suspension in the water without clogging. Then, when the soil has consolidated and is in close contact with the filter, the water is no longer charged with particles in suspension, or contains only very little (on condition that the internal stability of the soil to be filtered is established). It is necessary to check that the clogging level during the initial stage is not too high, and it would be beneficial if the circulating clear water could help unclog the geotextile, thereby ensuring better subsequent operation of the system.

### 2.1 Description of the filtration test

The test assembly consists of the following components - two upstream reservoirs, one for supplying water loaded with soil particles in suspension, and one constant-level reservoir to ensure the circulation of clear water (a three-way valve is used to switch instantaneously from one reservoir to the other),  
- a constant discharge pump to provide a constant solid and liquid flow when clogging is not too high,  
- a sample holder (effective diameter: 50 mm),  
- a constant-level downstream reservoir.

A pressure sensor is connected to the circuit 0.15 m upstream of the geotextile. This sensor monitors the time-dependent increase in pressure due to filter clogging.

### 2.2 Soil used

The retention criteria for geotextiles filters are based on the characteristic “geotextile filtration opening” size,  $O_f$ . If the value of  $O_f$  has been correctly chosen, the granular skeleton of the soil is retained (Giroud, 1996) and the risk of

Figure 1: Diagram of the test assembly used for filtering soils in suspension

clogging during the initial operating period of the filter is due only to the fine elements in the soil. This is the reason why the retention criterion of the CFG (French Geosynthetics Committee) requires a filtration opening  $O_f$  greater than  $80 \mu\text{m}$ , in the case of coherent soils, to allow particles smaller than  $80 \mu\text{m}$  to pass through the geotextile.

For the filtration tests on loaded water, a clayey soil was used with upper particle size limited to  $80 \mu\text{m}$ . The particle size range of this pottery-type clay (Figure 2) was measured without deflocculant because, during the test, it is used without deflocculant.

Figure 2: Particle size range of the soil for filtration tests of soil in suspension

### 2.3 Characteristics of geotextiles tested

All the geotextiles are made of non-woven polypropylene. The distinguishing parameters (cf. Table 1) are mass per unit area  $\mu_g$ , thickness  $T_g$  and fibre diameter  $d_f$ . Porosity can be then calculated by mean of :

$$n = 1 - \frac{\mu_g}{\rho_f T_g} \text{ where } \rho_f \text{ is the density of the fibres.}$$

Table 1: Characteristics of geotextiles tested (mean values)

Géotextile Lirigm name	Structure	$\mu_g$ g/m <sup>2</sup>	$T_g$ mm	$d_f$ mm	n %	O90 (Hyd. S) $\mu\text{m}$
CF130a	nw-needlepunched.	126	1.1	26	87.5	85
CF130b	nw-needlepunched.	127	1.3	37	89.4	155
HB130	heatbonded	137	0.5	42	70.2	140
SF130	nw-needlepunched.	134	2.5	31	94.2	175
CF300a	nw-needlepunched.	292	2.6	26	87.8	65
CF300b	nw-needlepunched.	286	2.8	37	88.9	105
HB300	heatbonded	294	0.8	42	60.1	65
SF300	nw-needlepunched.	269	3.9	31	92.5	100
CF400a	nw-needlepunched.	400	3.45	26	87.4	61
CF600a	nw-needlepunched.	633	4.5	26	84.7	59
CF600b	nw-needlepunched.	617	4.4	37	84.8	50
CF800a	nw-needlepunched.	816	5.9	26	85.0	60
SF1100	nw-needlepunched.	1119	7.8	49	84.7	101

The density of the geotextile is :  $\rho_g = \frac{\mu_g}{T_g}$

SF geotextiles are made with short fibres while CF materials are made with continuous filaments. The HB geotextiles are heat-bonded.

### 2.4 Test procedure

After installing the test sample and saturating the system, soil particles are tipped into the reservoir filled with water (capacity 25 l). The concentration  $C_o$  of the suspension is 0.5, 1 or 2 g/l. A mechanical stirrer ensures that the suspension remains homogeneous at all times. The flow rate is imposed by the pump with a speed of 40 mm/s. When the particles come into contact with the filter, recording of the pressure « u » starts. This pressure gradually increases. Then, when the clogging level is too high, the pressure suddenly increases at a much faster rate until the safety valve is tripped. (Figure 3). Overpressure is defined by the difference :  $u - u_o$  ( $u_o$  is the measured value of  $u$  at the beginning of the test with clear water).

### 2.5 Influence of geotextile structure

Figure 3 shows that the mass per unit area is not the main parameter governing the clogging rate: when  $O_f$  is greater than  $d_{max}$  of the soil (cf. CF300b and SF300), no clogging occurs: the pressure has hardly increased after all the water has flowed through. On the other hand, with a filtration opening size  $O_f < d_{max}$ , clogging occurs all the faster as the porosity is lower (HB300 and CF300a).

The density  $\rho_g$  ( $= \mu_g / T_g$ ) was calculated for each geotextile sample. This parameter gives an indication of the compactness of the fibrous medium (like the porosity).

Figure 3: Influence of geotextile structure 2.6 Influence of geotextile density (or porosity)

Figure 4: Clogging - Unclogging curves

To study the clogging phenomenon, the clogging rate was defined by the slope of the straight line tangent to the clogging pressure curve before the “elbow” ( $V_c = \Delta u / \Delta t$ )

Figure 5 shows the variation in  $V_c / C_o$  (to compare tests conducted with different concentrations  $C_o$ ) as a function of  $\rho_g$  for CFa geotextiles of the same fibre diameter and same needle-punched structure. Despite the dispersion, the compactness (or the porosity) would indeed seem to be the parameter most influencing the filter clogging rate, regardless of the weight per unit area. Clogging therefore occurs mainly on the surface or in the first layers of fibres.

Figure 5: Determining role of geotextile density

## 2.7 Unclogging

The ease with which a geotextile is likely to become clogged is controlled by the injection of clear water, always with a flow speed of 40 mm/s, as soon as the pressure reaches 10 kPa. The graphs in Figure 4 illustrate this phenomenon and clearly show the role of compactness (for CF400a filters). A high density filter remains less permeable than a low density filter although its clogging level was the same as the low density filter.

## 3 MECHANICAL DAMAGE:

If a geotextile incurs mechanical damage, during the installation procedure (punctures, tears), its filtration characteristics, permeability and filtration opening size are modified: the permeability increases and the filtration opening size as well. The question is to know whether these variations will disturb the filtering behaviour of the geotextile and, if so, in what proportions, and is it still operational after this damaging action?

- The permeability increases: this is a positive effect with regard to the permeability condition required by the filter criteria. However, a permeability test after a damaging action enables the level of filter damage to be estimated.

- The filtration opening size increases: the geotextile is now not so efficient at retaining the soil. To estimate the damage incurred on a geotextile, is the transmission observation method objective?

Damaging action tests were conducted with three stress levels and the filtration opening size of the damaged samples was then measured by wet sieving and by hydrodynamic sieving

### 3.1 Levels of damaging actions

Level 1: Tests were carried out according to the draft European Standard Procedure for simulating site damage. A geotextile specimen is laid between two gravel layers (corundum SD 5-10 mm) and subjected to cyclic loading of 900 kPa with a frequency of 1 Hz for 200 s (Figure 6).

Level 2: The test device used is the same as before. The damage is produced by a 230 mm square plate with 57 ASTM punches (ASTM D 5494 standard), Figure 7. The point of each punch has a pyramidal shape and the base is circular (25 mm diameter). Together, they form a triangular arrangement with a side length of 25 mm. The geotextile is laid on an 80 mm thick layer of sand (0-2 mm). The cross-section of the cell containing the sample is small (250 x 250 mm), slightly larger than the punch plate. The punches are in direct contact with the geotextile. A load of 380 kPa is applied (i.e. 0.35 kN per punch), for 200 cycles at 1 Hz.

Level 3: The punches consist of 23 mm high cones with an apex angle of 40° (Figure 8). 19 cones are fixed on a support plate in a triangular arrangement with a 60 mm side length. A load of 0.60 kN per cone, or an equivalent pressure of 150 kPa, is applied at 1 Hz for 200 cycles.

Figure 6: Test device for the level 1 damage test

Figure 7: ASTM punches for the level 2 damage test

Figure 8: Cones for the level 3 damage test

### 3.2 Results (Figure 9)

Not all the geotextiles were systematically subjected to the same stress levels. Depending on the results obtained, a higher or lower level was not necessarily applied. For example, when the HB130 geotextile suffered considerable damage at level 2, it was not considered necessary to apply level 3.

**Level 1 :** With level No 1 damaging action, only the HB130 geotextile would appear to have suffered any damage: many of the filaments are broken and perforation marks are visible. However, measurement of the O90 opening by the wet sieving test shows only a slight increase in O90: from 117 to 142 $\mu$ m.

For the other geotextiles no damage was observed or measured.

**Level 2 :** With level 2, of the 130 g/m<sup>2</sup> geotextiles, only the SF130 kept the same O90 value, although it suffered considerable strain. The heavier geotextiles (300 g/m<sup>2</sup>), despite showing the marks of the punches after the test, have suffered only minor damage and their O90 value has hardly increased, even for HB300.

**Level 3 :** With the stress applied at level 3, all the geotextiles are perforated: cone holes are clearly visible by

shining a light through the sample, although the size of the holes varies depending on the geotextile.

For the highly deformable SF300 and SF1100, the cone hole diameters are much smaller than those of the CF300a, in which the holes are more like cuts. However, it is worth noting that although the holes are several millimetres in size, the values of O90 remain well under 1 mm. There are two reasons for this:

- after the damage test, with the samples at rest, the perforations and cuts in the needle-punched material tend to close with time, a feature that is not found in heat-bonded geotextiles,
- the number of perforations (only 7) inside the sample (200 mm diameter) tested by wet sieving or hydrodynamic sieving is not sufficient. During sieving, a small quantity of soil passes through the holes and the proportion of large particles is insufficient.

Figure 9: O90 histogram after the damaging action

## 4 CONCLUSION

This study of the hydraulic behaviour of geotextile filters after incurring hydraulic or mechanical damage has highlighted the role played by characteristic parameters.

**Hydraulic damage** (water loaded with soil particles in suspension): filter clogging is delayed when the filtration opening size is greater than the  $d_{max}$  value of the soil in suspension. With an Of value equal to or slightly lower than the value of  $d_{max}$  of the tested soil in suspension (here  $d_{max} = 80 \mu$ m), the risk of clogging increases when the filter porosity is smaller.

**Mechanical damage:** the filtration opening size of geotextile filters is not modified at level 1. In order for the filtration opening size test to be sensitive to the filter damage, the number of perforations must be sufficiently great like with the level 2 damage test.

# Large-scale Performance Tests to Evaluate Filtration Processes

Th. Kossendey

LGA-Geotechnical Institute, Nuremberg, Germany

G. Karam

Du Pont de Nemours, Luxembourg, Luxembourg

**ABSTRACT:** The long-term filter performance of 5 geotextiles differing in permittivity, thickness, mass per unit area and type of polymer was studied experimentally in large permeameters supplied with three different soils. In three test series, the geotextile samples of 500 mm diameter were submitted to steady state seepage under different hydraulic gradients for 6 to 24 months. In the first two performance tests, the water flow was in the direction of gravity. The third test series simulated the case of upward water flow. Although the geotextiles differed in their parameters, their filter performance exhibited very similar characteristics and satisfied the requirements for stable filter performance. A detailed microscopic investigation into the soil structure directly above the geotextiles confirmed that the geotextiles formed an internal soil filter with a bridging network.

**KEYWORDS:** Long-Term Filtration, Clogging tests, Performance Evaluation, Microstructure

## 1 INTRODUCTION

Geotextile filters function adequately when they retain a majority of the soil particles at the interface between a finer and a coarser soil and permit the flow of water through the pores of the soils and the geotextile filter without any water pressure build up upstream of the filter. Many investigations were carried out to obtain reliable criteria for the design of geotextile filters, but it is difficult to predict the long-term filter behaviour. The long-term performance of geotextile filters depends primarily on the following factors:

- the properties of the filter,
- the properties of the soils,
- the type of water flow.

Since these major factors are variable, it is not possible at the present time to predict the long-term filter performance of different geotextiles quantitatively on a theoretical basis. The long-term filter performance can only be evaluated correctly on the basis of either field experience or large scale performance tests under well defined boundary conditions which can be related to the in-situ situation.

## 2 TESTING PROGRAMME

### 2.1 Soils used for the performance tests

According to the geotextile filter criteria currently applied in Germany (FGSV 1994), a soil is called a "problem soil" regarding the geotextile filtration, if any one of the following criteria applies:

- $C_u = d_{60}/d_{10} < 15$  and the soil contains some fines  $< 0.06$  mm
- $> 50$  % content of the grain size fraction  $0.02$  mm  $< d < 0.1$  mm
- $I_p < 15$  % (if not available: content of clay / content of silt  $< 0.5$ )

The fine-grained silt used for long-term filtration test

was a loess from a road construction site in the Central Hesse area, about 30 km north of Frankfurt/Main.

The soils A and B were blended from different quartz fractions. Thus, it was possible to design cohesionless soils with gradation curves which met the above-mentioned criteria for a "problem soil" with respect to geotextile filtration.

The soils used in the permeation tests fully satisfied all criteria for a "problem soil". The grain size distributions are shown on Figure 1. Details of the soil parameters used in the tests are given by Kossendey et al. (1996b).

Figure 1. Grain size distributions of the soils used in the long-term permeation tests

### 2.2 Geotextiles

5 different nonwovens (3 heat-bonded, PP and 2 needle-punched, PET) geotextiles were selected for the long-term performance tests. They comprised geotextiles of various polymers and different manufacturing technologies in a wide range of their properties. Details of the selected geotextiles are given in table 1. Their properties were determined by index tests at the laboratory of the LGA-Geotechnical Institute. The results of these tests served as reference data for the evaluation of changes in the geotextile properties after the long-term permeation.

### 2.3 Permeameter circuit

The test equipment used in these test series consists of 3 supply containers and 4 permeameters per circuit arranged radially around the supply container. They have a diameter of 50 cm and a height of 167.5 cm. A detailed description of the permeameters was given previously by Gartung et al. (1994) and Kossendey et al. (1996b).

### 2.4 Test conditions

In total, three long-term filtration test series differing in their boundary conditions were carried out. For the first two test series, a mesh was placed upon the conical bottom plate with a discharge opening at the centre in each of the permeameters. The geotextile sample was installed above the mesh and attached to the permeameter by a fixing ring. The soil layer was placed on the geotextile. The first long-term test series was carried out under a hydraulic gradient of  $i=3$  regarding the soil layer above the geotextiles. This hydraulic gradient falls into the range of typical hydraulic gradients for drainage applications under steady-state flow conditions, as noted by Davindenkoff (1976) and Luettich et al. (1992). During the second test series the hydraulic gradient was selected as  $i = 12$  to observe the permeation behaviour under higher hydraulic gradients. The permeation of the tests was in direction of gravity. In order to examine the filtration behaviour of a system geotextile/soil under conditions of upward permeation against the direction of gravity, a third test series was implemented with a hydraulic gradient  $i = 2,5$  (figure 2). The soil layers of each test implementation were only slightly compacted to test the filtration behaviour for the worst case.

Figure 2. Schematic sketch of the test with upward permeation

The test liquid (tap water) permeated uniformly through the system geotextile/soil. The determined values of dissolved oxygen in the different circuits were between 4.2 ppm and 5.5 ppm. Following the definition of de-aired water (maximum at 6 ppm), the criterion for the oxygen

content of de-aired water was met in the filtration tests.

### 2.5 Analysis of the microstructure

In order to analyse the microstructure at the interface geotextile/soil influenced by the interaction between geotextile and soil, microscopic sections were prepared. The undisturbed soil samples taken after the end of the tests were saturated by a resin in the same way as by water in the filtration tests to prevent the soil samples from any disturbance. The viscosity of the resin was similar to the water that permeated the system geotextile/ soil.

## 3 TEST RESULTS

### 3.1 Performance tests with a hydraulic gradient $i = 3$

During an initial period of approximately four weeks, an increase in the system permeability of the permeameters with the loess soil was observed. In spite of the increase in permeability, no soil particles were detected by the collecting glass. After about four weeks, the permeability of all permeameters began to decrease. With increasing test duration, the permeameters showed only small differences in the system permeabilities. They followed the same trend towards constant values. The system permeabilities of the permeameters are given in Figure 3. The coefficient of permeability of the loess soil tested by small scale index test was  $1.2 \cdot 10^{-8}$  m/s. The observed permeabilities of the large scale system geotextile/soil never fell below this value, so the permeabilities of the system soil / geotextile were higher than that of the small soil sample at all times. The reason for the discrepancy may be local variations in the density of the large permeameter sample, and associated inhomogeneities in the distributions of the coefficient of hydraulic conductivity.

The behaviour of the system permeabilities in the permeameters with soil A and soil B are similar to the results of the tests described by Kossendey et al. (1996a, 1996b). In permeameter with geotextile NP1 an additional load of 20 kPa was applied. The system permeabilities began to increase in all permeameters. In contrast to the test with the loess soil, the initial period of increasing permeabilities lasted only a few days.

Except for a slight cloudiness of the test liquid which could not be quantified, no particle migration was observed in the test circuit with soil A at the beginning of the tests. Although the geotextile HB1 was not dimensioned with respect to the criteria of FGSV, it satisfied the requirements for a sufficient filter performance. The greatest amount of migrated soil particles of NP1 was detected during the first 2 hours. With increasing test duration, the geotextile showed a stabilization like in the other permeameters. The reason for the higher amount might be details in the filling procedure of the permeameter. The cumulative amount of the migrated soil particles is given in table 1.

Table 1. Cumulative amount of migrated soil

Geotextile	Amount of migrated soil [g/m <sup>2</sup> ]	Soil
HB 1	19.02	A
HB 2	14.80	A
HB 3	5.97	A
NP 1*	78.38	A
HB 1	24.27	B
HB 2	9.15	B

\* with 20 kPa load

After that initial period, the flow rates became consistent and the various permeameters showed only very small differences. As a result of higher compaction of the soil layer, the measured permeabilities in the permeameters with geotextiles NP1 and HB2 (soil A) were lower. The system permeabilities of the permeameters with soils A and B stabilized to equilibrium conditions after 100 days, and then they varied only in a very small range for the remainder of the test period. Like in the test with the loess soil, there were no discernible differences in the performance between the types of geotextile. The system permeabilities are given also on figure 3.

The permeameters which were filled with soil B and the permeameter with the geotextile HB 1 and soil A showed a slight decrease in their permeabilities after 300 days, while all of the other permeameters were constant in their permeabilities. After the monthly addition of a disinfectant against microbiological growth, an immediate increase in the permeabilities of the treated permeameters was observed. Although a biofilm of algae was not observed at the surface of the soil layer, probably a microbial growth within the pores of the soil had to lead to a reduction of the system permeabilities. The measured permeabilities of the dismantled geotextiles were smaller than those of the virgin geotextiles by a factor of 10 at maximum, but they never fell below the permeability of the test soils.

### 3.2 Performance test with a hydraulic gradient $i = 12$

Two heat-bonded and two needle-punched nonwovens were selected for a second test series to evaluate the filter

performance under a hydraulic gradient of  $i = 12$ . In a first step, a layer of soil A with 5 cm thickness installed without compaction in the permeameters was permeated.

The development of the permeabilities of both tests under the hydraulic gradient  $i = 12$  was similar to the results of the first test series. After an initial period of increase, the permeabilities began to decrease slightly. The measured amount of migrated soil was higher than in the test with a hydraulic gradient  $i = 3$ , but after 2 hours permeation no measurable amounts of soil were detected. After a test duration of 85 days, the soil layer in the permeameters was brought into suspension to simulate the extreme case of the destruction of the internal soil filter. Like in the first test, there were no discernible differences in the performance between the geotextile types. The measured amounts of migrated soil were higher than the results before the disturbance, but piping of the soil stopped within 3 hours. A distinct trend of a better performance of thicker products regarding the retention of particles was not observed. The system permeabilities and the cumulative amount of migrated soil particles are given on Figures 4 and 5.

### 3.3 Performance tests with upward permeation

Four nonwovens (two heat-bonded and two needle-punched) were selected for a third test series to evaluate the filter performance with upward permeation under a hydraulic gradient  $i = 2.5$ . The behaviour of the permeabilities was similar to the results of the two test series mentioned above. During an initial period of about 10 days, the permeabilities showed a nonuniform permeation behaviour. After that initial period, the permeabilities in all permeameters adjusted to constant flow rates. In order to simulate the frequent case of interrupted water flow in a subsurface drainage system, the upward permeation of the test system was stopped after 40 days. After the renewed start of the permeation, following an initial period of instability, the system permeabilities remained again relatively constant with time. The system permeabilities are given on Figure 6.

Table 2. Geosynthetics used in the long-term permeation tests

	Geotextile	Polymer	Mass per unit area [g/m <sup>2</sup> ]	Thickness (2 kPa) [mm]	$O_{90,w}$ [mm] <sup>1</sup>	$k_v$ (20 kPa) [m/s] <sup>2</sup>	Permittivity (20 kPa) [s <sup>-1</sup> ] <sup>2</sup>
heat-bonded	HB 1	PP	113	0.44	0.18	$4.0 \cdot 10^{-4}$	1.34
	HB 2	PP	195	0.56	0.13	$2.4 \cdot 10^{-4}$	0.55
	HB 3	PP	300	0.82	0.09	$3.2 \cdot 10^{-4}$	0.42
needle-punched	NP 1	PET	250	2.97	0.10	$2.2 \cdot 10^{-3}$	0.83
	NP 2	PET	365	4.02	0.09	$2.3 \cdot 10^{-3}$	0.55

#### 4 MICROSTRUCTURAL ANALYSES

During the dismantling of permeameters of the test series permeated downward, undisturbed geotextile/soil samples were prepared for microscopic analyses. In all analysed microscopic sections, it was observed that soil particles

formed an internal soil filter in the form of a bridging network above the geotextiles. The geotextile filter layers acted as a catalyst for the formation of this internal filter system of the soil. The thickness of the bridging-zone was dependent on the hydraulic gradient. The thickness of the bridging-zone observed in the tests under the hydraulic

gradient  $i = 3$  was 5 mm at maximum and about 1 cm in the tests under a hydraulic gradient  $i = 12$ . A trapping of finer soil particles by the filter layer was noticed only in tests with the needle-punched geotextiles. However, the penetration was about 0.5 mm, so that the phenomena of deep filtration discussed by Heerten (1993) was not observed. The microstructures of soil A and the geotextiles HB2 and NP1 are given on figures 7 and 8.

## 5 CONCLUSION

Although the tested geotextiles differed in their material parameters, their filter performance exhibited essentially the same characteristics. They satisfied the requirements of stable permeation conditions. A review of the test results published by Kisskalt (1992), by Gartung et al. (1994) and by Kossendey et al. (1996a, 1996b), revealed that this observation applies to the geotextiles and test soils studied by Kisskalt and by Kossendey et al. as well. The test duration of up to 800 days and the large scale of the test equipment admit the application of these findings to conditions which are encountered in engineering practice (steady-state-flow conditions and lower hydraulic gradients). The opening size  $O_{90,w}$  (measured by the wet sieving method) of most of the recently obtainable nonwovens falls into the region from 0.07 to 0.13 mm. Following the obtained test results, it has to be assumed that geotextiles which meet the retention criterion based on  $O_{90,w}$  will perform successfully under these boundary conditions.

Along with the results of previous research investigations (Kisskalt 1992 and Kossendey et al., 1996a, 1996b), the findings of these long-term studies in filtration with 25 different geotextiles and 6 critical soils regarding filtration are a wide basis for the assessment of the long-term filter performance. All results confirmed that the thickness of a geotextile layer is not a relevant criterion for filtration under steady-state-flow conditions and the retention criterion based on  $O_{90,w}$ , has proved to be a reliable basis for the dimensioning of geotextile filter layers. Field examinations of geotextiles installed up to 15 years ago (Rollin et al., 1994 and Mlynarek et al., 1994) confirm the results with respect to the long-term performance.

The test results of the long-term test series reported in the present paper and compared to results of previous test series carried out at the LGA-Geotechnical Institute can be summarized as follows:

- all permeameters showed the same flow behaviour with increasing test duration
- stable flow conditions were obtained in all permeameters
- the system permeability was independent of the type of geotextile
- the thickness of a geotextile filter layer had definitely not any influence on the filtration behaviour under test conditions described above
- the microscopic analyses indicated that the

geotextile filter acts as a catalyst for the formation of an internal soil filter based on a bridging network

- the phenomenon of deep filtration was not observed
- no measurable migration of soil particles occurred after 48 h, stable hydraulic conditions were obtained in all permeameters
- even relatively openly designed geotextiles performed successfully
- no failure of the geotextile filter by clogging was found during the performance tests

# The Performance of a Geotextile Filter in Tropical Soil

M.G. Gardoni

Civil Engineer, University of Brasilia, Brasilia, Brazil

E.M. Palmeira

Associate Professor, University of Brasilia, Brasilia, Brazil

**ABSTRACT:** Problems with granular filters in residual soils from quartzite is well known by the Federal District Highway Department, Brasilia, Brazil. These soils are structurally formed by clusters of fine particles. However, geotextile filters have been used successfully under these conditions. This paper investigates a geotextile drain in residual soil from quartzite that have been performing well for the last 10 years. Soil and geotextile samples were collected from the drain and tested in the laboratory. Chemical and microscopic analyses were performed on the residual soil and on samples of the geotextile. Current filter criteria were also used and the results obtained suggest that the accuracy of a criterion prediction may be a function of the procedure used to obtain grain size distribution of the soil and on cluster resistance to high gradients. In general the drain is in good operational conditions.

**KEYWORDS:** nonwoven geotextile, filter, residual soil, geotextile permeability, filter criteria.

## 1. INTRODUCTION

Geotextile draining systems have consistently performed well in highways around Brasilia, Federal District, Brazil. In several similar situations granular filters have clogged when in contact with residuals soils from quartzite, which is very common in the region. Besides, local government environmental agencies have been very strict on the exploitation and use of natural materials such as sand and gravels. This causes these materials having to be transported from distant places for drain construction, which increases significantly the cost of granular drains in comparison to synthetic drains. Because of these reasons geotextile drains have become increasingly competitive in comparison to natural drains and the Federal District Highway Department has increased the acceptance of geotextile drainage systems in the region.

This paper presents a study of a 10 years old geotextile drain built in the BR-020 highway, close to Brasilia, in a region of residual soils from quartzite. The study involved the inspection of the geotextile in situ, collection of geotextile, soil and water samples for laboratory tests.

## 2. CHARACTERISTICS OF THE DRAIN, MATERIALS AND EQUIPMENTS USED

### 2.1 Drain characteristics

The drain in the BR-020 highway was constructed in a region of residual soil and weathered rock from quartzite, with the presence of meta-siltstone and meta-claystone. The drain is 400 m long at each side of the road and was constructed in a 0.6 m wide and 1.5 m deep trench. Figure 1 shows schematically the drain geometrical characteristics.

### 2.2 Soil, water and geotextile characteristics

A trench was excavated alongside the drain to collect soil and geotextile samples for testing. Undisturbed soil samples as well as geotextile samples on the side and on the top of the drain were collected. Visual inspection showed that the geotextile layer was in good state not being observed any damage that might have been inflicted to the geotextile during construction. The drain, as a whole, was in very good operational conditions. At this stage it was also very clear the greater contamination of gravel material not protected by the geotextile. Water samples were also collected for analyses.

Figure 1. Drain characteristics.

Standard laboratory tests were performed on the residual soil samples for the determination of grain size distribution, void ratio, moisture content, etc. Table 1 summarizes the main characteristics of the soil. The soil is

a fine sand (83% of sand particles) and its grain size distribution is shown in Figure 2. Two curves for the grain size distribution of the residual soil are presented in this figure. One is the curve obtained with the sedimentation test using deflocculant (standard procedure) and the other is the result with the sedimentation test without the use of deflocculant. The reason for the latter type of sedimentation test is due to the fact that soils in this region are commonly structurally composed of clusters of soil particles, forming strong larger grains, which may be loosened by the action of the deflocculating agent used in the tests but not necessarily by water flow in a drain or in filtration tests. Therefore, for the use of filtration criteria, the grain size curve obtained without the use of deflocculant may be the appropriate one under these circumstances. Figure 2 shows a marked difference between results of sedimentation tests with and without the use of deflocculant.

Figure 2. Grain size distributions of the soils.

Table 1. Soil properties.

Natural moisture content, %	11.4
Specific gravity (in situ), kN/m <sup>3</sup>	22.6
Void ratio	0.33
Density of the soil particles	2.71
Permeability coefficient, cm/s	$80 \times 10^{-4}$

It is important to note that depending on the grain size distribution chosen for filter design the values of grain diameters obtained can be significantly different. The same applies to the value of the coefficient of non-uniformity of the soil (CU) which may be 1.4 or 19, depending on the curve used. The latter value suggests that if the pack of grains is destroyed by the action of the water the soil can be highly sensitive to suffusion.

Chemical and mineralogical tests were also performed in the residual soil such as methylene blue and X-rays diffractometry. These tests yielded to results of coefficient of activity for the fine fraction of the soil equal to 6.88 g/g, specific surface of 7.35 m<sup>2</sup>/g and cations exchange capacity of 0.8 meq/100. Results of the chemical analysis are presented in Table 2. The soil can be then classified as a low activity lateritic soil. This was confirmed by the presence of kaolinite as the predominant clay mineral in the soil fine fraction in X-rays diffractometry tests.

Table 2. Chemical composition of the soil.

Substance	Percentage (%)
SiO <sub>2</sub>	89.10
Fe <sub>2</sub> O <sub>3</sub>	1.12
Al <sub>2</sub> O <sub>3</sub>	2.53
CaO	0.13
MgO	0.06

Tests with samples of the underground water in the region revealed a pH equal to 7.95 and low values of turbidity (0.7 NTU) and iron content (0.23 mg/l). These values are close to the values observed for distilled water.

A nonwoven needle punched geotextile, made of polyester, commercially available under the name Bidim OP20, was used to envelope the gravel material (Fig. 1). Table 3 presents the main characteristics of the geotextile used.

Table 3. Geotextile characteristics.

FOS, mm	0.130
AOS, mm	0.12-0.21
t <sub>GT</sub> , mm	2.2
k <sub>n</sub> , cm/s	0.55

Notes: FOS - filtration opening size (AFNOR G 38017); AOS - apparent opening size (ASTM D4751-87); t<sub>GT</sub> - geotextile thickness; k<sub>n</sub> - geotextile permeability coefficient normal to its plane (ASTM D4491-89).

### 2.3 Experimentals

Filtration tests with undisturbed soil samples and the same type of geotextile used in the drain were performed in the laboratory as well as geotextile permeability tests with geotextile samples exhumed from the drain. A permeameter similar to the one presented by Calhoun (1972) was employed for the filtration tests, which is composed of a pvc cell that can accommodate 100 mm diameter soil samples. A total system gradient of 2 was adopted for the filtration tests. The equipment also allows the execution of gradient ratio tests. However, for the present case the definition of gradient ratio may be irrelevant due to the fact that undisturbed samples, rather

than reconstituted samples, were tested. So, heterogeneities in the undisturbed soil mass can affect the value of the gradient ratio obtained. Nevertheless, the general procedure recommended by ASTM (1991) for gradient ratio tests (ASTM D 5101-90) was followed in the present case.

For the conformance of the cylindrical external face of the soil sample to the cylindrical internal surface of the permeameter cell the soil sample side was covered by a layer of paraffin which was then trimmed appropriately to achieve a satisfactory match between soil and cell diameters. The internal wall of the permeameter cell was greased to avoid any preferential flow along the soil-cell interface. Filtration tests with durations as long as 2500 hours ( $\cong$  3.5 months) were performed.

Distilled water was used in the laboratory tests and its composition after having crossed the soil sample was monitored during the test to assess variations in pH, turbidity, total iron and electrical conductivity.

To assess the loss of permeability of the geotextile in the drain after 10 years of operation the carefully exhumed geotextile samples were subjected to permeability tests in the laboratory. The equipment in this case is similar to the one presented in ASTM (1991) for the determination of the permeability of geotextiles normal to its plane (ASTM D 4491-89).

Investigations of the state of the exhumed samples of geotextile were also carried out using electronic microscopy. For this analysis samples of exhumed geotextile were firstly totally impregnated by polyesterene resin under vacuum. Slices of these samples could then be cut for the analysis by an electronic microscope.

Additional information on materials, equipments and methodologies can be found in Gardoni (1995).

### 3. RESULTS OBTAINED

#### 3.1 Filtration test

Figure 3 shows the result of a filtration test with an undisturbed residual soil sample and the same geotextile used in the drain. Approximately 2000 hours were necessary for the stabilization of water flow conditions.

At the end of the long term filtration test the soil mass close to the geotextile (one third of the original sample height) was tested for void ratio determination. It was observed that the void ratio increased from 0.33 to 0.53 in that region. This suggests that some level of suffusion occurred during the long term filtration test. This can be also inferred from the grain size distribution of the soil sample close to the geotextile after the filtration test, which is also presented in Figure 2 (grain size analysis with the use of deflocculant). This indicates that the mobility or dispersion of soil clusters may be dependent of the gradient used in the test.

Figure 2 also shows the grain size distributions of the gravel materials enveloped by the geotextile and on top of the drain (Fig. 1). It can be observed that the unprotected gravel was significantly contaminated by the fines from the residual soil while the gravel inside the drain was clean.

Figure 3. Flow rate versus time in a filtration test.

The analysis of the water that passed through the soil sample in comparison to the standard distilled water showed high values of turbidity and increases on iron content and pH, as shown in Table 4. These results suggest that there was iron precipitation under laboratory conditions.

Table 4. Water composition at the entrance and at the exit of the soil sample (end of the test).

Stage	ph	(1)	(2)	(3)	(4)
Entrance	6.8	0.028	0.38	3.10	1.8
Exit	7.1	2.22	82	10.6	7.4

Notes:

(1) - total iron (mg/l); (2) - turbidity (NTU); (3) electrical conductivity ( $\mu$ S/cm) and (4) - total dissolved solids (mg/l).

#### 3.2 Geotextile permeability

The geotextile samples taken from the drain side and top as well as the sample used in the filtration test discussed above were tested to assess their loss of permeability under field and laboratory conditions. Firstly, for this comparison, a series of geotextile permeability tests were performed on virgin samples of the same geotextile in order to determine its average permeability coefficient and the scatter of test results. As the mass per unit area of thin geotextiles can vary markedly along the geotextile layer, several samples of varying mass per unit area were tested. The results of normal geotextile permeability of virgin samples versus geotextile mass per unit area are presented in Figure 4 where a rather constant average normal

permeability with mass per unit area can be observed as well as a significant scatter of test results.

The results of permeability tests with geotextile samples from the drain and from the filtration test are also presented in Figure 4 and in Table 5. A reduction of geotextile permeability of 50 to 60% with respect to the average permeability of the virgin samples can be observed for the exhumed geotextile samples. The geotextile sample used in the filtration test retained only about 5% of its original normal permeability. These results suggest that much more severe conditions occurred in the laboratory filtration test than in the field (larger gradient, for instance). Nevertheless, the values of permeability coefficient or geotextile permittivity are still significantly high for practical purposes, as shown in Table 5.

Figure 4. Geotextile permeability test results.

Table 5. Geotextile permeability tests results.

Geotextile specimen	$t_{GT}$ (mm)	$M_A$ ( $g/m^2$ )	$k_n$ (cm/s)	$\psi$ ( $s^{-1}$ )
Drain top	1.6	340	0.24	1.50
Drain side	1.6	264	0.19	1.19
Filtration test	2.0	242	0.03	0.15

Notes:  $t_{GT}$  = geotextile thickness,  $M_A$  = geotextile mass per unit area,  $k_n$  = geotextile coefficient of permeability and  $\psi$  = geotextile permittivity.

### 3.3 Evaluation of filter criteria

As mentioned earlier in this work, for a proper application of filter criteria the grain size characteristics of the soil in contact with the geotextile have to be well determined. In the case of the residual soil investigated in the present work the value of relevant grain diameters depend on the use or not of deflocculant in the sedimentation test. Because the soil mass is mainly composed of coarse "grains" composed of clusters of particles that may or may not be dispersed by water flow or migrate through the soil

mass, the designer has to decide which grain size distribution curve should be used for design purposes. The aim of this section is to evaluate the results obtained by some design criteria available in the literature for the drain under investigation. The following filter criteria were employed: French Committee on Geotextiles and Geomembranes (CFGG, 1986), Canadian Geotechnical Society (CGS, 1992), Carroll (1983), Christopher and Holtz (1985), Giroud (1982), IRIGM (Grenoble)/Ecole Polytechnique de Montreal (Faure et al, 1986), Mlynarek et al (1990), Ontario Ministry of Transportation (OMT, 1992), University of British Columbia - UBC (Fannin et al, 1994), United States Federal Highway Administration (USFHWA, Christopher and Holtz, 1985) and United States Army Corp of Engineers (USACE, 1977). Table 6 summarises the results of filter criteria evaluation. It can be observed that most of the criteria would lead to the acceptance of the use of geotextile while only two would reject its use as filter for the residual soil. It is interesting to note that the criterion presented by Giroud (1982) would not be entirely applicable for the grain size distribution curve obtained in the sedimentation test with deflocculant because to some extent the soil could be considered as a gap graded soil by that criterion. Nevertheless, if the criterion was also applied in this case the geotextile would have failed to meet filter requirements. The geotextile may fail or not by the criterion presented in Mlynarek et al (1990) depending on the value of the apparent opening size used for the geotextile (maximum or minimum value in Table 3).

Table 6. Evaluation of filter criteria

Criterion	Grain Size Analysis	
	Without deflocculant	With deflocculant
CFGG (1986)	F	F
CGS	P	P
Carroll (1983)	P	P
Christopher & Holtz (1985)	P	P
Giroud (1982)	P	NA/F
Mlynarek et al (1990)	F/P	P
IRIGM/EPM	F	F
OMT (1992)	P	P
UBC	P	NA
USFHWA	P	P
USACE	P	P

Notes: F - geotextile failed; P - geotextile passed; NA - criterion is not applicable, F/P - failed or passed (see text for comments) and NA/F - Not applicable or failed (see text for comments).

From the results presented in Tables 1 and 5 it can be observed that the permeability coefficient of the exhumed geotextile samples is of the order of 25 times the soil permeability coefficient, which satisfies current

permeability criteria such as the ones presented by Carroll (1983), Giroud (1982) and Christopher and Holtz (1985)

### 3.4 Microscopic investigations of exhumed geotextile samples

The exhumed geotextile samples were observed under optical and electronic microscopes and photographs of some of the specimens are presented in Figures 5 to 8. In general it could be observed that the geotextile was in good conditions with the sample taken from the side wall of the drain with a greater degree of clogging but still maintaining a large amount of its openings free from soil particles, as shown in Figure 5. This is reasonable since water flow is more (or only) significant along the sides of the drain. Figure 6 shows that the grains retained in the geotextile were formed by clusters of soil particles, as commented earlier in this work. Figure 7 shows a detail of one of these clusters. These results emphasises the difficulty related to the choice of appropriate soil particle diameters to use in filter criteria for residual soils. Figure 8 shows that clay particles or clusters were also found bonded to individual geotextile fibers. Some level of damage of the geotextile fibers could be identified and may have been caused during drain construction or by the action of microorganisms. Figures 5 to 8 show that after 10 years of existence the geotextile layer is in good operational condition.

Figure 5. General view of the geotextile openings.

## 4. CONCLUSIONS

This work investigated the condition of a 10 years old geotextile drain in a residual sandy soil from quartzite. Clogging of granular drains in contact with this soil is common and nonwoven geotextiles have been successfully used as alternatives for granular drains. The main conclusions of the present work are summarised below:

. The geotextile was able to retain the fines from the residual soil and the enveloped gravel material in the drain was very clean in contrast to the contaminated gravel material in regions where geotextile layers were not used.

. Geotextile permeability tests suggest a 70% loss of the original permeability under field conditions for the drain investigated. The permeability loss observed in a laboratory filtration test was significantly greater than in the field which was probably due to the soil-geotextile system in the laboratory having been subjected to more severe conditions than the ones found in the field. The destruction of soil clusters and the consequent intensity of suffusion is also likely to be dependent of the gradient of flow.

. The investigation of the condition of the geotextile pores after 10 years of operation showed that a large amount of free pores is still available.

. Geotextile filter design for soils formed by clusters of particles is a complex task. The results presented in this work shows that the acceptance or not of a geotextile filter by current criteria or the applicability of some criteria can be even dependent of the procedure adopted in the grain size analysis of the soil. Soil chemical and mineralogical analyses are useful tools for the understanding of long term behaviour of geotextile drains in tropical soils. In spite of the encouraging results obtained in the present work, further research is required for a better understanding on the behaviour of geotextile filters in tropical soils.

# Effect of Cavities Between Soil and Geotextile Filter on Permeability

Prof. Dr. Erol Güler

Professor, Department of Civil Engineering, Boğazici University, Turkey

Emir Baran

Former M.Sc. Student, Turkey

**ABSTRACT:** During the placement of the geotextile filter, some free space can be left between the in-situ soil and the filter fabric. There is the possibility that the soil particles that separate from the soil matrix will accumulate on the surface of the filter geotextile and create an impermeable layer, which is called blinding. The aim of this study was to observe whether such blinding process really occurs. This was investigated by preparing samples with cavities of cylindrical shape. The diameters and the heights of the cavities varied. Two types of geotextiles, one of them needle-punched and the other spun-bonded, that are most commonly used as filters were used in the tests. Permeability tests conducted on the samples revealed that the presence of cavities did not cause any reduction in the permeability for the given clay and two geotextiles that have been used, compared to the permeability of the samples without cavities.

**KEYWORDS:** Blinding, Geotextile, Filtration, Permeability

## 1 INTRODUCTION

Geotextiles used for filtration and related applications should have similar functional criteria to those of aggregate filters. The fabric to soil system should permit free liquid flow across the plane of the fabric without clogging while preventing the escape of soil particles. There are several modes of failure that need to be considered in the design of a geotextile filter. The design for filtration, retention and long term clogging properties of geotextile filters has been studied by many researchers. (Giroud, 1982, Luettich et. al., 1994) Another possibility of failure is blinding. During the placement of the geotextile filter, some free space can be left between the in-situ soil and the filter fabric. There is the possibility that the soil particles that separate from the soil matrix will accumulate on the surface of the filter geotextile and create an impermeable layer. The aim of this study (Baran, 1996) was to observe whether such blinding process really occurs. This was investigated by preparing samples with cavities of cylindrical shape. The diameters and the heights of the cavities varied. Two types of geotextiles that are most commonly used as filters were used in the tests. One of the geotextiles was a needle-punched and the other a spun-bonded geotextile. Hydraulic conductivity tests were conducted on samples prepared with cavities.

## 2 METHODOLOGY

A mixture of kaolinite and bentonite clay was used in the tests. The percentages of kaolinite and bentonite were 75% and 25% respectively. Geotechnical properties of the clay mixture used in this study are given in Table 1.

In each sample, the geotextile filter was placed over gravel, and the soil sample with a cavity was placed over the

geotextile. The gravel used was a uniform sized gravel passing No. 4 sieve.

Table 1. Geotechnical properties of clay

Properties	Values
Dry unit weight( $\text{kN/m}^3$ )	15.2
Optimum water content(%)	23
Specific gravity	2.69
Activity	0.29
Smaller than 2 $\mu\text{m}$	47.1
Liquid limit(%)	85
Plastic limit(%)	25
Plasticity index(%)	60

Two types of geotextiles were used in all tests. The first one was nonwoven, needle-punched and the other one was nonwoven, spun bonded. The basic characteristics of the geotextiles used are listed in Table 2 and 3.

Table 2. Properties of spun-bonded geotextile

Properties	Test Method	Unit	Values
Unit weight	ASTM D3776	$\text{g/m}^2$	68
Thickness under 2 kPa pressure	ASTM D 1777	mm	0.36
Tensile strip test	BS/6906/1	kN/m	3.3
Permeability	EMPA/ITF	m/s	25E-04

The clay samples were prepared in an air-dried condition as a powder and mixed with each other properly before adding water to it. Then water was gradually added to the samples until the desired water content was reached. The samples prepared were allowed to sit for 24 hours to allow for the moisture to distribute evenly. All the samples were compacted at two percent dry of optimum. The compaction was conducted according to Standard Proctor compaction method as outlined in ASTM Standard D 698-78, Method A.

Properties	Test Method	Unit	Values
Unit weight	ASTM D3776	g/m <sup>2</sup>	95
Thickness under 2 kPa pressure	ASTM D 1777	mm	1.0
Tensile strip test	ASTM D 4595	kN/m	5.9
Permeability vertical under pressure 2 kN/m <sup>2</sup>	Franzius Inst.	cm/s	0.5
Permeability vertical under pressure 200 kN/m <sup>2</sup>	Franzius Inst.	cm/s	0.06

In preparation of samples which had cavities, special mold-bases as shown in Figure 1a, were laid down at the base of the compaction mold. Different mold bases with varying heights and diameters were used.

Figure 1. a) Special mold bases used to form cavities, b) Cross-section of a typical test sample

The chosen heights and diameters of the cavities were as follows: mold bases with height (h) of four mm and with height of six mm; For each height of cavity, there were three different diameters (d), twenty, forty and sixty mm.

After compaction, the mold bases under the samples were removed carefully leaving the cavities in the sample. The samples were placed over geotextile which was laid over a gravel layer because in a subsurface drainage installation, the downstream side of the geotextile is usually supported by gravel or rock. Cross section of a typical test sample is shown in Figure 1b.

Falling head permeability tests were conducted on the specimens in the molds in which they were compacted. Hydraulic head was on the average 135 cm. Measurements of the permeability tests were continued until permeability values reached an equilibrium condition.

### 3 TEST RESULTS

Permeability tests which were conducted on the samples which did not have a cavity, are given in Table 3.

Table 3. Result of permeability tests on samples without cavities

Sample type	Permeability (cm/s)
Soil only	$5.14 \times 10^{-8}$
Soil with spun-bonded geotextile	$5.58 \times 10^{-8}$
Soil with needle-punched geotextile	$7.83 \times 10^{-8}$

The results of the tests with varying cavity geometry and type of geotextile used are given in Table 4 and Table 5.

Table 4. Result of permeability tests on samples with spun-bonded geotextile, Permeability(cm/s)

Diameter (mm)	20	40	60
Height (mm)			
4	$6.80 \times 10^{-8}$	$9.03 \times 10^{-8}$	$8.55 \times 10^{-8}$
6	$8.48 \times 10^{-8}$	$1.07 \times 10^{-7}$	$9.77 \times 10^{-8}$
			$1.06 \times 10^{-7}$

Table 5. Result of permeability tests on samples with needle punched geotextile, Permeability(cm/s)

Diameter (mm)	20	40	60
Height (mm)			
4	$8.35 \times 10^{-8}$	$9.74 \times 10^{-8}$	$9.55 \times 10^{-8}$
6	$9.8.3 \times 10^{-8}$	$1.10 \times 10^{-7}$	$1.31 \times 10^{-8}$
			$1.38 \times 10^{-7}$

Permeability test results versus surface area of the cavities can be seen in Figure 2 for spun-bonded geotextiles and in Figure 3 for needle punched geotextiles. Surface area is described as the surface through which the

water leaves the soil and enters the cavity. Therefore, the surface area is calculated as the sum of the circular section plus the peripheral area of the cylindrical cavity. For spun-bonded geotextiles, increasing the diameter, increased the permeability value slightly. Further increase in diameter of the cavity did not result in further increases, instead a slight decrease was observed. Increasing the height of the cavity resulted in higher permeabilities for all diameters. When needle punched geotextiles were used, increasing the diameter revealed similar results with those of spun-bonded geotextiles when cavity height was 0.4 cm. However, increasing the cavity diameter further caused an increase in permeability for the cavity height of 0.6 cm.

Figure 2. Permeability versus cavity surface area for spun bonded geotextiles

Figure 3. Permeability versus cavity surface area for needle punched geotextiles

Permeability results for both types of geotextiles were also plotted against the volume of the cavity. The permeability results versus volume of the cavities are

shown in Figures 4 and 5 for spun-bonded and needle-punched geotextiles respectively. Similar conclusions can be drawn from these figures.

Figure 4. Permeability versus cavity volume for spun bonded geotextiles

Figure 5. Permeability versus cavity volume for needle punched geotextiles

#### 4 CONCLUSIONS

Permeability tests conducted on the samples revealed that the presence of cavities did not cause any reduction in the permeability for the given clay and the two types of geotextile that have been used compared to the permeability of the samples without cavities. A slight increase of the permeability was observed for smaller sized cavities. It was determined that the increase in the height of the cavity causes consistently an increase in the

permeability. An initial increase in the permeability was measured with an increase in the diameter. For spun bonded geotextiles, increasing the size of the cavity causes an increase in the permeability for up to a maximum permeability level. Increasing the size of cavity beyond this point slightly decreases the maximum permeability value. For needle punched geotextiles, the trend is similar for the cavity height of 0.4 cm. However, for a cavity height of 0.6 cm this reversal in behaviour is not observed and a further increase in permeability is measured with increasing cavity size. This indicates that the danger of blinding is even less for needle punched geotextiles, for the given cavity sizes.

**ABSTRACT:** This paper presents a description of the structure of nonwoven geotextiles, including the constriction size distribution curve and the opening size distribution curve, and a theoretical model that leads to a minimal required number of constrictions to ensure homogeneous opening size of the geotextile. Then, an analysis of the mechanism of filtration is presented, which quantifies the probability for a particle to be retained by (on or in) a nonwoven geotextile filter or to pass through the filter. This analysis shows that a needle-punched nonwoven geotextile filter having the minimal required number of constrictions is preferable to a thicker nonwoven geotextile filter. This leads to the concept of a two-layer geotextile filter where filtration is provided by a layer of needle-punched nonwoven material constructed with fine fibers and mechanical properties are provided by a layer of needle-punched nonwoven material constructed with coarse fibers.

**KEYWORDS:** Geotextiles, Nonwoven, Filtration, Opening size, Theory.

## 1 INTRODUCTION

Ever since geotextiles have been used as filters, filter thickness has been a subject of discussion. This paper sheds some light on the subject while providing a theoretical basis for the development of a two-layer geotextile filter. In Section 2, an analysis of the structure of nonwoven geotextiles shows that the opening size of nonwoven geotextile filters decreases with increasing thicknesses of geotextiles made from the same nonwoven material. In Section 3, an analysis of the mechanism of filtration shows that the probability for a particle to be retained by a geotextile filter depends on the thickness of the geotextile. It is concluded in Section 4 that a relatively thin needle-punched geotextile filter is desirable in many practical cases. However, a thin geotextile filter may not have the required mechanical properties to withstand mechanical damage and to resist deformations that could alter its opening size. To that end, a two-layer filter has been developed. This filter associates two layers of needle-punched nonwoven material: a layer constructed with fine fibers and having a thickness selected to provide optimal filtration characteristics; and a layer constructed with coarse fibers providing the required mechanical properties.

Figure 1. Constriction size.

## 2 STRUCTURE OF NONWOVEN FILTERS

### 2.1 Basic Definitions

#### 2.1.1 Constrictions

To pass through a nonwoven geotextile filter, a particle must pass between fibers. A constriction is a passage delimited by three or more fibers which are nearly, but not necessarily exactly, in the same plane. The size of a constriction can be defined as the diameter of the sphere which can just pass through the constriction (Figure 1). A constriction is different from a pore. Whereas a constriction is strictly defined, a pore is a loosely defined portion of the pore volume, i.e. the volume located between the fibers.

#### 2.1.2 Constriction Size Distribution Curve

If a block of nonwoven material is considered (i.e. a three-dimensional sample, not a quasi two-dimensional sample such as a geotextile), and if this block is large enough to be representative, it contains a representative set of the constrictions which exist in the considered nonwoven material. This set of constrictions is represented by a constriction size distribution curve (Figure 2, Curve C).

The constriction size distribution curve is an intrinsic characteristic of the nonwoven material. Therefore, it is related to parameters that characterize the nonwoven material (e.g. the porosity,  $n$ , and the fiber diameter,  $d_f$ ), but it is not related to parameters that depends on the geotextile, such as the geotextile thickness. Constriction sizes range from  $C_0$ , the size of the smallest constriction in the considered nonwoven material, to  $C_{100}$ , the size of the

Figure 2. Constriction size distribution curve (C) and opening size distribution curve (O) for a nonwoven geotextile.

largest constriction in the considered nonwoven material;  $C_{100}$  is such that 100% of the constrictions in the considered nonwoven material are smaller than or equal to  $C_{100}$ .

One could argue that the size of the smallest constriction is  $C_0 = 0$  because there is always the possibility that three fibers will meet at the same point, thus delimitating a passage with a zero size. However, from the viewpoint of filtration, constrictions with a size that is zero or very small should not be considered because a particle that meets such a constriction will not be stopped; instead, it will be diverted laterally. (The particles do not have to follow a straight path, and they naturally select the path of least resistance.)

### 2.1.3 Filtration Path

A soil particle that travels in a nonwoven geotextile filter follows a certain filtration path (Figure 3). A filtration path is tortuous, but its general direction is approximately perpendicular to the plane of the geotextile. As it travels along a filtration path, a particle passes through constrictions until it meets a constriction which is smaller

than it is. Unless it diverts the particle, this constriction stops the particle. The level at which a particle is stopped depends on the filtration path (Figure 3): this is an important consideration in the analysis of the filtration mechanism. Of course, if the considered particle is not stopped by a constriction, it passes through the geotextile.

### 2.1.4 Opening Size

In each filtration path, there is a constriction that is smaller than the others. This constriction plays an essential role: it determines the size of the largest particle that can pass through the geotextile following the considered filtration path. This constriction is called the *controlling constriction* of the considered path, a terminology proposed by Kenney et al. (1985) for sand filters. In a given filtration path, the size of the controlling constriction is the *opening size* of the filtration path; therefore, the opening size of a filtration path is the size of the largest particle which can travel through the geotextile filter following this filtration path.

### 2.1.5 Opening Size Distribution Curve

In a nonwoven geotextile filter, there are many filtration paths, and these paths are all different. A given particle can be stopped in a certain filtration path, but it may pass through the filter if it follows another path. Each filtration path is characterized by its opening size. Therefore, a geotextile filter is characterized by an opening size distribution curve (Figure 2, Curve O). The size of the openings of a nonwoven geotextile (i.e. the sizes of the openings of the various filtration paths of the geotextile) range from  $O_0$ , the size of the smallest opening in the considered nonwoven geotextile, to  $O_{100}$ , the size of the largest opening in the considered nonwoven geotextile. It will be shown in Section 2.2.4 that  $O_0$  is equal to  $C_0$ ;  $O_{100}$  is such that 100% of the filtration paths in the considered geotextile have openings that are smaller than or equal to  $O_{100}$ . In other words, 100% of the openings of a geotextile are smaller than or equal to  $O_{100}$ . The opening size distribution curve is a characteristic of the geotextile and, in particular, the largest opening,  $O_{100}$ , is a characteristic of the geotextile, called the *opening size of the geotextile*. The opening size of a geotextile is the size of the largest particle that can pass through the geotextile provided it migrates individually through the geotextile and it is not attracted electrostatically or otherwise to the geotextile fibers.

## 2.2 Relationship Between Constrictions and Openings

### 2.2.1 Influence of the Thickness of a Nonwoven Filter

The constriction size distribution curve is an intrinsic characteristic of the material that constitutes a geotextile whereas the opening size distribution curve is a

Figure 3. Filtration paths ( $t_{GT}$  = geotextile thickness).

characteristic of the geotextile. The relationship between the constriction size distribution curve of the material that constitutes a geotextile and the opening size distribution curve of this geotextile depends on the thickness of the geotextile. To establish the relationship between these two types of curves, three nonwoven geotextiles with different thicknesses are considered. These three geotextiles are assumed to be made with the same nonwoven material (i.e. a material characterized by a given fiber diameter, a given porosity, and a given type of fiber arrangement).

Two extreme cases will be considered first, the case of a nonwoven geotextile with a zero thickness (Section 2.2.2) and the case of a nonwoven geotextile with an infinite thickness (Section 2.2.3); then the case of a nonwoven geotextile with a finite thickness will be considered (Section 2.2.4).

### 2.2.2 Infinitely Thin Nonwoven Geotextile

In a hypothetical infinitely thin nonwoven geotextile, each filtration path has only one constriction. Therefore, the opening size of each filtration path is equal to the size of the unique constriction of this filtration path. As a result, in the case of a hypothetical infinitely thin nonwoven geotextile, the opening size distribution curve is identical to the constriction size distribution curve (Figure 4, Curve 4).

Figure 4. Opening size distribution curves for four geotextiles made from the same nonwoven material, but having different thicknesses: (1) infinitely thick, (2) thick, (3) thin, and (4) infinitely thin. (Curve 4 is also the constriction size distribution curve for the four geotextiles.)

### 2.2.3 Infinitely Thick Nonwoven Geotextile

In a hypothetical infinitely thick nonwoven geotextile, each filtration path contains an infinite number of constrictions. Therefore, in this case, there is a 100% probability that all constriction sizes are present in each filtration path. Thus, each filtration path contains the smallest constriction,  $C_0$ . When a filtration path contains the smallest constriction, this constriction is the controlling constriction. Therefore,

in a hypothetical infinitely thick nonwoven geotextile, all filtration paths have the same controlling constriction, hence the same opening size ( $O_0 = O_n = O_{100} = C_0$ , where  $0 < n < 100$ ). As a result, the opening size distribution curve of this geotextile is a vertical line (Figure 4, Curve 1). In other words, in a hypothetical infinitely thick nonwoven geotextile, all filtration paths have the same opening size, which is the opening size of the geotextile and which is equal to the smallest constriction size.

### 2.2.4 Nonwoven Geotextile Having a Finite Thickness

The case of a nonwoven geotextile having a finite thickness is considered. Elementary calculations show that, in typical nonwoven geotextiles, the number of filtration paths is greater than  $1000/\text{cm}^2$ . Therefore, if the considered specimen is large enough to be representative, it contains a very large (quasi infinite) number of filtration paths. The probability that at least one filtration path contains the smallest constriction is virtually 100%. When a filtration path contains the smallest constriction,  $C_0$ , this constriction is the controlling constriction, i.e. the opening size of the filtration path. A filtration path which has an opening size equal to the size of the smallest constriction is, of course, a filtration path that has the smallest opening size. Therefore,  $O_0 = C_0$  (Figure 2).

In a given filtration path, the number of constrictions, in the case of a typical nonwoven geotextile, is not very large (for example, between 10 and 50, as indicated in Section 2.3.3). Therefore, the probability that the smallest constriction is present in all filtration paths is smaller than 100%. As a result, a certain number of filtration paths have a controlling constriction (i.e. an opening size) greater than  $C_0$ . Therefore,  $O_n > C_0$ .

The largest constriction size is  $C_{100}$ ; therefore, the largest possible opening size is  $C_{100}$ . However, for a filtration path to have such an opening size, would require that all the constrictions of this filtration path be equal to  $C_{100}$ . But, in a given filtration path, the probability that all the constrictions are identical is virtually zero. Therefore, the maximal opening size that a filtration path may have (i.e. the opening size of the geotextile) is smaller than the maximal constriction size. Therefore,  $O_{100} < C_{100}$ .

The relationship, demonstrated above, between the constriction size distribution curve and the opening size distribution curve of a nonwoven geotextile having a finite thickness is illustrated in Figure 2. The opening size distribution curves of two nonwoven geotextiles with a finite thickness are shown in Figure 4: Curve 2 for a relatively thick geotextile and Curve 3 for a relatively thin geotextile. In Figure 4, it is important to note that Curve 4, which is the opening size distribution curve for the hypothetical infinitely thin nonwoven geotextile, is also the constriction size distribution curve for all four nonwoven geotextiles made with the same nonwoven material.

## 2.3 Theoretical Model of Nonwoven Geotextile Filters

### 2.3.1 Description of Chart

A theoretical model of the structure of nonwoven geotextiles (Giroud 1996) made it possible to develop a chart (Figure 5) that provides relationships between the following parameters: the geotextile opening size,  $O_{100}$ , the thickness of the geotextile,  $t_{GT}$ , the diameter of the fibers,  $d_f$ , and the porosity of the geotextile,  $n$  (solid curves for a given value of the porosity, and dashed curves for a given value of  $\mu_{GT}/(\rho_f d_f)$  where  $\mu_{GT}$  = geotextile mass per unit area,  $\rho_f$  = fiber density, and  $d_f$  = fiber diameter). This chart is in good agreement with the results of numerous tests performed on needle-punched (and some heat-bonded) nonwoven geotextile filters (Giroud 1996). The chart also gives an approximate value of the average number of constrictions,  $m$ , that a particle traveling through a nonwoven geotextile filter can be expected to pass through (dotted curves in Figure 5).

Figure 5. Chart giving three relationships between the geotextile opening size/fiber diameter ratio and the geotextile thickness/fiber diameter ratio for nonwoven geotextile filters.

### 2.3.2 Size of Constrictions

The chart in Figure 5 shows that, for a given nonwoven material characterized by its porosity,  $n$ , the opening sizes of geotextiles having different thicknesses made with this nonwoven material decrease for increasing thicknesses (solid curves) and tend to reach an asymptote as the

geotextile thickness (and the geotextile mass per unit area) tend toward infinity. The horizontal asymptotes of the solid curves in Figure 5 correspond to the case of the hypothetical infinitely thick nonwoven geotextile used in the demonstrations presented in Section 2.2.3. Therefore, the geotextile opening size that corresponds to the horizontal asymptotes in Figure 5 is a theoretical value of the smallest opening size,  $O_0$ , and the smallest constriction size,  $C_0$  ( $O_0 = C_0$ , as demonstrated in Section 2.2.4). On the other hand, the chart does not provide information on the size of the largest constrictions ( $C_{100}$ ) because the theoretical model used to establish the chart presented in Figure 5 is not valid for extremely small values of the geotextile thickness/fiber diameter ratio (e.g.  $t_{GT} / d_f < 10$ ); in other words, the chart presented in Figure 5 cannot represent the case of the hypothetical infinitely thin nonwoven geotextile discussed in Section 2.2.2.

### 2.3.3 Influence of the Number of Constrictions

In Section 2.2, the parameter used to compare geotextiles was the geotextile thickness. This was appropriate because the geotextiles considered had the same porosity and fiber diameter. In Sections 2.3.3 and 2.3.5, it will be seen that the appropriate parameter to compare nonwoven geotextiles having different porosities and/or fiber diameters is the number of constrictions.

The difference  $O_{100} - O_0$  between the geotextile opening size,  $O_{100}$  (i.e. the size of the largest opening of the geotextile), and the value of the asymptote of the solid curves in Figure 5,  $O_0$  (i.e. the size of the smallest opening of the geotextile), characterizes the homogeneity of the geotextile filter with respect to opening size: a small value of  $O_{100} - O_0$  indicates an homogeneous geotextile, whereas a large value indicates an heterogeneous geotextile. The chart in Figure 5 shows that, for less than approximately 15 constrictions ( $m < 15$ ),  $O_{100} - O_0$  is large, whereas, when the number of constrictions is greater than approximately 25 to 30,  $O_{100} - O_0$  is small and does not significantly decrease with increasing geotextile thicknesses. Therefore, it may be *qualitatively* said that: (i) to avoid using an heterogeneous geotextile filter, the number of constrictions should be greater than 15; and (ii) in cases where a very homogenous geotextile filter is required, the number of constrictions should be greater than approximately 25-30.

A very homogenous filter is required in cases, such as bank protection systems, where a large amount of particles must pass through the filter to ensure filtration while minimizing the risk of clogging. Indeed, in these cases, if the range of opening sizes of the filter is large, there is a high probability that the filter will stop some particles smaller than the geotextile opening size,  $O_{100}$ .

An attempt to *quantitatively* determine the required value of the number of constrictions consisted of performing the four following calculations (not shown

here, but to be published elsewhere): (i) the derivative of  $(O_{100} - O_0) / d_f$  with respect to  $t_{gr} / d_f$ ; (ii) the derivative of  $(O_{100} - O_0) / d_f$  with respect to  $\mu_{gr} / (\rho_f d_f)$ ; (iii) the ratio  $(O_{100} - O_0) / d_f$ ; and (iv) the ratio  $(O_{100} - O_0) / O_0$ . These four calculations gave four relationships between the geotextile porosity and the minimal values required for the number of constrictions,  $m$ , to ensure that  $O_{100} - O_0$  does not vary significantly as a function of the considered parameter, i.e.  $t_{gr} / d_f$ ,  $\mu_{gr} / (\rho_f d_f)$ ,  $d_f$ , or  $O_0$ . A parametric study, based on these four relationships, showed that the required minimal number of constrictions is of the order of 15 to 40 depending on the geotextile porosity and the considered parameter, with numbers of constrictions equal to or greater than approximately 25-30 being required to obtain a very homogeneous filter.

### 2.3.4 Influence of Geotextile Porosity

The chart presented in Figure 5 shows that the porosity of the nonwoven *material* has a large influence on the geotextile opening size. Nonwoven *materials* that have the same porosity and fiber arrangement are said to have the same structure. They are represented by a curve  $n = \text{constant}$  in Figure 5. Nonwoven *materials* that have the same structure differ only by the diameter of the fibers; and their constriction sizes are proportional to the fiber diameter. Thus, for nonwoven *geotextiles* made with nonwoven *materials* that have the same structure, the constriction size distribution curves: (i) are proportional to the fiber diameter; and (ii) consequently, in the traditional semi-logarithmic axes, are derived from one another by translations. Nonwoven *geotextiles* that have the same structure differ in general by their thickness; these geotextiles have the same constriction size distribution curve but different opening size distribution curves.

A parametric study, based on the theoretical model described in Section 2.3, showed that the geotextile porosity has a significant influence on the opening size values that can be achieved. The usually required opening sizes (e.g. 70 to 200  $\mu\text{m}$ ) can be provided economically (i.e. using relatively fine fibers and relatively small masses per unit area) by a nonwoven geotextile that has the minimal number of constrictions mentioned in Section 2.3.3 (i.e. 25-30) if the geotextile porosity is in the 0.85 to 0.95 range, which is typical for needle-punched nonwoven geotextiles, whereas nonwoven geotextiles with porosities smaller than 0.7 would require very coarse fibers and/or very large masses per unit area to have the usually required opening sizes while meeting the above minimal number of constrictions. The parametric study also showed that, with the typical porosities of needle-punched nonwoven geotextiles, it is possible to obtain geotextile opening sizes of the order of 80  $\mu\text{m}$  by using fibers having a diameter of 25  $\mu\text{m}$ , and of the order of 150  $\mu\text{m}$  or more by using fibers having a greater diameter (e.g. 30 to 50  $\mu\text{m}$ ).

### 2.3.5 Importance of Constrictions

A parametric study, based on the theoretical model described in Section 2.3, showed that nonwoven geotextiles having the same number of constrictions and the same opening size ( $O_{100}$ ) have approximately the same opening size distribution curve regardless of the values of the geotextile porosity and fiber diameter (provided, of course, that the appropriate relationship exists between porosity and fiber diameter to achieve the given  $O_{100}$ ). This important finding shows that the number of constrictions is the most significant parameter for comparing geotextile filters. Also, when two nonwoven geotextiles have approximately the same opening size distribution curve, they have approximately the same constriction size distribution curve because approximately identical cumulative probability curves (i.e. the opening size distribution curves) must be based on approximately identical statistical sets (i.e. the constrictions).

## 3 ANALYSIS OF THE FILTRATION MECHANISM

### 3.1 Filtration Probabilities

Consider the two curves defined in Section 2.1, the constriction size distribution curve (which characterizes the material of which the geotextile is made) and the opening size distribution curve (which characterizes the geotextile). Both curves are cumulative probability curves. Thus, the constriction size distribution curve gives the probability,  $P_c$ , that a particle of size  $d$  will be retained at the surface of the geotextile and, correlatively, the probability,  $1 - P_c$ , that the particle will not be retained at the surface of the geotextile (Figure 6). The particles which are not retained at the surface of the geotextile either are retained in the geotextile or pass through the geotextile, and the opening size distribution curve gives the probabilities related to these two possibilities: the opening size distribution curve gives the probability,  $P_o$ , that a particle will be retained by (on or in) the geotextile and, correlatively, the probability  $1 - P_o$  that a particle will not be retained, i.e. will pass through the geotextile (Figure 6). Thus, the following probabilities can be defined: probability that a particle will pass through the geotextile,  $P_{\text{PASS}} = 1 - P_o$ ; probability that a particle will be retained in the geotextile,  $P_{\text{IN}} = P_o - P_c$ ; probability that a particle will be retained on the geotextile,  $P_{\text{ON}} = P_c$ ; and probability that a particle will be retained by (on or in) the geotextile,  $P_{\text{RETAIN}} = P_o = P_{\text{ON}} + P_{\text{IN}}$ .

Four situations can be considered depending on the size,  $d$ , of a particle relative to the extremities of the two curves ( $O_0$ ,  $O_{100}$ ,  $C_0$  and  $C_{100}$ ): (i) if  $d > C_{100}$ , the particle is retained at the surface of the geotextile because, in this case, there is no constriction larger than  $d$  ( $P_{\text{RETAIN}} = P_{\text{ON}} = 1 = 100\%$ ,  $P_{\text{PASS}} = 0$ ); (ii) if  $O_{100} < d < C_{100}$ , the particle cannot pass

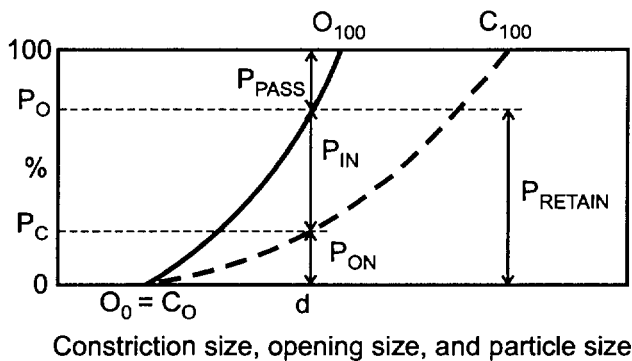

Figure 6. Probability that a particle will pass through a geotextile or will be retained in or on the geotextile.

through the geotextile because there is no filtration path with an opening size greater than  $d$ , and the particle either moves into the geotextile until it meets a constriction that stops or it remains at the surface of the geotextile if it happens that the constriction that stops it is at the geotextile surface ( $P_{\text{RETAIN}} = P_{\text{ON}} + P_{\text{IN}} = 1 = 100\%$ ,  $P_{\text{PASS}} = 0$ ); (iii) if  $O_0 < d < O_{100}$ , the particle has all of three possibilities, it can be retained in or on the geotextile or it can pass through the geotextile ( $P_{\text{ON}} + P_{\text{IN}} + P_{\text{PASS}} = 1 = 100\%$ ); and (iv) if  $d < O_0$ , the particle passes through the geotextile ( $P_{\text{RETAIN}} = 0$ ,  $P_{\text{PASS}} = 1 = 100\%$ ).

### 3.2 Influence of Number of Constrictions on Filtration

In Section 2.3.3, it was shown that a minimal number of constrictions of 25-30 was required to ensure that the geotextile filter is very homogenous. The filtration analysis that follows shows that a greater number of constrictions may be more detrimental than beneficial.

The probabilities indicated in Section 3.1 and illustrated in Figure 6 can be used to compare the mode of particle retention by different geotextiles. Retention is a complex mechanism that includes the *retention* of skeleton particles and the *non-retention* of fine particles (Giroud 1996). Therefore, two particles will be considered: a skeleton particle of size  $d_s$ , which should be retained (Section 3.2), and a fine particle of size  $d_p$ , which should not be retained (Section 3.3). As indicated by Giroud (1996), skeleton particles are retained by a filter if the filter opening size is equal to or less than  $\lambda d_s$ , where  $\lambda$  is a factor greater than one that accounts for particle bridging (hence a "factored size",  $\lambda d_s$ , for the skeleton particles).

Two nonwoven geotextiles with the same opening size,  $O_{100}$ , are compared in Figure 7. This is a typical situation faced by a designer who has to make a choice between two apparently equivalent geotextile filters. These two geotextiles are assumed to have different opening size distribution curves and, consequently, they have different values of  $O_0$  and  $O_{100} - O_0$ . Therefore, they have different

Figure 7. Probabilities of retention of two particles, one being a skeleton particle of size,  $d_s$ , the other being a fine particle of size,  $d_p$ , by two nonwoven geotextile filters having the same opening size,  $O_{100}$ , and having: (a) 30 constrictions ; (b) 60 constrictions.

numbers of constrictions, according to Section 2.3.3. The geotextile represented in Figure 7a has 30 constrictions, i.e. a number of constrictions sufficient to ensure that the geotextile filter is very homogenous (see Section 2.3.3), whereas the geotextile represented in Figure 7b has 60 constrictions. These two geotextiles, having a different  $O_0$ , have different constriction size distribution curves. Combining the demonstrations presented in Sections 2.3.4 and 2.3.5 shows that the two constriction size distribution curves must be derived from one another by translation in the traditional semi-logarithmic axes. It is seen in Figure 7 that a particle of size  $d_s$  such that its factored size is greater than the geotextile opening size ( $\lambda d_s > O_{100}$ ), as should be the case if the filter is properly designed, is: (i) more likely to be retained *on* the geotextile in the case of a nonwoven geotextile filter having 30 constrictions than in the case of a nonwoven geotextile filter having a greater number of constrictions; and (ii) correlatively more likely to be retained *in* the geotextile in the case of a nonwoven geotextile filter having 60 constrictions than in the case of a nonwoven geotextile filter having 30 constrictions. Skeleton particles move less and, therefore, the skeleton structure is less disturbed if more particles are retained *on* than *in* the geotextile filter (see Section 2.1.3 on the level at which a particle is stopped). Also, if, as a result of a design error or an unexpected variation of the soil characteristics, the skeleton particle factored size is smaller than the filter

opening size ( $\lambda d_s < O_{100}$ ), Figure 7 shows that less skeleton particles pass through the geotextile filter in the case of the filter having 30 constrictions than in the case of the filter having more constrictions.

From the above analysis, it appears that a nonwoven geotextile filter having 30 constrictions is preferable to a nonwoven geotextile filter having more constrictions because: (i) in the normal case where the soil skeleton particle factored sizes are greater than the geotextile opening size, the nonwoven geotextile filter having 30 constrictions retains soil skeleton particles with less disturbance of the skeleton structure than a nonwoven geotextile filter having more constrictions; and (ii) in the case where (as a result of a design error or an unexpected variation of the soil characteristics) the soil skeleton particle factored sizes are smaller than the geotextile opening size, the nonwoven geotextile filter having 30 constrictions is more likely to retain skeleton particles than a nonwoven geotextile filter having more constrictions.

### 3.3 Influence of Porosity and Fiber Diameter

As pointed out at the beginning of Section 3.2, it is important not only to retain the skeleton particles, but also *not to retain* the fine particles that must pass through the filter to prevent clogging. To that end, the smallest geotextile opening size,  $O_0$ , must be larger than a minimal value which can be determined as follows.

According to Mitchell (1970), grout particles flow easily through a soil being grouted if they are smaller than 1/25 times the  $d_{15}$  of the soil, i.e. smaller than 1/5 times the size of openings between the soil particles, since openings in granular materials are approximately equal to  $d_{15}/5$  according to Kenney et al. (1985). This may be adapted to geotextile filters as follows. The soil particles most likely to cause filter clogging are the particles that may exhibit cohesion and may, therefore, adhere to fibers or to other particles. Particles that may exhibit cohesion are the particles smaller than approximately 5  $\mu\text{m}$ . Therefore,  $O_0$  should be greater than approximately 25  $\mu\text{m}$ .

A parametric study based on the model presented in Section 2.3 showed that  $O_0$  significantly depends on the geotextile porosity and fiber diameter and that, for usual values of needle-punched nonwoven geotextile porosity and fiber diameter,  $O_0$  is always significantly greater than 25  $\mu\text{m}$ . Therefore, the typical particles likely to cause clogging should pass easily through usual needle-punched nonwoven geotextile filters. Thus, it appears that the *non-retention* of fine particles is a criterion that is easily met by usual needle-punched nonwoven geotextile filters.

In conclusion, the comparison between two needle-punched nonwoven geotextile filters should be made essentially on the basis of the *retention* of the skeleton particles and not on the basis of the *non-retention* of fine particles. This approach is used in Section 3.4.

### 3.4 Retention of a Non-Uniform Soil

The method illustrated in Figure 7 can be extended to the case where the size of the skeleton particles ranges within two known limits (non-uniform soil). This case is illustrated in Figure 8, which shows that the various retention probabilities are proportional to areas delimited by the constriction size distribution curve and the opening size distribution curve. Figure 8 leads to the same conclusions as Figure 7: (i) in the case where all of the skeleton particles are greater than the opening size of the filter ( $d_s > O_{100}$ ), the skeleton particles are more likely to be retained *on* a nonwoven geotextile having 30 constrictions than *on* a nonwoven geotextile having more constrictions; and (ii) in the case where the range of skeleton particles includes sizes that are smaller than the opening size of the filter ( $d_s < O_{100}$ ), the amount of skeleton particles likely to pass through a nonwoven geotextile filter having 30 constrictions is smaller than through a nonwoven geotextile filter having more constrictions. Essentially, Figure 8 shows that a nonwoven geotextile filter having 30 constrictions is more reliable than a nonwoven geotextile filter having more constrictions because it is less sensitive to variations of the soil particle size distribution curve.

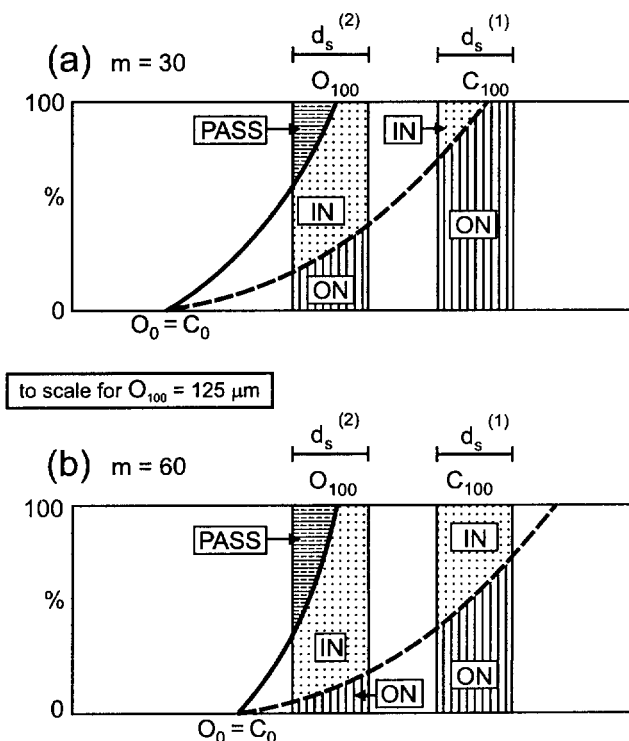

Figure 8. Probabilities of retention of skeleton particles by two nonwoven geotextiles having the same opening size,  $O_{100}$ , but having different numbers of constrictions : (a)  $m = 30$ ; (b)  $m = 60$ . Two soils are considered: (1) all of the skeleton particles are larger than  $O_{100}$ ; (2) some of the skeleton particles are smaller than  $O_{100}$ .

#### 4.1 Concept of Two-Layer Filter

Based on the analyses and discussions presented in Sections 2 and 3, a needle-punched nonwoven geotextile filter having approximately 25 to 30 constrictions is recommended for applications where a very homogenous filter is required. However, while such a geotextile can provide adequate filtration performance, it may not have the required mechanical properties to withstand mechanical damage and to resist deformations that could alter its opening size. Based on these considerations, a series of two-layer filters has been developed. These filters associate two layers of needle-punched nonwoven material: a functional layer constructed with fine fibers and having the required thickness to provide approximately 25 to 30 constrictions for optimal filtration characteristics; and a protective layer constructed with coarse fibers providing the required mechanical properties to protect the layer of fine fibers. For example, in one of the filters of the series, the fiber diameter is 25  $\mu\text{m}$  for the fine fibers and 50  $\mu\text{m}$  for the coarse fibers, each of the two layers having a mass per unit area of 200  $\text{g}/\text{m}^2$ , hence a total mass per unit area of 400  $\text{g}/\text{m}^2$  for the two-layer nonwoven geotextile filter.

#### 4.2 Opening Size of a Two-Layer Geotextile Filter

To minimize the risk of clogging, particles that pass through the layer of fine fibers should pass easily through the layer of coarse fibers. To that end, the opening size of the layer of coarse fibers must be significantly larger than the opening size of the layer of fine fibers. If this condition is met, only the layer of fine fibers must be considered when filter criteria are used, i.e. there is no need for special filter criteria for two-layer geotextile filters if there is a large difference of opening sizes between the two layers; the relationship between the opening sizes of the two layers depends on several parameters (such as porosity, thickness, and fiber diameter) and it is necessary to check on a case-by-case basis that the opening size of the layer of coarse fibers is much larger than the opening size of the layer of fine fibers. This can be done using the chart presented in Figure 5. For example, in the case of the two-layer geotextile filter described in Section 4.1, the following values are obtained: (i) for a fine fiber layer having a mass per unit area of 200  $\text{g}/\text{m}^2$ , a fiber diameter of 25  $\mu\text{m}$  and a porosity of 0.87: number of constrictions, 25; thickness, 1.7 mm; and opening size, 70  $\mu\text{m}$ ; and (ii) for a coarse fiber layer having a mass per unit area of 200  $\text{g}/\text{m}^2$ , a fiber diameter of 50  $\mu\text{m}$  and a porosity of 0.87: thickness, 1.7 mm; and opening size, 190  $\mu\text{m}$  (the number of constrictions is irrelevant for the coarse fiber layer). It appears that, for the considered two-layer geotextile, there is a large difference between the opening sizes of the two layers.

This paper shows that the performance of nonwoven geotextile filters is significantly influenced by the porosity of the nonwoven material and the thickness of the geotextile. Both parameters govern the number of constrictions, i.e. the number of passages between fibers that a particle has to go through. An analysis of the structure of nonwoven geotextiles (Section 2) shows that a number of constrictions equal to or greater than approximately 25 to 30 should ensure homogeneity of the filtration characteristics. An analysis of the filtration mechanism (Section 3) shows that the probabilities for soil particles to be retained by, or to pass through, a geotextile filter can be derived from a comparison of the constriction size distribution curve of the geotextile material and the opening size distribution curve of the geotextile. The analysis shows that, in the practical situations reviewed, a better performance may be expected from a nonwoven geotextile filter with approximately 25-30 constrictions than from a nonwoven geotextile filter with more constrictions. These considerations led to the development of two-layer nonwoven geotextile filters. However, in addition to providing the theoretical basis for the development of two-layer filters, this paper shows that considerable information is now available regarding the structure of nonwoven geotextiles and the understanding of filtration mechanisms in geotextiles. In particular, this paper shows that, to analyse filtration mechanisms, it is necessary to use the entire opening size distribution curve, and not only the geotextile opening size, and that it is also necessary to use the constriction size distribution curve. This should open up the way to new filter design methods.

#### ACKNOWLEDGMENTS

The authors express their gratitude to K.L. Soderman for his comments, and to K. Holcomb and S.L. Berdy for their assistance in the preparation of this paper.

**ABSTRACT:** Particle removal in municipal water treatment involves adsorption, sedimentation and filtration. The particles vary from materials in true solution to coarse suspensions and range in size from colloidal materials to coarse particles. This research explores the use of nonwoven geotextiles to enhance a pretreatment, screening procedure prior to rapid sand filtration. Laboratory and field tests were conducted to determine long term filtration efficiencies for a polypropylene, needlefelt fabric at a municipal water treatment plant.

Removal efficiency of particles was determined by particle counting. Scanning electron microscopy was used to elucidate the filtration process. A variety of capture phenomena are involved for suspended particles less than 20  $\mu\text{m}$ : entrapment, surface attraction and aggregation. This research shows that a nonwoven fabric with openings of 300  $\mu\text{m}$  can successfully remove particles less than 10  $\mu\text{m}$ . This innovative work represents new technology and is an opportunity for new markets for traditional needlefelt and new geotextiles. In this application these textiles would be better named aquatextiles.

## 1 INTRODUCTION

Since their inception in the early 1970's geotextiles have become widely used in geotechnical applications. New markets for geosynthetics have concentrated on third generation: textiles designed for specific installations. Use of woven and nonwoven geotextiles has increased in what have now become traditional applications. This research project was designed to study new uses for conventional geotextiles in water treatment engineering rather than in geotechnical engineering. Innovative applications could open new markets for standard and new geotextile fabrics.

The objective of this research was to explore the possibility of using geotextile materials in filtration operations in municipal water treatment. Geotextiles have been used successfully in subsurface drainage applications since 1970 and it appeared possible to transfer that technology to the area of water treatment. Geotextiles appear to be promising filter media due to the variety of fibers and fabric constructions available commercially.

Liquid-particle separation in potable water treatment involves a wide range of techniques broadly divided into filtration and sedimentation. The main purposes of separation are to decrease waterborne disease through reduction in the number of harmful microorganisms and to increase aesthetics through reduction of suspended solids. Filtration in water treatment differs markedly from subsurface filtration/drainage applications in that the concentration of suspended particles is low and the volume of water flowing through a filter is very high.

The research project involved four components: development of a laboratory protocol for using textiles as a water filtration medium, testing a variety of geotextiles as possible media choices, development of a long term, field testing protocol and field testing at a municipal water treatment plant. The objective of this paper is to report the results of field testing where geotextiles were used for particulate removal at a municipal water treatment plant.

## 2 MATERIALS AND METHODS

### 2.1 Screening Studies

In the initial laboratory evaluation of potential fabrics a filtration device was designed which consisted of a simple filter apparatus with a constant pressure drop (Richards *et al.*, 1997). The particulate suspension used was the test dust for the American National Standard/NSF International Standard for Drinking Water Treatment Units at a concentration of 10 mg/L. Eleven polypropylene geotextiles were tested in the laboratory and six fabrics were selected for additional laboratory testing at a water treatment plant. One fabric was chosen for further testing and the filtration device was modified to meet the demands of long term, field testing (Figure 1). The apparatus consisted of a peristaltic pump set to give a constant flow, the filtering device, a surge tank and a constant pressure drop tank. Change in pressure was measured with a float device in the surge tank, which was connected to a

Lakewood datalogger. The filtration device consisted of an enclosed glass funnel with exit ports for air bubbles. The fabric sample was placed at the center of the funnel, resting on a wire mesh.

Figure 1. Profile view of experimental equipment for field testing in a municipal water treatment plant.

## 2.2 Fabric

The fabric selected for long term testing was a needlepunched, nonwoven, polypropylene fabric. The fabric mass and thickness as measured in the laboratory were 457 g/m<sup>2</sup> and 4.14 mm under a load of 2 kPa. The manufacturer's specification states a permittivity of 0.7 sec<sup>-1</sup> at a flow rate of 34 L/(m<sup>2</sup>s) and an apparent opening size of 300 μm. This is a relatively thick, standard goetextile which is commonly used for underground drainage applications.

## 2.3 Experimental Procedure

The treatment steps at the Rossdale Water Treatment Plant located on the Saskatchewan River follow a standard procedure for municipal water purification (Figure 2). A coarse screening to remove large debris is followed by alum/polymer flocculation and coagulation to remove

suspended particles. The water is softened with lime and the calcium carbonate precipitate over 20 μm in size settles through tube settlers in a still basin. There are additions of carbon dioxide to adjust the pH after softening, of chlorine for disinfection and of fluorine prior to final settling in the contactor basin. Filtration through a sand filter is the final treatment step prior to distribution to the city.

For this experimental program the influent was taken from the beginning of the contactor basin, after the addition of carbon dioxide, chlorine and fluorine. Of interest in this research were the particles in the water after softening, predominantly calcium carbonate, with sizes 20 μm or less, not including submicron sized particles. The influent was pumped from the still basin to the equipment, in excess of that needed for the testing, to keep the velocity of the influent constant at 10 m<sup>3</sup>/(m<sup>2</sup>hr). Testing was conducted from October to December in 1996 at the Aqualta Rossdale Water Treatment Plant in Edmonton, Alberta, Canada.

## 2.4 Influent Characteristics

The influent remained relatively constant with respect to the distribution of particle sizes, from 1 μm up to and including 20 μm, but varied with respect to the number of particles from day to day and within a given experiment. During the testing period the total number of particles/mL varied from 2,090 to 20,370. The distribution of particles showed a peak at the five μm size, with the number of 15 and 20 μm particles remaining relatively constant. During each run of 6 to 11 hours there would be a change in influent over time with one or two peak periods. There was no consistency for the time during the day for the peaks and they did not relate to plant operations. Figure 3 illustrates the change in influent over time for Run 30.

## 2.5 Removal

Filter performance is measured by effluent water quality. Removal efficiency, expressed by percent removal for the number of particles of a given size, was determined by particle counting with an HIAC/ROYCO Model 8000A particle counter. Particles less than 20 μm were

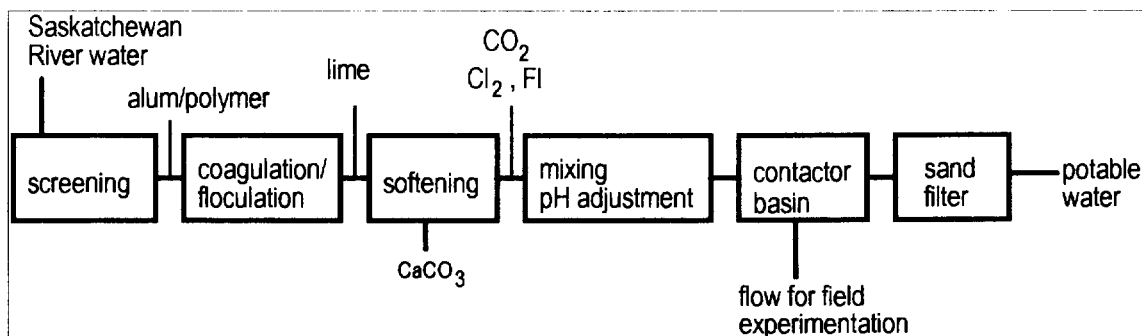

Figure 2. Steps in the municipal water treatment process at the Aqualta Rossdale Water Treatment Plant, Edmonton, Alberta,

counted. Four and five  $\mu\text{m}$  particle removals were of particular interest as the *Cryptosporidium parvum* cyst which causes Cryptosporidiosis (diarrhea) is about 4  $\mu\text{m}$  in diameter.

Figure 3. Change in influent particle size over time, Run 30, December 12, 1996.

### 3 FIELD TEST RESULTS

#### 3.1 Removal

Removal of particles varied with time. For each experimental run there was an initial period of adjustment, followed by an increase in removal to a peak of removal efficiency, and then declining removal. The time of peak removal for different runs varied between 0.5 to 3.5 hours (Figure 4).

Figure 4. Removal efficiency over time showing the periods of initial adjustment, peak removal and declining removal for one layer of fabric, Run 30.

Examination of removal curves for all runs shows a similar pattern. The removal pattern is not smooth but shows a zigzag shape, especially after 4.5 hours. It appears that when the particulate loading on the filter reaches a critical level, particles detach from the fibers. The fabric is then able to capture particles more efficiently with a subsequent increase in removal efficiency. When the fabric is again unable to hold more particles the particles are detached. However, gradually the removal efficiency of the filter decreases with time. Varying the thickness of the filter layer by using additional layers of fabric increased the removal efficiency slightly.

#### 3.2 Headloss

There was an increase in headloss with time as shown in Figure 5. As the number of layers of fabric increased, the headloss increased. An examination of the patterns of increased head required to maintain a constant flow velocity showed variations between runs as well as with the number of layers of fabric. An examination of headloss increase with the cumulative number of particles captured showed a consistent pattern. The cumulative number of 2 to 5  $\mu\text{m}$  sized particles increased and then levelled off. The cumulative number of particles over 10  $\mu\text{m}$  continued to increase with time. When this data is compared to the patterns of headloss it is the larger particles, the 10 to 20  $\mu\text{m}$  particles, which determine headloss.

Figure 5: Pattern of headloss with one and two layers of fabric for concurrent tests, Run 30.

#### 3.3 Scanning Electron Microscope

An Hitachi 2-2500 scanning electron microscope was used to examine fabric specimens after filtration. Examination of the photomicrographs showed an increasing number of particles captured with time (Figure 6). At the end of a filtration run the fabrics were loaded with calcium carbonate particles which were attached to

the surface of the fibers. Cracks or roughness on the surface of the fibers also served as anchoring points for the calcium carbonate. As time increased an aggregation of small particles was observed.

#### 4 DISCUSSION

While particle counting is a useful technique for measuring filtration efficiency it is the SEM analysis which elucidates the capture phenomena. SEM analysis shows a variety of removal phenomena of the suspended particles. It is postulated that the transport mechanisms of interception, inertia and sedimentation occur. The attachment mechanisms involve surface attraction between the calcium carbonate and the polypropylene fibers. In addition there appears to be entrapment of the calcium carbonate between adjacent fibers and aggregation of the particles on the fibers and between adjacent fibers. Detachment mechanisms were thought to be the result of particle shearing and scour due to an increase in interstitial fluid velocity.

The retention of particles less than 10  $\mu\text{m}$  by nonwoven fabrics suggests that these fabrics could be used to enhance traditional water treatment practices when the influent contains suspended particles. While ideally a filter medium would remove all 4 and 5  $\mu\text{m}$  sized particles to ensure removal of the *Cryptosporidium parvum* cysts, removal of 40% of this sized particles puts a decreased load on the sand filter. By placing a needlefelt fabric upstream of a sand filter the filtration run of the sand filter can be extended, thus increasing run length and efficiency.

#### 5 CONCLUSIONS

1. Nonwoven geotextiles show sufficient removal

Figure 6. Scanning electron photomicrographs. Various times of capture of calcium carbonate particles a) 1.0 hour (Run 29), b) 10.75 hours (end, Run 29). c) Capture phenomena of surface attachment  $\rightarrow$ , entrapment  $\blacktriangleright$ , and aggregation  $\Rightarrow$ .

performance, for limited time periods, to be of interest as a potential medium for removal of 2 to 10 micron particles in water treatment applications. It is suggested that these textiles be termed aquatextiles, rather than geotextiles.

2. The removal over time of 2 to 10 micron particles is a function of the particle size. There appears to be a limit to the amount of particles that a nonwoven fabric can hold that is specific to each particle size. Near this limit the retention of particles becomes somewhat unstable.

3. A polypropylene fabric with an apparent opening size of 300 microns effectively captured 2 to 20 micron particles. The influence of fabric structure and fiber composition on removal will be a promising area of filtration research.

4. Increasing the thickness of the fabric layer through using two layers of fabric increased particulate removal.

5. The use of nonwoven textiles in water treatment filtration applications will offer new markets for traditional geotextile fabrics as well as an opportunity to develop new fabrics with better capture properties.

#### ACKNOWLEDGEMENTS

The authors wish to thank: Mr. Riyaz Shariff and the operators at the Aqualta Rosedale Water Treatment Plant, Edmonton, Alberta; Dr. Ming Chen, University of Alberta, for his supervision of the electron microscope work; and Mr. J. Dobroseilski of AMOCO Fabrics and Fibers Company for supplying the experimental fabrics.

# Turbulence and dynamics in the falling head test

Adam Bezuijen

Sen. Consultant, Delft Geotechnics, Delft, the Netherlands.

**ABSTRACT:** The falling head test is elaborated theoretically. A closed form solution is presented for the course of the head loss in time during such a test, neglecting the contribution of inertia. Furthermore the influence of the mass of the oscillating water column is investigated. The governing equations are presented. Simulations with these equations show good agreement with the results of measurements. The results of calculations show that dynamics can have a distinct influence on the result of the test. Not only if oscillations are observed in the head loss over the geotextile, but also if only a monotone descending head loss is found in the test.

**KEYWORDS:** Laboratory tests, Permeability, Falling head test, Forchheimer, Inertia effects.

## 1 INTRODUCTION

A falling head test can be performed quicker than a constant head test. Electronic data acquisition equipment is necessary for the falling head test, but the price for this equipment decreases every year. Inter laboratory tests have shown that comparable results can be obtained with both tests. Both tests are incorporated in the CEN-Norm "Water flow capacity perpendicular to the plane, without load" prEN 12040 of the TC189 "Geotextiles" (CEN, 1955). It therefore can be expected that the falling head test will be used more and more in the future.

The principle of the falling head test is shown in Figure 1. A geotextile is placed in a U-shaped tube with a valve. The valve is closed before the test and there is a difference in water level in both sides of the tube. At the beginning of the test the valve is opened and the water starts to flow. Continuous monitoring of the pressure, with the pressure gauge shown, allows to monitor the water level in the tubes as a function of time, from which the head loss over the geotextile can be calculated. The water flow capacity of the geotextile tested on is determined by the head loss over the geotextile and the flow through the geotextile.

Evaluation of the results of a falling head test is nowadays automated by means of a computer program, in which the permittivity at a certain head loss is calculated from the measured head loss and its rate of decrease. In this paper a different approach is followed. The differential equation that governs the flow in a falling head test is solved analytically, assuming the Forchheimer flow equation. Using this formula the parameters in the flow equation are determined by non-linear regression.

## 2 THEORY

### 2.1 Turbulence

Using the Forchheimer relation and neglecting dynamic terms, the relation between head loss and specific discharge can be written as:

$$h = a_h q + b_h q^2 \quad (1)$$

Where  $h$  is the head loss,  $q$  the specific discharge and  $a_h$  and  $b_h$  are coefficients determining the permittivity of the geotextile with dimensions of  $s$  and  $s^2/m$  respectively.

In a falling head test there is a relation between the change in head loss and the specific discharge:

Figure 1: Sketch of a falling head apparatus.

$$q = -\alpha \frac{dh}{dt} \quad (2)$$

$\alpha$  depends on the geometry of the falling head apparatus. For the normal apparatus with two equal tubes, as shown in Figure 1,  $\alpha=0.5$ . If there is a constant head at the down flow side (this is the case if there would be no tube right from the valve in Figure 1),  $\alpha = 1$ . Inserting equation (2) in (1) and rearranging leads to the following differential equation:

$$\alpha^2 b_h \left(\frac{dh}{dt}\right)^2 - \alpha a_h \left(\frac{dh}{dt}\right) - h = 0 \quad (3)$$

Since  $\frac{dh}{dt} < 0$  (it is a falling head test), this can also be written as:

$$\frac{dh}{dt} = \frac{1 - \sqrt{1 + 4b_h h / a_h^2}}{2\alpha b_h / a_h} \quad (4)$$

Substituting

$$z = 1 - \sqrt{1 + 4b_h h / a_h^2} \quad (5)$$

the differential equation reads:

$$dz - \frac{1}{z} dz = \frac{dt}{\alpha a_h} \quad (6)$$

Taking at  $t = 0$ ,  $z = z_0$ , and calculating  $z_0$  from (5), assuming that  $h=H_0$  at  $t=0$ , (6) leads to:

$$\frac{t}{\alpha a_h} = z - z_0 - \ln \frac{z}{z_0} \quad (7)$$

Substituting back equation (4) leads to the final relation between  $t$  and  $h$ :

$$t = \alpha a_h \left[ \sqrt{1 + 4 \frac{b_h H_0}{a_h^2}} - \sqrt{1 + 4 \frac{b_h h}{a_h^2}} - \ln \left( \frac{\sqrt{1 + 4 \frac{b_h h}{a_h^2}} - 1}{\sqrt{1 + 4 \frac{b_h H_0}{a_h^2}} - 1} \right) \right] \quad (8)$$

Figure 2 shows the result of a comparison between measurements on a relatively impermeable geotextile (the influence of dynamics in the test was expected to be small) and a calculation using Equation (8), in which  $a_h$  and  $b_h$  were obtained by non-linear regression on the measurement data, showing almost perfect agreement.

## 2.2 Dynamic effects

If the geotextile is very permeable, the inertia of the water column cannot be neglected. The head loss not only contributes to overcome the flow resistance in the geotextile, but also contributes to accelerate or decelerate the water column. An extreme example is the falling head test on a circular plate as was performed in the CEN round robin test (Dierickx, 1995), but it was also found in some permeable geotextiles, see Figure 3. To describe the results of

Figure 2: Falling head test on a less permeable geotextile (G2, see Section 2.2) and fit using Equation (8),  $a_h=2.44$  s,  $b_h=148$  s<sup>2</sup>/m.

such tests equation (1) was extended with a term that includes inertia of the water column in the falling head apparatus. Taking this into account equation (1) reads:

$$h = a_h q + b_h |q|q + \frac{L}{g} \frac{dq}{dt} \quad (9)$$

The absolute sign is now necessary because the possibility of flow reversal. Using (2), (9) can be written as:

$$\alpha^2 b_h^* \left(\frac{dh}{dt}\right)^2 - \alpha a_h \left(\frac{dh}{dt}\right) - \alpha \frac{L}{g} \frac{d^2 h}{dt^2} = h \quad (10)$$

Where  $b_h^* = b_h$  if  $q > 0$  and  $b_h^* = -b_h$  if  $q < 0$ . In this way the absolute sign in equation (9) is incorporated.

This equation was solved using an explicit finite difference scheme, using the following approximations:

$$\frac{dh}{dt} \approx \frac{h_{i+1} - h_i}{\Delta t} \quad \text{and} \quad \frac{d^2 h}{dt^2} \approx \frac{h_{i+1} - 2h_i + h_{i-1}}{\Delta t^2} \quad (11)$$

Where  $h_i$  is the head loss at time step  $i$  and  $\Delta t$  is the time increment between 2 time steps. Inserting (11) in (10),  $h_{i+1}$  can be written as:

$$h_{i+1} = \frac{-B + \sqrt{B^2 - 4AC}}{2A} \quad (12)$$

with:

$$A = \alpha^2 \frac{b_h^*}{\Delta t^2}$$

$$B = -\alpha \left[ 2\alpha \left(\frac{b_h^*}{\Delta t}\right)^2 h_i + \frac{a_h}{\Delta t} + \frac{L}{g\Delta t^2} \right] \quad (13)$$

$$C = \left( \alpha \frac{a_h}{\Delta t} + \alpha^2 \frac{b_h^*}{\Delta t^2} h_i - 1 \right) h_i + \alpha \frac{L}{g\Delta t^2} (2h_i - h_{i-1})$$

Figure 3: Measured and calculated piezometric head for a perforated plate (inox) and two different geotextiles.

Using these equations it is also possible to simulate the measured head loss in a falling head test as a function of time also for very permeable material quite accurately, see Figure 3. This figure shows measurements and calculations for 3 different geotextiles: The perforated plate used in the CEN tests and two geotextiles with different permeability. UCO (Terrasafe) 4000, which will be referred to as G1, a needle punched slightly head bonded nonwoven with a thickness of approximately 3.8 mm and Lotrak 16/15, referred to as G2, a woven geotextile (tape/tape) with a thickness of approximately 0.5 mm. The permeability of G2 is clearly less than that of G1. The whole curve of G2 is shown in Figure 2.

### 3 INFLUENCE DYNAMICS ON PARAMETERS

In the CEN norm “Water flow capacity normal to the plane, without load”, prEN 12040, dynamics is not taken into account. Time  $t=0$  is the time the valve is completely opened and the first time  $dh/dt=0$  is taken as the end of the test. The permeability of the geotextile is determined in this part of the curve, assuming that the difference in the head loss is zero when  $dh/dt=0$ , see Figure 4, which is a modified version from the figure in the norm. Figure 3 shows that the head loss can be less than zero due to dynamics. If this is the case, the curve is shifted along the Y-axis before the evaluation, to obtain a head loss of zero at  $dh/dt=0$ .

Taking one value for the parameters  $a_h$  and  $b_h$  in equations (12) and (13), it is possible to calculate the influence of dynamics by changing the length  $L$  of the water in the tube. The larger this length the larger the influence of dynamics. The CEN procedure described above and the non-linear regression technique can be used to obtain values for  $a'_h$  and  $b'_h$ . (the accents indicate that the parameters are determined in a different way) using the solution without dynamics, Equation (8). If the CEN procedure is cor-

rect, then  $a'_h$  and  $b'_h$  should be equal to the input values for  $a_h$  and  $b_h$ .

This procedure was performed for the 3 different values of  $a_h$  and  $b_h$ , describing the permeability of the materials mentioned before. Table 1 shows the results of this procedure.

Table 1: Calculated values of the Forchheimer coefficients  $a_h$  (s) and  $b_h$  ( $s^2/m$ ) and the velocity (VI) (m/s) and head loss (HI) (m) index. See also text.

	Perf. Plate				G1			G2		
L (m)	1.6	0	1.6	3	1.6	0	1.6	1.6	0	1.6
	D				D		D			
$a_h, a'_h$	0.01	0.0	0.0	0.0	0.65	0.63	0.16	2.4	2.3	2.2
$b_h, b'_h$	3.5	3.4	3.6	3.6	2.8	2.8	4.6	148	148	151
VI ( $\cdot 10^{-3}$ )	120	120	120	120	61	62	88	12	12	12
HI ( $\cdot 10^{-3}$ )	1.6	1.4	1.5	1.5	14	14	5.0	108	106	105

The column with D presents the parameters  $a_h$  and  $b_h$  used in the calculation including dynamics (equations (12) and (13)), resulting in the fits of Figure 3. When values for  $a_h$  and  $b_h$  were found, calculations were run with the same  $a_h$  and  $b_h$  for various lengths of the water column  $L$  (0, 1.6 and for the perforated plate also 3 m). The results of those calculations were used as an input for determination of  $a'_h$  and  $b'_h$  (presented in the columns with  $L = 0, 1.6$  and 3 m without D). The method described in prEN 12040 has been used to obtain the part of the curve appropriate for calculations and Equation (8) and non-linear regression to obtain the parameters  $a'_h$  and  $b'_h$ . For the theoretical case  $L=0$  (in reality the length of the column must always have a certain length, but this value is used to exclude the last term in equation (9)) there is no influence of dynamics. In that case the parameters  $a'_h$  and  $b'_h$  should be the same as  $a_h$  and  $b_h$  used in the dynamic calculation (D). In this case the procedure is just a check of the accuracy of both solutions. If  $L$  has a realistic length, there can be deviations. The calculation with  $L=1.6$  m shows the influence of dynamics on the result of the test for the equipment used. The values for  $a'_h$  and  $b'_h$  mentioned for  $L=1.6$  m are the values that will be found using the procedure of prEN 12040, thus

Figure 4: Sketch from prEN 12040 (modified) to calculate the water flow capacity.

neglecting dynamics.

The procedure of prEN12040 was slightly changed. The time the valve is completely opened is never known exactly and therefore the part of the curve with the steepest gradient is taken as the beginning of the test. In case the results are influenced by dynamics, this is a bit later than the moment the valve is open. A difference of approximately 0.3 s was found in the tests.

#### 4 DISCUSSION ON THE RESULTS

Table 1 shows that the parameters used in the numerical calculations are in close agreement with  $a'_h$  and  $b'_h$  when the numerical results for  $L=0$  are fitted with equation (8). This means that without dynamic effects both solutions correspond to each other, as could be expected. Small deviations occur due to the finite differences used in the numerical method. The small value of  $a_h$ , used to simulate the behaviour of the perforated plate, could not be found when the result of the numerical calculation with  $L=0$  was used to obtain  $a'_h$ . The influence of such a small value of  $a_h$  can be found in the damping of the oscillations (for  $\text{time} > 2$  s in Figure 3), but is negligible in the first part of the curve, where turbulent flow is dominant.

The results of the non-linear regression on the numerical simulations with a finite length  $L$  (and therefore influenced by dynamics), result in different values of  $a'_h$  and  $b'_h$  compared with the results for  $L=0$ . Remarkably the difference is only small in case the parameters for the perforated plate are used, but significant for geotextile G1 and still perceptible for the much less permeable geotextile G2. The parameters  $a'_h$  and  $b'_h$  differ considerably from  $a_h$  and  $b_h$  for G1. It is known that slight changes in the results of falling head tests can lead to relatively large changes in the parameters  $a_h$  and  $b_h$  (Bezuijen et al. 1994). However, also the velocity index and head index differ significantly. For G1 the This means that the procedure as suggested in prEN 12040 will not lead to the right values of  $a_h$  and  $b_h$  when there is an influence of dynamics. If dynamics has an influence, the flow capacity of the material is overestimated. Neglecting dynamics for geotextile G1 leads to a velocity index VI that is 30 % too high and to a head loss index that is 180 % too low.

For geotextile G2 the influence is only small. However, simulations has shown that for geotextiles with a velocity index of 34 mm/s, dynamics has still a considerable influence for an apparatus with a length of 1.6 m water column. For such a geotextile there will be hardly any overshoot in the head loss below zero, as is still present in geotextile G1 (see Figure 3). Neglecting dynamics for a geotextile with a velocity index of 34 mm/s leads to a VI that is 14% too high and a HI that is 47 % too high.

From this it can be concluded that is not sufficient to look at overshoot in the head loss to determine whether or

not dynamic effects have an influence. The influence depends on the apparatus, but is significant (errors of more than 14 % and up to 180%) for the apparatus shown in Figure 1, with a water column of 1.6 m length, when the head loss reaches values close to zero between 1.5 and 4 seconds.

#### 5 CONCLUSIONS

This study has led to the following conclusions:

1. The results of a falling head test on geotextiles can be described with Equations (12) and (13). In case dynamic effects can be neglected Equation (8) can be used.
2. The procedure as presented in prEN 12040 to deal with dynamic effects that occur in a falling head test on permeable geotextiles can lead to inaccurate results, even if no overshoot is visible in the head loss versus time plot. Considerable errors (from 14 % up to 180 %) were found when the head loss reaches values close to zero between 1.5 and 4 seconds.
3. The error found when using the procedure of prEN 12040 was largest in the head loss index.
4. It is advised to include the influence of dynamics in the interpretation of a falling head test when relatively permeable geotextiles are tested, or to use a constant head test.
5. More tests are needed to determine the entire range where dynamics has an influence.

#### ACKNOWLEDGEMENT

I would like to thank Dr. W. Dierickx of the Belgian Research Station for Agricultural Engineering for providing the measurement data and for stimulating discussion.

**ABSTRACT:** Effects of various testing parameters on the hydraulic transmissivity of geocomposite drain systems commonly used in leak detection and leachate collection systems of modern landfills are investigated. A laboratory testing program was performed utilizing different geonet, geotextile, geomembrane and geosynthetic clay liner (GCL) products. The test results indicate that, the configuration of the geocomposite system, the intensity and the duration of the sustained vertical stress, and the hydraulic gradient can strongly influence the hydraulic transmissivity of a geocomposite drain.

**KEYWORDS:** drainage, geonets, geocomposite, transmissivity, laboratory testing

## 1 INTRODUCTION

Modern landfill liner-system design commonly includes leak detection and leachate collection systems, which often consist of a geonet sandwiched between two geotextile layers, or between a geotextile and a geomembrane layer (both configuration herein are referred to as geocomposite drains). Hydraulic transmissivity of a geocomposite drain is known to be affected by various factors including: (i) physical characteristics of the geonet, geotextile, and when applicable, geomembrane components, (ii) the intensity and duration of the applied vertical stress, (iii) the hydraulic gradient, and (iv) presence of an overlying geosynthetic clay liner (GCL). The effects of these parameters on the hydraulic transmissivity of geocomposite drains were studied with a laboratory testing program utilizing different geonet, geotextile, geomembrane and GCL products in various geocomposite drain configurations.

## 2 TEST EQUIPMENT AND SETUP

The constant head hydraulic transmissivity test method described by the American Society for Testing and Materials (ASTM) test standard D 4716 was utilized in the testing program. A simplified schematic diagram of the test equipment and setup is presented in Figure 1. Referring to the figure, hydraulic transmissivity is calculated utilizing the following equation:

$$\theta = \frac{Q}{B \times (h/L)} \quad (1)$$

where,  $\theta$  is the hydraulic transmissivity ( $m^2/s$ ),  $Q$  is the volume of discharged fluid per unit time ( $m^3/s$ ),  $L$  is the length of the specimen ( $m$ ),  $B$  is the width of the specimen ( $m$ ), and  $h$  is the difference in the total head across the specimen ( $m$ ). The hydraulic gradient is equal to the ratio of  $h$  to  $L$ .

Figure 1. Schematic diagram of the test equipment and setup.

## 3 TEST MATERIALS

One geomembrane, two different geonets, three different geotextiles and one GCL product were used in the testing program. Table 1 provides general information on each product.

## 4 TEST SPECIMEN CONFIGURATION

Referring to Figure 2, the following test specimen configurations were used:

Table 1. Test material general information.

Test Material			
Designation	Type	Trade Name	Remarks
GM	Geomembrane	Gundline HD	High density polyethylene, smooth, $t=1.5$ mm
GN1	Geonet	Tensar NS140551	Polyethylene, $t=5.0$ mm, $\theta=1E-3$ m <sup>2</sup> /s @ $\sigma=720$ kPa and $i=1.0$
GN2	Geonet	NSC PN 3000	Polyethylene, $t=5.0$ mm, $\theta=1E-3$ m <sup>2</sup> /s @ $\sigma=720$ kPa and $i=1.0$
GT1	Geotextile	LINQ Typar 3601	Polypropylene, nonwoven, $M_A=203$ g/m <sup>2</sup> , AOS=0.1 mm, and $\psi=0.1$ s <sup>-1</sup>

$t$ : thickness (mm),  $M_A$ : mass per unit area (g/m<sup>2</sup>), AOS: apparent opening size (mm),  $\psi$ : permittivity (s<sup>-1</sup>),  $\sigma$ : vertical stress (kPa), and  $i$ : hydraulic gradient (-)

Configuration I - a geonet sandwiched between two geomembranes to evaluate the baseline hydraulic transmissivity of the geonet.

Configuration II - a composite of a geotextile and a geonet sandwiched between two geomembranes to evaluate the effects of a single geotextile layer over the geonet on its transmissivity.

Configuration III - a GCL placed over the geotextile component of a geocomposite drain (secondary backing against the geotextile) to evaluate the effects of an overlying GCL on the transmissivity of a geocomposite drain.

Configuration IV - a GCL directly placed over a geonet (primary backing directly against the geonet) to evaluate the effects of an overlying GCL on the transmissivity of a geonet.

duration (i.e., the period of applied vertical stress) varied from several days in the case of Tests 1 through 7 to approximately 120 days in the case of Tests 8 and 9.

Table 2. Summary of laboratory testing program.

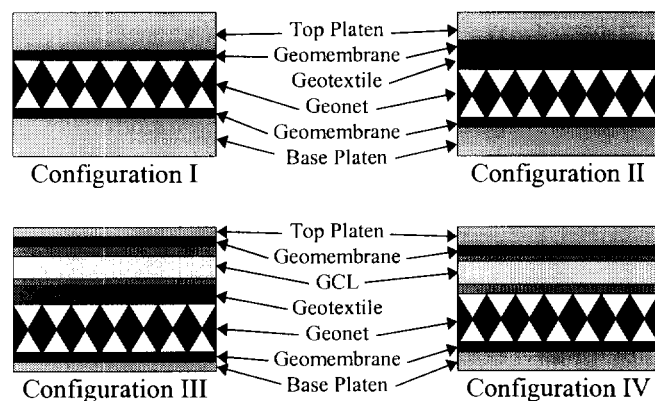

Figure 2. Schematic diagram of four different test configurations.

## 5 TESTING PROGRAM

Nine transmissivity tests were performed, as presented in Table 2. The tests were performed utilizing vertical stresses ranging from 24 to 766 kPa and hydraulic gradients ranging from 0.1 to 0.5. These boundaries were selected to encompass commonly encountered field conditions. Test

## 6 TEST RESULTS

The test results are graphically presented in Figures 3 to 7. The results and the observations made during the tests are summarized in the following paragraphs.

Hydraulic gradient - Referring to Figures 3, 5 and 6, it appears that higher hydraulic gradients result in lower measured transmissivity values. This suggests that as the hydraulic gradient increases the flow regime becomes turbulent and Darcy's law may not be fully applicable (Williams, et al., 1984 and Cancelli, et al., 1987).

Geotextile - Referring to Figure 3 (a), it appears that presence of a geotextile over a geonet reduces its transmissivity. This is likely due to penetration of the overlying geotextile into the geonet channels (Williams, et al., 1984 and Koerner, 1990).

As illustrated in Figure 3 (b), the type of the overlying geotextile may have a significant impact on the hydraulic transmissivity of a geocomposite drain. For the geonets and geotextiles used in this investigation, the test results indicate that the hydraulic transmissivity may decrease by approximately half an order of magnitude when the heaviest/thickest geotextile is used.

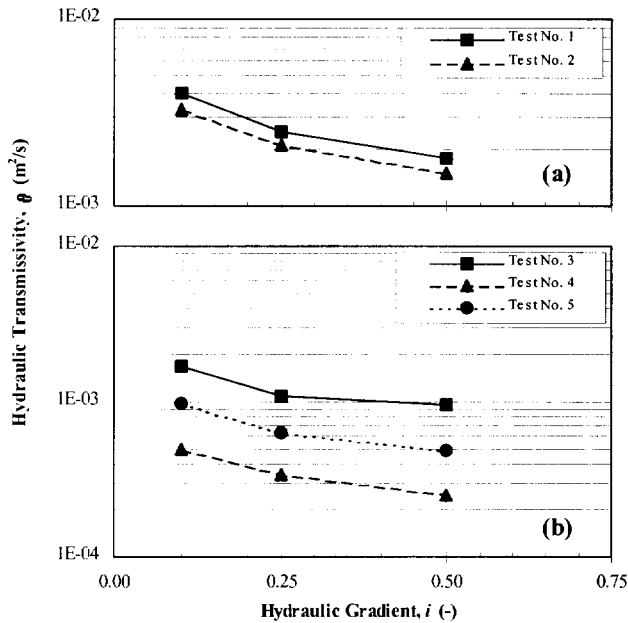

Figure 3. Effect of geotextile on transmissivity of geocomposite drains ( $\sigma=766$  kPa).

**Vertical Stress** - The effect of the vertical stress on the transmissivity of geocomposite drains is depicted in Figure 4. Referring to the figure, hydraulic transmissivity decreases as the vertical stress increases. The decrease in the hydraulic transmissivity is likely due to: (i) compression of the geonet ribs, and (ii) increasing penetration of the overlying geotextile into the net (Williams, et al., 1984 and Fannin and Choy, 1995). As presented in the figure, for the geotextiles and geonets used in this investigation the

Figure 4. Effect of vertical stress and geotextile on the transmissivity of the geocomposite drains ( $i=0.25$ ).

Figure 5. Effect of GCL on transmissivity of geocomposite drains with various geotextiles ( $\sigma=766$  kPa).

transmissivity may decrease by 30 to 60% as the vertical stress increases from 24 to 766 kPa. In general, the heavier/thicker the geotextile the stronger the decrease in the overall transmissivity of the geocomposite drains.

**GCL** - As illustrated in Figures 5 and 6, presence of an overlying GCL may reduce the transmissivity of a geocomposite drain by 30 to 70 %. Referring to Figure 5, the effect of GCL on the transmissivity is generally dependent on the type of geotextile used to separate the GCL from the geonet. For the materials used in this investigation, the reduction in the transmissivity was less when a heavier/thicker geotextile was used. It should be noted, however, that this observation contradicts the results presented in Figure 3 (b). Thus, more research in this area is needed before a final conclusion can be drawn.

As presented in Figure 6, direct placement of a GCL on a geonet results in approximately an order of magnitude reduction in its transmissivity. Notwithstanding the transmissivity reduction, direct placement of GCL on a geonet may be an economical approach for some landfill designs. It should be noted, however, that the geotextile backing of the GCL placed against the geonet should have appropriate mechanical and physical properties to: (i) withstand potential damage under the applied vertical stress and construction activities, and (ii) limit migration of bentonite from the GCL into the geonet.

**Duration of vertical stress** - The effects of the duration of sustained vertical stress on transmissivity of geocomposite drains are presented in Figure 7. Referring to the figure, the transmissivity of a geocomposite drain decreases as the duration of the applied vertical stress increases. For the geocomposite drains and test duration used in this

Figure 6. Effect of GCL on transmissivity of geocomposite drains with or without geotextile ( $\sigma=766$  kPa).

investigation most of the reduction occurred in the first 50 to 60 days. The maximum transmissivity reduction was approximately 30 to 40%. The observed decrease in the transmissivity is likely due to: (i) creeping of the geonet ribs (Smith and Kraemer, 1987), and (ii) creeping of the overlying geotextile into the geonet channels.

## 7 CONCLUSION

The purpose of this investigation was to evaluate the effect(s) of various parameters on the hydraulic transmissivity of geonets and geocomposite drains. Based on the results obtained in this study the following conclusions can be drawn:

(i) the higher the hydraulic gradient the lower the hydraulic transmissivity value;

(ii) the higher the vertical load the lower the hydraulic transmissivity value;

(iii) an overlying geotextile may reduce the hydraulic transmissivity of a geonet due to possible penetration of the geotextile into the geonet channels;

(iv) the physical and mechanical properties of the material(s) used in a geocomposite drain affect its overall transmissivity;

(v) direct placement of a GCL on a geonet may strongly reduce its overall hydraulic transmissivity due to penetration of GCL and possible migration of its bentonite component into the geonet channels;

(vi) presence of a layer of geotextile between the GCL and the geonet reduces the GCL effect on the transmissivity of the geonet; and

Figure 7. Long-term effect of applied vertical stress on the transmissivity ( $\sigma=766$  kPa,  $i=0.25$ ).

(vii) long-term application of vertical stress may reduce hydraulic transmissivity of a geocomposite drain.

The authors recommend that the actual design configurations be simulated, as closely as possible, in the laboratory to determine representative field hydraulic transmissivity values.

# Comparison of transmissivity tests DIN-ASTM-CEN

J. Müller-Rochholz

Professor, Department of Civil Engineering, Fachhochschule Münster, Labor für Baustoffe, Münster, Germany

Z. Bronstein

Institut für textile Bau-und Umwelttechnik, Greven, Germany

**ABSTRACT:** Working on harmonising tests, there were 3 different test available. They differ in specimen size, lateral pressure material, water input to specimen. These standards were tested in comparison on a set of identical materials with different hydraulic gradients. The results are given in plots flow us hydraulic.

**KEYWORDS:** Hydraulic transmissivity, In-plane flow, Drainage capacity, Drainage, Transmissivity

## 1 INTRODUCTION

World wide trade needs generally accepted technical values for the products traded. The work on international standards in the International Standard Organisation ISO is accelerated in the geosynthetic area by the Vienna-contract, which states a common speed and a mutual acceptance of standards between ISO and the Comité Européenne de Normalisation CEN. For drainage applications of geosynthetics the drainage capacity is the design parameter. This property may be tested by prEN ISO 12958 November 1995 or ASTM D 4716-87 or an old German Proposed made by Franzius Institute (DIN 60500 T7). This comparison included 10 Materials and the 3 standardised methods.

## 2 DEFINITIONS

**In-plane water flow capacity:** The volumetric in plane rate of water per unit width of the GTX or GRP, at defined gradients and loads, in a direction parallel to the plane of the product.

**Transmissivity  $\theta$ :** The in-plane water flow capacity of the GTX or GRP under laminar conditions at a hydraulic gradient of unity.

**Hydraulic gradient  $\Delta h$ :** Ratio of the head loss in the GTX or GRP to the distance between two mesasuring points.

## 3 TEST METHODS

The 3 methods described in

- prEN ISO 12958 November 1995
- ASTM D 4716-87
- Franzius Institute method
- 

are synoptic shown in fig. 1, 2 and 3.

Figure 1: Schematic sketch of test condition DIN 60500 T7

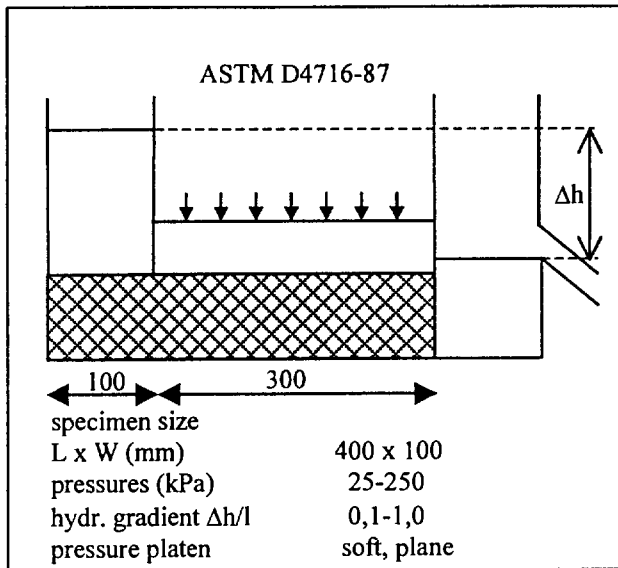

Figure 2: Schematic sketch of test condition ASTM D4716-87

Figure 3: Schematic sketch of test condition prEN ISO 12958

The differences are specimen size, water input direction to specimen, kind of confining plate material.

### 3 MATERIALS TESTED

A wide set of materials covering typical products for drainage application were tested, the generic description is given hereunder.

#### Number of Materials

-Random wire mats	-	4
-Oriented wire mats	-	1
-extruded geonet	-	2
-Cuspated sheet	-	1
-nowoven composite	-	1
-PE foam-particle	-	1

### 4 RESULTS

The results of comparison tests are given in figures 4 to 8.

#### Influence of pressure on drainage materials

The generic products show different behaviour, the lines of flow vs stress drop rapidly for random wire products, show less decrease for oriented wires and again less for geonet and cuspated film type products. Be aware that the flow axis is scaled differently, the flow at 2 kPa for wire products is very high.

Figure 4: Oriented PA wire between nonwovens (Sterz, Breuer 1995, Ehler, Rohde 1995)

Figure 5: Random PP wire between nonwovens (Sterz, Breuer 1995, Ehler, Rohde 1995)

Figure 6: Extruded geonet with nonwoven (Sterz, Breuer 1995, Ehler, Rohde 1995)

Influence of hard/soft platen

The soft (cellular rubber) platen of CEN simulating soft soil pressure on the geotextile filter leads to a strong decrease of the curves ( see fig 7) by confining the flow section.

Figure 7: Cuspated sheet with nonwoven (Sterz, Breuer 1995, Ehler, Rohde 1995)

Figure 8: PE foam-particles with nonwoven cover (Sterz, Breuer 1995, Ehler, Rohde 1995)

Influence of gradient

The dependence from gradient is not always linear (see fig 9), so if a value measured at a gradient not equal to 1 is than calculated for Transmissivity at gradient 1, the mistake is significant.

Figure 9: PE foam-particles with nonwoven

Influence of test method

From the curves given in fig 4 .. 8 tables were derived, giving the comparative values for the 3 standard methods for 3 materials (see table 1, 2, 3). Roughly evaluated the test according to ISO and CEN leads to product specific correlation values, a factor, valid for all materials is not extractable.

# The Optimization Analysis Between Processing Parameters and Physical Properties of Geocomposites Composed of Multi-layered Nonwovens

H.Y. Jeon

Associate Professor, Department of Textile Engineering, Chonnam National University, Kwangju, Korea

J.Y. Kim

Research Associate, Department of Textile and Apparel Technology and Management, North Carolina State University, Raleigh, NC, USA

**ABSTRACT:** The geocomposites of needle punched(NB) and spunbonded(SB) nonwovens having reinforcement and drainage functions were manufactured by thermal bonding method. The physical properties (e.g. tensile, tear and bursting strength, permittivity) of these multi-layered nonwovens were varied by processing parameters - temperatures, pressures, bonding periods etc. - in manufacturing by thermal bonding method. Therefore, it is very meaningful to optimize the processing parameters and physical properties of the geocomposites by thermal bonding method. An algorithm has been developed to optimize the process of the geocomposites using an artificial neural network (ANN). The geocomposites were employed to examine the effects of manufacturing methods on the analysis results and the neural network simulations have been applied to predict the changes of the nonwovens performances by varying the processing parameters.

**KEYWORD:** Multi-layered nonwovens, Thermal bonding method, Processing parameters, Optimization analysis.

## 1 INTRODUCTION

The function of nonwoven geotextiles are reinforcement, separation, filtration, drainage and liquid barrier (Ingold 1994; Koerner 1994). Multi-layered nonwovens as a kind of geocomposites are manufactured by needle punching or thermal bonding to develop the above one or two functions of geotextile (Lünenschloss and Albrecht 1981; Gourc, Faure, Rollin and LeFlear 1982). Especially, in the case of application to thermal bonding to manufacture geocomposites (multi-layered nonwovens), the processing parameters e.g. temperature, pressure, time etc, were affected by the physical properties of geocomposites. From this view, it is very reasonable that the optimization analysis is applied to examine the deviations and correlations between these parameters.

Process optimization is one of the most important topics in modern non-woven research because it directly influences many physical properties of the thermal bonded nonwoven geocomposite. It has been known that there exist very complicated interaction between processing parameters and material properties. The popular regression approaches always neglects some significant interactions between processing parameters in order to simplify the model and often have some difficulty in finding a reliable multivariable nonlinear model which must be considered as a model.

Very recently, the feed-forward multi-layered neural network approach has been widely used in many areas of engineering and science (Hornik 1989). Commonly, the neural networks can be employed in order to analyze some of the most complex non-linear system. The recent theoretical work has proven that neural networks can be

successfully applied to express most classes of continuous functions with bounded inputs and outputs with any specified precision (Sharpe 1994).

In this paper, a neural network algorithm for optimizing the correlations between physical properties and processing parameters of multi-layered nonwovens to be manufactured at the different processing conditions was used and the optimum condition of these was derived from analytical results.

## 2 EXPERIMENTAL

### 2.1 Manufacturing of Geocomposites

Spunbonded(SB) nonwoven(18g/m<sup>2</sup>) of polypropylene filament(7d) and needle punched(NB) nonwoven (163g/m<sup>2</sup>) of polypropylene staple fiber (12d) were used as raw materials for geocomposites composed of multi-layered nonwovens. A special designed thermal bonding apparatus was used to bind geocomposites and the plate which are available to heat and press was adapted to thermal bonding apparatus.

#### 2.1.1 The processing conditions

Processing conditions of thermal bonding for manufacturing geocomposites composed of multi-layered nonwovens are as follows:

- (1) Temperatures: 180 ~ 190 °C (at 2 °C intervals)
- (2) Pressures: 4, 5, 6 kgf/m<sup>2</sup>
- (3) Times: 2, 3, 4 seconds

## 2.1.2 Types of geocomposites

The following types of geocomposites were manufactured at the above conditions:

- (1) NP-thermal bonded
- (2) NP/SB
- (3) NP/NP
- (4) SB/NP/SB

## 2.2 Physical Properties

Physical properties of multi-layered nonwovens were estimated in accordance with the following ASTM methods:

- (1) Tensile strength for MD (machine direction) and CD (cross direction)- ASTM D 4632-91
- (1) Tear strength - ASTM D 4533-91
- (2) Bursting strength - ASTM D 3786
- (3) Permittivity - ASTM D 4491-92

## 3 NEURAL NETWORK

In this paper, the feedforward back propagation algorithm is applied to model manufacturing process of non-woven materials. A basic multi-layer neural network structure is shown in Figure 1 depicting the hidden layer, and output layer.

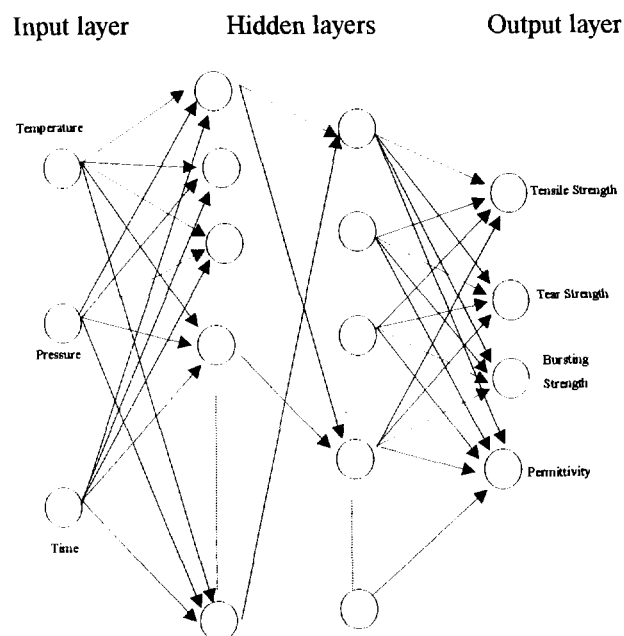

Figure 1. Architecture of a neural network having two layers.

This neural network has one input layer, one output layer, and any number of hidden layers. Each network consists of nodes (neurons). The input layer of the neural network takes information from the outside world and sends it to the nodes in the hidden layers. Similarly, the output layer of the neural network transmits the processed information to the external world.

To apply an  $m$ -variate signal input to a one-layer neural network consisting of  $n$  neurons each having  $m$  weights, we multiply an  $m$ -variate vector  $X$  ( $x_1, x_2, \dots, x_{m-1}, 1$ ) with the  $(n \times m)$ -variate weight matrix  $W$ . The result is an  $n$ -variate net input vector  $s$  ( $s_1, s_2, \dots, s_n$ ). Then, we can show how each component  $s_j$  is calculated for layer 1:

$$s_j = \sum_{i=1}^n w_{ji} v_i + b_j = w_j T \cdot v + b_j, j=1,2,\dots,k \quad (1)$$

The index  $j$  spans the  $n$  neurons, while  $i$  spans the  $m$  weights in the  $j$ th neuron. The number of weights in the neuron is one of more than the number of input variables,  $x_i$ ; the remaining one input variable is the bias, which is always equal to 1.

The quantity  $s_j$  is processed by an activation function to give the output  $o_j$  of the  $j$ th neuron:

$$o_j = f(s_j) \quad (2)$$

The input consists of process variables such as pressure, temperature and processing time. The network output are predicted values of physical properties at possible process conditions. The network training is performed using the nonlinear least square methods. The error at the output neuron can be defined as

$$E = \frac{1}{2} (t_k - o_k)^2 \quad (3)$$

where  $t_k$  is the target value of the output neuron. The backpropagation algorithms make use of the gradient descent methods for minimizing  $E$ . The error signal defined by

$$\delta_j = -\frac{\partial E}{\partial o_j} \quad (4)$$

leads to the result of general delta rule

$$\Delta w_{ji} = \eta \delta_j o_i \quad (5)$$

where  $\eta$  is an adaptation gain and  $\delta_j$  is computed based on whether or not neuron  $j$  is in the output layer. If neuron  $j$  is one of the output neurons, then

$$\delta_j = (t - o_j) o_j (1 - o_j) \quad (6)$$

On the other hand, if neuron is not in the output layer,

$$\delta_j = o_j (1 - o_j) \sum_i \delta_i w_{ji} \quad (7)$$

For a fast convergence, the momentum with gain  $\alpha$  will be introduced by following equation:

$$\Delta w_{ji}(k+1) = \eta \delta_j o_i + \alpha \Delta w_{ji}(k), \quad (8)$$

(, where k is the iteration step. )

#### 4 RESULTS AND DISCUSSION

The feedforward back propagation algorithm based on the generalized delta rule and the minimum mean squared error (MSE) principle were used for the data sets. In a feedforward network, the processing units can be divided into several layers: input layer, hidden layers and output layer. The input components consist of process variables such as pressure, temperature and processing time which are considered to be the important parameters. Outputs of the network are the predicted physical properties at the given process condition. The number of units in the hidden layers were set to be 16 following a series of optimization experiments. The networks have been used for training hundreds of experimental data sets, namely, pairs of process conditions and physical properties of different multi-layered nonwovens produced by varying the process conditions.

The prediction results are shown in Figures 2-5. As shown in the figures, several physical properties were predicted quite well with small errors. Figure 2 shows predicted permittivity at different process conditions. From this, it is known that a high permittivity value can be obtained when geocomposites are made at 180°C. Same tendency like this is observed for short processing time and lower temperature ranges. But in very high pressure and long processing time, the property is deteriorated significantly below unacceptable region. Figure 3 shows effect of process condition on tear strength of nonwovens. It was clearly seen that process time affects significantly the tear strength in such a way that longer process time enhances the tear strength over whole temperature regions investigated. But pressure effect is really negative, that is, high pressure caused the decrease of tear strength of nonwovens. Tensile strength difference and burst strength of geocomposites represented in Figure 4 and Figure 5, show the same tendency of the case of tear strength. In Figure 4, tensile strength difference between MD and CD doesn't depend on processing conditions except for 190°C. Using a simulation model, we tried to find some optimal process conditions which optimize several physical

properties in such a way that permittivity, tensile, tear strengths are maximized and tensile strength difference is minimized. From this, it is known that the optimum condition is found to be 182°C, 3sec and 4.9 kgf/cm<sup>2</sup>, respectively.

Figure 2. Prediction of permittivity using neural network.

Figure 3. Prediction of tear strength using neural network.

Figure 4. Prediction of tensile strength difference.

Figure 5. Prediction of burst strength using neural network.

The optimization analysis by neural network were used to examine the relations between processing parameters and physical properties of multi-layered nonwovens. Using this tool, we developed an algorithm for optimization of the geocomposite performances without a significant loss of physical properties. The simulated response surfaces were found to be highly effective in predicting the qualities of resulting geocomposites without actually producing them.

# Static and Cyclic Behaviour of Sand Reinforced by Mesh Elements

J.C. Morel

Research Scientist, Ecole Nationale des Travaux Publics de l'Etat, Lyons, France

J.P. Gourc,

Professor, Lirigm, University Joseph Fourier, Grenoble, France

**ABSTRACT:** The technique involving micro-reinforcement of sand by mesh elements is used for surface soil layers that are likely to be subjected to cyclic loading conditions. Based on the triaxial test, a comparative study of reinforced and non-reinforced sand is carried out. The behaviour of the sand is enhanced by the presence of the micro-reinforcement elements: under low cyclic loading, the reinforced soil has a higher elasticity; under high cyclic loading, the mesh elements take up the load and the compressive strength is improved.

**KEYWORDS:** Micro-reinforcement, Triaxial test, Cyclic loading.

## 1. INTRODUCTION

This research paper concerns the change in behaviour of a sand when it is reinforced with small polypropylene mesh elements with external dimensions of 100 mm x 50 mm. Each individual mesh is a 10 mm x 10 mm square. This type of reinforcement was designed by Mercer (Mercer et al., 1984) and optimised by Hytiris (Hytiris, 1986). The basic concept is the same as that of short-fibre reinforcement. However, the structure of the grid changes the implementation procedure and behaviour.

This type of reinforced sand has been the subject of a number of studies at the Lirigm, using the large shear box (Morel et al., 1997), and the biaxial compression test (Gourc et al., 1994, Morel et al., 1996) in plane strain conditions. The additional study presented here relates mainly to the behaviour of this material under cyclic compression using a triaxial testing apparatus.

Reinforced soils are reputed to have improved resistance to dynamic loading and fatigue compared to the same non-reinforced soils. Moreover, one of the main applications of this type of reinforcement concerns the surface layers subjected to repeated loading, for example as a result of traffic (this type of reinforcement can be used for unpaved roads). A comparative study of a sand with and without mesh elements would therefore seem to be of interest, especially as Lirigm was able to provide a high-performance triaxial test apparatus for cyclic loading.

Note that, in the case of the surface layer application, the reinforcing inclusions are required not only to improve the bearing capacity of the layer, but also to preserve its permeability, especially as this layer often serves as a draining layer. The compressibility under cyclic loading must therefore be reduced by the presence of the mesh elements.

## 2. EXPERIMENTAL CONDITIONS

The cyclic triaxial test apparatus at the Lirigm (Billet et al., 1990) can be used to test cylindrical samples of 70 mm diameter circular cross-section. The slenderness ratio (ratio of height to diameter) chosen here is equal to 1.9. The apparatus enables both the axial stress  $\sigma_1$  and the lateral stress  $\sigma_3$  to be cyclically slaved. During the tests described here, only  $\sigma_1$  will vary cyclically. The cyclic loading is sinusoidal with time (frequency of 0.5 Hz in this case). This apparatus has already been successfully used to study the liquefaction of geotextile-reinforced sand (Billet et al., 1994; Richa, 1992; Vercueil et al., 1997). The lateral confining stress is kept constant at 100 kPa in all the tests presented.

The sand used for these tests has already been studied on numerous occasions at the University of Grenoble. It is known as Hostun RF sand, a siliceous sand of mean diameter  $D_{50} = 0.35$  mm and uniformity coefficient  $C_u = 1.7$ . The grain density is  $\rho = 2.7$  Mg/m<sup>3</sup>.

Triaxial "static" compression tests were conducted for a unit weight value of 15 kN/m<sup>3</sup>, corresponding respectively to void ratios of  $e = 0.73$  and 0.66. All the "cyclic" compression tests were performed for  $e = 0.73$ , corresponding to a relative density  $D_r = 56\%$ .

The proportion of mesh elements added to the sand is characterised by the "reinforcement density,  $d_m$ " which, in %, is equal to the ratio of weight of mesh element with respect to the weight of the sand. It has been shown elsewhere (Gourc et al., 1994), that  $d_m = 0.4\%$  was the reinforcement density providing the best compromise between:

- the favourable effect of the increase in number of mesh elements, implying a greater quantity of mesh elements

subjected to tensile stress and thus improved overall strength of the reinforced soil.

- the unfavourable effect of the increase in number of mesh elements, involving disarrangement of the sand grains and thus a reduction in sand strength.

All the tests presented are for a value of  $d_m = 0.4\%$ . The sand - mesh elements mixture is made after having moistened the sand (sand water content  $w = 10\%$ ) in order to obtain isotropic distribution of the inclusions. To make allowance for the scale of the test sample, the meshes are cut into 50 mm x 25 mm elements, without any asperities to avoid piercing the test sample membrane.

### 3. BIAXIAL TRIAXIAL COMPARISON (STATIC)

The Lirigm biaxial compression prototype testing apparatus can be used to perform tests in plane strain state (Gourc et al., 1994) but, with its present set-up, it cannot be used for cyclic compression tests. As a previous publication by the same authors described a study of mesh-element reinforcement based essentially on the biaxial apparatus, it seemed of interest to compare triaxial test results with biaxial test results, under the same "static" compression conditions. The test sample for the biaxial test was 340 mm long in the main vertical compression direction, 150 mm wide and 60 mm thick. Another experimental difference is that the biaxial test samples have lubrication on the ends whereas the triaxial samples do not.

Figure 1 : Comparison of « static » tests, triaxial and biaxial tests

Lee (1970) and subsequently other authors showed on a non-reinforced sand that the angle of friction in the biaxial test is greater than the angle of friction in the triaxial test. This fact is confirmed by the tests described here.

Figure 1 compares the results obtained at Lirigm for a non-reinforced or reinforced ( $d_m = 0.4\%$ ) sand, presenting conventionally  $\sigma_1/\sigma_3$  as a function of axial strain  $\epsilon_1$ . The test is performed for an axial compression rate of 2 mm/min. In actual fact, this presentation can be justified

only in the small strain range. For large strains, localised failure occurs and the mechanism involved is a block-on-block sliding mechanism (Desrues et al., 1985), as shown on photo 1 for a reinforced sand sample at the end of the test. In such cases it is more proper to present  $\sigma_1/\sigma_3$  as a function of axial displacement: the curves obtained in biaxial and triaxial tests have much closer slopes in the large strain domain.

Generally speaking, the ductility of reinforced sand is clearly apparent. For the large strains reached, very few of the mesh elements had failed.

Photo 1 : Reinforced sand sample after failure at a « static » triaxial test.

### 4. BEHAVIOUR UNDER CYCLIC LOADING

The test procedure is similar in all cases:

- the confining pressure is kept constant (100 kPa),
- the first stage of the test ("static") corresponds to an increase in the deviatoric stress ( $\sigma_1 - \sigma_3$ ) of 200 kPa/min.
- the second stage of the test corresponds to 500 cycles of 0.5 Hz frequency and 100 kPa amplitude from the initial value of the pre-defined deviatoric stress,
- the third stage of the test ("static") corresponds to the continued crushing of the test sample at a vertical displacement rate of 9.6 mm/min.

Figure 2 shows the change in axial settlement of the test sample during the cyclic loading stage, for three initial values of the deviatoric stress : 100 kPa, 200 kPa and 500 kPa. The behaviour of non-reinforced and reinforced sand is compared, except for the 500 kPa initial deviatoric stress because the non-reinforced sand failed for a deviatoric stress of 350 kPa under "static" conditions.

- ♦ Settlement on initial loading ( $N = 1$ ) systematically reaches a greater value for the non-reinforced sand.
- ♦ The increase in vertical displacement with the number of cycles is also systematically higher for the non-reinforced sand.

Figure 2: Cyclic loading stage: variation in vertical displacements as a function of number of cycles.

Figure 3: Cyclic loading stage (0-100kPa): variation in vertical displacements as a function of number of cycles, as from an initial loading of 100kPa

- ◆ A soil is generally considered to show acceptable behaviour under cyclic loading if the relationship between vertical displacement and log N is linear. In this case, it was found that this law is not obeyed for the non-reinforced sand (200-300 kPa) nor for the

reinforced sand (500-600 kPa). The samples show a clear deviation from elastic behaviour.

The cyclic loading domain (0-100 kPa) is interesting because it corresponds to a possible range of use (surface layer) of this type of reinforcement. Both the reinforced sand and the non-reinforced sand are a long way from their failure state. Figure 3 adopts the same presentation as figure 2, except that the displacement under initial loading (N = 1) is not taken into account. The displacement scale is obviously different from that in figure 2. Two tests performed under the identical conditions are presented on the same graph, thereby showing the good repeatability of this relatively difficult type of test.

Vertical displacement for the reinforced sand is halved but, more surprisingly, the variation is no longer linear for values of N greater than 100 cycles.

### 5. INFLUENCE OF CYCLIC LOADING ON STATIC BEHAVIOUR

Figure 4 compares the behaviour of non-reinforced and reinforced test samples under triaxial compression with and without transient cyclic loading of 500 cycles between 200 and 300 kPa: for the reinforced sand, it is found that the test curves with or without transient cyclic loading coincide after the cyclic loading stage as if the material had somehow "forgotten" its loading history.

Figure 4: Comparative overall behaviour with and without transient cyclic loading (500 cycles) for reinforced or non-reinforced sand.

Figure 5 concerns only the reinforced sand and it is found that, contrary to the previous case, the cycles (500-600 kPa) well beyond the strength limit of the non-reinforced sand, have an effect on the post-cycle strength: the strength of the sand is increased through cyclic loading which has no doubt contributed to the mesh elements taking up the tensile stress. In a real-life situation, this could doubtless be obtained by controlled compacting.

Figure 5: Comparative overall behaviour with and without transient cyclic loading (500 cycles) for reinforced sand.

## 6. INFLUENCE OF MESH-ELEMENT ORIENTATION

In the triaxial compression test, the direction of maximum strain is horizontal. The preferential orientation of the reinforcing inclusions should increase their efficiency. To verify this, a series of tests was conducted (fig. 6) in which the mesh elements are no longer placed randomly but in regularly spaced horizontal layers. In this case as well, the behaviour was compared for cases with and without cyclic loading. The reinforcement density ( $d_m = 0.4\%$ ) is the same for the mesh elements oriented horizontally or randomly.

Figure 6: Comparative overall behaviour with and without transient cyclic loading (500 cycles) for horizontally or randomly reinforced sand.

For a given axial strain  $\epsilon_1$ , the deviatoric stress is notably higher for the sample with mesh elements arranged horizontally. The strain values obtained under cyclic loading conditions are also much lower for horizontal mesh elements. However, the tests were not continued long enough to obtain sufficient strain values to achieve a possible coincidence of the curves corresponding to the tests with or without cyclic loading.

## 7. CONCLUSIONS

Triaxial compression tests under cyclic loading conditions were undertaken and show that reinforcement using mesh elements is a high-performance method, not only under "static" loading but also under "cyclic" loading conditions. These observations should be used to improve their implementation procedures (pretensioning on compaction) and to find new applications.

# Stabilization of Earth Slopes with Fiber Reinforcement

Garry H. Gregory

Vice President - Senior Geotechnical Consultant, Fugro South, Inc., Fort Worth, Texas, USA

David S. Chill

Business Manager – Geofibers Business Unit, Synthetic Industries, Inc., Chattanooga, Tennessee, USA

**ABSTRACT:** The use of fiber reinforcement (geofibers) for stabilization of earth slopes was investigated by laboratory testing of non-reinforced and fiber-reinforced clay soils in the direct shear and triaxial shear apparatus. Fiber contents included 0.2 and 0.25 percent by dry weight for this study. The test results show increases in maximum shear stress ( $\tau'$ ) at failure in the range of 20 to 50 percent for the fiber-reinforced specimens. Slope stability analyses were performed for a highway interchange embankment in Beaumont, Texas, USA, which had experienced repeated slope failures. The stability analyses produced an increase in calculated factor of safety from essentially one (imminent failure) for the non-reinforced case, to above 1.5 for the fiber-reinforced case. The slope was repaired with fiber-reinforced soil at a dosage rate of 0.25 percent, and has performed well to date.

**KEYWORDS:** Geofibers, Micro-reinforcement, Slope Stabilization, Earth slopes, Factor of Safety

## 1 INTRODUCTION

The use of geofibers for earth slope reinforcement has attracted significant interest in the past five years. Geofibers consist of relatively small fiber inclusions, distributed as an additive throughout the soil mass in the reinforced zone. Accordingly, the geofibers may be categorized as micro-reinforcement. Planar or continuous-sheet reinforcement elements, such as geotextiles and geogrids, are placed at discrete locations (usually horizontally) within the soil mass, with non-reinforced soil intervals between. Planar materials may be categorized as macro-reinforcement. Geosynthetic macro-reinforcement materials provide an effective solution to a wide variety of slope reinforcement problems, but have limitations in applications where the required anchorage zone is not available due to obstructions, as illustrated in Figures 1(a) and 1(b). Micro-reinforcement materials do not have these limitations since they reinforce the entire soil mass as a soil additive. The large anchorage zone is not required, and it is only necessary to extend the fiber-reinforced zone approximately 0.3 to 0.6 meters beyond the critical failure surface as illustrated in Figure 1(c). Therefore, micro-reinforcement geofibers can provide ideal solutions to slope stability conditions which previously were not practical with geosynthetics. The geofibers used in this study consisted of fibrillated polypropylene (FIBERGRIDS<sup>®</sup>, Synthetic Industries, Chattanooga, Tennessee, USA) in nominal 25 mm and 50 mm lengths.

## 2 BEAUMONT SLOPE

### 2.1 Project Description

The highway interchange embankment (Beaumont slope) is located at the intersection of U.S. Highway 69 and F.M. 347 in Beaumont, Texas, USA. The embankment is approximately 6 m in height at the tallest section, and has a slope ratio of 2.5 horizontal to 1 vertical (2.5H:1V) at the steepest section.

The fill soil in the slopes consists of a brown clay with some sand, gravel, and shells. The embankment soil has a liquid limit of 50, and a plastic limit of 17, with 68 percent passing the US No. 200 sieve. The material classifies as fat clay (CH), in accordance with ASTM D 2487. The

(c) large anchorage zone not required for geofibers

Figure 1. Anchorage-zone limitations of planar reinforcement compared to reinforced zone for geofibers.

embankment slopes on the northeast and northwest quadrants of this intersection had experienced repeated slope failures over the years. The failure-surface geometry typically consisted of a near-vertical scarp near the slope crest, a central failure surface about 1.5 to 2 m deep parallel to the slope, with an exit point about 1 to 1.5 m above the toe. These failures were typically repaired by excavating the failed areas and recompacting the same soil back into the

slope without the use of soil additives or reinforcement. In the fall of 1995 both the northeast and northwest slopes had failed again. The northeast slope was repaired as previously described, without reinforcement or additives. The northwest slope was repaired with geofibers reinforcement. The laboratory testing program, slope stability analyses, and slope repair details are presented in subsequent sections.

## 2.2 Conceptual Model

A conceptual model was developed of the slope failure mechanism for use in planning the laboratory testing program and slope stability analyses. Embankment slopes of clay soils, with height ranges of 6 to 10 m and slope ratios in the range of 2.5H:1V to 3H:1V, often experience shallow failures within a few years after construction. The compacted soils initially have relatively high shear strength values throughout, and may have a significant level of preconsolidation stress induced by the compaction process.

Slope stability analyses using the "as compacted" shear strength properties do not predict the shallow failures. From these analyses, it is apparent that the initial as-compacted shear strengths deteriorate with time in the shallow zone. The strength loss is caused by a number of factors such as desiccation, shrink-swell, water infiltration, and down-hill creep. The principal author has investigated a large number of shallow slope failures in clay soils. The loss of shear strength is not uniform throughout the shallow zone. Three distinct soil zones are usually present, consisting of a weak zone along the failure surface, a weathered zone above the failure surface, and the relatively undisturbed zone below the failure surface. The actual failure surface may be less than 10 mm thick in many cases. The material in the thin failure zone is usually of a soft, paste-like consistency, with a high moisture content. This zone has obviously lost the preconsolidation stress induced during the compaction process, and has degraded to a normally-consolidated condition at the shallow overburden pressure. Consequently, under effective-stress conditions, the soil in the failure zone will have  $c' = 0$ . The principal author has found similar thin, paste-like weak zones paralleling the surface at depths of about 1.5 to 2 m in adjacent embankments which had not experienced slope failures, but which later failed. Accordingly, it is believed that the weak normally-consolidated zone is created prior to actual failure by the weathering processes previously discussed, and by stress concentrations at the base of the weathered zone due to down-hill creep. The weathered soil in the zone above the failure surface generally contains many desiccation cracks and secondary weathering features, and the soil mass in this zone has a substantially lower shear strength than when initially compacted. However, this zone may still retain some long-term cohesion, and will exhibit a higher mass shear strength than the failure zone. The embankment soil below the failure surface in the deeper zone may remain relatively undisturbed and retain most or all of its initial shear strength. The laboratory testing program and slope stability analyses were performed in a manner consistent with the three distinct soil zones.

## 3 LABORATORY TESTING PROGRAM

### 3.1 Sample Preparation and Testing

The laboratory testing program included non-reinforced (control) and fiber-reinforced soil specimens. The direct shear tests were performed as consolidated-drained (CD)

tests, and included nominal 100-mm and 300-mm square specimens, and the ICU triaxial tests were performed on nominal 70 mm-diameter by 150 mm-length specimens. The direct shear tests included specimens prepared by standard compaction methods (95 percent ASTM D 698), and slurry-processed normally-consolidated (SPNC) specimens. All triaxial tests for this study were performed on specimens prepared by standard compaction methods. A consolidation test was also performed on a compacted specimen of the Beaumont clay, to determine the preconsolidation stress induced by the compaction process. The preconsolidation value was used in interpreting the direct shear test results.

The SPNC specimens were prepared by blending the soil in a mixer with sufficient water to form a thick slurry. The slurry was then partially consolidated in a 150-mm diameter CBR apparatus under approximately 70 percent of the normal stress to be used in the direct shear device. Following a consolidation period of about 24 hours, the sample reached a thick paste-like consistency, at which time it was removed from the CBR apparatus and trimmed into a 100-mm square shear box for testing. The remainder of the consolidation stage was completed in the direct shear machine, with the final consolidation stress equal to the normal stress to be used during the shear test. The normal stress range was selected to represent conditions along the actual failure surface in the slope. This procedure assured that the specimen would be normally consolidated during the test, to model the condition along the actual failure surface. Standard-compaction specimens were prepared using a controlled weight-volume relationship and static compaction techniques. The reinforced specimens were prepared by mixing the fibers and soil in a heavy-duty 19-liter mixer. Detailed descriptions of the sample preparation methods are available in a design guide for fiber-reinforced slopes (Gregory 1996).

### 3.2 Test Results

A total of 86 direct shear specimens and 32 triaxial shear specimens of clay soils were tested for this study. Twenty-one of the direct shear specimens were tested in the 300 mm square shear device, and the remainder were tested in the 100 mm square shear device. Twenty of the direct shear specimens and 12 of the triaxial shear specimens were performed for the Beaumont slope project. The remainder of the tests were performed for other slope projects or for research purposes.

Direct shear test results performed on 12 specimens of the Beaumont clay are presented on shear stress-normal stress plots in Figure 2. These tests were performed in a 100 mm square by 30 mm deep shear box. The geofibers were 25 mm in length for the reinforced specimens. The strain rate was 0.0076 mm/minute for all direct shear tests.

Figure 2 contains results for 8 specimens prepared with standard compaction methods. Figure 2 (a) was plotted using a bilinear fit. The first three points on each envelope have normal stress values below the preconsolidation stress induced by compaction ( $P_{cc}$ ), and the fourth point is above the  $P_{cc}$  value. Clay soils during shearing, with normal stresses below the preconsolidation stress, may exhibit significant effective cohesion ( $c'$ ), while those with normal stress values above the preconsolidation value exhibit  $c' = 0$  (Gregory and Doane, 1996). Accordingly, the strength envelopes in Figure 2(a) were fit with a bilinear line to obtain shear strength parameters in both the preconsolidated and normally consolidated (NC) ranges of normal stress. The test results show an increase of approximately 35 percent in  $c'$  for the reinforced specimens compared to the non-reinforced.

Increases in  $\phi'$  were 15 and 27 percent, respectively, for the preconsolidated and NC ranges of normal stress.

Figure 2(b) contains results performed on 6 specimens prepared by SPNC methods. The results in this figure were plotted with a linear fit since all specimens were normally consolidated during the tests. These results show an increase in  $\phi'$  of 33 percent for the reinforced specimens compared to the non-reinforced. Triaxial shear test results performed on 6 specimens of the Beaumont clay are presented in Figure 3. These specimens were prepared using standard compaction methods, and were performed as ICU tests, with pore-pressure measurements. A strain rate of 0.015 mm/minute was used for these tests.

Figure 3(a) contains the results of three non-reinforced specimens plotted on a mohr-coulomb shear stress-normal stress diagram. Figure 3(b) contains the results of three specimens reinforced with 0.25 percent, 25 mm-long fibers. The test results on the specimens reinforced with 25 mm-long fibers in Figure 3(b) show an increase in  $\phi'$  of 16.5 percent, and an increase in  $c'$  of 8.5 percent, when compared to the control test results.

Four mechanisms are believed to be involved in the increased shear strength of fiber-reinforced soil. These mechanisms are : (1) friction between individual fibers and the surrounding soil, (2) adhesion between individual fibers and the surrounding soil, in soils exhibiting significant cohesion properties, (3) micro-bearing capacity of the soil mobilized during pull-out resistance of looped fibers crossing the shear plane, and (4) increased localized normal stress in the soil across the shear surface resulting from the pull-out resistance of the fibers during shearing of the soil. The individual interaction and contribution of these mechanisms to the apparent increase in shear strength is complex and difficult to determine accurately. However, the combined effects, including any synergistic effects, is relatively easy to determine by conducting shear strength tests on both non-reinforced and reinforced specimens, as was performed for this study.

A summary of average direct shear and triaxial shear test results from all specimens tested during this study is presented in Table 1.

(a) Standard Compaction

(b) SPNC Preparation

Figure 2. Direct shear test results on 100 mm Specimens.

(a) Non-reinforced Specimens

(b) Reinforced Specimens

Figure 3. Triaxial test results on 70mm diameter specimens.

Table 1. Summary of Direct Shear and Triaxial Shear Test Results (Average values, including 0.2 and 0.25 % fibers)

Test Description	Number of Specimens	$\phi'$ (Deg.)	$c'$ (kPa)
Direct Shear – 100mm Non-Reinforced	25	32.6	6.6
Direct Shear – 100mm Reinforced – 25mm Fibers	40	38.0	10.0
Direct Shear – 300mm Non-Reinforced	6	27.7	3.1
Direct Shear – 300mm Reinforced – 25mm Fibers	9	27.3	6.7
Direct Shear – 300mm Reinforced – 50mm Fibers	6	22.8	9.5
Triaxial Shear Non-Reinforced	9	22.0	14.8
Triaxial Shear Reinforced – 25mm Fibers	16	24.4	15.9
Triaxial Shear Reinforced – 50mm Fibers	7	30.8	15.4

It should be understood that the results in Table 1 are average values, based upon a range of fat clay (CH) and lean clay (CL) soils tested for this study. The averages for the direct shear tests in the 100mm device show increases of approximately 17 percent and 52 percent in  $\phi'$  and  $c'$ , respectively, for the reinforced specimens. The averages for the direct shear tests in the 300mm device show essentially the same  $\phi'$  values, and an increase in  $c'$  values of 116 percent for the specimens reinforced with 25mm fibers. The average results from the 300mm direct shear device also show a decrease of 21 percent in  $\phi'$  values and an increase of 206 percent in  $c'$  values for the specimens reinforced with 50mm fibers. The triaxial shear test average results show an increase in  $\phi'$  values of 11 percent and an increase in  $c'$  values of 7 percent for the specimens reinforced with 25mm fibers. The average triaxial results with the 50mm fibers show an increase of 40 percent in  $\phi'$  values, and an increase of 4 percent in  $c'$  values. In all cases where one shear strength parameter increased only a small amount or decreased slightly, the other parameter increased by a relatively large amount. Averaging the results in Table 1 for all clay types tested resulted in considerably more scatter than was observed for each individual soil type tested.

## 4 SLOPE STABILITY ANALYSES

### 4.1 Slope Geometry

The geometry of the existing slope, slide geometry, and subsurface stratigraphy were obtained from observations and measurements in the field, and from existing data and a new soil boring provided by the Texas Department of Transportation (TxDOT).

### 4.2 Soil Parameters

The soil parameters were obtained from the laboratory test results, adjusted in accordance with local practice. The unit weight values for the in situ soils were obtained from thin-wall tube samples taken from the boring. The unit weight values of the compacted soils were taken as 95 percent of maximum density as determined by ASTM D 698. Soil shear-strength parameters selected for the analyses are presented in Table 2. The labels and soil type numbers match those on the graphical output sheets from the

computer analyses, presented in subsequent sections. The unit weight values are not included in Table 2, in order to conserve space. Unit weight values of 18.9 and 20.9 KN/m<sup>3</sup> were used for moist and saturated unit weights, respectively.

### 4.3 Analysis Methodology

Slope stability analyses of the Beaumont slope were performed using the computer program GSTABL7, an enhanced version of PCSTABL6 (Humphrey and Holtz, 1986), modified by the principal author. The limit equilibrium method, using a sliding-block search routine and the Modified Janbu method (Janbu 1954, 1973), was used in the analyses.

Table 2. Soil Parameters Selected for the Stability Analyses  
Analysis of Initial Failure (Non-Reinforced)

Label	Soil type No.	$c'$ (kPa)	$\phi'$ (Degrees)
Surface-CH clay	1	9.3	24
Shoulder-CH clay	2	9.3	24
Weak-CH clay (failure surface)	3	0.0	32
Fill-CH clay	4	11.1	24
Base-CH clay	5	11.1	24
Deep-CH clay	6	11.1	24
<u>Analysis of Repaired Slope (Fiber-Reinforced)</u>			
Surface-CH clay	1	10.2	24
Shoulder-CH clay	2	10.2	24
Weak-CH clay (failure surface)	3	0.0	42
Fill-CH clay	4	11.1	24
Base-CH clay	5	11.1	24
Deep-CH clay	6	11.1	24

The shear strength of the failure surface zone (Weak-CH clay) was obtained from the direct shear test results on the SPNC specimens. The shear strength of the undisturbed embankment fill (Fill-CH clay) below the failure surface and in the protected shoulder of the roadway was obtained from the direct shear test results on the specimens prepared with standard compaction methods. In accordance with local practice and experience with similar soils, the  $\phi'$  and  $c'$  values obtained in the tests were reduced by approximately 12 percent for use in the analyses, to account for uncertainties in stratigraphic distribution and construction quality control.

The shear strength of the surficial soil in the weathered zone (Surface-CH clay) above the failure surface cannot be obtained readily with laboratory tests. Samples taken from this zone will not be representative of the desiccation cracks and secondary weathering features throughout the soil mass. However, the apparent shear strength of the weathered zone may be obtained by computer analyses, using the known data.

The shear strength values of the failure-surface and undisturbed-fill zones are known from laboratory test results. The geometry of the failure surface is known from observations and measurements in the field, following failure. It is also known that the stability factor of safety (resisting forces and moments divided by the driving forces and moments) for the slope at the time of failure was one or slightly below one. Therefore, stability analyses of the failed slope can be performed with the known shear strengths of the failure-surface and undisturbed fill zones, and an initial estimate of the mass shear strength parameters in the weathered zone. An iterative analysis can then be performed by changing the estimated shear strength

Figure 4. Graphical Computer output for the fiber-reinforced slope analysis.

parameters in each successive run until the calculated factor of safety converges to one or slightly below one. The changes in strength parameters can generally be applied uniformly to both  $\phi'$  and  $c'$ . It has been found from experience that a good initial estimate of the shear strength parameters for the weathered zone is approximately 50 percent of those of the undisturbed fill zone.

The mass shear strength of the fiber-reinforced weathered zone may be determined as follows. Assume that the ratio of the shear strength of the reinforced weathered zone to the shear strength of the fiber-reinforced laboratory specimens, is the same as the ratio of the shear strength of the non-reinforced weathered zone to the shear strength of the non-reinforced laboratory specimens. The shear strength of the non-reinforced weathered zone to be used in the ratio comparisons is the value determined in the iterative analyses discussed previously. This approach provides rational values of shear strength parameters in all soil zones, for both the initial failure condition and fiber-reinforced slope condition.

The stability analyses were performed using the sliding-block search routine by forcing the trial failure surfaces to pass through the failure zone parallel to the slope, while allowing the trial surfaces to exit near the upper and lower ends of the slope in a more random manner. The weathered zone was assigned anisotropic properties in the analyses,

with zero shear strength within zones plus or minus 10 degrees from vertical, to model tension cracks. The failure-surface zone was modeled as 150 mm thick for convenience in the analyses, although it is much thinner in the actual slope. For each analysis run, 110 trial failure surfaces were evaluated. The results of the slope stability analysis for the fiber-reinforced slope are presented in Figure 4 for illustration purposes. The initial failure analysis is not shown to conserve space. The 10 most critical (with respect to calculated factor of safety) trial failure surfaces are plotted in the figure. The most critical trial failure surface is shown with the heavy line. The failure surfaces are labeled with lower case letters, in ascending order of calculated factor of safety. The soil types are numbered below each boundary. The highway traffic loading at the top of the slope was included as a uniformly distributed load with an intensity of 9.6 kPa, and is shown on the figure by the designation L1. The ground-water surface detected in the boring is shown near the toe elevation with the designation w1. The ground-water surface and soil zones below the failure-surface zone were not used in the shallow failure analyses, but were used in a deep-seated global analysis performed for this slope, but not included in this study.

The slope stability analyses show an increase in calculated factor of safety from 1.007 (imminent failure) for the initial failure to 1.508 for the repaired, fiber-reinforced slope. This

is an increase in calculated factor of safety of approximately 50 percent due to the geofiber inclusion.

## 5 CONSTRUCTION AND PERFORMANCE

### 5.1 Construction

The slope was repaired in late November of 1995 in general accordance with the assumptions made in the analyses. The area was prepared by excavating the failed area approximately 0.6 m below the primary failure surface. The excavated soil was spread in approximately 200 mm-thick loose lifts prior to compaction. Geofibers were spread at the calculated dosage rate of 0.25 percent by dry weight of soil, and each lift was processed and the 25 mm-length fibers mixed into the soil with a minimum of three passes of a roto-till pulverizing mixer of the type commonly used in lime-subgrade stabilization. Each lift was compacted to approximately 95 percent of maximum dry density at a moisture in the general range of optimum to 5 percentage points wet of optimum in accordance with ASTM D 698. The fill was placed in essentially horizontal lifts.

### 5.2 Performance

The fiber-reinforced northwest slope has performed well to date. No additional signs of movement have been observed. The northeast slope at the same interchange was repaired without fiber reinforcement approximately six weeks prior to the northwest slope. The non-reinforced slope has again failed.

## 6 ADDITIONAL PROJECTS

The authors have been involved in more than 10 slope projects on which geofibers were utilized for slope repair and stabilization. These projects have included roadway embankments, pipeline embankments adjacent to rivers or creeks, and an earth-fill dam. One of the pipeline projects involved the use of geofibers for deep-seated stability, as well as shallow stability. The oldest installation of geofibers on these projects was completed approximately six years ago. Most of the other projects were completed within the past three years. These installations have performed well. A detailed discussion of these projects is not possible due to space limitations.

## 7 CONCLUSIONS

The use of geofibers for earth slope reinforcement was investigated by laboratory testing of non-reinforced and fiber-reinforced specimens of compacted clay soils. A highway embankment slope in Beaumont, Texas, USA, was used as the primary case study. Extensive slope stability analyses were performed for the initial failure and fiber-reinforced slope conditions. The factor of safety was increased from essentially one at the initial failure condition, to approximately 1.5 for the repaired slope using the same soil reinforced with geofibers.

Increases in effective shear strength ( $\tau'$ ) in the range of 20 to 50 percent due to geofibers inclusion were observed for this study, based upon  $\phi'$  and  $c'$  increases from laboratory tests and the slope geometries considered. Similar increases

in shear-strength parameters using fiber reinforcement have been reported by other researchers (Maher and Ho 1994, Alwahaab and Al-Ourna 1995, Nataraj and McManis 1997). Additional research and development of analysis methods for the reinforcement mechanisms and influence of fiber properties are needed. Ranjan, et al (1996) performed a study of these influences and proposed a model for analysis of fiber-reinforced cohesionless soils.

Based upon the results of this study, observation of actual installations of fiber-reinforced slopes, and research performed by others, the geofibers are a viable and cost effective method for slope repair using micro-reinforcement where macro-reinforcement elements may not be practical due to space limitations for the anchorage zone. The geofibers can provide solutions to an entire class of slope problems which were not previously practical with geosynthetics.

Additional research is desirable using a broader range of fiber lengths and soil types. Standardization of laboratory testing and analysis methods is needed. Additional case histories are needed, and are expected to occur at an accelerated rate due to the increased use of geofibers.

# Effect of Geotextile Reinforcement on the Stress-Strain and Volumetric Behavior of Sand

A.K. Ashmawy

Assistant Professor, Department of Civil and Environmental Engineering, University of South Florida, Tampa, Florida, USA.

P.L. Bourdeau

Associate Professor, School of Civil Engineering, Purdue University, West Lafayette, Indiana, USA.

**ABSTRACT:** Geosynthetic-reinforced soils exhibit a significant increase in strength compared with unreinforced soils. In this study, triaxial test results for a sand reinforced with horizontal geotextile inclusions and subjected to both monotonic and cyclic loading are presented. The influence of the inclusions on the stress-strain and volumetric behavior is investigated. It is shown that a large increase in deviator strength is attained when reinforcement is used. An increase in ductility is also observed, and is essentially due to the blocking of development and propagation of the shear band within the specimen. When subjected to cyclic loading, the reinforced sand accumulates less axial deformation than the unreinforced sand. Even though the unreinforced soil is contractive, a reduction in potential for volume change is introduced by the geotextile reinforcement. It is demonstrated that this reduction in volume change potential is mainly due to the increase in confinement.

**KEYWORDS:** Geotextiles, Reinforcement, Cyclic, Shear strength, Deformation.

## 1. INTRODUCTION

Over the past few decades, a large number of geosynthetic-reinforced earth structures, such as retaining walls, have been constructed worldwide. In order to better understand the reinforcement mechanisms acting in large-scale reinforced soil structures, it is necessary to first evaluate such mechanisms at the small-scale in a controlled laboratory environment. So far, three reinforcement mechanisms have been identified in the literature, namely passive or pullout anchorage, membrane action, and confinement enhancement (Ashmawy and Bourdeau 1995). Confinement enhancement has been attributed to the mobilization of shear stresses along the soil-geosynthetic interface, thereby reducing the lateral spread of the soil, as illustrated in Figure 1.

Most of the earlier experimental studies have focused on assessing the confinement enhancement mechanism under monotonic loading conditions. For example, Ingold and Miller (1983) investigated the confinement enhancement mechanism with the aid of radiographic analysis on clay specimens reinforced with plastic porous discs. The influence of the permeability of the reinforcement was examined in a study by Fabian and Fourie (1986) who tested high and low permeability inclusions. Ling and Tatsuoka (1994) conducted plane strain tests on a silty clay reinforced with three types of geosynthetics, to simulate the response of retaining walls.

Analytical models were proposed by Ingold and Miller (1983) and Chandrasekaran et al. (1989) to estimate the increase in monotonic strength of axisymmetric soil specimens reinforced with horizontal discs. In the latter model, the increase in strength is essentially expressed as a function of reinforcement spacing and specimen diameter. In both models, assumptions need to be made concerning the amount of shear stress mobilization along the reinforcement-soil interface.

One of the few studies dealing with the influence of confinement enhancement on the cyclic response of sand was conducted by Madani et al. (1979). The reinforcement material consisted of horizontal discs of aluminum foil, equally spaced along the triaxial specimen. It was concluded that the cyclic response of the reinforced sand essentially depends on the reinforcement spacing. In the present study, drained monotonic and cyclic triaxial tests are performed on sand reinforced with horizontal discs of woven and nonwoven geotextiles. The main purpose of the study is to

**Figure 1.** Confinement enhancement mechanism (a) interface shear stresses ; (b) equivalent confining pressure.

compare the performance of the specimens under monotonic and cyclic loading conditions, and to evaluate, experimentally, the contribution of confinement enhancement to the monotonic strength and to the deformability of the reinforced sand under cyclic loading.

## 2. TESTING PROGRAM

The tests were performed on a commercially available "Concrete Sand" reinforced with horizontal discs of woven and nonwoven geotextiles. The properties of the sand and the geotextiles are listed in Table 1 and 2, respectively.

Table 1. Properties of Concrete Sand.

Maximum unit weight	18.8 kN/m <sup>3</sup>
Minimum unit weight	15.5 kN/m <sup>3</sup>
Coefficient of uniformity	3.6
Coefficient of curvature	1.5
Specific gravity	2.65

Table 2. Properties of geotextiles.

Classification	Woven	Nonwoven
Product name	Stabilenka 200	Typar 3801
Mass/unit area <sup>a</sup>	450 g/m <sup>2</sup>	261 g/m <sup>2</sup>
Tensile strength <sup>b</sup>	220 kN/m	20 kN/m
Stiffness at 10% strain <sup>b</sup>	2000 kN/m	120 kN/m

<sup>a</sup> ASTM D3776

<sup>b</sup> ASTM D 4595

The 71 mm diameter sand specimens were moist-tamped at six layers, each 28.3 mm high. A target dry unit weight of 16.5 kN/m<sup>3</sup> was selected, corresponding to a relative density of 35%. In general, sands do not exhibit contractive behavior in axial compression except at very loose states or at high confining pressures. Consequently, dilation was observed for the unreinforced sand specimens tested under both undrained and drained conditions. Based on drained and undrained monotonic tests on the unreinforced sand, the effective angle of internal friction,  $\phi'$  was found to be 37°, within the effective confining stress range of 0 to 400 kPa.

The reinforcement was placed between the moist-tamped layers. In total, five horizontal discs of geotextile were equally spaced at 28.3 mm along each specimen. In addition, geotextile discs were placed at both specimen ends. The specimens were then saturated by flowing de-aired water and back-pressuring.

The testing program is outlined in Table 3. All tests were performed at a confining pressure of 50 kPa. It is believed that such low stress levels are typical in reinforced soil

applications, such as small retaining walls and embankments. For the cyclic tests, a deviator cyclic stress amplitude corresponding to 80% of the monotonic strength of the unreinforced soil was selected. Axial load and volume change were measured during the displacement-controlled monotonic tests, while axial deformation was recorded as a function of number of cycles during the load-controlled cyclic tests.

Table 3. Outline of the testing program.

Test	Loading mode	Geotextile
U-UR	Monotonic undrained	None (unreinforced)
M-UR	Monotonic drained	None (unreinforced)
M-NW	Monotonic drained	Nonwoven
C-UR	Cyclic drained	None (unreinforced)
C-NW	Cyclic drained	Nonwoven
C-WV	Cyclic drained	Woven

## 3. EXPERIMENTAL RESULTS

The monotonic test results indicate, as expected, a significant increase in terms of strength when the geotextile reinforcement is used. As shown in Figure 2a, the failure strength of the reinforced sand under drained conditions is approximately four times greater than that of the unreinforced. Although the initial stiffness is almost the same for both cases, the reinforced specimen exhibited less brittle behavior and reached its maximum strength at a much higher strain level. From the volume change versus axial strain plot in Figure 2b, it is concluded that the presence of geotextile reinforcement also reduces the potential of volume change.

Unreinforced undrained and drained, and reinforced drained stress paths are plotted in Figure 3, where  $p = \frac{1}{2}(\sigma_1 + \sigma_3)$ ,  $p' = \frac{1}{2}(\sigma'_1 + \sigma'_3)$ , and  $q = \frac{1}{2}(\sigma_1 - \sigma_3)$ . In the unreinforced undrained case, the stress path is distinctly traveling along the failure envelope beyond a mean effective stress of approximately 100 kPa. The strength increase introduced due to the presence of the reinforcement can be interpreted as an increase in the effective angle of internal friction ( $\phi'$ ). The apparent effective friction angle of the reinforced soil is 62°. An apparent increase in  $\phi'$  of 25° was therefore introduced by the nonwoven geotextile reinforcement.

Plots of cumulative axial and volumetric strain versus number of cycles are presented in figure 4. It is interesting to note the cyclic volume change response. Although the sand was dilative during monotonic loading, its cyclic behavior is purely contractive. This is attributed to the fact that, unlike monotonic loading, cyclic loading allows for a gradual rearrangement of particle packing, thereby causing continuous changes in soil structure as a function of loading

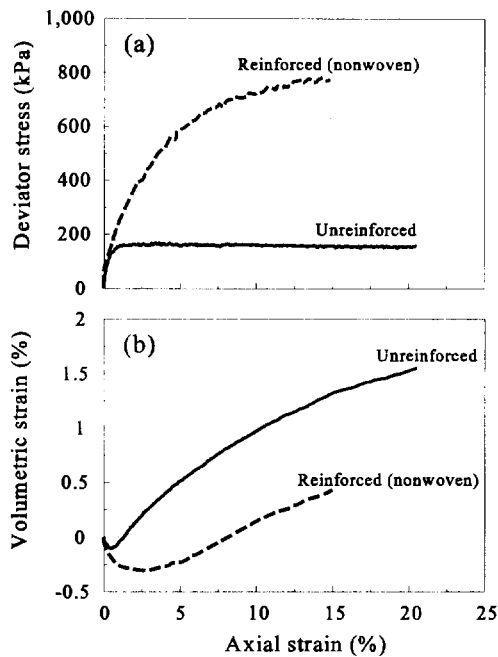

Figure 2. (a) Stress-strain and (b) volumetric response of unreinforced and reinforced concrete sand.

cycles. From a conceptual standpoint, if the amplitude of cyclic loading is not large enough to cause dilation during a given loading cycle, the volume will either remain unchanged, or more likely will slightly increase.

As shown in Figure 4, the use of geotextile reinforcement caused the rate and magnitude of cumulative axial strains to decrease. Also the tendency of the material to change its volume is smaller. This decrease in volume change tendency or potential is attributed to the enhanced lateral confinement provided by the geotextile reinforcement. The woven

Figure 3. Stress paths and failure envelopes for unreinforced and reinforced specimens.

geotextile provided better reinforcement than the nonwoven. Although no tests were performed to characterize the sand-geotextile interface properties, it is believed that, because of its geometry, the woven geotextile pore size matches better the soil particle size.

#### 4. DISCUSSION

As mentioned earlier, the presence of the reinforcement during monotonic loading causes the sand to have a lower tendency for volume change under both drained and undrained conditions. In Figure 1, the mobilized frictional stresses along the interface act toward reducing the lateral or radial spreading of the material.

In the cyclic case, however, the sand is contractive rather than dilative, which may lead one to believe that the use of the reinforcement would be ineffective. It is difficult to understand the role of the reinforcement in this case without looking at the change in average area rather than volume, versus number of cycles. The plot shown in Figure 5 demonstrates that although the volume of all the specimens decreases with increasing number of cycles, the area does not. For the unreinforced case, the area of the specimen continuously increases, albeit at a decreasing rate, even at a high number of cycles. This outward radial spreading of the material, accompanied by the reduction in volume due to cyclic loading, causes a rapid increase in cumulative axial strains.

Figure 4. Variation in axial and volumetric strain as a function of number of cycles.

**Figure 5.** Change in specimen area as a function of number of cycles for the unreinforced and reinforced cases.

When geotextile reinforcement is used, the confinement enhancement causes a reduction in this radial spreading. After a very small initial increase in area during the first few cycles, the area of the specimen barely changes. Although a slight decrease of approximately  $10 \text{ mm}^3$  was measured beyond a certain point for the nonwoven-reinforced specimens, this does not seem to be logically possible and is essentially due to the low resolution of the volume change measurement system. A significant difference in change in area is, however, evident when the response of the reinforced specimens is compared with that of the unreinforced specimen. The additional enhanced confinement, physically reflected in the smaller change in area, causes an increase in the average effective confining stress within the soil, therefore reducing its tendency for volume change.

## 5. CONCLUSIONS

Monotonic and cyclic drained triaxial tests were performed on unreinforced and reinforced sand specimens. The reinforcement consisted of geotextile discs, both woven and nonwoven, placed horizontally at equal spacing along the specimens. The experimental results indicate that the presence of the reinforcement resulted in a significant increase in monotonic shear strength of the soil and a reduction in its cyclic deformability. The volume change potential decreased in both the monotonic and cyclic cases when reinforcement was used, regardless of the tendency for contraction or dilation of the unreinforced soil. Under both monotonic and cyclic loading, the reduction in volume change was attributed to the equivalent confinement enhancement introduced by the geotextile reinforcement. The confinement enhancement mechanism was verified experimentally by monitoring the change in average specimen area during loading.

## ACKNOWLEDGMENTS

Financial support was provided by the Swiss Federal Department of Transportation, Communication, and Energy, Grant No. OFR 2/92. The geotextile specimens were supplied by Reemay, Inc., and by the Nicolon Corporation. Additional support was supplied by the School of Civil Engineering at Purdue University.

# Numerical Simulation of Dynamic Behavior of Soil with Reinforcement

R.H. CHEN

Professor, Institute of Civil Engineering, National Taiwan University, R.O.C.

T.C. CHEN

Ph.D. Candidate, Institute of Civil Engineering, National Taiwan University, R.O.C.

**ABSTRACT:** Dynamic tests on soils with reinforcement are generally time consuming and expensive. Numerical simulation is another approach to improve the understanding of the dynamic behavior of reinforced soils. The numerical simulation of dynamic triaxial tests presented in this paper considers the reinforced soil a homogenous material with transversely isotropic property. The reinforcement is polyethylene sheets, representing the stiff reinforcement. For the purpose of comparison, laboratory tests are performed as well. As the results show, there is agreement between the simulation and the testing results.

**KEYWORDS:** Reinforced soil, Numerical simulation, Dynamic triaxial test.

## 1 INTRODUCTION

The property tests of reinforced soils are generally difficult to perform, because of difficulty preparing reinforced specimen and estimating representative specimen size. Moreover, due to lack of instruments and devices and the high operational skill needed, performing dynamic triaxial tests is not common. However, numerical simulation is another approach that may be used to improve our understanding of the dynamic behavior of reinforced soils. In this paper the numerical simulation is studied. Firstly, the reinforced soil is considered as a homogenous composite with nonlinear (or piece-wise linear) anisotropic elasticity constitutive properties. The cyclic loading and boundary conditions are similar to those of real tests. Numerical methods are used to evaluate the performance of this equivalent composite. For comparison, a series of dynamic triaxial tests are performed as well.

## 2 LITERATURE REVIEW

In numerically simulation of reinforced soils, two methods generally used, i.e., the separated method and the equivalent homogenous method. The former represents each component of reinforced soil, soil and reinforcement, are represented by different mathematical elements. The latter considers, from a macroscopic view, reinforced soil as a homogenous medium. The advantage of the separated method is that the interaction between soil and reinforcements as well as the internal forces of reinforcements can be found. However, it requires more complex parameters in numerical simulation, such as the material properties of both soil and reinforcements. Additionally, the interaction model between soil and reinforcements is needed and plays a very important role, yet an acceptable model has not been developed.

The homogenized approach employs the composite concept with anisotropic mechanical theory to characterize

the complex behavior of reinforced soils. Lesniewska (1996) pointed out that, to use this method the structure should be at least in accordance with mechanically homogeneity.

In homogenous methods, the reinforced soil can be simulated as an anisotropic homogenous medium by distributing the strength or the stiffness of reinforcements upon that of the soil element from a weighted viewpoint (Romstad et al. 1976; Sawicki 1983; De Buhan et al. 1989; Wu 1989; White and Holtz 1992). Among the anisotropic models, orthotropic and transversely isotropic models are most commonly used. In an equivalent homogenous method, Harrison and Gerrad (1972) considered the soil reinforced by non-extensible strips as an equivalent homogenous material in elastic condition. The stress-strain relation of reinforced soil is assumed cross-anisotropic elastic, and elastic constants were derived. However, the nonlinear property of reinforced soils was not considered.

## 3 NUMERICAL MODELING

### 3.1 Constitutive Relation

There are several considerations important in simulation. The composite concept is used to homogenize the reinforced soils into an equivalent homogenous medium with the transversely isotropic model to characterize reinforced soil. Since the stress-strain relation of soil is nonlinear, the soil behavior is simulated by a hyperbolic model. A plane strain condition is considered as well, because of considering real structures situation.

The scheme of soil and the reinforcement as well as the equivalent homogenous element are shown in Figure 1. Both the soil and the reinforcement are assumed isotropic.

In short, the constitutive model is derived and formulated as follows, according to the force equilibrium, strain compatibility, and anisotropy elasticity.

$$E_h = \frac{(A+B)^2 - (v_r A + v_s B)^2}{A+B}$$

$$\frac{1}{E_v} = \frac{1}{E_r}(\eta_r - 2v_r C) + \frac{1}{E_s}(\eta_s - 2v_s D) + \frac{2(C+D)}{\frac{E_r C}{v_r} + \frac{E_s D}{v_s}}$$

$$v_{hh} = \frac{v_r A + v_s B}{A+B}$$

$$v_{hv} = \frac{(1-v_r)A + (1-v_s)B}{A+B} [C+D]$$

$$\frac{1}{G_{vh}} = \eta_r \frac{2(1+v_r)}{E_r} + \eta_s \frac{2(1+v_s)}{E_s}$$

$$A = \frac{\eta_r E_r}{1-v_r^2}; \quad B = \frac{\eta_s E_s}{1-v_s^2}; \quad C = \frac{\eta_r v_r}{1-v_r}; \quad D = \frac{\eta_s v_s}{1-v_s}$$

$$E_s = E_{si} \left(1 - \frac{E_{si} \varepsilon}{(\sigma_1 - \sigma_3)_{ult} + E_{si} \varepsilon}\right)^{ns}; \quad E_{si} = K_s Pa \left(\frac{\sigma_m}{Pa}\right)^{ns}$$

where

$E_h$ : tangent modulus of the composite in horizontal direction

$E_v$ : tangent modulus of the composite in vertical direction

$v_{hh}$ : Poisson's ratio of the composite that characterizes the transverse strain in horizontal direction due to the horizontal stress.

$v_{hv}$ : Poisson's ratio of the composite that characterizes the transverse strain in horizontal direction due to the vertical stress.

$G_{vh}$ : shear modulus of the composite in vertical direction

$E_r$ : tangent modulus of the reinforcement

$v_r$ : Poisson's ratio of the reinforcement

$\eta_r$ : volumetric ratio of the reinforcement

$E_s$ : tangent modulus of the soil

$v_s$ : Poisson's ratio of the soil

$\eta_s$ : volumetric ratio of the soil

$E_{si}$ : initial tangent modulus of the soil

$K_s$ : soil constant

$ns$ : soil constant

$\sigma_m$ : mean stress

$\varepsilon$ : strain

$Pa$ : atmospheric pressure

### 3.2 Analysis Procedure

The FLAC computer program (1993) was used in the numerical analysis. The analytical procedure is shown in Figure 2. The constitutive law of the above formulae is introduced into numerical model by the FISH function of FLAC. Basically, FLAC code solves the fundamental governing equations of a continuum by an explicit finite difference method, thus the stress-deformation relation of a continuum is found. The step starts from the input of soil and reinforcement properties. The input of material

Figure 1. Schematic of (a) reinforced soil element, (b) equivalent composite.

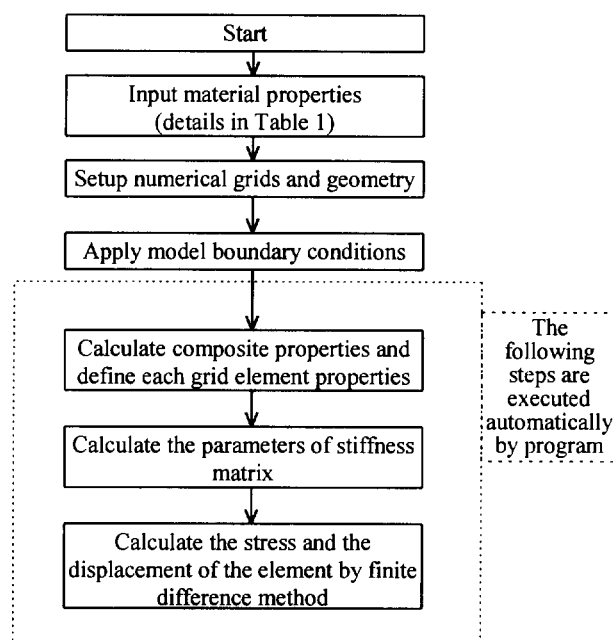

Figure 2. Numerical simulation procedure.

properties and parameters shown in Table 1 are adopted from soil and reinforcement testing, according to ATSM standard, individually. In addition, Table 2 lists the initial tangent moduli of the soil tested for hyperbolic model (Duncan and Chang 1970). The reinforcement is polyethylene sheet and is considered to be linear elastic in small strain conditions. The next step is generating the numerical grid and the boundary conditions. After completing this step, the remaining operations will be executed by the program until the result is found.

### 3.3 Dynamic Triaxial Test and Numerical Simulation Model

For qualitative comparison and simplicity, a series of

75	260.02
100	303.66

Figure 4. Axial strain versus elapsed time under 50 kPa confining pressure.

commonly used dynamic triaxial tests on reinforced soils are performed. This is because plane strain tests are rarely available in practice. The dynamic triaxial testing equipment is designed by Chan and Mulilis (U.C. Berkeley), and a cyclic loading and stress controlling device was used. The test methods are briefly mentioned below.

The soil is C109 Ottawa Sand, which consists primarily of rounded quartz particles. It is prepared with a relative density of 73%. The specimen is 71.2 mm in diameter, 171 mm in height. Three, equally spaced, horizontal layers of polyethylene sheet reinforcement were placed in the specimen. The polyethylene sheet is 68 mm in diameter and 0.2 mm thick. The Young's modulus and the tensile strength are 2171 MPa and 7.78 kN/m respectively, according to ASTM D4595-86 testing specification. Two different confining pressures 50 kPa and 75 kPa are applied.

In accordance with the test situation, the numerical model

Figure 3. Numerical grid and boundary conditions of the specimen.

Figure 5. Deviator stress versus axial strain under 50 kPa confining pressure.

of the specimen is arranged as shown in Figure 3. Hinges are set at the bottom and rollers are set at the top of the core, respectively. The loading process used in the numerical analysis is similar to the testing procedure.

#### 4 RESULTS AND DISCUSSION

The comparison between testing and simulation results are shown in Figures 4 to 7. Figures 4 and 5 are for confining pressure equal to 50 kPa, and Figures 6 to 7 are for confining pressure equal to 75 kPa. In the figures, the dashed lines and solid lines stand for the simulation and test results, respectively.

Figure 4 shows that both the results appear a slightly viscous characteristic. The axial strain of numeric

Figure 6. Axial strain versus elapsed time under 75 kPa confining pressure.

Figure 7. Deviator stress versus axial strain under 75kPa confining pressure.

simulation decayed with time, with each cycle of loading, and the hysteresis loops enlarged, shown in Figure 5. In contrast, the result from the testing maintained the same loop size than the simulation result. This is because the numerical model has introduced nonlinear properties of soil, and the viscous characteristic of reinforced soil is considered in this study. Thus, the simulation result shows the hysteresis behavior. It is noticed that the testing curve seems to be a little twist, this is because the curve is plotted from the raw testing data without regression. Except for the viscous influence, the amplitude and trajectory of axial strain in Figure 4 and the slopes of stress and strain in Figure 5 show good agreement.

In Figures 6 and 7, because the confining pressure increases, both average slopes of solid and dashed lines are larger than those in Figures 4 and 5. The hysteresis loops in Figure 7 are also more condensed than those in Figure 5. This means that the energy dissipation under higher confining pressure is less than under lower confining pressure for each cycle of applied load. The other evidence of this, finding in Figure 6, is the trajectory of the solid lines does not decay. The paths of both lines coincide but slightly differ in the maximum amplitude. This difference is due to testing device, non-uniformity in the cross sectional area of the specimen, imperfect homogeneity of a specimen, and not exactly plane strain condition of testing. However, the result of the simulation is reasonable. From the figures shown above, there is agreement between the simulation and the testing results.

## 5 CONCLUSION

This study attempts to characterize reinforced soils under cyclic loading by an equivalent homogenous approach. The reinforced soil is considered as a composite by employing

the transversely isotropic properties and nonlinear stress-strain relations. Comparison of results from dynamic triaxial tests and numerical simulation show that there is agreement between the two.

# Rail Transport Support Upgradation - Potential Evaluation of Innovative Geosynthetics

V.K. Jain

Executive Director, Geotechnical Engg., Research, Designs & Standards Organisation, Ministry of Railways, Manak Nagar, Lucknow-226011, India.

A. Azeem

Geotechnical Research Engineer, Research, Designs & Standards Organisation, Ministry of Railways, Manak Nagar, Lucknow-226011, India.

**ABSTRACT:** Indian Railways have recorded manifold increase in traffic levels, speeds and axle loads in recent decades. Since the track formation was initially constructed to cater for a very low level of traffic, speed and axle load, the increase in structural demand on old formations have lead to severe failures. The paper examines the factors governing stability of subgrades, reviews the practice/methodologies of its design and strengthening. It also gives details and findings of field trials using low strength, low modulus geotextiles and geomeshes. Based on model studies, the potential of high strength, high modulus bi-oriented geogrids is established which is under evaluation through field trials.

**KEYWORDS:** Geogrids, Geotextiles, Model tests, Rail Road Applications, Reinforcement.

## 1 INTRODUCTION

On Indian Railways, manifold increase in traffic level, speed and axle loads have been recorded in the recent decades.

Parameter	Year		Projected (2000)
	1950	1996	
Traffic level (Gross Million Tonne)	100	400	500
Speed (Kmph)	75	140	160
Axle Load (tonne)	14	20.32	25

Most of this increase is on core routes known as golden quadrilateral of approx. length 11500 Kms. With liberalisation, Indian economy is growing at a targeted rate of 6 to 7% per year and railway traffic is expected to increase by 8 to 9%. As majority of track subgrades were initially constructed to cater for a very low level of traffic, axle loads and speeds, the manifold increase in traffic levels have placed a much greater level of structural demand on the existing track support. This has resulted in several subgrade failures. As on March 97, 750 Km of track is under permanent speed restriction due to weak subgrade. In addition, temporary speed restrictions are imposed during monsoons for about 500 Km. This results in slow down of trains, loss of carrying capacity and greater maintenance inputs.

Conventional method of subgrade improvement is replacement of poor subgrade with granular material. In most of the locations, the depth of replacement is worked

out to be 70cm and above. This is difficult to implement in field due to high volume of traffic and lack of track possession. This depth can be reduced by 30 to 40% if granular material is reinforced with one layer of high strength high modulus bi-oriented geogrids. With reduced depth, the work can be executed under running traffic conditions without needing track possession.

## 2 METHODOLOGY OF TRACK SUB-STRUCTURE DESIGN

Till recently, track subgrade designs were largely based on empirical approaches. Collaborated studies were carried out to assess the state of stresses inside the subgrade and to evolve a rational methodology for its design. Its main features are :

- i) The graphs have been developed for induced stresses for different modular ratios (ratio of elastic modulus of subgrade to elastic modulus of soil), depth of construction and axle load. A graph for 25t axle load is placed as Fig.1. (Yudhbir et- al,1993)
- ii) Undisturbed soil samples are collected from the site and are tested on Dynamic Triaxial Apparatus simulating field loading in laboratory to assess its threshold strength.
- iii) The depth of subgrade construction is designed on the principle that induced stresses on the soil should be less than its threshold strength.

## 3 SUBGRADE STABILIZATION TRIALS USING INNOVATIVE GEOTEXTILES.

Based on extensive literature studies, tentative specifications for geotextiles to be used for stabilization of

subgrade were formulated (Table-1). Trial laying of geotextiles conforming to the above specifications were undertaken on a problematic fine grained subgrade needing excessive maintenance inputs on a double line track. Geotextile was placed under a ballast cushion of 250mm, sandwiched between two nominal sand layers of thickness 50mm each. The post-treatment observations revealed that the upward migration of fines was checked by geotextile, however, the fabric continued to deform and eventually ruptured under outer rail seat (Fig.2). The study revealed that light weight, low modulus non-woven geotextiles are only effective in controlling upward migration of fines but could not contribute in arresting the shear failures.

Figure 1. Induced Stresses at Subgrade( Yudhbir et- al,1993)

Figure 2. Subgrade Stabilization Trial using Geotextiles.

It was then decided to use available varieties of low strength, low modulus unoriented unstretched geomeshes (Netlon - India Grade CE 121, CE 131) in the similar fashion on problematic subgrades failing in shear on a single line track. Similar to geotextiles, this geomesh also continued to deform under passage of traffic and eventually ruptured near the rail seats (Fig.3).

Field trials using low modulus geotextiles as well as geomeshes amply demonstrated their limitations in preventing subgrade shear failures. The potential of high strength high modulus bi-oriented geogrids was thereafter evaluated.

Table 1. Specifications of Geotextile for Track Stabilizations

Parameters	Specifications
1. Composition	Polypropylene/Polyester. (Polyester to be used only in non-alkaline environment. Coloured fabric be preferred being more resistant to ultra Violet).
2. Mode of Manufacture	Non-woven, Needle punched
3. Denier	4 to 10.
4. Thickness (Under Surcharge pressure of 2 KPa)	3.00 mm and above.
5. Weight	400 gm/m <sup>2</sup>
6. Tensile strength (By cut strip test 200 x 50mm)	Min. 60 Kg.
7. Elongation at break (By cut strip test 200 x 50mm)	40% to 100%
8. Pore size	Max. 120 micron.
9. Equivalent\ Opening Size (EOS) 0 <sub>90</sub>	40 to 75 micron.

Figure 3. Subgrade Stabilisation trial using Geomesh.

#### 4 MODEL STUDIES

Model studies were carried out in the laboratory using a large size metal box 300 mm x 300 mm x 200 mm. The mould was filled with non-cohesive sub-ballast material conforming to Indian Railways specifications and compacted to desired density (90% of MDD). The test conditions included the following :

- i) Sub-ballast material only (unreinforced),
- ii) Sub-ballast with one layer of biaxially oriented geogrid (Tenax LBO 301) placed at the mid-height.

iii) Sub-ballast with two layers of biaxially oriented geogrid (Tenax LBO 301) placed at heights 1/3rd and 2/3rd respectively.

The relevant properties of biaxially oriented geogrid Tenax LBO 301 are as follows :

	MD	TD
• Peak Tensile Strength (KN/m)	19.5	31.6
• Yield Point Elongation (%)	16.0	11.0
• Aperture Size (mm)	30	40
• Unit Weight (gm/m <sup>2</sup> )	350	

The vertical load was applied through a square steel plate 125 mm x 125 mm size.

The ratio of mould dimension to footing dimension was 5.76 and its influence on test results are considered as marginal only.

The observations included recording of incremental vertical load and corresponding vertical deformations at the four corners of the box. The load deformation characteristics for the three test conditions are shown in Fig.4 which reveal the following :

Figure 4. Model Studies – Load Deformation Curves with & without reinforcements

\* In all cases, settlement increased with increasing load. Settlement was maximum for unreinforced conditions.

\* Runaway deformations were noted at a vertical load of 3 tonnes in case of unreinforced sub-ballast and at 4 tonnes in case of reinforced sub-ballast.

\* When compared with unreinforced conditions at a vertical load of 3t. the percentage decrease in deformation was 46% in case of single layer reinforcement and 54% in case of double layer reinforcement.

\* Under these test conditions, the modulus of elasticity is worked out to be 63 MPa for unreinforced condition and 111 MPa for single layer reinforced condition. This data have been used for design of subgrade thickness for a case study on Cuttack-Bhadrak Section.

## 5 CASE STUDY

Cuttack-Bhadrak Section is a vital main line railway track between Howrah-Madras and connects Paradeep Port with Talcher-Shalimar. Maximum permissible speed of the section is 105 Kmph. A speed restriction of 30 and 50 Kmph is imposed on the stretch from Km 389/1 to 392/15 Dn line during rainy and dry seasons respectively due to weak subgrade. To strengthen the weak formation, detailed field investigations including testing of undisturbed and disturbed soil samples from site were undertaken by RDSO. The undisturbed soil samples have been tested in a Dynamic Triaxial Apparatus for confining pressure of 20 KPa (equivalent to a depth of 90 cm) and 35 KPa (equivalent to a depth of 180cm). With these values, a graph has been plotted between depth of construction and threshold strength of the soil. (Fig.5)

Figure 5. Threshold strength Vs Depth of Construction.

The depth of construction is worked out to be 75 cm (25 cm ballast + 50 cm sub-ballast). This depth is reduced to 55cm (25cm ballast and 30cm sub-ballast) by reinforcing sub-ballast with one layer of bi-oriented geogrid. Sample calculation is presented in Appendix-I.

With the use of geogrid reinforcement, the depth of sub-ballast is reduced from 50cm to 30cm, resulting in a saving of 40%. The most important feature of this design is that while interposing a sub-ballast of 50cm thickness requires track possession, no track possession is required for interposing 30cm thick sub-ballast layer. Since this is a core route, track possession is difficult. Therefore, provision of reinforcement will help in executing the work under running traffic.

## 6 CONCLUSION

Maintenance of railway subgrade is important due to manyfold increase in traffic levels, speeds and axle loads. Induced stresses in the subgrade should be less than threshold strength of the soil.

Strengthening of weak formation is required to be done under running traffic without track possession due to heavy traffic.

Soil is poor in tension. Provision of reinforcement will enhance the soil modulus.

Low strength low modulus geotextiles and geomeshes are not suitable for subgrade stabilisation.

High strength high modulus bi-oriented geogrid is more suitable for formation rehabilitation. One layer of geogrid reinforcement will reduce the sub-ballast thickness by about 40%.

Further studies would be needed to work out optimum modulus and strength characteristics of geogrid and sub-ballast characteristics for achieving higher economies, especially where depth of sub-ballast worked out is higher than 70cm.

## Computations for depth of sub-structure

Eb	=	Young's Modulus of ballast
Esb	=	Young's Modulus of subballast
Es	=	Young's Modulus of soil
db	=	Depth of ballast
dsb	=	Depth of subballast
dt	=	Total depth of construction

Case-I - Without geogrid reinforcement:

db	=	25cm
dsb	=	50cm
dt	=	db + dsb = 75cm

Eb	=	130 MPa,
Esb	=	63 MPa (from model test)
Es	=	40 MPa

$$E_{eq} = \frac{E_b \times db + E_{sb} \times dsb}{db + dsb} = 85.33$$

$$\text{Modular ratio, } m = \frac{E_{eq}}{E_s} = \frac{85.33}{40} = 2.13$$

For dt = 75cm, Induced stress = 48.2 KPa (from Fig.1)

Threshold strength of soil = 48.7 KPa (from Fig.5)

Hence safe.

Case-II – Using one layer of geogrid reinforcement LBO-301:

db	=	25cm
dsb	=	30cm
dt	=	db+dsb = 55 cm

Eb	=	130 MPa
Esb	=	111 MPa (from model test)
Es	=	40 MPa
Eeq	=	119.63 & m = 2.99 (computed as in Case I above)

For dt = 55cm, Induced stress = 48 KPa (from Fig.1)

Threshold strength of soil = 48.3 KPa (from Fig.5)

Hence safe.

# The Use of Geotextiles for the Construction of the European High Speed Train Network

Frans De Meerleer  
Director - TEXION. Commercial Consultants to LYS-FABRICS, Belgium.

Frank Donckers  
General Manager Business Unit Raw Materials - IDEAL GROUP, LYS-FABRICS, Belgium.

**ABSTRACT:** The construction of a network of high speed trains in Europe involves the use of geotextiles for many applications. The Authors describe the general uses of geosynthetics in railway sub-ballast and construction applications, but point out those aspects where geotextiles play a particular part in assisting in the extreme environment of high speed train earthworks. The paper goes on to describe some actual applications where the main network has used geotextiles and outlines some of the difficulties involved in their specification, particularly bearing in mind the European decision to not standardise on geotextile classifications between Member Countries.

## 1 THE USE OF GEOTEXTILES TO ASSIST WITH SUBGRADE PROBLEMS

It has long been recognised that subgrade pumping beneath railways is a problem that can be ameliorated by the use of a geotextile at the ballast/subgrade interface. (Refs.1 & 2) The design difficulty has always been how to know which type of geotextile is the most suitable. With time, experienced railtrack engineers came to the opinion that low permeability and fine pore size were the preferable criteria for railways. The function of a geotextile beneath a railway is fundamentally different from that beneath a temporary access road or a permanent highway. The essential differences are a) that the ballast used to provide sleeper support is very coarse, uniform and angular, b) the regular repetition of the vibration from the axles can set up sympathetic resonant harmonic oscillations in the soil and c) the rail track system feeds a unique long distance wave of both negative and positive pressure into the ground ahead of the train itself.

The geotextile improves the structural integrity of the track and reduces the need for maintenance. It is generally considered (as shown in Fig.1), that the shedding of precipitation, caused by the fine pore size of the textile, is of particular benefit to the structural integrity of the track, whereas the filtration objective of the textile in preventing the upward migration of fines is of prime relevance to the maintenance requirements.

The new high speed train lines are multi-track systems (as opposed to low speed single track lines often encountered in developing countries), so maintenance is not such a critical problem as structural integrity. Therefore, in considering the geotextile requirements for this purpose, prevention of degradation of the subgrade is the main consideration. This logic has led to the conclusion that fine pore size and puncture resistance of the textile are the most important requirements. However, these properties can be found in a variety of different textiles including both woven and nonwoven types. Naturally, lightweight nonwovens are not suitable for this purpose since they can be

damaged too easily. However, the heavy grades of needlepunched and woven tape textiles have been selected for sub-ballast separation.

The European Union has made substantial progress with regard to the standardisation of design approach for all civil and structural engineering matters including geosynthetics. However, there has been the positive decision not to standardise the classification of geosynthetics for particular purposes. This appears to have been a pragmatic decision which holds the situation as at present, based upon different national, commercial and experience considerations for the utilisation of these products. No doubt this will have to be addressed in due course, but at the moment it leads to apparent anomalies in pan-European projects such as the high speed train system. Where the lines cross a national border, it has proved necessary to employ a different material because of different national preferences, experiences and classification systems, even though the ground conditions on each side of the border may be identical. The Authors feel that this should not be viewed as a failure of the concept of the European Union, but an indication of how difficult and time consuming it is to join together and blend a large number of sophisticated developed countries.

Fig.1. Rainfall shedding and pumping prevention by highly impermeable geotextile.

For, example, the Belgian Railways (N.M.B.S.) prefers to use nonwovens for this purpose, whilst the German Railways (D.B.) prefers woven tape products.

These filtration and drainage applications at sub-ballast level are particularly important in areas of cuttings, where water tables are high.

In addition to the prevention of contamination and saturation that a sub-ballast textile can provide, in high speed track conditions consideration must be given to the fundamental role of stress absorption. As can be seen in Fig.2 (Ref.3), although vertical stress is absorbed by the ballast layer, there is still a considerable amount of vertical stress remaining at the base of the ballast, to be passed down into the relatively soft subgrade. In embankment situations, where the subgrade is a pre-specified and pre-compacted material, and where drainage may be good, this stress may be absorbed adequately. However, a strong geotextile at this horizon can absorb stress and reduce the impinged load onto the subgrade. By reducing lateral shear stresses in the subgrade, the textile will help to increase its overall bearing capacity. Cohesive soils under shear exhibit a lower bearing capacity than those that are not. Under these circumstances - which include soft subgrades, wet subgrades and high speed train environments, it could be considered advantageous to choose stiffer woven products rather than nonwovens.

Fig.2. Typical variation of stress vertically beneath a rail line without the benefit of a geotextile (Ref.3).

The critically important contribution of a geotextile is shown in Fig.3 (Ref.4) which shows the typical results of a series of cyclical triaxial test in which the shear stress on the soil sample is continuously varied to simulate the passage of a high speed train.

Note that in this case, when the shear stress imposed on the soil exceeded  $65\text{kN/m}^2$ , the soil rapidly deteriorated with increasing induced strain until failure was reached at only 10,000 cycles. Below a shear of  $65\text{kN/m}^2$ , the soil stabilised up to and beyond one million cycles. The impact of

reducing shear on performance and maintenance cannot therefore be overstated. A high strength geotextile can contribute significantly to this providing that it has adequate durability (abrasion resistance and polymer longevity). There are doubts expressed about the potential longevity of woven slit film textiles, for example.

Fig.3. Effect of shear stress on cyclically induced cumulative strain in a soil without the benefit of geotextile (Ref.4).

## 2 GEOTEXTILES AS DRAINAGE COMPONENTS BENEATH NEW EMBANKMENTS

It is common to use geotextiles as separators at the base of new embankments. As mentioned previously, since in the case of high speed trains, structural stability is of paramount importance, the European system has commonly included the use of geotextiles as elementary separators at the base of embankments not only to act as construction aids, ensuring the highest level of integrity for the structure, but also as components in drainage elements, thus ensuring the reduction of water levels in the basal zones of the embankments. Especially where embankments are relatively more permeable than the underlying formation material, the use of low permeability geosynthetic textiles can lead to a reduction in received precipitation water in much the same way as is achieved beneath the ballast layer itself.

Once more, in this application, there have proved to be national differences, with the French Railways (S.N.F.C.) using woven geotextiles and immediately across the border, the Belgian Railways using nonwovens.

## 3 GEOTEXTILES AS REINFORCING COMPONENTS BENEATH NEW EMBANKMENTS

Even more so than highway embankments, high speed rail embankments are subject to potential lateral slope failures. The front of a high speed train

is preceded by a force wave within the rail and sleeper system which actively pushes down on the soil before the train arrives, followed by a continuously high surcharge load during the train passage. To counteract this effect, geotextiles are used in the sloping sides of banks as reinforcement layers and in particular, they are used as horizontal reinforcing layers at the basal horizon of embankments, to protect against slip circle failure. Not only are the dynamic forces greater with high speed trains, but as can be seen in Table 1, (Ref.5.) rail and sleeper weights also increase directly as the train speed increases. Although relatively small, this must also be taken into account in the slope design.

Axle wt. Tonnes	Speed Km/hr	Rail Wt. Kg/m
35	50	57
35	140	65
35	200	70

Table 1. Typical rail weights

It is interesting to note that although overall slope load is increased, the use of heavier weight rails reduces the direct shear loading of the ballast and sub-soil system. For example, increasing the rail weight from 48 to 68 kg/m diminishes soil shear stress by 20%.

The need for structural integrity is generated principally by the need for consistent and even track alignment both vertically and horizontally. Deformation levels that might be tolerated for ordinary railway trains are not permissible on high speed tracks.

South of Brussels, the Belgian Railways have employed the traditional high strength polyester woven geotextiles as the basal reinforcement layer for their sector of the European Network leading to Paris. This was not the usual standard reinforcing detail, but at the location of the River Zenne, the existing track structure had to be widened as well as refurbished to take the high speed traffic. The Zenne was running parallel to the old railway track and the widening involved displacing the river laterally to construct the new extension.

The cross section of this location is shown in Fig.4., where it can be seen that geotextiles were used to contain the entire fill body that infilled the old river bed and channel. The river was accommodated in a newly constructed canal built away from the new high speed track. Naturally, geotextiles were used in the banks of the canal as well, for erosion protection.

One of the interesting principles of the European High Speed Train Network is that the stations were to be located in the centre of cities to provide true

accessibility for the public. In practice, this meant that existing main line stations were to be upgraded for the new high speed trains.

This led to a problem experienced by the Japanese in the construction of their high speed inter-city trains - lack of space. In order to widen the track zone in city areas, it has become necessary to utilise reinforced soil technology as the most modern, cost-effective method of construction. Not only is reinforced soil construction cost-effective, but it is also environmentally friendly, permitting the adoption of a number of green grass and vegetated face finishes.

Fig.4. Widening of the Belgium - Paris sector parallel to the River Zenne.

The Japanese experience with earthquakes has highlighted the benefits of reinforced soil structures in areas of vibration. During recent major earthquakes, reinforced soil structures were invariable, the only ones left standing. In the light of these results, it is not surprising that reinforced soil should be adopted to support high speed train lines which are a major source of vibration.

#### 4 GEOTEXTILES IN THE CONSTRUCTION OF HIGH SPEED BRIDGES AND RAIL FLY-OVERS

The impermeability of bridge decks and fly-overs was a major concern for the Network designers. As a result of considerable technical input and research, a number of special composite geotextiles were developed impregnated with bitumen.

The geotextiles themselves were composite heavy nonwoven needlepunched (1500 g/m<sup>2</sup>) and strong woven (100 kN/m) which offered a cost-effective and reliable solution. Although well proven in laboratory testing, it is interesting to await the outcome of several years of real use to evaluate the results. Their use is shown in Fig.5.

Fig.5. Location of bitumen impregnated composite between ballast and bridge decking.

### 5 LIFE EXPECTANCY OF GEOTEXTILES IN HIGH SPEED RAILWAY SYSTEMS

It is interesting to note that the life expectancy requirements of geotextiles in high speed designs varies depending upon where the textile is situated in the design. For example, the basal reinforcing geotextiles used to prevent slip circle failure should be designed to last in excess of 100 years, whereas, the sub-ballast textiles could be designed for less. The reasons for the less stringent requirements for the sub-ballast textile are that in addition to the ballast layer experiencing unavoidable deformations and in addition to potential frequent replacement of textiles during ballast maintenance, the predicted life of the concrete sleepers will, in any event, only be some 40 to 50 years, thus necessitating a major upper level refurbishment at that interval period. A longer planned life expectancy for the textile at this level would therefore not be cost effective.

Note: The Authors wish to acknowledge that the opinions expressed herein are their personal opinions and do not represent the views of their respective organisations.

# Geosynthetic System for the Facing of Bovilla Dam

P. Sembenelli

Geotechnical Consultant and Managing Director, SC Sembenelli Consulting, Milan, Italy

G. Sembenelli

Geotechnical Consultant, SC Sembenelli Consulting, Milan, Italy

A. M. Scuro

Technical Director, Carpi Group, Arona, Italy

**ABSTRACT:** Bovilla Dam is currently the highest embankment dam incorporating a polymer (PVC) geomembrane installed within a system of geosynthetics, to provide the necessary waterproofing to the top 58 m of an 81 m high structure. Bovilla dam is the last of several such dams, of increasing height, designed and built in the last decade, along the lines set forth since the pioneering projects of 1959 - 1960. The position of the waterproofing system is on the upstream face of the dam, the waterproofing element is a 3 mm thick, plasticized and stabilised PVC geomembrane and the geosynthetic system is protected with a facing of cast-in-place, concrete slabs.

**KEYWORDS:** Dam, Geocomposites, Geomembranes, Protective cushioning, Seepage control

## 1 INTRODUCTION

Bovilla Dam, across Terkuze river in Albania, was originally designed as a concrete faced, gravel fill. It was not possible to reconstruct the basis for selecting a 1V/1.6H slope typical for rockfill but definitely steep for a sand-and-gravel fill. The design of the facing was developed around 1994 along the earliest schemes for such facings: a grid of concrete beams run under both the vertical and the horizontal joints of the facing slabs. The thickness of the slabs was about 0.5 m. The reinforcing of beams and slabs was quite complex and even more so was the system of the copper and PVC waterstops.

During the construction of the embankment, mostly built with alluvial gravel-and-sand, gulying of the upstream face by rainfalls developed. Attempts to reconstitute the face and recompact the fill gave unsatisfactory results. A growing concern for the end quality of the concrete facing and a compelling need to reduce both construction cost and time, suggested to look for alternate facing solutions.

A geosynthetic system essentially based on PVC geomembrane and geotextiles, finally proved to be a solution compatible with the fill materials, applicable notwithstanding of the slope of the face, requiring a much shorter placement time and nearly halving the cost of the design solution.

Late in 1994 the change in design was decided and design of the new facing system started. Placement of the bedding and drainage layer started in mid 1995 and was completed by the end of the year. Placement of the geosynthetic system started in May 1996 and was carried out in 3 parts: centre, left and right. The left and right parts were placed only after grouting of the foundation rock along the side beam was completed. For this reason placement of the 3 parts was not continuous. Placement of the geosynthetic system was completed in September and the waterproofing protection completed in November 1996. Figure 1 shows the upstream slope of Bovilla dam when placement of the waterproofing and protection were in progress. The net time required for the placement of the

Figure 1. Upstream slope of Bovilla dam in 1996. Protection has been completed in the centre part of the face.

geosynthetic system was 30 days with an average placement rate of 300 m<sup>2</sup>/day. The net time required to place the concrete protection was 100 days with an average placement rate of 90 m<sup>2</sup>/day.

The cost of the waterproofing system, including bedding, geosynthetics system, peripheral seal and concrete facing was on the order of 160 US\$/m<sup>2</sup>, in 1996 costs. All geosynthetics were imported from Italy and placement was directed by expatriate personnel.

## 2 THE FORERUNNERS OF TODAY'S DAMS

The first synthetic material tested as a waterproofing element was Butyl Rubber RI (Sabetta dam 1959) soon followed by Polyvinyl chloride PVC (Dobsina Dam 1960 and Terzaghi dam 1962). Low density polyethylene LDPE was used for the first time in 1964 (Toktogul cofferdam).

In later years the preferred choice became PVC in Europe and high density Polyethylene HDPE in the USA. According to a list of 83 earth and rock dams, major reservoirs and cofferdams waterproofed with geomembranes, prepared by the Senior Author, 54 structures have been built in Europe, 10 in Australasia, 5 in Africa and 14 in the Americas. PVC has been used on 33 known cases of the total. In Europe PVC has been used on 24 cases and in the Americas on 3 cases only. Waterproofings for high dams were mostly based on PVC. The Authors believe that part of PVC's success is due to the easily installed and well-performing welds possible with this polymer.

During the pioneering period, design practice developed along 2 lines: -i) thin geomembranes ( $< 0.5$  mm) and -ii) thick geomembranes ( $> 1.0$  mm). Thin geomembranes were selected mainly based on seepage loss considerations overlooking the possibility of damage during placement. Practical difficulties in welding very thin geomembranes, suggested using glued joints and often such geomembranes have been installed using folded connections. Negative experiences were the result of this type of design (Sembenelli 1995). Thick geomembranes and welded connections were adopted as a result of considering proper placement and welding as relevant requirements.

The selection of PVC and HDPE allowed production of continuous, high quality welds. Hot-air welding with hand-held blowers, soon evolved into machine welding by hot air and hot points. As a result of attention to the quality of the seams, the senior Author developed, in the early 70s the double track seam which made possible testing of the entire seams' length.

Bovilla is the latest example of more than 70 cofferdams, large reservoirs and dams designed along the concepts developed in Italy since Sabetta. The Italian practice always adopted thick geomembranes to provide extra strength against handling and placement damages and to allow high quality, controlled welds. Soon after the pioneering examples based on Butyl rubber RI and Chlorosulphonated polyethylene CSPE, Italian practice adopted PVC as the polymer. Quite early geocomposites consisting of a PVC geomembrane + a Polyethylene terephthalate PETP nonwoven geotextile were substituted for plain PVC sheets. Multi-layer geocomposites, incorporating a diffused reinforcement were developed and applied along this line of thinking.

The design of Bovilla dam was based on the experience gained with large scale testing, in designing and in supervising construction of several dams in Italy and abroad. Possibly the most significant experience related to the type of geocomposite adopted is Alpe Gera Dam (174 m high). The protection with cast in place concrete slabs was successfully adopted at Jibiya Dam (Sembenelli

Figure 2. The plan of Bovilla dam with waterproofing based on a geosynthetic system and a cast-in-place concrete slab as a protection.

1990). The peripheral connection was perfected in the application of geomembrane waterproofings on several concrete dams like Pracana Dam.

## 3 THE EMBANKMENT OF BOVILLA

The dam, as shown in Figure 2, is placed in a narrow, winding gorge cut through a ridge of limestone rock just downstream from a tectonic contact with a schist formation. The relatively soft schists have been eroded and the limestone forms a long and high wall at the South-West end of the reservoir. A diversion tunnel has been cut through the limestone of the left bank. The limestone is heavily karstified and a large spring exists under the right abutment of the dam. Except for the excavation required to set the side beam, no excavation was carried out on the abutments. A deep, karstic niche was backfilled with concrete prior to filling against it.

At the upstream toe of the dam, river bottom rock was reached some 10 m below riverbed and the channel was filled with a concrete plug. The plug was raised some 15 m above riverbed elevation thus creating a gravity toe block nearly 25 m high. Figure 3 shows the cross section of Bovilla.

In order to condition the riverbed materials under the future fill, the rock on the sides of the gorge was demolished to a distance sufficient to permit the transit of construction equipment. Rock fragments covered by clean,

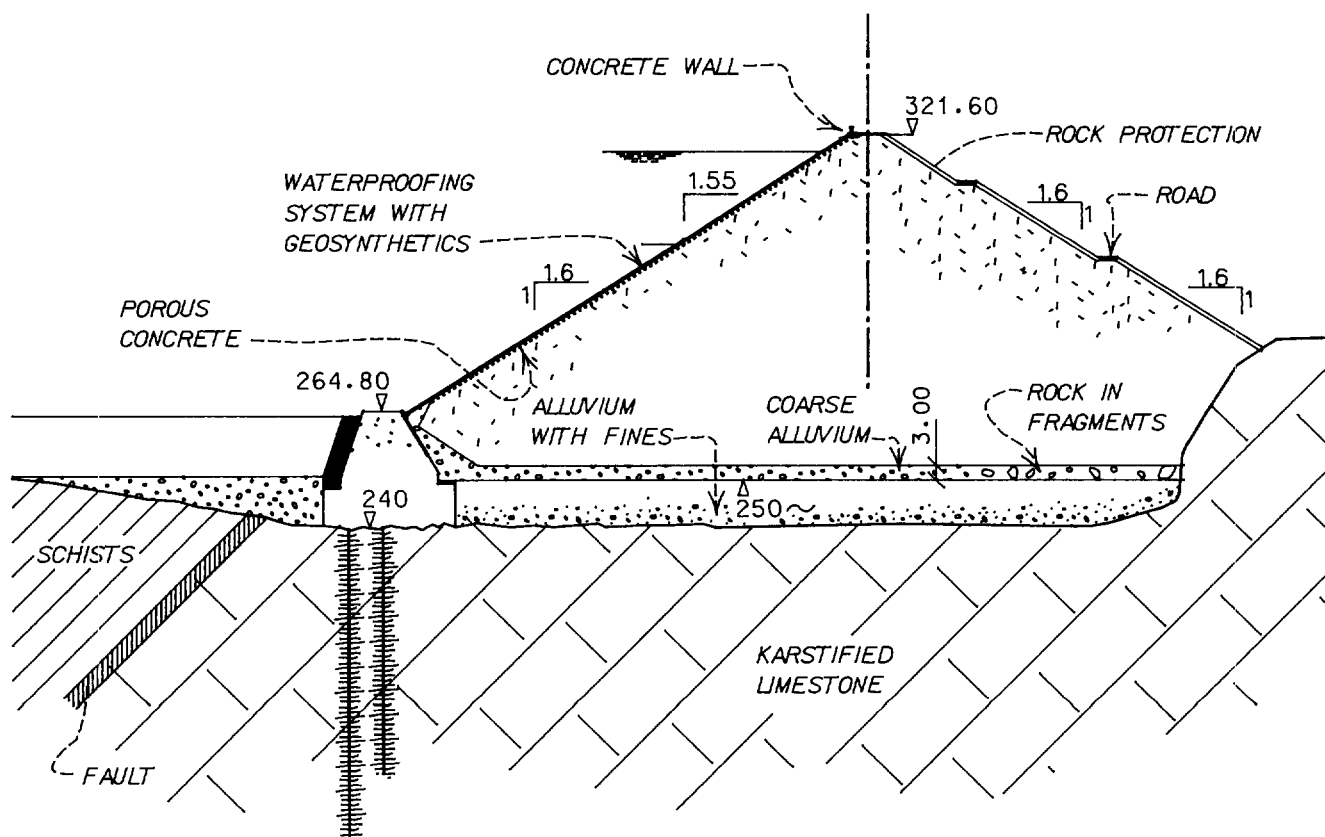

Figure 3. Main cross section of Bovilla dam on the Terkuze river. The maximum height of the dam is 81 m and the geosynthetic system has been applied over the top 57 m. The crest length of the dam is about 140 m.

coarse gravel were leveled and compacted in the riverbed channel thus creating an efficient bottom drain.

A substantial deposit of alluvial materials existed in the expanse of the reservoir and the embankment was filled with borrow-run sand-and-gravel. The alluvium is well graded and contains a certain amount of fines so that the permeability of the compacted embankment is quite low and certainly not uniform. The high percentage of fines was hindering proper compaction near the slope and favoured gullying along the compacted face. Difficulties experienced at properly filling and forming the face, suggested placing the centre and downstream parts of the fill only, while a proper solution was worked out. Hence the lower 40 m of the embankment were built in 2 separate stages which increased the potential for non uniform settlement of the face, under hydrostatic loads.

The rock line for the side beam was designed so as to obtain a profile in the plane of the face as regular as feasible. Fairly extensive excavations were necessary at given locations to smooth corners and to eliminate overhangs. The rock bench where the side beam had to be set, was designed with a gentle inward slope.

To eliminate gullying by rainwaters and to provide a free-draining, strong and uniform support to the waterproofing system, a sand-free, low-cement concrete was adopted which could be placed to produce a smooth surface. The specified aggregate size was 15 - 25 mm with  $C_u < 2$  and the cement just enough to hold the grains

together. Laboratory tests carried out on the cemented granular bedding proved that its coefficient of permeability was  $k > 1 \text{ cm/s}$ . The cemented granular bedding was placed from the top of the fill, as the fill was raised, in 2 m high bands, smoothed and compacted with a vibratory plate mounted on the arm of an excavator.

The thickness of the free-draining bedding layer was increased all along the periphery to widen the length of the contact between the drain and the abutment rock, with the aim of improving the collection of any seepage underpassing the side beam.

The toe block and side beam, part of the original design, had been cast as an unreinforced concrete block sitting over the abutment rock. As part of the design of the geosynthetic facing, the abutment surface, immediately below the side beam, was modified so as to avoid too steep as well as too flat profiles at the contact with the embankment. This was obtained by trimming the rock in excess or by concrete castings, where the abutment's rock was dipping too steeply.

A second stage reinforced concrete slab was placed over the surface of the side beam to reduce the danger of concentrated seepage in the concrete, which could eventually bypass the peripheral connection. Low pressure concrete grouting was applied systematically to the concrete-to-concrete and concrete-to-rock joints trough holes drilled from the face of the side beam.

As an additional measure against short circuit seepage,

the surface of the side beam's concrete, immediately above the geomembrane-to-concrete connection line, was treated with epoxy resins to fill honeycombs and hair cracks.

#### 4 THE WATERPROOFING SYSTEM

The waterproofing system of Bovilla dam was based on the previous designs of similar dams (Semenelli and Amigò 1996) and on experiences and studies regarding seepage flow through holed geomembranes. The choice of a geocomposite was dictated by the benefits provided by a geotextile backing, particularly if intimately connected to the geomembrane, in reducing the level of losses and in avoiding channelized flow under the liner (Fukuoka 1986).

The basis for selecting a geocomposite developed by the special Contractor CARPI was the proven performance of the liner under water heads far greater than that expected at Bovilla although, most of the precedents available were concrete or masonry dams (Scuero 1997). Other geosynthetics, like HDPE, would require finding adequate solutions to accept a more than tenfold larger coefficient of thermal expansion. A thermally stable geosynthetic makes much easier welding and protection with light weight slabs.

The waterproofing system, shown in Figure 4, consists of a 3 mm geomembrane coupled to a 700 g/m<sup>2</sup> geotextile. The geomembrane is a monolayer PVC (polyvinyl chloride) extruded from a straight-head extruder. The geotextile is a nonwoven, needle punched, continuous filament, PP (polypropylene) fibre. The coupling is obtained by calendaring the geotextile on the hot PVC sheet as it leaves the extruder. A selvedge of 50 mm is left on one side, for proper longitudinal welding of adjacent rolls. The geocomposite is produced in 2.05 m wide rolls of indefinite length.

Large scale loading tests were conducted on a high capacity cell. The support was the granular bedding, on 1 to 1 scale, and the maximum test pressure was 900 kPa i.e. 50 % in excess of the maximum expected water pressure on the face. Each test consisted of 3 loading-unloading cycles, with a first loading bench at 500 kPa, 24 hours of sustained load at 900 kPa and 6 hours recovery time in unloaded conditions in between cycles. The profile of the geocomposite under maximum load was obtained.

Another set of tests were carried out as shown in Figure 5 to simulate a collapse of the granular bedding surface. A sharp edge, vertical sided hole 0.3 m in diameter and 0.2 m deep was created under the geomembrane and a water pressure equal to 150 % of the full reservoir load was applied. The geocomposite stretched into the hole beyond the failure strain of the geotextile backing (about 34 % as determined with large scale burst tests) but the PVC geomembrane did not burst. The geotextile tore at an early stage of the test but, being on the underside of the geomembrane, its failure could not be observed in detail.

The geocomposite was factory cut to the exact lengths assigned by the design to each roll so that placement could be faster and more accurate, all horizontal seams could be eliminated, and wastage kept below 1 %.

Figure 4. Cross section of the waterproofing system used at Bovilla dam.

Each roll of geocomposite was carried to the crest, unloaded and fastened to the concrete beam running along the upstream edge, with a tie down system (bolts and nuts). The roll was hence winched downslope and manually guided to its final position. The friction angle between geotextile and granular bedding was measured in the laboratory and proven to be 38°, about 20% larger than the slope angle. Hence a substantial grip developed between geotextile and granular bedding, enough to support the full dead weight of the geocomposite.

The geocomposite was ballasted against wind actions with strings of sand bags supported with ropes. The distance between ballast strings was about 6 m.

In spite of the ballast, however, a light but sustained wind circulating through the voids of the bedding layer, cut the frictional resistance to nearly zero and the full roll length ended hanging from the top beam. The geocomposite stretched about 0.5 % and some readjusting cuts had to be made at the toe of the slope.

The geocomposite was welded with butt welds 30 mm wide. Welds were all made with hot air equipment and about 50 % of the welding was manual. All welds were inspected and tested with a blade.

The design of the periphery of the geocomposite was such as to allow sharp, differential settlements of the fill with respect to the tie-down line. A reserve length of geocomposite was provided, sandwiched between anti-grip sheets of HDPE and nonwoven geotextile.

A geomembrane strip (without geotextile backing) was used to form the peripheral connection along the block toe and side beam. The connection was of the tie down type (bolts and nuts) with a prior application of a flattening polymer paste and soft rubber gasket. The tie down was obtained with embedded 10 mm bolts spaced 0.2 m and an 8 mm stainless steel flat profile and nuts. Each nut was

closed with a dynamometric wrench.

A detailed inspection of the geomembrane surface and a detailed approval procedure was specified prior to covering the geocomposite with the geotextile. This operation was deliberately done just before starting the casting operations so as to minimise the possibility that undetected damages could happen to the geomembrane while covered.

One of the key checks of the inspection was aimed at assessing the conditions of the supporting layer. Loose stones or other small objects accidentally entrapped under the geocomposite were located. A rule was set to decide when the characteristics of the geomembrane would not permit draping the foreign object, given its dimensions or shape. In such cases the geocomposite was slit open and the object removed. The cut was hence repaired by superimposing a piece of geomembrane.

## 5 THE PROTECTION OF THE GEOMEMBRANE

In many dams exposed geomembranes have been adopted with success and have proved their adequacy to a lasting service (Amigò 1994). Protection of the geomembrane is often avoided to allow inspection and easy maintenance while the presence of a protective layer may forbid checks and hinder repairs.

Protection also adds to the cost of the dam and may sometimes require an investment comparable to that of the waterproofing system itself. Timewise, protection requires, in general, construction times which are longer than those needed to place, weld and test the waterproofing system itself. The decision to protect the geosynthetic system needs therefore to be justified and, in general, light solutions are preferable to heavy ones.

The rationale for deciding to protect the facing of Bovilla was based on several reasons: the steepness of the gorge and the consequent danger of falling rocks, which would damage the waterproofing system, the steepness of the face reducing to nearly zero the possibility of supporting the geosynthetic system by friction and, finally, the remoteness of the site and the fear that the geosynthetics could be vandalised.

Cast in place, unreinforced concrete slabs were selected as protection. The thickness of the slabs was 0.3 m in the lower parts of the facing where the length of the free standing slab exceeds 100 m and was reduced to 0.2 m over the upper 50 m of the face. A nonwoven, needle punched, continuous fibre, PP (polypropylene) filament geotextile 800 g/m<sup>2</sup> was placed over the geocomposite to work as a decoupling layer, as well as a protection to the geomembrane against mechanical damage during concreting operations. The PP geotextile proved to work efficiently also as a light reinforcement to the slab (Sembenelli 1996).

Shear tests carried out on a large sample of the geocomposite resting on the granular bedding and covered with the specified geotextile, enabled the measurement of the actual friction at the geomembrane-to-geotextile interface. Tests proved that a friction angle of 22° was the maximum that could be relied upon. This angle is 70% of the slope angle. Therefore a substantial portion of the

Figure 5. Large scale survivability test of the geomembrane simulating a collapsed hole in the bedding layer. The test was carried out in a high pressure vessel under 1.5 the maximum reservoir pressure. The granular support used in the testing chamber is the actual bedding placed on the dam.

protective slabs dead weight will have to be taken by the toe block. A reduction coefficient must be applied to the geotextile-to-support friction angle to account for the effects of construction and with related vibrations.

The joint pattern was based on continuous vertical and staggered horizontal joints. Shear keys were created along the sides of all slabs so as to block them, both ways. At horizontal joints, where appreciable angular deformations were considered likely to occur, through-going dowels were provided. Horizontal joints have the only purpose of allowing angular deformations to copy the deformed profile of the embankment facing, under full hydrostatic load. Horizontal joints are therefore obtained with the interposition of 1 ply of 350 g/m<sup>2</sup> geotextile. Vertical joints are assigned the key function of relieving any uplift pressure existing under the slabs upon draw down. A 3 ply packing of geotextile is therefore provided along them all. While along all horizontal joints the geotextile undergoes a substantial compression, negligible forces compress the geotextile interface along vertical joints. The in-plane permeability of the geotextile remains hence close to that of the material under a nominal normal stress. Slabs were cast in successive horizontal rows which allows halving the required length of forms as shown in Figure 6. The surface finish required for the slabs was obtained by straight-edge and trowel.

Figure 6. Joint pattern of the slabs forming the protection at Bovilla dam and casting sequence.

Each vertical slab rests, with most of its weight, against the toe block or against the side beam. Proper thickening

and reinforcement of the concrete section was hence introduced so as to keep the compressive stresses at the contact, within acceptable limits (the maximum compressive stress is on the order of 800 kPa). The design was developed so as to make each slab self-supporting. Several sections exist, along the side beam, where the contact line between the slab and the beam dips steeper than the concrete-to-concrete friction angle (assumed as 35°). Along such sections, the profile of the side beam was shaped in a jig-saw manner so as to prevent side way slippage of the slab foot.

An offset in the toe block profile locates the contact line between block and protection so that it stays off the vertical of the peripheral connection to ensure that the inevitable settlement of the edge of the facing slabs, with respect to the toe of the block, would not damage the connection. A styrofoam cap placed over the profile and the nuts, in its turn enclosed in a pocket of uniform sand, was added for the same purpose as shown in Figure 7.

Protection was placed from the bottom upward in 3 sections. The centre portion first was placed and, later, the 2 sides. The reasons for such unusual placement (which resulted in an increased length of side forms and in some complication in welding a geocomposite placed long before, to a newly laid one) were a need for drilling and grouting works along the side beam which could not be completed on time. Figure 8 shows the protection slabs during casting.

No personnel traffic was allowed on the geocomposite and/or on the geotextile. The Contractor thus selected to

Figure 7. Connection between the waterproofing system and the toe block. A similar connection is used along the side beam.

serve the casting front from the toe of the dam. All walkways were arranged over the completed slabs and concrete was pumped to the placement zone.

A precast wave wall was part of the design of the crest of the dam. The precast elements were conceived so as to provide an early protection of the geocomposite from possible damage produced by falling objects.

## 6 THE MONITORING OF THE FACE

Monitoring localised water losses through the geomembrane is the main goal for a dam such as Bovilla. A diffused monitoring is possible today but still waiting further testing and certainly a costly measure. An overall monitoring system was hence selected which consisted of 3 open piezometers installed on the surface of the free draining bedding, immediately under the waterproofing system. The piezometer tips were limited to the lowest 2 m of the facing and piezometers pipes were of such diameter as to allow inserting a remote control electric pore pressure transducer at any later time in the future for continuous readings.

The size and distribution of the settlements of the face are of paramount importance for a waterproofing system based on geosynthetics. To survey settlements induced by the hydrostatic load, a lattice of reference points has been set into the concrete of the protecting slabs. Such points can be surveyed again when the reservoir is lowered and will make it possible to know the permanent deflection of the facing. Measuring the maximum inward deflection of a 110 m long face, while the reservoir pressure is on, is more complex and was not considered practicable at Bovilla. No post-loading readings are available so far.

## 7 CONCLUSIONS

Several successful dams in operation since 30 or more years prove that waterproofing earth and rock dams with geosynthetics is a viable and durable solution.

There has been a remarkable evolution as far as the type of the polymers most used in dams. Recent cases point to plasticized and stabilised PVC as the most widely used polymer nowadays.

Dams up to 60 m have been commissioned and all indications point to the adequacy of geosynthetics to build dams up to 100 m in height or even more. To the increasing height of dams (and acting water heads) Designers have answered with progressively more sophisticated "waterproofing systems" incorporating several layers of different geosynthetics. A similar evolution has taken place in welds, details of periphery, protections and QC procedures.

Specific testing and design procedures have been developed and are now available for a responsible design and a performing construction.

Monitoring equipments for the waterproofing system are becoming more and more sophisticated and tailored to suit modern solutions and needs.

It is not difficult to foresee that an array of geosynthe-

Figure 8. Close up of the cast-in-place, unreinforced concrete slab protection adopted at Bovilla dam.

tics will be more and more present in the dams of the future.

# Long Term Performance of Exposed Geomembranes on Dams in Italian Alps

Daniele Cazzuffi

ENEL Ricerca - Polo Idraulico e Strutturale, Milano, Italy

**ABSTRACT:** The paper presents the more recent results of an experimental program related to the behaviour vs. time of PVC geomembranes and PVC-PET geocomposites applied for rehabilitation of different types of dams owned by ENEL on the Alps. In particular, the behaviour vs. time of geosynthetics has been studied for the masonry dams of Lago Miller and Camposecco and for the concrete dams of Lago Nero, Piano Barbellino, Cignana and Pantano d'Avio. The considered geosynthetics are without any external protection and the related dams are in the West and Central regions of Alps at an elevation of more than 1,800 m above the sea level. The laboratory tests, carried out at the Special Materials and Geosynthetics Laboratories of ENEL Ricerca in Milano, allowed to determine the following characteristics: plasticizer content, hardness Shore A, tensile and water vapour transmission properties. According to the first observation programs and laboratory tests, the considered geosynthetics exhibit generally a satisfactory behaviour vs. time.

**KEYWORDS:** Dams, Geomembranes, Geocomposites, Laboratory Tests, Performance Evaluation.

## 1 INTRODUCTION

The first complete application of a PVC geomembrane at an old dam on the Alps was carried out in Italy in 1976 at the 11 m-high Lago Miller masonry dam, built between 1925 and 1926. Significant leakage led to the installation of a 2.0 mm-thick PVC geomembrane.

The geomembrane is also unprotected, so that it is exposed to the action of ice and ultra violet rays, particularly important as Lago Miller dam is located at an elevation of 2,170 m (Cazzuffi, 1987).

Another Italian installation of a PVC geomembrane for dam maintenance purposes was in 1980/1981 at the Lago Nero concrete dam. This 40 m-high structure was built from 1924 to 1929. A 2.0 mm-thick PVC geomembrane was placed without any external protection.

The 2.5 m-wide PVC geomembrane sheets were applied using a unique system, now patented by the firm Carpi, which allowed for continuous fastening along the vertical lines and also horizontal prestressing of the geomembrane itself.

A polyester needle-punched staple filament nonwoven geotextile (with a mass per unit area of 350 g/m<sup>2</sup>) was thermobonded in factory to the geomembrane, thus forming a geocomposite before application on site (Monari, 1984).

Other applications of PVC geomembranes to vertical upstream facings of old Italian concrete or masonry dams were performed more recently with very similar techniques. In the applications to Cignana and Piano Barbellino concrete dams, the stainless steel ribs are embedded in an extra layer of concrete placed on the upstream facing.

The maintenance of the Piano Barbellino dam was finished in 1987 (Photo 1): the geocomposite was constituted with a PVC geomembrane of 2 mm thickness and a PET geotextile of 1.5 mm thickness (Scuero, 1989). Differently, the maintenance of the Cignana dam was

achieved in 1988 and the geocomposite was constituted with a PVC geomembrane of 2.5 mm thickness and a PET geotextile of a 1.5 mm thickness.

Similar geosynthetic was applied in 1991-1992 on the cellular gravity concrete dam of Pantano d'Avio (Photo 2), 63 m height and built in the Fifties at the very remarkable elevation of 2,378 m (Cazzuffi, 1996).

Moreover, a PVC-PET geocomposite (with a geomembrane 2.5 mm thick) was applied in 1993 to the vertical upstream facing of Camposecco masonry dam (Photo 3), 27 m height and built in the Twenties at the considerable elevation of 2,337 m (Scuero and Vaschetti, 1996).

Table 1 summarises the characteristics of the 6 dams discussed in this communication (Lago Miller, Lago Nero, Piano Barbellino, Cignana, Pantano d'Avio and Camposecco), while Fig. 1 shows their location.

Figure 1. Location map of Italian dams on the Alps considered in the present paper.

Photo 2. Pantano d'Avio dam.

## 2 OBSERVATION PROGRAM AND LABORATORY TESTS

During the recent observations (since 1995), different samples of geosynthetics were taken on the different dams, mainly on the upper part, exposed to weathering.

Only for the Pantano d'Avio dam (Photo 2) and for the third year sampling (Photo 4), samples were taken at the water level area submitted to the tidal range (dry and wetting zone).

The laboratory tests were carried out at the Special Materials and Geosynthetics Laboratories of ENEL Ricerca in Milano.

Among the different laboratory tests performed on the different geomembrane samples, the more relevant were as following:

- plasticizer content (according to ISO 6424);
- hardness Shore A (according to ISO R 868);
- tensile properties (according to ISO 527);
- water vapour transmission test (according to ASTM E 96).

For the geocomposite samples, the tests were performed only on the PVC geomembrane: the PET geotextile layer was taken away in laboratory, with the same methodology described also by Cazzuffi (1995).

Tests results on reference samples were only available for the Pantano d'Avio and Camposecco dams. Considering that the PVC geomembranes were produced by the same manufacturer, it was decided to use the same scale to show the results on all the samples taken on the different dams; the evolution of the properties vs. time since application is presented in Figure 2.

Table 1. List of dams considered in the paper (in chronological order according to geosynthetic application).

Dam	Lago Miller	Lago Nero	Piano Barbellino	Cignana	Pantano d'Avio	Camposecco

### 3 CONCLUSIONS

The main results achieved by this extensive experimental program are as following:

- the PVC geomembranes exhibit generally a satisfactory behaviour vs. time;
- the plasticizer content exhibits a small decrease vs. time, even if it remains very high, for example about 28% after 19 years since application in Lago Miller dam;
- correspondingly, the hardness Shore A exhibits a certain tendency to limited increase, i.e. the geomembranes seem to be subjected to become a little bit more rigid;
- the results of the tensile properties confirm the above mentioned trend, i.e. the tensile strengths (both in longitudinal and transversal directions) generally tend to increase, while the corresponding strains tend to be subjected to limited decrease, thus forming a more rigid product;
- the water vapour transmission test results have been reported to permeability coefficient values according to the equations proposed by Giroud (1984) even if recently these equations have been questioned in literature (see, for example, Eloy-Giorni et al., 1996); in any case, being in this experimental study more interested to the comparative results than to the absolute values, it's important to remark that the permeability coefficient is quite constant vs. time, ranging from  $2 \times 10^{-13}$  m/s to  $1 \times 10^{-13}$  m/s.

Based on these results, similar rehabilitation systems of dams may be generalised, considering that a particular attention has to be taken into account during all phases of design and geosynthetic installation.

Finally, considering the lack of protection, survey and regular control during time of the geomembrane characteristics seem to be necessary.

Particular attention should be paid when geomembranes are exposed to South orientation, thus receiving the most of UV radiations.

# A Sail-Shaped Dam Made of High-strength Composite Geomembrane

Jiang Kun'e and Yuan Lixin

Research Institute of Water Resources and Hydropower, Liaoning Province, P. R. China

**ABSTRACT:** This paper recommends the design and construction of a membrane dam, also known as sail-shaped dam, made of high-strength composite geomembrane. The bottom edge of the dam is anchored onto the concrete base plate, and the top edge is hung on a cable across the river. The dam height may be regulated by changing the length of cable, even to flatten it to the base plate when discharging the flow. This new type of hydraulic flexible dam has an artistic profile and a distinctive style. The cost of this dam is also less than any other types of gate or dam with the same height. To date, two sail-shaped dams have been built on non-gated spillways of reservoir in our province and have made the most of the water projects.

**KEYWORDS:** Dams, Geomembranes, Composite materials

## 1 INTRODUCTION

The membrane dam, also known as sail-shaped dam, is a low-head water retaining structure made of high-strength composite geomembrane. The bottom and two side edges are anchored on a concrete base plate and side wall respectively, and the top edge is hung on cable across the river, the two ends of which are twined around winches located on both banks. The dam height may be regulated by changing the length of cable, raising the water level for irrigation or power generation, or flattening the dam on the river bed for discharging flood or navigation. When it is installed on a non-gated spillway of a reservoir, it can increase the common storage to make the most of the water project.

Building hydraulic flexible structures with geosynthetics is an initiative work. It is necessary to meet the requirements of strength, impermeability, and durability, as well as the frost-resistance if the structure is located in a cold region. Through a series of laboratory and field tests, we have selected polypropylene woven geotextile coated with ethylene vinyl acetate copolymers (EVA) to serve as the dam material to build sail-shaped dams on the spillways of Heiyushan reservoir (Fushun city) and Lanshan reservoir (Changtu county) in Liaoning province in 1996 and early 1997 respectively. The Lanshan sail-shaped dam has three continuous spans of 15m each, the two existing bridge piers are taken as the supports of cable transferring the cables to the winches by pulleys, so as to move the three spans synchronously. This type of structure is easy to construct, simple and convenient to operate, making it unnecessary to install pipelines and inflat/deflat equipment. therefore the cost of this system is the lowest as compared with other types of closed hydraulic flexible structures with the same height.

## 2 WORKING CONDITIONS AND DESIGN CALCULATION

### 2.1 Calculation of Configuration of Membrane

During the process of water-retaining, the membrane is subjected to tensile stress only when the water pressure is applied on it, no compressive stress and bending moment occur. and no stress in the direction of the dam axis, as it is long enough in compared with the height of dam. Therefore it is considered as two-dimensional problem.

Fig. 1 Calculating sketch of membrane dam

When the water depth on the upstream side of membrane dam is  $H$ , and no water on the downstream side. The total upstream water pressure is  $P = \frac{1}{2} \gamma H^2$ , where  $\gamma =$  unit weight of water  $= 1 \text{ t/m}^3$ . From the equilibrium of all horizontal forces, we have:

$$T = \frac{\gamma H^2}{2(\cos\alpha_1 + \cos\alpha_2)} \quad (1)$$

in which: T = tangential tension of the membrane. In Fig.1, considering ds is very small,  $\widehat{ds} = ab$ .  $\Delta abo \sim \Delta ecd$ , then

$$\frac{R}{ab} = \frac{T}{cd} \quad \text{or} \quad \frac{R}{ds} = \frac{T}{pds}$$

where p = unit water pressure at that point, and R = radius of curvature. Therefore

$$R = \frac{T}{p} \quad (2)$$

Using above relationship, we can compute the geometric configuration of the membrane simply by diagrammatic method, the error of which will not exceed 5%, so it can meet the practical requirement. In the diagrammatic method, the upstream water depth is divided into a number of equal divisions, and the average unit water pressure of each division is computed, and the radius of curvature is calculated by Eq.2. Join circular arcs of each division together, to form finally the whole configuration of the membrane dam.

Fig. 2 Determine configuration of membrane dam by diagrammatic method: 1-computed curve, 2-Tested curve by hydraulic model study.

Now, we take the membrane dam of the spillway at Heiyushan reservoir as an example:  $H = 1.50\text{m}$ ,  $\alpha_1 = 0^\circ$ ,  $\alpha_2 = 12^\circ$ , We have

$$T = \frac{\gamma H^2}{2(\cos\alpha_1 + \cos\alpha_2)} = \frac{1 \times 1.50^2}{2(1 + 0.978)} = 0.569 \text{ tf/m or}$$

5.69 KN/m

Ten equal divisions are made for H, the radius of curvature of the first division is

$$R_1 = \frac{T}{p_1} = \frac{5.69}{\frac{1}{2}(0 + 1.5)} = 7.58\text{m}$$

Similarly, for the second division

$$R_2 = \frac{5.69}{\frac{1}{2}(1.5 + 3.0)} = 2.53\text{m}$$

The rest may be done in the same way. The configuration is drawn as in Fig. 2. From which, the total length of membrane is 3.05m, and the horizontal distance between anchor and crest is 1.56m.

## 2.2 Calculation of Cables

Fig. 3 Layout plan of membrane dam: 1-dam, 2-main cable, 3-secondary cables

The layout plan of the membrane dam is shown in Fig. 3. The main cable is a river crossing cable, and the secondary cables are used to tie the membrane dam onto the main cable. The spacing of which depends on the strength of membrane and the junction points. If the spacing is 1m, the tensile stress of each secondary cable is  $T = 5.69 \text{ KN}$ . The maximum tensile stress of the main cable may be computed by the following formula:

$$S_{\max} = \frac{TB^2}{8f} \sqrt{1 + 16 \frac{f^2}{B^2}} \quad (3)$$

Table 1. Test results of high strength composite geomembrane for sail-shaped dam.

Item	Unit	Amount	Remark
Weight	g/m <sup>2</sup>	975	
Total thickness	mm	1.2	
Thickness of EVA coater	mm	2 × 0.3	
Tensile strength(warp)	KN/m	42.6	Refer to ASTM D - 1682
(weft)	KN/m	38.7	
Elongation (warp)	%	7.05	Refer to ASTM D - 1682
(weft)	%	8.43	
Tearing strength	KN	1.04	Refer to ASTM D - 1117 - 80
puncture strength	MPa	1.7	Refer to ASTM D - 3780
Fatigue test	Times	100000	strength kept unchanged
Grab test	KN	11.0	Width of clamp = 30cm The tensile strength of the joint between membrane and cable.
Freez-thaw test	—	—	After 428 freezing-thawing cycles, tensile strength reduced by 24.5%.

In this example, we have

$$S_{max} = \frac{5.69 \times 15^2}{8 \times 5} \sqrt{1 + 16 \frac{5^2}{15^2}} = 53.34 \text{ KN}$$

If the curvilinear equation of main cable is

$$y = \frac{fx^2}{(\frac{B}{2})^2} = \frac{5x^2}{(\frac{15}{2})^2} = 0.0889x^2$$

$$(\frac{dy}{dx})^2 = 0.0316x^2$$

The length of the main cable

$$L = 2 \int_0^{B/2} \sqrt{1 + (\frac{dy}{dx})^2} dx = 2 \int_0^{7.5} \sqrt{1 + 0.0316x^2} dx$$

$$= 2 \left[ \frac{x}{2} \sqrt{1 + 0.0316x^2} + \frac{1}{2 \sqrt{0.0316}} \cdot \ln (x \sqrt{0.0316} + \sqrt{1 + 0.0316x^2}) \right]_0^{7.5}$$

$$= 2 \times 9.34 = 18.68m$$

The length of the secondary cable may be computed by following formula:

$$L_i = \frac{fx_i^2}{(\frac{B}{2})^2} + L_0 \tag{4}$$

In which:  $L_i$  = Length of the cable at point i,  
 $L_0$  = Length of the cable at center of span,  
 $x_i$  = Distance from center of span to point i.

If  $L_0 = 1.0m$ , Therefore:

$$L_1 = \frac{5 \times 1^2}{(\frac{15}{2})^2} + 1 = 1.089 \text{ m}$$

$$L_2 = \frac{5 \times 2^2}{(\frac{15}{2})^2} + 1 = 1.356 \text{ m}$$

The rest may be done in the same way.

In order to check the reliability of the results computed by approximate methods, we have conducted hydraulic model study (1: 5). It is indicated that the results are basically coincidence.

### 3 SELECTION OF MATERIAL

The sail-shaped dam is a hydraulic flexible structure exposed to the air and sunlight, or soaked in water over a long period of time, so that the flexible material must have sufficient tensile strength, watertightness, durability, tearing strength, flexibility, fatigue strength, and frost-resistance, etc. For this reason, after qualitative tests on several polymeric materials, we have decided to use polypropylene woven geotextile as the skeleton of composite geomembrane, and coated with ethylene vinyl acetate copolymers (EVA) adding an age-inhibiting agent. It is also required that the geotextile must be treated, so as to provide high cohesiveness with EVA. According to the concrete working condition of sail-shaped dam, we have conducted various tests of physical and mechanical

properties of processed material. The results are listed in Table 1.

An appropriate factor of safety should be considered in design of a sail-shaped dam, because of error in calculation, nonuniformity of skeleton material, loss of strength during operation, as well as the safety demand according to importance of the project, which is usually in the range of 3 to 5. The factor of safety of the two dams described in this paper are 6.8 and 11.1.

#### 4 JOINT OF THE MEMBRANES

Due to the limitation of the width of the geomembrane, it is necessary to piece together by lap joint. We have sewn up with polyamide fibre thread (density of stitches 2~3mm). The holes of needle are sealed by thermo-bonding EVA pieces of the same thickness to prevent from leakage. The test results of lap length and number of stitching rows effect on shearing strength are shown in Table 2.

Table 2. Test results of shearing stress of lap joint

Lap length (mm)	Number of stitching row	shearing strength (KN/m)
80	2	28.3
80	3	37.5
80	4	38.9

80mm lap length and 3-row stitches are adopted

#### 5 ANCHORAGE

The anchorage of a membrane dam on the concrete base plate or side wall is composed of built-in bolts (spacing 20cm), steel plate, pipe and channel. To punch bolt holes in the membrane is unnecessary. The pull-out resistance test was conducted before installation. The detail of anchorage is shown in Fig.4

#### 6 CONCLUSION

It is an attempt to use high-strength composite geomembrane to build low-head water-retaining structures, in order to open up the application of geosynthetics. Through careful design and experimental study, it is indicated that the properties of this special material can meet the requirement of working conditions of the dam. So far, two sail-shaped membrane dams, 1.17m and 1.5m high, 15m and 3×15m span, have been built on spillways of reservoirs in our province. This

simple type of structure with low engineering cost is a large benefit to the projects. Practice has proven that they are successful. However, the field observation is still taking place. At present, the height of the dam is limited by the strength of material. In order to acquire still greater results, it is necessary to take up effective measures to develop geosynthetics with higher strengths, to improve the lap joints, and to reduce wrinkles on the dam, so as to make the structure more perfect and safe.

Y. Ikeguchi

Deputy Manager, Okinawa Seawater Pumped-Storage Project Construction Office, Electric Power Development Co., Ltd., Okinawa, Japan

**ABSTRACT:** This paper presents a new technology for dam surfacing based on the use of rubber sheet which will be used in the construction of the world's first seawater pumped-storage power plant. The plant, presently under construction on Okinawa Main Island, is planned and financed by the Ministry of International Trade and Industry (MITI), Japan, with the Electric Power Development Co., Ltd. (EPDC), under a consignment contract with MITI, being in charge of surveys, research, designs and supervision of the construction. In designing this pilot plant, the sheet foundation design, the sheet anchoring method, selection of the sheet material, structural designs, and leakage water detection and dewatering system have been newly developed in consideration of the requirements imposed on a seawater pumped-storage power plant. This paper presents the design concept, construction work, the method and outcome of the quality management and observed behavior of sheets during typhoon conditions.

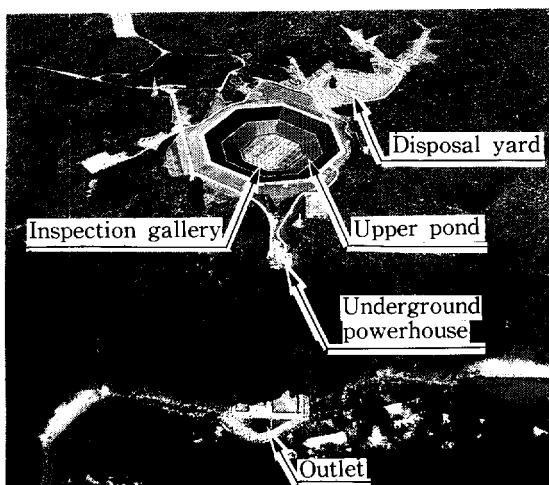

**KEYWORDS:** Construction, Dams, Design, Geomembranes, Pond Liners

## 1 INTRODUCTION

The objective of this plant is to develop seawater pumped-storage power generation technology for commercial use. The technology will be validated through a 5-year test operation and its application technology established accordingly.

The plant's upper pond is located on a plateau at approximately 150m elevation on the Pacific coast of Okinawa Main Island. The ocean is directly utilized as the lower pond. Power is generated at a maximum 30MW output at a powerhouse installed approximately 150m underground. As seawater is employed, a synthetic rubber sheet is used for the surface lining of the upper pond. Various new materials and new construction methods are also employed, including fiberglass reinforced plastic for the penstock. The seawater resistance and durability of each structure will be verified accordingly.

As a complicated configuration would provide difficulties in surface lining installation, the upper pond is designed with a layout of maximum possible simplicity. To improve workability, the dam body is an octagonal mortise earth fill dam. The slope is 1:2.5 (v:h) considering the stability of the embankment. Excluding the transition layer, the overall embankment volume is approximately 420,000m<sup>3</sup>. As shown in Figure 1, the surface lining is formed with a sheet anchor (filling concrete included), a transition layer (sheet foundation with crushed rock), and a lining sheet (main sheet, cushion fabric, cover sheet, etc.). The surface area of the sheet lining is approximately 53,000m<sup>2</sup>. Started in November, 1994, the surface lining work was completed in February, 1996.

Photograph 1. Panoramic view of the plant.

Figure 1. Structure of sheet lining.

## 2. SELECTION OF UPPER POND SURFACE LINING

### 2.1 Surface Lining Structure

The following conditions are required for the plant's

surface lining.

1. The lining materials are required to have virtually zero-permeability to provide a barrier preventing seawater leakage into the natural ground.
2. The surface lining is required to maintain impervious sealing performance against repetitive water level fluctuation.

Although it was possible to consider a concrete, asphalt or sheet lining as the surface lining, the sheet lining was finally selected for the following reasons. It is made of materials which provide a much lower permeability than concrete or asphaltic linings. Concrete lining has joints which present weak points in terms of the watertight integrity of the lining structure overall. Sheet lining construction costs are also lower than those for concrete or asphaltic linings.

In sheet lining structures, the sheet surface can either be exposed or protected by earth materials or concrete. Here, an exposed structure was selected as it permits easy repair in the event of sheet damage while assuring high reliability subject to appropriate maintenance inspection.

## 2.2 Sheet Materials

The following conditions are required for the plant's sheet materials.

1. As an exposed sheet lining structure was selected for the pumped-storage pond, the water level of which may be frequently changed, and with the plant located in sub-tropical Okinawa, sheet materials which provided less temperature sensitivity are suitable for the plant's sheet lining. (Temperature sensitivity shows extents of physical properties changes such as an ultimate elongation and a tensile strength caused by temperature change.)
2. Since the surface lining must be resistant to repetitive cyclic load and its structure must ensure impervious sealing performance in the location in which the intake and inspection gallery adjoin the structure, the sheet materials are more suitable due to their superior elongation and flexibility.

Table 1. Characteristics of the sheet materials.

Materials	EPDM	PVC	HDPVC	HDPE
Ultimate elongation(%)	450	300	400	700
Tensile strength(N/cm <sup>2</sup> )	750	1632	1423	2957
Temperature sensitivity				
at high temperature	L.S.	S.	S.	S.
at low temperature	L.S.	S.	L.S.	S.

Notes: Values in table are minimum values of the standard sheets. L.S. and S. denote less sensitive and sensitive.

Synthetic rubber (EPDM), soft polyvinyl chloride (PVC), high density soft polyvinyl chloride (HDPVC: specially developed PVC for improvement of the physical properties and feeling (like rubber) with increase of PVC molecular weight and the addition of plasticizer), or high density polyethylene (HDPE) are generally employed for the surface lining of sheet linings. The characteristics of the sheet materials are compared in Table 1. EPDM was

selected after studies and comparisons of the material performance and workability of these materials. Since HDPE provides a low elongation at yield (although its ultimate elongation is high.), HDPE was judged less suitable for the plant's sheet materials.

An outdoor exposure test near the site, bacteria proof test, seawater resistance test, and marine organism deposit test were carried out on the EPDM sheet used in this plant to determine its characteristics under near-real conditions. The long term durability of the EPDM sheet was confirmed.

## 3. DESIGN OF SUBGRADE FOR SURFACE LINING

The requirements for the subgrade of a rubber sheet lining for a seawater pumped-storage upper pond, are listed below:

1. It must provide a surface sufficiently hard to support the sheet, and ensure sufficient slope stability.
2. It drains the spring water from the natural ground, thereby dispersing the pore water pressure on the back of the sheet.
3. In the event of sheet failure, it diverts leakage water downward, finally leading to the inspection gallery built around the pond bottom, thereby preventing infiltration of seawater into the natural ground. (A dam body with a permeability coefficient in the order of  $10^{-4} \sim 10^{-6}$  cm/s has very low permeability.)
4. The residual air behind the sheet should be exhausted, because such air may inflate the sheet like a balloon when water is filled, or the negative pressure created by strong wind may pull the sheet up.

A crusher run with a maximum particle size of 20mm was selected from a number of materials meeting the above requirements in terms of water permeability and air porosity, with due consideration given to economy and seismic stability. The layer thickness was designed at 50cm. In this project, this crusher run foundation is termed the 'transition layer' as it is an intermediate transition layer between the dam body and the sheet lining.

## 4. DESIGN OF SHEET ANCHOR

### 4.1 Study of Sheet Anchoring Method

An exposed surface lining is used in this plant. In this structure, on-site adherence works may present structural weakness. For this reason, the concrete block anchoring method was adopted in order to alleviate on-site adhering works. In this method, the on-site sheet adhesions are embedded into specially designed U-shaped concrete blocks with filling concrete. No sheet-edge bonding work is performed on-site except for the cover sheets that provide an impervious lining over the anchoring works. As this anchor method is sufficiently heavy and wraps the sheet completely, it prevents wind damage experienced by anchoring by flat bar or by wrapping into buried pipe. Also, with the sheet surrounded by the sheet anchor, a sheet failure would not extend beyond the surrounding area.

## 4.2 Sheet Anchor Block Design

The following functions are required for the sheet anchor.

1. It must anchor the lining sheet firmly.
2. The main sheet surface must not adhere on site.
3. Its configurations and weight must be durable against sheet deformation resulting from an earthquake or a strong wind such as a typhoon.
4. It must provide an effective exhaust capability.

The U-shaped precast concrete blocks provide the functions given in 1, 2 and 3. To include the function described in 4, therefore, a precast unit with built-in PVC tubes was designed, as shown in Figure 2. One of the main reasons for designing a concrete block with built-in PVC tubes was that it requires less filtration installation area than the method which uses a buried perforated tube to prevent clogging of fine particles during stone crushing, thereby significantly reducing the risk of fine particle loss due to filter failure. Another reason was that it prevents the risk of sheet break due to subsidence of the transition layer caused by a tube break resulting from uneven settling of the transition layer. The exhaust tube also promotes drainage of leaked water in the event of sheet failure. A patent application for this type of sheet anchor structure has been filed.

Figure 2. Anchor block.

## 4.3 Study of the Sheet Anchor Interval

According to this principle which is to eliminate on-site adhesion work on the exposed side of the sheet, the interval in the horizontal direction of sheet anchors was selected so that this would be as large as possible in reference to the maximum width of a sheet capable of being manufactured and transported to the construction site. This synthetic sheet is usually manufactured in 1.2 m wide belts which are joined at the manufacturer's plant into a single wide sheet. Considering the restrictions in the sheet transportation and the handling / fabricating limitations at the manufacturer's plant, the lateral interval of the anchor works was taken as 8.5m for slopes and 17m at the pond bottom.

For the interval in the slope direction, the sheet conditions during a strong wind such as a typhoon were considered. Strong wind induces negative pressure on the sheet surface. If air enters under the sheet, the sheet swells to maintain the balance of the inside and outside pressure. In this case, the sheet anchor intervals in the slope direction were determined considering the relationship between the sheet deformation (swell height) and the

anchor intervals in the slope direction. Regarding sheet deformation, a rectangular rubber sheet sample was anchored at its four sides and caused to swell with compressed air supplied from behind. In addition to this model experiment, numerical analysis was conducted with a finite element method (code name; ABAQUS) that permits the handling of super-elasticity materials such as rubber sheet. Where the aspect ratio (ratio of short side to long side at the sheet anchored area) was 1:2 and 1:5, the model test showed no significant difference in deformation under the same pressure. This analysis also indicated no significant difference in sheet deformation where the aspect ratio was larger than 1:2. The test indicated that deformation does not exceed a maximum 28% increase. It is, therefore, unnecessary to install a sheet anchor in the horizontal direction on the slope when the anchor intervals in the sheet horizontal direction are controlled. Consequently, the sheet anchor in the horizontal direction on the slope is located at the crest of the pond, berm, and at the toe of the slope.

## 4.4 Sheet Anchor Stability Against Sheet Swell

Sheet swelling due to strong wind induces tensile stress in the sheet and causes the sheet anchor to lift. In this case, sheet anchor stability was studied using the sheet deformation calculation model shown in Figure 3. The results of the study were compared with those of the previously described model test and it was confirmed that the values derived from the model test and the two-dimensional calculation model matched.

Figure 3. Sheet deformation calculation model.

The calculation method is outlined below. The negative pressure on the sheet,  $P_a$ , can be determined from equation (1).

$$P_a = \frac{\gamma_a}{2g} C v^2 \quad (1)$$

where:  $\gamma_a$  = weight of air unit volume;  $C$  = coefficient of wind force;  $v$  = wind velocity; and  $g$  = gravitational acceleration. The mechanical equilibrium of forces is expressed in equations (2) and (3).

$$T \sin \theta = P_a ds \cos \theta + (T + dT) \sin(\theta + d\theta) \quad (2)$$

$$T \cos \theta + P_a ds \sin \theta = (T + dT) \cos(\theta + d\theta) \quad (3)$$

where:  $T$  = tensile force induced in sheet; and  $\theta$  = swell angle. Relation of  $T = f(v, \theta, L_0)$  and  $L = f(v, \theta, L_0)$  is led from the equations (1) through (3). Also, the length of the sheet after swelling,  $L$ , can be determined from equation (4).

$$L = \frac{\sigma_t}{E} L_0 + L_0 \quad (4)$$

where:  $\sigma_t$  = tensile stress ( $T/A$ ) induced in sheet;  $A$  = cross area of sheet; and  $E$  = elasticity coefficient of EPDM sheet. Substituting the relative equation between  $E$  and  $\sigma_t$  obtained from the model experiment for Equation (4), leads to another equation, i.e.,  $L = f(v, \theta, L_0)$  due to the relation  $T = f(v, \theta, L_0)$ . Therefore, iteration the calculations for the unknown  $v$  and  $\theta$  until  $L$  obtained from the two equations match, the sheet deformation (deflection angle, swell height, and distortion) and the induced stress in response to the optional wind velocity can be calculated.

Assuming a sheet anchor interval of 8.5m and a deformation reaching the limit of  $\theta = 90^\circ$  (semicircle), the mean wind velocity, distortion, and tensile stress were calculated from the above equations. Consequently, the sheet distortion becomes 57.1% and the tensile stress  $118\text{N/cm}^2$  at approximately 43m/s wind velocity. These are sufficiently below the standard values of the main sheet (EPDM) shown in Table 2. The force toward the upper sheet anchor is determined from the tensile stress induced in the sheet is 4,710N/m, which is less than the sheet anchor weight of 5,370N/m. Assuming a sheet swell, the sheet anchor would therefore not be lifted.

## 5. DESIGN OF LINING SHEET

### 5.1 Member Structure and Lining Sheet Material

As described, the major lining sheet members for this plant are the main sheet, cushion fabric, and cover sheet. The functions and materials of each member are described hereafter.

#### 5.1.1 Main sheet

The main sheet is a trunk member of the lining sheet and inhibits seawater leakage. As the lining sheet of this plant is exposed, to improve its ozone resistance the proportion of EPDM in the rubber content is higher at a minimum of 70%.

The basic specifications are shown in Table 2. The thickness is established by considering the strength, resistance to irregularities, and workability. No special conversion of the plant production line was necessary for the 2.0mm thick EPDM sheet. The ultimate elongation is determined by considering the partial deformation. Since the sheet used in the plant was improved to reduce the tension set, its tensile strength exceeds that of the standard sheet ( $750\text{N/cm}^2$ ).

Table 2. Basic specifications of the main sheet.

Thickness (mm)	2.0~2.3
Ultimate elongation in tensile shear test (%)	450 or more
Tensile strength in tensile shear test ( $\text{N/cm}^2$ )	981 or more

Sheets joined and widened at the manufacturer's plant are used for the main sheet. To minimize irregularities in the adhering surface of the cover sheet by reducing the number of joints wrapped in the sheet anchor, the main sheet is joined in the slope direction. The tensile strength of the joints is greater than that of the original sheet. A test was performed to check its impervious sealing performance. The results confirmed there would be no air suction due to negative pressure. According to records regarding agricultural ponds, it is clear that with no water leakage through the joints, therefore, it provides the necessary high reliability.

#### 5.1.2 Cushion fabric

The cushion fabric prevents small irregularities and protrusion onto the surface of the transition layer and concrete from affecting the sheet. It protects the sheet from the edges of the crushed stone and concrete. It also prevents sheet failure due to local deformation as it makes the sheets installed surface smooth, thereby completely distributing sheet distortion to prevent local deformation of the base. (Elongation ratio in proportion to the same deformation is reduced.)

Long-fiber non-woven spun bonded fabric is generally used as the lining sheet cushion material. Compared with polyester and polypropylene, polyester was selected for the raw materials of the cushion materials, because of its excellent heat resistance and for water-proof performance. A repetitive hydraulic resistance test was carried out for the on-site sheet adhesions of which the base was a 20mm diameter simple grain material, assuming a loss of fine particles from the transition layer. Consequently, a minimum of  $800\text{g/m}^2$  is taken as the standard value of weight (mass per unit area).

#### 5.1.3 Cover sheet

The cover sheet provides an impervious sealing performance of the sheet anchor concrete surface which can become a weak point due to crack formation, etc. (The sheet anchor fixes the sheet mechanically. Its structure is dynamically stable. It does not, however, provide a water impervious seal.) Its material and specifications are the same as those of the main sheet.

### 5.2 Cover Sheet Adhesion Method

The adhering areas of the main and cover sheets are exposed. As this is the most important area for the water impervious seal of the surface lining, an adhesive tape (self-curing adhesive isobutylene-isoprene rubber tape) was used. The adhesive tape prevents condensation due to the adhesive when the sheet is cooled. Condensation can occur due to the heat of vaporization associated with the

adhesive's organic solvent. The isobutylene-isoprene rubber adhesive is initially combined with a curing agent. As this tape cures slowly, it eliminates any extra work required such as brushing, and results in a homogeneous adhesion surface.

Figure 4. 180° peel test results

A 180° peel test was conducted on the adhering rubber sheet both after using a two-component adhesive and the adhesive tape. (Accelerated curing was used for test pieces at high temperature so that they provide the final adhesive strength.) The test results are shown in Figure 4. The peel strength of the adhesive tape is greater than that of the two-component adhesive. Here, the most important factor is that the adhesive tape shows smaller fluctuations in adhesive strength on peeling. Consequently, the adhesive tape ensures a higher water impervious seal. Adhesion with this tape prevents the formation of water leak routes.

## 6. QUALITY CONTROL IN SURFACE LINING INSTALLATION

### 6.1 Transition Layer Works

Stable quality is expected in the transition layer works since all materials are purchased from an existing crushing plant for concrete and road-base materials. In compaction, the finished density and surface conditions may, however, vary and quality control is, therefore, most important. The control standards were developed for precise quality control including a compaction method specifying the compaction equipment, spread depth, and tamping frequencies / times.

The control standards were developed based on the following basic conditions.

1. The material grain size shall be appropriate. The material shall be dynamically stable. Its structure shall also be stable in terms of the soil hydrology.
2. Compaction shall be sufficient.
3. The surface shall be smooth and dense.

The focal control points for the materials, compaction and surface finishing are grain distribution, dry density and flatness respectively. The controlled value of the field density was set at 1.92 t/m<sup>3</sup>, 70% of the relative density, in reference to the compaction test data for the material

containing natural water. This value was shown to provide sufficient strength for the embankment slope stability under the natural water content or saturation (postulating sheet failure) according to the triaxial compression test (CD test), and was selected with due consideration to its workability. Regarding the site density test method, the RI (radioisotope) method was used mainly as it allows measurement on the slope and is a simple method. The water replacement method was used in addition in the flat area and in the bottom of the crest and berm.

The quality control test showed that the values satisfied the control standards in all works (Table 3). The on-site permeability test also showed sufficient permeability for the transition layer. The site test conducted after compaction by the tamping method used in the actual installation showed that in the case of a minimum 10<sup>-2</sup> cm/s permeability coefficient, the transition layer performance of the residual air exhaust under the sheet was assured, with an air permeability coefficient in the order of 10<sup>0</sup> cm/s.

Table 3. Quality control test results of transition layer.

Items	Spec.	Ave.	Max.	Min.
Dry density (t/m <sup>3</sup> )	≥ 1.92	2.03	2.37	1.92
Permeability Coefficient (cm/s)	—	0.27	1.50	0.014

### 6.2 Lining Sheet Installation

For the lining sheet installation, control standards were developed to specify the installation conditions based on the temperature, humidity, wind velocity, etc., control method for the adhering area of the cover sheet, adhesion width of each member, and the adhesion location in detail.

Regarding the material quality, an inspection was conducted on all points of the basic specifications every 1,000m<sup>2</sup>. The rubber sheet quality may vary depending on the quality control in the raw material mixture process, pressure in the curing process, and the temperature control accuracy.

The cover sheet is the only member providing an impervious seal to the on-site sheet adhesions and thus requires a highly reliable adhesion. Quality control includes visual inspection and confirmation by touch to check for adhesion defects. Inspection with an inspection spatula confirmed no partial gaps remained not to adhere at the edges of the adhering areas. A negative pressure test was conducted throughout the adhering area. (Apply soapy water to the adhering area, depressurize at a minimum 0.51MPa over 10 seconds and check for foaming.)

Table 4. Quality control test results of adhesion work.

Items	180° peel strength	Tensile shear strength	
	(N per 25mm)	(N per 25mm)	
Curing period	7 days	7 days	3 months
Spec.	24.5 or more	196 or more	392 or more
Max.	80.4	503	631
Min.	29.1	314	405
Ave.	55.0	434	509

Test pieces produced under the same conditions were cured for 7 days, and the 180° peel strength and tensile shear strength were measured. The tests confirmed a stable adhering surface had been formed. The tensile shear strength was re-evaluated after a 3-month curing period and it was confirmed that the adhering area provided a strength equivalent to that of the main sheet. The test results are shown in Table 4.

## 7. OUTLINE OF WATER LEAK DETECTION AND DEWATERING SYSTEM

The system leads water leaking from the sheet to the inspection gallery (height=2.0m, width=2.0m) through the transition layer or PVC tube built into the sheet anchor. Since the groundwater from the drain hole on the ground is also led to the inspection gallery, it would be possible for the seawater and the fresh water to mix. To prevent such mixture, a pipe is installed from each conduit to each drain pit directly to collect the water. The leakage from the sheet only is pumped back to the upper pond. The groundwater is discharged to a nearby stream through a drainage tunnel. The seawater is, therefore, not discharged to the outside but returned to the upper pond and discharged back into the ocean after power generation. As the fresh water is discharged to the stream, the system is ecologically friendly.

Leakage from the sheet is detected by a salt analyzer (electronic conductivity measuring unit) and the fluctuation in the volume of leakage are measured by flow meter. Both instruments are installed on the conduit. To divide the slope into 55 and the bottom into 9 sections, a transparent conduit (acrylic) was installed to facilitate visual verification of the leakage locations in each section.

## 8. LINING SHEET BEHAVIOR UNDER STRONG WIND

Photograph 2. Sheet swell behavior in strong wind

In 1996, five typhoons approached Okinawa Main Island and provided opportunities to observe sheet swell behavior. When typhoon No.12 (Maximum instantaneous velocity; 49m/s, 10min. mean velocity; maximum 28m/s) approached in August, the water detection / dewatering

system piping, etc., had not been completed. Air was able to enter the sheet without restriction through the built-in sheet anchor tube. Consequently, a maximum sheet swelling of approximately 1.5m height took place (10min. mean velocity; maximum 18m/s, Photograph 2). The lining condition after the typhoon approach, was checked by visual inspection when it was confirmed that there were no problems such as sheet failure, and almost no residual sheet distortion or transition layer interruption.

Although typhoon No.21 approached in September, with an equal wind velocity, sheet swelling was controlled to approximately 1/3 by cutting off the air supply from the built-in sheet anchor tube. Since the crest road was paved, it was reasonable to assume that air inflow from the crest into the transition layer would be effectively prevented, thereby further controlling sheet swelling.

## 9. CONCLUSIONS

Following the completion of the lining in February, 1996, fresh water (rainfall and groundwater pumped up from the underground powerhouse) has been stored in the upper pond since June, 1996, to protect the lining sheet and to eliminate residual air from behind the sheet prior to the actual operation of the plant. No water leakage has occurred. This sheet lining has complete technically and has become the main development toward the realization of the world's first seawater pumped-storage power plant. Also, it raised the sealing confidence in the sheet lining used in agricultural ponds etc.

The paper presents the following suggestions for future projects with the rubber sheet lining for better technology.

1. Further improvement in the adhesion performance for on-site sheet adhesions is needed to enable application in ponds with larger water depths.
2. Transition layer material has been developed for low cost performance and better workability to meet the necessary functional performance.
3. Minimizing the 'human factor' in lining sheet installation would improve work stability and efficiency.
4. Where this lining is applied to store fresh water, the lining performance can be dropped to some degree compared with seawater storage. Cost reduction resulting from a more streamlined design will be the subject of a future project.

## ACKNOWLEDGMENTS

The writers wish to express their sincere gratitude to the members of MITI and all those concerned for their excellent cooperation and kind guidance.

# A Scheme of Using Geosynthetics to Treat Cracks on A Reservoir Blanket

Z.Y. Liu

Director, Technical Inquiry Committee of Water Conservancy Bureau of Hebei Province, China

**ABSTRACT:** A reservoir in the Hebei province of China has been in operation since 1961. A natural cohesive soil layer was used as the horizontal impervious blanket for the auxiliary dam. Cracks often occurred on the blanket and in the foundation of the dam during the operation. A scheme of using geosynthetics to treat the cracks was proposed. The scheme is composed of three reaches, namely, the anti-seepage reach, the drainage reach and the dam slope reach. Geomembrane, geomembrane-geotextile composite, and geopipes were used. A series of tests were made. The methods of testing and design will be presented in this paper.

**KEYWORDS:** Blanket, Cracks, Geocomposite, Design scheme.

## 1 INTRODUCTION

Huangbizhuang Reservoir in the Hebei Province of China was constructed from 1958 to 1961 with a catchment area of 23400 km<sup>2</sup> and a capacity of 1.21 billion cu. m. It has an auxiliary dam with a length of 7000 m and a maximum height of 19.2 m. The overburden layer of the foundation is composed of cohesive soil, sand, gravel and cobbles. The cohesive soil layer with thickness of 3~10 m was used as natural horizontal impervious blanket. A lot of cracks occurred on several parts of the blanket after storage of water for more than 35 years due to the unequal settlement of the soil layer under the water and dam load. The cracks were traditionally treated by digging ditches and backfilled with cohesive soil or by grouting with mud or cement. All of these measures had very little effect. In recent years some cracks were found under the dam and might extend in the foundation as far as the downstream side of the dam. It was found after exploration and excavation that most cracks on the blanket had silted up and those under the dam were mostly kept empty. It was generally considered that the cracks on the blanket would do little harm to the reservoir but those under the dam might cause seepage failure in the foundation. In order to refrain the water in the reservoir from flowing directly into the cracks under the dam and on the blanket near the dam, a scheme of using geosynthetics to treat the cracks was proposed. The whole work consists of a series of laboratory tests and a conceptual design. Geomembranes, geotextiles and geopipes were used in the scheme.

## 2 TESTS OF HYDRAULIC TRANSMISSIVITY OF THE SPACE BETWEEN THE GEOMEMBRANE AND THE SOIL

### 2.1 Test Equipment and Samples

#### 2.1.1 Test box

A box with size of 2.5 m × 0.5 m × 1.0 m is made of steel and divided into two stories. The height of each story is 0.5 m. Flange plates and rubber water-tight seal were used to prevent the leakage of water between stories. Inlet and outlet pressure gauges were installed as shown in Figure 1.

#### 2.1.2 Properties of geosynthetics and soil sample.

Two types of geosynthetics were used in the tests. One is PVC geomembrane with a thickness of 0.6 mm, and the other is geomembrane-geotextile composite composed of 0.45 mm PVC geomembrane and 210 g/m<sup>2</sup> needle-punched non-woven geotextile. Their properties are presented in Table 1.

Three kinds of soil samples were excavated from the blanket of the reservoir. Their properties are presented in Table 2.

Figure 1. Test box.

Table 1. Properties of geosynthetics.

Types of geosynthetics	Thickness of geomembrane (mm)	Weight of geotextile (g/m <sup>2</sup> )	Stripe tensile strength (KN/m)	Elongation at break (%)
PVC geomembrane	0.6	—	9.49	282
PVC geomembrane-geotextile composite	0.45	210	12.44	83

Table 2. Properties of soil samples.

Soil samples	$\gamma_d$ (KN/m <sup>3</sup> )	Distribution of grain size (%)				Coefficient of permeability (cm/s)
		0.25-0.1 mm	0.1-0.05 mm	0.05-0.005 mm	<0.005 mm	
No.1	15.2	10.5	39.5	44.9	5.1	$7.09 \times 10^{-5}$
No.2	15.0		6.5	63.0	30.5	$2.63 \times 10^{-5}$
No.3	14.4	1.0	34.0	61.9	3.1	$9.23 \times 10^{-5}$

A mixture of three kinds of soil samples was used in the tests with a thickness of 0.5 m and dry density  $\gamma_d = 15 \text{ KN/m}^3$ . A sand drain with a width of 30 cm was placed at the outlet end of the box. A steel plate was welded on the front and back sides of the box to separate the sand drain from the soil sample. Geomembrane was put on the soil surface with a 30 cm gap to allow the water flowing into the geomembrane-soil interface. Glue was used to prevent leakage along the inner faces of the box. Four piezometers were put under the geomembrane with 1# on the sand and 2#, 3#, 4# on the soil. Another piezometer, 5# was put outside the geomembrane. Some pore pressure cells were buried in the soil sample. The detailed layout is shown in Fig. 1. The soil sample was pre-saturated. Water was supplied with varied heads of 1m, 3m, 6m and 9m. Each head was kept for 4 to 14 days until the discharge of the interface flow through the space between the geomembrane and the soil becoming stable. From the records of the pore pressure cells buried in the soil sample, the seepage water through the soil body was quite small and could be neglected.

Table 3. Results of Test No.1.

Water head H (m)	Duration (days)	Discharge ( $10^4 \text{ m}^3/\text{s}$ )	Reading of piezometers					Calculated results of each segment									
			5#	4#	3#	2#	1#	5#-4#, l=0.38m		4#-3#, l=1.0m		3#-2#, l=0.50m		2#-1#, l=0.05m		5#-1#, l=1.93m	
								$\Delta H$ (m)	$\theta$ ( $10^4 \text{ m}^3/\text{s}$ )	$\Delta H$ (m)	$\theta$ ( $10^4 \text{ m}^3/\text{s}$ )	$\Delta H$ (m)	$\theta$ ( $10^4 \text{ m}^3/\text{s}$ )	$\Delta H$ (m)	$\theta$ ( $10^4 \text{ m}^3/\text{s}$ )	$\Delta H$ (m)	$\theta$ ( $10^4 \text{ m}^3/\text{s}$ )
1.0	5	0.013	0.90	0.51	—	0.11	0.02	0.39	0.032					0.09	0.018	0.88	0.071
3.0	4	0.042	2.80	2.14	0.89	0.75	0.04	0.66	0.060	1.25	0.084	0.14	0.30	0.71	0.007	2.76	0.073
6.0	4	0.11	6.10	4.90	2.35	1.75	0.05	1.20	0.087	2.55	0.108	0.60	0.23	1.70	0.008	6.05	0.088
9.0	14	0.197	9.00	7.95	4.75	3.30	0.04	1.05	0.178	3.20	0.154	1.45	0.17	3.26	0.007	8.96	0.106

The above table shows that the values of transmissivity  $\theta$  vary significantly for different water heads at different positions along the interface. The factors affecting the values of  $\theta$  are : ①, the difference of water pressures above and below the geomembrane, ②, the water pressure acting on the soil surface, and ③, the head loss at the inlet and outlet of the interface. We can see that the values of  $\theta$  in the case of lower water heads ( $H=3 \text{ m}$  and  $H=6 \text{ m}$ ) at the inlet segment (between 5# and 4# piezometers) are smaller than those at the middle segments (between 4# and 3# piezometers, and 3# and 2# piezometers), which might be caused by the head loss at the inlet. But in the case of higher water head ( $H=9 \text{ m}$ ),  $\theta$  at the inlet segment becomes larger, which might be caused by the larger settlement of the soil body under higher water pressure and a larger space between the geomembrane and the soil being formed.

On the other hand, all the values of  $\theta$  at the outlet segment (between 2# and 1# piezometers) are smaller than those at other segments because the geomembrane at the outlet segment was subjected to a large pressure difference which made a large deformation of the geomembrane while the soil sample was subjected to a very small water pressure which made very little settlement of the soil body. Hence the interface space between the geomembrane and the soil is very small in this segment. At other segments the values of  $\theta$  vary with the water heads which made different deformations of the geomembrane and the soil sample and affected the transmissivity of the interface space between the geomembrane and the soil.

Eight tests were carried out from 1994 to 1995. The discharge of the interface flow, and the readings of the piezometers were recorded. The hydraulic gradients  $I$  between the piezometers were calculated and the hydraulic transmissivity  $\theta$  of each segment between every two piezometers can be calculated by the following equation:

$$\theta = \frac{Q}{BI}$$

where:  $\theta$  = hydraulic transmissivity of the space between geomembrane and soil ( $\text{m}^2/\text{s}$ );  $Q$  = discharge of interface flow ( $\text{m}^3/\text{s}$ );  $B$  = width of the box (m);  $I$  = hydraulic gradient between two piezometers,  $I = \Delta H/L$ ;  $L$  = distance between two piezometers(m);  $\Delta H$  = water heads difference between two piezometers(m).

The results of one of the tests, Test No.1, for example, in which 0.6 mm PVC geomembrane was used, are given in Table 3.

### 3 PERMEABILITY OF GEOMEMBRANES

The permeability of geomembranes can be determined by the WVT (Water Vapor Transmission) test method suggested by ASTM E96.

Haxo (1984) carried out a series of tests for different kinds of Polymeric membranes. The values of WVT can be converted into coefficients of permeability  $k$  by the following equation(after Lord and Koerner):

$$k = \frac{WVT}{S(R_1 - R_2) \times 1.175 \times 10^{10}} \Delta l$$

where:  $k$  = coefficient of geomembrane( $\text{cm}/\text{s}$ );  $WVT$  = Water Vapor Transmission( $\text{g}/\text{m}^2, \text{ day}$ );  $S$  = the saturation vapor pressure at test temperature( $\text{mm}$  of mercury),  $S = 32 \text{ mm}$  at  $20^\circ\text{C}$ ;  $R_1$  = the relative humidity within the test cup,  $R_1 = 1.0$  in Haxo's test;  $R_2$  = the relative humidity outside the test cup,  $R_2 = 0.2$  in Haxo's test;  $\Delta l$  = thickness of the membrane (mm).

The WVT test results and the corresponding values of  $k$  of PVC membrane are presented in Table 4

Table 4. Values of WVT and k of PVC membrane.

Thickness of PVC membrane(mm)	WVT(g/m <sup>2</sup> , day)	k(cm/s)
0.28	4.42	4 × 10 <sup>-12</sup>
0.51	2.97	5 × 10 <sup>-12</sup>
0.76	1.94	5 × 10 <sup>-12</sup>
0.79	1.85	5 × 10 <sup>-12</sup>

Hence the value k of PVC membrane ranges from 4 to 5 × 10<sup>-12</sup> cm/s.

#### 4 DESIGN SCHEME

##### 4.1 General Description

The width of the geocomposite on the blanket is 100 m, where cracks generally occurred and that on the dam slope is 70 m determined by the high water level. The Scheme is composed of three reaches on the cross-section, namely, the anti-seepage reach, the drainage reach, and the dam-slope reach. A single layer of 0.5 mm geomembrane with a length of 50m is put on the blanket of the anti-seepage reach, a composite made of 0.5mm geomembrane and 250g/m<sup>2</sup> needle-punched geotextile with a length of 50m on the drainage reach and a composite of geotextile-geomembrane-geotextile with a length of about 70m on the dam slope. A drainage system is provided to keep low water pressure under the geomembrane and geocomposite on the blanket. It consists of nine longitudinal drainage pipes at intervals of 10m, one transversal drainage pipe, a collecting well and a sump pump to collect and pump out seepage water. The layout is shown in Figure 2.

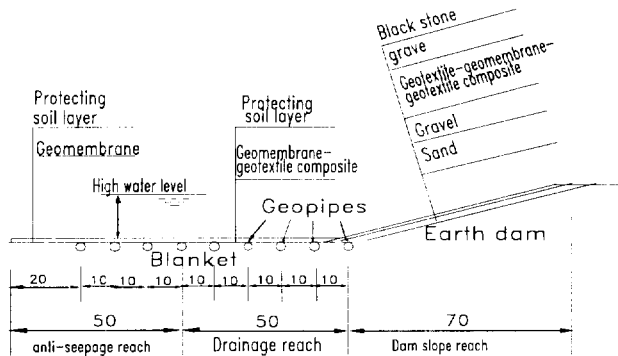

Figure 2. Cross-section of design scheme.

##### 4.2 Pressure Heads under the Geomembrane between Pipes.

###### 4.2.1 The water head equation under the geomembrane between two pipes (Figure 3)

Let the distance between any two pipes be 2L, set the origin at the mid-point of the interval between two pipes. Let y be the pressure head under the geomembrane at a distance x from the origin. The depth of water is 18m. The quantity of water permeating through the geomembrane will be

Figure 3. The curve of water head between two pipes

$$q = kIA = kIl \text{ per unit width} \quad (1)$$

where: q = quantity of water permeating through the geomembrane; l = length of permeating area, here l = dx, q = dq (m<sup>3</sup>/s per unit width); k = permeability of geomembrane, k = 5 × 10<sup>-12</sup> m/s; I = hydraulic gradient, I = ΔH/l, ΔH = difference of pressure head above and below the geomembrane, ΔH = 18-y; t = thickness of geomembrane, t = 5 × 10<sup>-4</sup> m

Substituting into eq.(1), we get: dq = 10<sup>-10</sup> (18-y)dx

The quantity of water permeating through the geomembrane from the origin O to a distance x will be q<sub>x</sub> = ∫<sub>0</sub><sup>x</sup> dq, or

$$q_x = 10^{-10} \int_0^x (18-y)dx \quad (2)$$

The interface discharge through the space between the geomembrane and the soil will be

$$q = I\theta \quad (3)$$

where: q = interface discharge (m<sup>3</sup>/s per unit width), at a distance x from the origin, q = q<sub>x</sub>; I = hydraulic gradient, here I = dy/dx; θ = transmissivity of the space. Hence

$$q_x = \frac{dy}{dx} \theta \quad (4)$$

Suppose the water pressure head y varies curvilinearly with x and the equation of the curve is

$$y = ax^2 + bx + c \quad (5)$$

The boundary conditions are: ① x = 0, y = H where H is the max. head at the origin; ② x = L, y = 0 because there is a drainage pipe at a distance L from the origin; ③ x = 0, dy/dx = 0, because at the origin no water would seep in opposite directions, and q = dy/dx θ = 0, therefore dy/dx = 0, substituting them into eq.(5) we get the pressure head equation

$$y = -\frac{H}{L^2} x^2 + H \quad (6)$$

4.2.2 The maximum head under the geomembrane between two pipes.

Substituting eq.(6) into (2)

$$q_x = \int_0^x 10^{-10} \left\{ 18 - \left( \frac{H}{L^2} x^2 + H \right) \right\} dx = 10^{-10} \left( 18x + \frac{1}{3} \frac{H}{L^2} x^3 - Hx \right) \quad (7)$$

which must be equal to the quantity of interface discharge represented by eq.(4), into which substituting eq.(6) we get

$$q_x = \frac{dy}{dx} \theta = \frac{d}{dx} \left( -\frac{H}{L^2} x^2 + H \right) \theta = -\frac{2Hx}{L^2} \theta \quad (8)$$

Balancing eq.(7) and (8)

$$10^{-10} \left( 18x + \frac{1}{3} \frac{H}{L^2} x^3 - Hx \right) = -\frac{2Hx}{L^2} \theta$$

we get the max. head at the origin

$$H = \frac{18x}{x - \frac{1}{3} \frac{x^3}{L^2} - \frac{2x}{L^2} \theta \times 10^{10}} \quad (9)$$

In the anti-seepage reach,  $L = 102 = 5\text{ m}$ ,  $\theta = 0.155 \times 10^{-6} \text{ m}^2/\text{s}$ , substituting into eq.(9) we get the max. head  $H = -0.146 \text{ m}$ .

In the drainage reach,  $L = 5\text{ m}$ ,  $\theta = 0.35 \times 10^{-6} \text{ m}^2/\text{s}$ , substituting into eq. (9) we get the max. head  $H = -0.064 \text{ m}$

4.2.3 Quantity of water flowing into pipes due to seepage and permeation.

By using equations (1) and (3) the quantity of water flowing into different longitudinal pipes at different positions could be estimated as shown in table 5.

Table 5. Quantity of water flowing into pipes.

Position of pipe	Quantity of water ( $10^{-8} \text{ m}^3/\text{s}$ per unit width)
The upstream pipe	16.7
Pipe in anti-seepage and drainage reach	1.8
Pipe at dam foot	7.2

4.2.4 Quantity of water flowing through the defects of the geomembrane.

In the design of a drainage system a defect of one hole with size of  $1 \text{ cm}^2$  per  $4000 \text{ m}^2$  of the geomembrane would be considered (Giroud, 1989). Accordingly the quantity of water flowing through the defect would be estimated by  $q = \mu A \sqrt{2gh}$ , where:  $\mu$  = discharge coefficient = 0.65;  $A$  = area of hole =  $1 \text{ cm}^2$ ;  $h = 18 \text{ m}$ . After substitution we get  $q = 1.22 \times 10^3 \text{ m}^3/\text{s}$  per  $4000 \text{ m}^2$ . The total length of three reaches of the geomembrane is about  $170 \text{ m}$ , hence  $4000 \text{ m}^2$  corresponds to a width of  $4000/170 = 23.5 \text{ m}$ . The quantity of water flowing through the defects per unit width will be  $q_6 = 1.22 \times 10^3 / 23.5 = 5.2 \times 10^5 \text{ m}^3/\text{s}$  (per unit width)

CONCLUSIONS

1. Cracks often occur in the foundation and on the blanket of an earth dam if it is built on a soil foundation and lined with a horizontal soil blanket. From economic and safety points of view the use of geosynthetics to treat the cracks might be more effective and appropriate than other measures. A scheme composed of three reaches, the anti-seepage reach, the drainage reach and the dam-slope reach, is recommended.

2. A drainage system must be provided to keep a low water pressure under the geomembrane. High water pressure under the geomembrane must be avoided because it might cause splitting action on the cracks, seepage failure of the soil foundation and rupture of the geomembrane during storage of water or rapid falling of water level. In this scheme there might be a high water pressure under the upstream part of the geomembrane (from the end to the first pipe), but it is quite far from the dam and would have little effect on the safety of the dam.

3. The functions of the geotextile affiliated with the geocomposite used in the drainage reach are to keep a further low water pressure under the geomembrane near the dam and to protect the geomembrane from being destroyed.

4. The quantity of water through the defects of the geomembrane is much greater than that due to seepage or permeation, anyway, it must be considered in the design of drainage pipes, and a certain factor of safety should be taken into account.

**ABSTRACT :** The SELVET dam, located in the center of France, at an altitude of 1050 meters, was completed during the summer of 1996. It is 18 meters high and, with a crest length of 250 meters, can store 600 000 m<sup>3</sup> for drinking water purposes. Its backfill in stony gravel is waterproofed by a bituminous geomembrane placed on the upstream face. The choice of this geomembrane was the result of tenders from the relevant companies ; the design of the support and protection layers of the geomembrane and the implementation conditions are presented. In particular, field tests were performed to simulate installation damage during construction : 6 different structures were tested to define the Geomembrane Lining System (GLS), the purpose being to use local materials with sharp stones. Results of laboratory puncture tests are also given.

**KEYWORDS :** Geomembrane, Dam, Installation damage field test, Bi-axial tensile test, Puncture test, Slope stability

## 1 PRESENTATION

The substratum is a permeable basalt. The initial solution consisted of an embankment dam, constructed with a 0/150 mm basaltic random rockfill together with a watertight seal provided by a central diaphragm wall inserted in a silty gravel transition core (0/50 mm). A grout curtain was necessary to waterproof the foundation.

In this case an alternative solution was adopted using an elastomeric bitumen geomembrane placed on the upstream face. This was more economical and allowed the work to be completed in a shorter time. Because the fill was entirely random rockfill (0/150 mm) and not affected by rainwater, dam construction could take place in the winter.

The choice of the geomembrane was the result of tenders from the relevant companies and was justified by its competitive price and its references in France for this type of dam. The support and protection layers of the geomembrane had to satisfy the usual economic objectives for dams of this nature and the specific technical constraints at this site (in particular, resistance to puncturing from any sharp stones found in the fill and to the thick ice during winter). The final specification depended on installation damage tests realised under actual site conditions (on-site vehicles running over the protective layer). The six different Geomembrane Lining System (GLS) tested ranged from a minimum GLS, where the geomembrane was laid directly on the basaltic random rockfill (with any especially large stones removed) to the most complex one which was carried out with a bitumen stabilised support layer and anti-

puncturing geocomposites. The article describes these field tests and the results obtained from visual inspection and burst testing. These tests helped to determine the final choice for the GLS (figure 1). Its installation, together with the precautions taken and the stability calculations carried out are described in detail.

- 1 : 0 / 300 mm random rockfill ( 0.60 m to 1.40 m thick)
- 2 : 0 / 31.5 mm gravel (300 mm thick)
- 3 : Geocomposite (800 g/m<sup>2</sup>)
- 4 : Bituminous geomembrane (4 mm thick)
- 5 : Geocomposite (500 g/m<sup>2</sup>)
- 6 : Gravel - bitumen emulsion mix (150 mm thick)
- 7 : 0 / 100 mm random rockfill

Figure 1. Cross section of the Geomembrane Lining System

Complementary laboratory testing (puncture tests) was also performed for research purposes ; comparisons of the results of these tests were made with the results of the installation damage tests in the field.

## 2 ADVANTAGES OF A GEOMEMBRANE LINING SYSTEM (GLS)

### 2.1 Basic solution

A first study carried out in 1991 had evidenced that various types of dams could be considered for this site, namely in concrete (gravity dam), rock or earth. The geological and geotechnical surveys, continued in 1994 and 1995, evidenced that a flexible, backfill type dam was more suited to the context of the site than a concrete dam.

The materials available on the site consisted of :

- coarse 0/150 mm gravel, obtained by the blowing up of a basalt deposit situated on the right bank, providing large quantities of material ;
- 0/50 mm silty gravel in the bottom of the valley, but with an availability of only 30,000 m<sup>3</sup>.

Given these conditions, the typical profile adopted as a basic solution for the backfill included the following zones :

- a pseudo central core, 5 metres wide, in silty gravel sealed by a diaphragm wall in extension of a grouting curtain previously made in the foundation ;
- upstream and downstream fill in coarse gravel.

### 2.2 Type of dam retained

After consulting relevant firms, this basic solution was finally abandoned in favour of a homogenous backfill, with upstream sealing by a geomembrane. This choice was based on the following :

- it proved to be more economical (cost lower by approximately 10%) ;
- it provided the opportunity for an easier, later intervention on the grouting curtain then situated at the upstream toe of the dam ;
- it proved to be time-saving, as the grouting curtain and the backfill could be carried out simultaneously ;
- the construction of the backfill, solely in 0/150 mm coarse gravel, is less sensitive to the vagaries of climate and could therefore be considered in winter ;
- maintenance of silty gravel at the bottom of the valley is propitious for the sealing of the basin ;
- there is currently a considerable corpus of experience in the use of geomembranes for sealing dams, including large dams (ICOLD, 1991).

## 3 DESIGN OF THE GLS

### 3.1 Constraints specific to the site

The Geomembrane Lining System (GLS) had to meet the economic objectives specific to this type of small dam and the technical constraints specific to the site, in particular the mechanical aggressivity of the local materials proposed for support and protection, and the risk of thick ice in winter.

This latter factor resulted in the recommendation of protecting the entire surface of the geomembrane. The coarse 0/100 mm gravel of the upstream part of the backfill on which the GLS was to be installed was obtained by blasting on one of the slopes of the pond. It consisted of sharp stones without any cohesion, given the close grading of 50/100 mm and the absence of fines. Moreover, for economic reasons, use of rockfill, also obtained by blasting of the on-site basalt to obtain a grading larger than that of the backfill, had to be used for the protection of the geomembrane.

The geomembrane adopted was that proposed by the company awarded the contract, namely an elastomeric bitumen geomembrane with appropriate characteristics and references for the dam to be built.

### 3.2 Field damage tests

In such a context, damage tests of the geomembrane had to be made under installation conditions (figure 2) to determine the transition layers to be implemented on each side of the geomembrane. In view of the nature of the support and protection layers, the implementation of the protective structure by machines driving over the surface probably represented the highest risks of damage for the geomembrane.

Figure 2. View of the installation of the geomembrane on a test area.

Six on site tests were thus prepared. The geosynthetic materials used for the tests and the retained GLS were as follows :

- TERANAP 431 TP Elastomeric Bitumen Geomembrane, called GMB in the rest of the text, 4 mm thick and with a mass per unit area of 4.8 kg/m<sup>2</sup> ;

Table 1 : Geomembrane Lining Systems tested

Test N°	Support layer (over backfill)	Support geosynthetic	Sealing	Protective geosynthetic	Transition layer (under rip-rap)
1	Silty gravel from the site	None	GMB	GTX1	0/80 mm basalt (20 cm thick)
2	0/80 mm basalt	GTX2	GMB	GTX1	0/80 mm basalt (20 cm thick)
3	0/80 mm basalt	GCP2	GMB	GTX2	0/80 mm basalt (20 cm thick)
4	0/80 mm basalt	GCP2	GMB	GCP2	0/80 mm basalt (20 cm thick)
5	0/80 mm basalt covered with 6/10 mm fine gravel	GCP2	GMB	GTX2	Crushed quarry gravel 0/31.5 mm (20 cm thick)
6	0/80 mm basalt covered with 6/10 mm fine gravel	GCP2	GMB	GCP2	0/80 mm basalt (20 cm thick)

- heat-bonded, non-woven TERRAM geotextiles, type T6 or T7, called GTX1 and GTX2, 1.6 mm thick (NF 38-012, under 2 kN/m<sup>2</sup>) and with a respective mass per unit area of 280 and 330 g/m<sup>2</sup> (NF G 38-013) ;
- PRODRAIN 1-FT3 and 1-FT4 geocomposites, called anti-puncture geocomposites GCP1 and GCP2, with a mass per unit area of 500 and 800 g/m<sup>2</sup> respectively. They are composed of T3 (135 g/m<sup>2</sup> ; 0.9 mm) and T4 (190 g/m<sup>2</sup> ; 1.2 mm) geotextiles (same producer as T6 and T7, but thinner), with short textile fibers needle-punched on to them.

The lining systems tested were laid on the 0/150 mm coarse gravel backfill and topped with a 80 cm thick layer of 100/500 mm rip-rap, as described in Table 1.

The support layer was compacted in all the on site tests with a smooth, heavy vibrating roller, and the protection layers were positioned as work progressed by a loader driving over the rip-rap. The gravel placed above the geomembrane was compacted with a small tandem roller.

The tests were performed on a backfill installed for that purpose in the area of borrowed material, 15 m wide, with a 30 % slope, and 10 m long. Each test area was 2 m wide.

Two samples of 1 m<sup>2</sup> each of the geosynthetic materials installed were taken at random from each of the 6 tests. Analysis of the damage to the geomembrane included a detailed visual examination of the 12 samples and bi-axial tensile tests on the parts of each sample which appeared to have suffered the most damage.

Above all, the visual examination evidenced the following elements :

- severe damage on test No. 1, with punch marks over the entire surface, 8 of which came close to piercing ; more localized damage with nonetheless the presence of several impacts, close to piercing, in each of the tests Nos. 2, 3 and 4 (with one identified hole on test No. 2) ;

- the samples from tests Nos. 5 and 6 revealed only a few local, shallow punch marks.

### 3.3 Bi-axial tensile tests (Burst tests)

The bi-axial tensile tests were adopted to characterize, in the laboratory, the extent of the damage to the geomembrane. On the one hand, these tests integrated several parameters (tensile strength, deformability, leak detection, etc.) of particular interest in this case, and, on the other hand, were compatible with the short time-frame required by the site. Two samples were therefore cut from each of the 1 x 1 m panels taken from the site. These samples were taken from the areas which had visibly suffered the greatest damage (while avoiding the visually identified hole for which test would have been pointless).

Figure 3. Bi-axial tensile test

The bi-axial tensile tests were performed on specimens with a diameter of 350 mm compressed by pressurised air with 200 mm diameter openings. The pressure was applied progressively in steps of 20 kPa, with a hold of 2 minutes between each step. Displacement was measured at the top of the geomembrane at the end of each step, and the burst pressure was recorded.

Figure 4. Summary of the bi-axial tensile tests for the 6 areas

The results of the tests were summarized in the form of a satisfaction index corresponding to the ratio between the mean of the displacements upon breakage recorded on the 4 samples from the same test area, and the mean of the displacements of 4 virgin samples. These values are shown in Figure 4.

Only the tests Nos. 5 and 6 gave a satisfaction index equal to 1, which confirmed the detailed visual examination of the geomembranes. Similar results were given by an equivalent index corresponding to the values of the bursting pressures.

### 3.4 Puncturing tests

These tests were performed after completion of the site, for research purposes, according to the French standard NF P 84-507, to determine the static puncturing resistance under the following conditions :

- . opening diameter = 45 mm,
- . punch diameter = 8 mm,
- . puncturing speed = 50 mm/min,
- . measurements : recording of the force applied and of the depth of the puncture.

For each GLS, 3 specimens were subjected to the test, whereas only one was taken for each geosynthetic tested.

The test was performed, of course, only on the geosynthetics. In that respect, it will be seen (Table 1) that test area No. 5 is the equivalent of test area No. 3 and test area No. 6 the equivalent of test area No. 4. The synthetic results shown in figure 5 correspond to the GLS of test areas 1 to 4. The GLS called « test area 7 » corresponds to the system implemented at the dam. For the static

puncturing test, the geosynthetics were arranged as in the field :

- . the smooth face of the geocomposite faced upwards (towards the punch) ;
- . for the GCP1 and GCP2 geomembranes, the « short fibre » face was in contact with the geomembrane.

Examination of the results in figure 5 evidence a better behaviour for test areas 4 and 6, which correlates with the results of the in-situ test areas (observations and results of the bi-axial tensile tests). The result for test area 7 is close to that of test area 6 (GLS of similar constitution). On the other hand, test area 5, the behaviour of which in-situ was considered satisfactory, behaves less well under static puncturing, whereas the GTX2 (used in test area 5) has a resistance equal to or greater than the GCP1 and GCP2 (test areas 4, 6 and 7). This evidences that the short fibres play a significant part in improving puncturing resistance.

In summary, the puncturing test is a simple test which provides valuable information for the comparison of the different geosynthetics tested for the protection of the geomembrane. It is, however, an index test which fails to take account of the granular layers of the support and protection structures, and cannot therefore be used alone for the sizing of a GLS. In our case, the in situ tests evidenced that the better quality of the support implemented for test area 5 compensates for the use of a less effective protective geocomposite.

Figure 5. Summary results of the puncture tests

### 3.5 Description of the GLS adopted

Given the previously described on-site tests, it proved impossible to ensure a support layer solely with the on-site materials. At the very least, this layer had to be covered with fine gravel (tests Nos. 5 and 6). This solution, however, presented difficulties in implementation over a wide area (7,500 m<sup>2</sup>), due to the lack of cohesion of the gravel, which meant that the stones were likely to roll down the facing under the geomembrane upon its installation. To

avoid this installation difficulty, the support layer was finally made of gravel mixed with a bitumen emulsion. Under such conditions, with an improved quality of the support, it was decided to replace the GCP2 geosynthetic support under the geomembrane by a lighter-weight geocomposite (GCP1). Furthermore, to protect the geomembrane, the safest components of tests were adopted : the anti-puncturing geocomposite (test No. 6) and the crushed quarry gravel (test No.5). The GLS thus obtained is shown in figure1.

### 3.6 Stability of the GLS

To avoid eventual tensioning of the geomembrane, this one was installed with the smooth face uppermost. In these conditions, the weakest interface of the GLS as far as slippage stability is concerned consists of the contact between the geomembrane and the upper geotextile. The friction angle ( $\delta$ ) was measured between these two elements of the GLS with an inclined plane test (Gourc et al.1996 ; Girard et al. 1994). This test consisted of installing the geosynthetics to be studied on a flat frame, hinged on one side. The geosynthetics are then subjected to a low vertical stress by means of a layer of soil placed on the upper geotextile, held in place by a mobile, freely sliding frame (not fixed to the flat frame). The flat frame is then raised until slippage occurs along the interface being studied. The slippage angle is then measured. In the case in hand, the geomembrane was fixed to the flat frame ; the upper geotextile was then loaded with 30 cm of 0/31.5 mm gravel as used on the site. Slippage of the geotextile was obtained at values of 22 and 24 degrees (2 tests). A conservative value of 22° was taken in the calculations for the friction angle between the smooth face of the geomembrane and the upper geotextile.

The first stability calculation was performed taking account of a constant protection thickness equal to 1 metre, made up of a 30 cm layer of 0/31.5 mm gravel topped by 70 cm of random rockfill taken from the site. The mechanical characteristics adopted for these materials are  $c=0$  (zero cohesion) and  $\phi = 45^\circ$ . Furthermore, given the high permeability of these materials, it can be considered that when the dam is empty the protection layer is never saturated.

The calculations were performed according to the hypotheses defined above taking the highest profile of the upstream face. In this section, the total height of the slope is 17 m, with a slope of 1 / 2.5. The stability analysis is performed with the dam empty, by the blocks method (Soong and Koerner, 1996).

The safety coefficient thus obtained is equal to 1.22. This was considered too low, and to improve slippage safety the protection layer was therefore increased to 1.40 m at the foot of the slope and reduced to 0.60 m at the top. The calculations made with this variable thickness produced a slightly higher safety coefficient of 1.32. A calculation

performed using the ETAGE software (Soyez et al. 1990) developed by the Central Civil Engineering Laboratory (LCPC) produced the same result. We subsequently verified that slippage safety was also ensured during the filling of the dam ; in this case, the minimum coefficient obtained was equal to 1.20 at the beginning of the filling.

This profile with a variable thickness, as described above, was thus adopted for protection. The increase in the toe trench made it possible to increase considerably the slippage safety, which is thus ensured without taking account of tensile stress that can be absorbed by the upper geotextile (GCP2) anchored at the top of the slope.

## 4 IMPLEMENTATION OF THE GLS ADOPTED

A transition area (0/100 mm) was installed between the body of the backfill (0/150 mm) and the emulsified gravel, over a width of 3 metres, following completion of the grouting curtain at the toe of the upstream face. Its surface, parallel to the slope, was reworked with an excavator, and carefully finished by hand, to eliminate all of the larger pieces. The gravel-bitumen emulsion mix (0/14 mm) layer, 15 cm thick, was laid on the slope with a crawler-mounted loader and spread with a rake. Compacting was performed along the slope with a tandem roller anchored to the top of the slope, and the final surface then brushed.

The anti-puncturing geocomposite was then unrolled over the slope working downwards from the crest. The 2 m wide sections were sewn together. The geomembrane, delivered to the site in 4 m rolls, was unrolled downwards from the crest, the roll being hung from a hoisting tackle mounted on a shovel loader. The smooth face of the geomembrane was laid uppermost to avoid tensile stresses from settlement of the protection layer. A detailed pattern lay-out enabled the sections to be adapted to the length of the slope to avoid transverse joints.

Figure 6. Installation of the geomembrane

Geomembrane sections were joined with a blow-torch,

with a 20 cm overlap. The project manager performed a visual inspection of all the seams.

The connection of the geomembrane to the grouting curtain at the foot of the slope was an important factor for sealing of the dam. The solution adopted consisted of lowering the geomembrane into a trench filled with concrete with the addition of bentonite (150 kg cement, 400 l with 10% of bentonite, 950 kg of 0/3 mm sand and 500 kg of 8/14 mm gravel). This trench was cut in the basalt with a trencher to a depth of 1 m along the centre line of the grouting curtain, then filled in 2 phases. The concrete was poured into the dam side part of the trench (using shuttering) to obtain a smooth vertical face. The geomembrane was then installed, and the upstream part of the trench filled. To improve the sealing of this sensitive transition area, an overlap strip of the same geomembrane (1 m wide) was then installed and seamed with the main geomembrane on one side and with the concrete (upstream part of the trench) on the other side. The geomembrane was anchored to the crest by a classic trench filled with gravel.

Figure 7. Installation of the protective layer of the GLS

The protection layer was installed as work progressed from the foot of the slope using a loader and a crawler-mounted shovel loader, after the installation of the top pierce-proof geocomposite. The two machines moved over the full thickness of the protection layer (gravel layer plus random rockfill) to restrict stresses on the geomembrane and to take advantage of the stability of the random rockfill resting at the foot of the slope up against a support fill.

## 5 CONCLUSION

The dam was built between October 1995 and August 1996, the backfill being completed during the winter. The installation of the GLS was performed without any particular difficulty between April and July 1996. The dam was filled in early 1997.

The damage on site installation tests made it possible to define a GLS adapted to the specific conditions of the dam with, in particular, the use of rip-rap taken from the site to form the protection layer.

The comparison between the results of the installation field tests (observations and bi-axial tensile tests) and laboratory puncture tests gave interesting information about the use of the latter.

## ACKNOWLEDGMENTS

We should like to thank the Viadène SIAEP, owner of the Selvet dam, the DDAF of Aveyron department and MERLIN consulting engineers, project managers who enabled us to complete this study and participated in the design and the construction of the GLS.

# BITUMEN GEOMEMBRANES IN IRRIGATION - CASE HISTORIES FROM A RANGE OF CLIMATES

B. Breul

Colas S.A., Direction Recherche et Développement, 92653 Boulogne Billancourt, France

R. Herment

Société des Pétroles Shell, Direction Bitumes, 92563 Rueil Malmaison, France

**ABSTRACT:** Bitumen was in use 5000 years ago for irrigation works that are still in good condition. Today, bituminous geomembranes are providing efficient, durable waterproof linings to irrigation canals, ponds and reservoirs throughout the world. They are either fluid-applied or delivered in rolls 4 metres wide. A survey of twenty irrigation dams around 10m high built between 1973 and 1983 in France with unprotected geomembrane facings found them performing well after 10-20 years service. Linings to a reservoir at Goudel in Niger and canals cut in laterite near Niamey have demonstrated their suitability in tropical climates. In North Africa, the Gulf States, Singapore, India and New Zealand, 5m-wide bituminous geomembranes have been in use on irrigation canals for some ten years and are still performing satisfactorily. In the USA, leaky areas on a large concrete-lined canal were stopped with an SBS bitumen-based geomembrane available in 4m widths in France.

**KEYWORDS:** Aging, Canal Liners, Case Study, Dams, Embankment, Geomembranes, Bitumen

## 1 INTRODUCTION

Five thousand years ago, crude petroleum was only accessible where it emerged from deep fissures in the ground. The heavy residue contained a high percentage of bitumen, which the ancients, especially in the Middle East, used for its waterproofing properties. Since those early times, it has been used to build and repair wells, reservoirs, canals and baths and consolidate irrigation canal embankments. Many of these constructions are still in good condition.

Bitumen emerged as a standard 20th century waterproofing material in civil and water engineering in the form of bituminous concrete, asphalt and bituminous geomembranes. The last-mentioned are lightweight materials that are easy to lay and repair, with waterproofing properties that make them ideal for irrigation works. They may take one of three forms:

- ◆ Bitumen can be sprayed onto a geotextile in situ (ISBGs)
- ◆ They may be prepared (prefabricated) in the factory and delivered to site in rolls (PBGs)
- ◆ An impervious asphalt may be laid on the canal or reservoir floor with the membrane confined to the sloping sides.

## 2 BITUMINOUS GEOMEMBRANE FOR IRRIGATION WORKS

The material underlying the lining must be free from grass or other organic matter, and well drained if it is not naturally impervious. Gas collection wells are also needed

if there is a risk of fermentation. It must be stable, smooth, with no sharp stones, and compacted to at least 90% Proctor optimum.

Although not always necessary, a protective covering should be added if the geomembrane is exposed to uplift pressures, wind suction, severe sunlight, impact, ice, debris, animals or wilful damage. It usually consists of unprocessed natural material although stabilisation with cement or bitumen reduces the thickness required.

Bituminous geomembranes, 3.3mm to 5.6mm thick with a density of 1.15, are three times heavier than polymer geomembranes, and therefore less affected by wind action.

## 3 EXAMPLES OF IN SITU BITUMINOUS GEOMEMBRANES

### 3.1. France

In situ bituminous geomembranes (ISBGs) were used in France in the early sixties under railway track and for renovating old roads; the ballast and top foundation courses respectively were removed to a depth of up to 800mm and the bituminous membrane was sprayed in two 3-5mm coats with a glass fleece or non-woven polyester geotextile in between, before covering with new material. The membrane isolates the overlying material from contaminated groundwater and shields the foundation from percolating surface runoff.

This approach was used again on the Huningue (1962) and Nord (1966) ship canals. It usefully reduces leakage through the canal floor. It must be protected on the banks against erosion and wave action.

When water reservoirs began to be lined in the seventies, it was found necessary to design special reinforcing arrangements to control root damage.

The choice of bitumen grade is governed by air temperatures at the site, altitude and exposure to sunlight. The bitumen is sprayed from a tanker through a spraybar at the rear or extending out to one side, horizontally or at an angle when spraying slopes. The geotextile is normally unrolled after the first coat has been sprayed.

The first application of an ISBG to a mountain reservoir 1800m asl in the French Alps was followed by several coastal reservoirs near Toulon with capacities ranging from 3000 m<sup>3</sup> to 40,000 m<sup>3</sup>, where the membrane was laid on pervious material and protected with 8cm of lean concrete.

Surface protection is not always necessary. Two small rockfill dams, 4-13m high, were built in 1973 and 1975 in southern France, each faced with an ISBG exposed to direct sunlight. The agricultural ministry's research institute CEMAGREF monitored the performance of the facings and reported the appearance of only one tear at the crest after eight years, which remained unchanged over the following seven years. A strip of geotextile that had not been impregnated with bitumen and had aged was easily repaired. The other dam showed no flaws after more than 20 years.

Use of ISBGs was slowed in France because the country's dense road network accessible to heavy trucks favoured prefabricated bituminous geomembranes, but they are an excellent answer for narrow inaccessible sites and for covering large flat areas.

### 3.2 USA

There has been a special ISBG working group within ASTM committee D35-10 since 1996.

#### 3.2.1. Irrigation Canals

The United States has a very extensive irrigation canal system and the US Bureau of Reclamation has issued tables correlating canal size and capacity, slopes, fill material and thickness.

#### 3.2.2. Reservoirs

American engineers use ISBGs to line large reservoirs with capacities in excess of 1 Mm<sup>3</sup>.

At Oakland, the ISBG is covered with 100mm of concrete and lies on a foundation of 10cm of dense and porous asphalt.

Engineers and scientists at the Department of Energy's Hanford site in Washington have developed a maintenance-free waste-site surface barrier made from natural materials that will last for 1000 years. They monitor a 5-acre prototype constructed in 1993 over a decommissioned wastewater disposal facility. There is a multi-layer barrier of various natural materials (sand, gravel, clay, etc.) 4.50 metres thick. In addition, an ISBG was laid on 150mm of asphalt.

## 4 PREFABRICATED BITUMINOUS GEO-MEMBRANE RESERVOIR LININGS

A few interesting examples are described in the following.

### 4.1. France: Embankments Less than 18m High

Seventeen water reservoirs impounded by rockfill embankments have been monitored by CEMAGREF over the last twenty years. Only four linings had protective coverings and all the underlying rockfill was free-draining. Reported damage was minor, consisting of a single case of a PBG being punctured by sharp stones underneath, one tear by vandals, and one section of seam that separated. The three spots were quickly repaired in a durable manner.

The only reported damage on the other embankments was minor damage to seams from plant roots, which was easily repaired. Mud curling was observed on the PBG without surface protection although it had no effect on watertightness and the process always stopped at the geotextile.

There are many other geomembrane linings ranging from 1500 m<sup>2</sup> to 10,000 m<sup>2</sup> in area all over France that have been giving complete satisfaction for the last twenty years.

### 4.2 France: Large Irrigation Works

Ospedal dam, 26m high, with a 5000 m<sup>2</sup> PBG facing laid on porous asphalt and a geotextile and protected with interlocking pavings, was built in Corsica in 1978 and remains in excellent condition, as evidenced by 19 years of periodic inspection.

In 1976, an irrigation reservoir was built at Gap in southern France with a 25,000 m<sup>2</sup> PBG facing, and Ortole rockfill dam in Corsica was completed with a similar 6800 m<sup>2</sup> facing. Problems were experienced with the poorly compacted soil when first filling the Gap reservoir. A tear in the geomembrane where it joined a concrete pipe allowed leakage to wash away material from the embankment, but it was easily repaired.

The Ortollo facing was laid on a elaborate base (25-30mm ballast impregnated with 3 kg/m<sup>2</sup> bitumen emulsion and 100mm cold laid asphalt) plus a geotextile. The protective covering was geotextile plus 140mm in situ fibre reinforced concrete (polypropylene fibre, length 30mm, weight 1kg/m<sup>3</sup>). All seams were 100% tested with an automatic ultrasound tester. The quality of construction enabled the structure to withstand exceptional floods successfully.

#### 4.3. Reservoirs in Hot Climates

From 1981 to 1983, large jobs ranging in size from 50,000 m<sup>2</sup> to 80,000 m<sup>2</sup> were completed in Saudi Arabia at Hail, Riyadh, Taif and Dorman at the Royal Palace. They included many ornamental ponds.

At Goudel near Niamey, a river water storage reservoir was lined with 4500 m<sup>2</sup> of PBG in 1981 and remains in good condition apart from some tears at junctions with concrete structures.

In 1989 at Palma, Majorca, 22,500 m<sup>2</sup> of PBG was used to line an aeration lagoon.

In 1991, reservoirs in the gulf of Marrakech had 90,000 m<sup>2</sup> of elastomeric bitumen PBG laid directly on the sand, without any protective covering.

In the same period, large reservoirs were lined with 30,000 m<sup>2</sup> PBG in Abu Dhabi.

In 1996, 110,000 m<sup>2</sup> of PBG was used at a settling pond in Nigeria.

All these prefabricated bituminous geomembranes performed well with respect to sunlight and temperatures in these hot climates.

## 5. CANALS

### 5.1. France

PBGs are used extensively for lining irrigation ditches and canals. Tests performed after fifteen years service near Le Mans revealed that PBGs covered with soil and grassed, were ageing well. They performed valuable service in controlling leakage from critical canal sections in the Freyssinet system. The largest job was the 260,000 m<sup>2</sup> of elastomeric bitumen PBG lining to the Nieffer canal near Mulhouse.

### 5.2. Very Hot Climates in Africa and Asia

Prefabricated bituminous geomembranes were effective in the construction of Ishagi canal, Iraq, in 1981 and the Mines d'Or canal at Poula in Burkina Faso. They also

successfully repaired the 64,000 m<sup>2</sup> of leaking concrete lining to the Tanorga irrigation canal in 1985, and controlled leakage over 22,000 m<sup>2</sup> of Tungabhadra canal in India in 1987. A geotextile underlay and slate gravel protective covering were provided for the Mines d'Or canal PBG.

### 5.3. North America

Two of three leaking sections of the Caspa District canal in Wyoming, USA, were repaired with 9000 m<sup>2</sup> and 60,000 m<sup>2</sup> elastomeric bitumen PBG in 1992 and 1994 respectively. The third, slightly larger (80,000 m<sup>2</sup>) section was repaired in 1995 by the canal operator's own employees.

When the West canal in Oklahoma was leaking in 152 places, PBG repairs to an 800m section restored irrigation supplies to 120 ha of farmland.

California has the densest canal system in the USA, and PBG has been used extensively to repair earth and concrete-lined canals.

Two water treatment ponds covering 75,000 m<sup>2</sup> and 6.50m deep, lined with elastomeric bitumen PBG, lost only 1 litre per square metre per day as against the design criterion of not more than 20 litres.

### 5.4. Special Problems in Livestock Farming Areas in Developing countries

Near Niamey in Niger, canals cut into the laterite were lined with 20,000 m<sup>2</sup> of PBG in 1991, and six years later, it was observed that:

- ◆ Canals in vegetable-growing areas were in good condition.
- ◆ Canals in livestock farming areas had been damaged at cattle crossings.
- ◆ Local residents had purposely torn the geomembrane in places to take water. It is also said that bituminous geomembrane material is popular for re-soling shoes.

This means that special measures are needed to combat damage of animal and human origin, such as fencing, thorn hedges, concrete cattle crossings and more water offtakes.

In Niger as in many other places, special care is needed when joining geomembrane to concrete, and should include firm cold jointing, double membrane thickness and clamp bars.

## 6. CONCLUSION

Laying bituminous geomembranes, with or without surface protection, is such a simple job that it can be successfully performed in many countries with standard tools and trained local labour, to build and repair irrigation canals and reservoirs. The examples described also illustrate that bituminous geomembranes are easy to repair, retain their waterproofing properties over time and age well.

The choice between in situ and prefabricated alternatives or combining bituminous geomembranes with asphalt is governed by local cost factors, since all three approaches have proved their worth.

## 7. ACKNOWLEDGEMENTS

Thanks are due to Messrs Siplast and Hypofors for permission to quote details of their jobs.

# Construction Technology of Geotextile Mattresses for Bank Protection of Liaohe River, Liaoning Province, P. R. China

Wang Dianwu,

Research Institute of Water Resources and Hydropower, Liaoning Province

Wang Xiaobai

Management Office of Agricultural Development Projects Using World Bank Loan, Liaoning Province

**ABSTRACT:** Since early 1980's, the experimental study of application of geotextiles to the bank protection of Liaohe river in our province has been carried on. We have innovated in construction technology, featuring the cold region in our country, such as sinking geotextile mattresses on/under the ice cover, and on a boat / floating bridge, etc. This paper briefs these construction methods, the properties of geotextiles in use for mattresses and the design principles are also provided.

**KEYWORDS:** Geotextiles, Embankments, Erosion control, Construction

## 1 INTRODUCTION

To handle dangerous section of a dike has always been the crux to river training works. Since last decade or so, geotextile mattresses have been used in such sections along the trunk of Liaohe river. According to the statistics, a total of 2 million sqm or more geotextiles were used in some 150 bank protection works. It has saved a great deal of investment and about 150 thousand tons of twig as compared with traditional fascine bundles and riprap works, which is corresponding to protecting thousands hectares of rapid growth forest, that is beneficial not only to ecological environment, but also to saving expense of transportation, as the total weight of 2 million sqm of geotextiles is only 300-500 tons, which is far less than that of twig. When the GT mattresses are used, the most appropriate construction method may be chosen, and the work efficiency could be increased by 50% or more, the quality of project and operating results may be guaranteed as well.

## 2 MANUFACTURE AND WEIGHT OF GEOTEXTILE MATTRESSES

### 2.1 Material of Geotextile Mattress

Five kinds of polypropylene woven geotextiles were used mainly in bank protection of Liaohe river. The main properties of GT are shown in table 1.

As seen by Table 1, the mechanical properties of the five kinds of GT can all meet the engineering requirement, but in consideration of that the larger the opening size, the lower the cost, so that, under the permissible filter condition, we choose the GT with opening size as large as possible.

According to laboratory filter test, field erosion

test and analysis on engineering practice for these five kinds of geotextile, the design criterion of filter is taken as:

$$O_{90} \leq A d_{90} \quad (1)$$

In which, the coefficient A is 10 for clay and loam; 2~5 for sandy loam and sand.

### 2.2 Determination of the Size of GT Mattress

Transversal (normal to the stream) length of the GT mattress is composed of two parts, i. e. the above-water part and under-water part. The transversal length of the above-water part is determined similar to the normal bank protection, and that of the under-water part will be calculated in reference to the thalweg if the main flow of the river is near the bank; or in reference to maximum eroding depth if the thalweg is far from the bank.

The transversal length of under-water GT mattress calculated with thalweg is:

$$L = L_1 + L_2 + L_3 \quad (2)$$

Where: L = total length of under-water GT mattress (m);  $L_1$  = length of mattress required for connecting to that of above-water part and for anchoring (m);  $L_2 = S_1 S_2 \sqrt{X^2 + H^2}$ , in which:  $S_1$  and  $S_2$  are coefficients of wrinkle and contraction under-water respectively. The actual measurement values for Liaohe river are  $S_1 = 1.4$  and  $S_2 = 1.05$ ; X = horizontal distance between thalweg and water surface on the bank during low water level (m); H = depth of water at thalweg during low water level (m);  $L_3 =$  overlength beyond the thalweg, or  $L_3 = K_0 h \sqrt{1 + m_0^2}$ ; in which:  $K_0$  = safety factor;  $m_0 =$

Table 1. Properties of GT used in the Bank Protection of Liaohe River

Polypropylene woven GT	Weight (g/sqm)	Thickness (mm)	Tensile strength (N/5cm)		Elongation per unit length(%)		Equivalent opening size $O_{90}$ (mm)	Permeability (cm/s)
			warp	weft	warp	weft		
A	100	2.0	496	408	26.0	20.0	0.70	$6.84 \times 10^{-4}$
B	110	2.5	511	666	28.6	25.0	0.72	$3.57 \times 10^{-3}$
C	103	2.1	584	526	13.0	17.5	0.15	
D			540	480	15.3	13.8	0.66	
E			392	357	19.5	17.5	0.33	

stable slope rate under-water;  $h$  = maximum eroding depth(m).

If transversal length of under-water GT mattress is calculated with maximum eroding depth, the total length of it will be:

$$L = L_1 + L_2 \quad (3)$$

where:  $L_1$  is the same as in Eq. (2);  $L_2 = K_0 h \sqrt{1 + m_0^2} (H_m + H_{max})$ . in which:  $H_m$  = mean depth during low water level(m);  $H_{max} = H_m(2B/R_m + 1)$ . in which:  $B$  = width of river corresponding to the bed forming discharge (m); and  $R_m$  = radius of curvature at river bend(m); and  $H_m$  = mean depth before erosion at the section in question.

The longitudinal length (in the direction of stream) of GT mattress was adopted 20 ~ 50m for on/under ice cover construction, and 10 ~ 20m for on boat/raft construction in Liaoning Province.

The dimension of GT mattress for base protection of spur /longitudinal dike may be computed by following formula:

$$L = l + m_1 h + l_0 + a \quad (4)$$

$$B = b + 2m_2 h + 2l_0 + a \quad (5)$$

In which:  $L$  and  $B$  = length of mattress parallel and perpendicular to the axis of dike, respectively, (m),  $m_1$  and  $m_2$  = end slope and side slope of dike, respectively,  $l$  = length of dike(m),  $b$  = top width of dike (m),  $l_0 = K_0 \sqrt{1 + m_0^2} h_s$ , where:  $h_s$  = depth of local erosion around the dike (m), which may be calculated by formula or determined by experiment, the actual measurement value for Liaohe river is  $h_s = 1.1 \sim 2.8m$ ,  $K_0$  and  $m_0$  are the same as in Eq. (2).  $a$  = additional length including wrinkle and contraction under-water(m).

### 2.3 Manufacture of Geotextile Mattress

The four edges around the GT mattress and every 0.50 ~ 0.60m in the transversal direction should fold up and sew into a sleeve-like pipe for penetrating nylon rope to act as reinforcements.

Now the factories can produce the GT mattress according to designed size and disposition of reinforcements.

### 2.4 Geotextile Mattress Weight

The types of weight for GT mattress are as follows:

1. precast concrete blocks put on sides of the mattress, and arranged in checkers inside the mattress, dump additional stone within the checkers make the mean weight up to  $1.2kN/m^2$ , and  $1.6kN/m^2$  for side one.
2. Put willow or oak twig bundles on two-layer GT mattress to form  $1.0 \times 1.0m$  checkers with riprap within it. The weight of which may be  $3.7 \sim 5.6 kN/m^2$ .
3. Earth pillow weight, this is a bag made of coated woven geotextile, filled with earth in situ, then sewn up. The length of which used in Liaohe river is 5 ~ 10m, 0.30 ~ 0.40m in diameter and single weight 10 ~ 20kN.
4. Put gabions, 0.30 ~ 0.60m in diameter, on edges of GT mattress; and arranged in checkers on it. Then dump riprap within checkers for 0.30 ~ 0.50m thick.
5. Combined weight of gabion, riprap, and earth pillow. The gabions are used for side weight and an additional weight of gabions at 10 ~ 20m spacing. The riprap or earth pillows are placed between the gabions. The weight is about  $1.0 \sim 2.0kN/m^2$

## 3 CONSTRUCTION TECHNOLOGY

### 3.1 Sinking Mattresses on Ice Cover

The construction period in our province is usually from the last ten days of December to the first ten days of March the following year.

Table 2. Field experimental results of ultimate bearing capacity of ice cover in Liaohe river area

Thickness of ice cover (cm)	Freezing period				Thawing period			
	10	20	30	40	10	20	30	40
Bearing capacity (kN/m <sup>2</sup> )	5.60	9.20	14.66	20.00	2.40	4.00	4.95	5.80

Figure 1. Sinking mattresses on ice cover

Dig an ice pit according to the size of GT mattress, construction period, designed weight and bearing capacity of ice cover.

The field experimental results of ultimate bearing capacity of ice cover for various thicknesses during freezing and thawing periods in Liaohe river area are listed in Table 2.

Place the GT mattress into the ice pit, the adjacent mattresses should be lapped or sewn on.

The weight should be put firstly on the downstream side of mattress, then extended progressively from upstream to downstream. When the weight reaches designed amount, the mattress body will sink itself uniformly within a short time.

With regard to the construction of GT mattress for base protection of spur /longitudinal dike, it should be done during thawing period when the bearing capacity of ice cover is greater, or determined in accordance with the law of thawing ice cover in local area, weight of dike, and loading of construction. To ensure safety for construction and shorten the time of construction as far as possible. The procedures are as follows: positioning on ice surface, spreading GT mattresses, putting weight on it, and building dike according to designed shape preliminarily. The dike deformed as soon as the thaw of river, to build again the dike to design section after thawing is basically stable.

### 3.2 Sinking GT Mattress Under Ice Cover

To dig through two longitudinal ice trenches, one near the bank and the other on the midstream side

of the mattress, and two transversal ice trenches at upstream and downstream ends. The trenches should not meet each other, they are used to pull mattress under ice cover. and to dump weight through them.

Figure 2. Sinking GT mattress under ice cover

Fold up the first GT mattress longitudinally and keep downstream end of it on the surface. Put the folded mattress on the upstream side of the first transversal ice trench.

Tie the upstream end of mattress to the piles driven through ice to the river bed, and hold down it on the ice cover with earth pillow.

Tie polyethylene (PE) ropes on each corner of downstream end of mattress(which is on the top of folded mattress), then throw the ropes into water through transversal ice trench and draw out from longitudinal ice trench (on the midstream side) by means of a stalk-hook. Then the mattress will follow the ropes passing through the water under ice cover, and be drawn out and put on the ice cover. The next mattress should then be sewn to the former. The rest may be done by the same way.

Throw the ropes into water through that longitudinal ice trench and draw out from another longitudinal ice trench (on the bank side). Pull the ropes to place the GT mattress (which floats on the water under ice cover), then fix it to bank and midstream ice surface. Finally, to give weight through transversal and longitudinal trenches on it. The mattress will sink onto the river bed.

### 3.3 Sinking GT Mattress on Boat/Raft

During bank protection construction period in

Liaoning province (the low water level period), the depth of water in the river is usually not more than 1.0m, and the velocity is about 0.5 ~ 1.5m/s. In practice, a realistic measure of sinking GT mattress by sliding it off while drawing the ropes in on the boat has been used. The main procedures of construction are as follows:

Positioning the two sides of GT mattress by transit or surveying rods, drive a pile on river bank and drop an anchor in river to fix steel rope used for guiding the boat to pull the GT mattress.

Place the GT mattress on the regulated slope of the bank, put and fix the precast concrete blocks on it. A steel pipe is installed on the front edge of the mattress. The PE ropes (16mm in diameter) spaced 2 ~ 3m centers are tied on the steel pipe and the boat.

The boat moves along the steel rope and pull the mattress with the PE ropes, the mattress will be developed gradually under the water until it reaches desired position.

Then, dump additional weight on the mattress from the boat.

### 3.4 Sinking GT Mattress on a Floating Bridge

The floating bridge is made up of raft or boat located near the river bank. The length of which should be longer than the transversal length (normal to the stream) of GT mattress. The loading capacity must be more than the total weight of earth pillows, gabions, and workers. The position of the floating bridge is held by steel or PE ropes to an anchor.

The procedure of sinking mattress is as follows:

Carry the processed GT mattress onto the floating bridge, which is rolled in transversal direction.

Make a sinking pillow (earth pillow or gabion) which is as long as the transversal length of mattress and wrapped up by the upstream end of the mattress, then sewn up with nylon thread.

Throw the GT mattress into the water as soon as the sinking pillow is completed. The rolled mattress will be opened up gradually and spread over the water surface under the floating bridge depending on dynamic force of flow.

Fasten the longitudinal reinforcement of mattress to the wooden piles on the bank to prevent the mattress from sliding to river bed while it is sinking. The drift is that the mattress travels downstream with the current during it sinks to the river bed. It is necessary to determine the drift by field experiment in advance, as the position of floating bridge used for sinking next GT mattress is related to this value and length of lapping joint of the two mattresses.

Put transversal side weight (earth pillow or gabion) onto the end of the mattress from the boat, and then dump bulk weight on it.

### 3.5 Placing GT Mattress Under Water

The discharge before flood season is very small on the upstream reaches of Liaohe river, even zero in some reaches. These cases would occur in medium and small sized rivers. During such period of time, the construction of GT mattress may be done simply by manpower. In this method, the mattresses should be constructed the same way as in sinking it on boat described above, then pull into place by standing in shallow water or opposite bank, or placing GT mattresses directly onto the river bed when the water depth is less than 1.0m, and then put the weight on it.

## 4 CONCLUSION

Through experimental study and engineering practice, some construction methods for placing GT mattresses in seasonal rivers in cold region have been developed. The method should be chosen in accordance with local conditions. However, practice has indicated that sinking GT mattress on ice cover is an optimal method for bank protection of frost-prone rivers in cold regions, because the construction on ice cover has following advantages:

1. Making mattresses, positioning, sinking mattresses, and placing weight will be more accurate, and easier to control the quality of construction.
2. The boat/raft and anchors are unnecessary for construction on ice cover. In addition, it is convenient to transport.
3. High efficiency, so as to shorten construction period and to save the cost of project.
4. Farmers are often employed in construction of bank protection work in China. The period from ice thawing till flood is the busy season in farming, while the winter is slack season, so that the labour force will be optimized.

# A New Structure for Protecting the Banks of Waterways

J. Yan

Research Engineer, Hydraulic Engineering Department , Nanjing Hydraulic Research Institute , Nanjing 210029, P. R. China.

**ABSTRACT:** This paper describes a new type of reinforcement for steep-faced embankment by roughened woven geotextile for protecting the bank of waterways. First , the authors have developed a new type of roughened woven geotextile , and have studied the engineering properties of roughened woven geotextile for reinforcing the soil body ( fractional coefficient between geotextile and clay about 0.4 ) . In this paper, the coupling calculation and analysis of stress-seepage for the soil body of embankment have been performed by finite element method for determining the design factors of this structure and laying disposition of the geotextile, at the same time the action of reinforcement materials on the stability of soil embankment have been considered . Finally, the paper describes a case of bank protection in a fourth-grade waterway. In comparison to the common type of bank protection engineering, the structure proposed in this paper have advantages of rapid construction, low cost, and high safety.

**KEYWORDS:** Waterway, Revetment , Friction, Woven Fabrics, Design.

## 1 INTRODUCTION

The purposes of bank revetment of waterways are primarily protect direct erosion and attack of shipping wave. Geotextile was usually put to use as geotextile soft caisson etc. in waterways in the past . But wrap-around reinforcement steep-faced embankment was applied to roads and railways etc. . We probes into applying wrap-around reinforcement steep-faced revetment in waterways in this paper, and proves its feasibility from selecting reinforcement materials and designing reinforcement embankment and analyzing states of stress-strain of embankment, calculating stability of embankment. Finally , the paper describes a case of bank revetment in a fourth-grade waterway, and it have success preliminarily .

## 2 ROUGHENED WOVEN GEOTEXTILE

We have researched and developed a new type of roughened woven geotextile (PP) for fitting the need of engineering, and have carried out the permeability characteristics testing, and engineering properties testing of woven geotextile in the laboratory, its properties are shown in table 1.

Table 1. Properties of woven geotextile (PP)

Test project	Unit	Measured value	Test method
Weight per unit	g/m <sup>2</sup>	290	GB/T 13762-92
Strip tensile	T	55.2	ASTM D4595
	W	52.2	
Trapezoidal tear	T	1.78	GB/T 13762-92
	W	1.60	
Permeability	cm/s	1.49×10 <sup>-3</sup>	NHRI-89
Frictional angle	$\mu_1$	21.9	Sample Size 200×200mm <sup>2</sup>
	$\mu_2$	30.0	

Notes:  $\mu_1$  = frictional angle between geotextile and loam ( ° ) ;  $\mu_2$  = frictional angle both geotextiles ( ° ) , GB/T = National Trial Standard of China , NHRI = Nanjing Hydraulic Research Institute .

## 3 DESIGN OF WRAP-AROUND REINFORCEMENT EMBANKMENT

When designing wrap-around reinforcement steep-faced embankment, we primarily take into account several aspects, such as high of embankment, length of embankment, gradient of embankment, loads of embankment, geological conditions of ground, and

characteristics of reinforcement materials and soil-filled . And define the rational position of reinforcement material in the soil-filled, the required reinforcement length, the vertical spacing , and the fold-over length.

We adopt to traditional way “ Limit equilibrium concepts” and design wrap-around reinforcement steep-faced embankment. Design ways in detail reference “Geotextiles” ( N.W.M.John,1987 ) , but we take into account simultaneously water pressure in course of designing in waterways .

#### 4 SEEPAGE-STRESS COUPLING CALCULATION

In fact, the stress within the body of the embankment will change the porosity of the fill, thus changing the permeability of the fill through the embankment body and affecting the distribution of seepage forces. In turn, seepage flow affects seepage forces and thereby influences the distribution of stress in the revetment. This indicates the need to simultaneously consider the interaction between stress fields and seepage fields. Seepage-Stress Coupling Calculation can give states of stress and strain during construction and using in reinforcement and the different positions of embankment body. the reinforcement will be rational used .

##### 4.1 Mathematical Modeling

###### 4.1.1 Seepage-Stress Coupling

The equations which represent the coupled seepage and strain in an embankment body are based on the Biot consolidation theory , stress equilibrium , a hyperbolic constitutive model for soil ( Duncan and Zhang, 1970 ; Duncan etc. ,1980 ) , and stress equilibrium and continuity of pore fluid ( Zhu and Shen , 1990 ) . These equations can be expressed in the following matrix form:

$$\left. \begin{aligned} [k][\Delta u] + \rho g [Q][h]^{n+1} &= [\Delta F_1] - [Q][h]^n \\ [Q][\Delta u] + ([s] + [R]\Delta t)[h]^{n+1} &= [\Delta F_2]\Delta t - [s][h]^n \end{aligned} \right\} \quad (1)$$

Where:  $[k]$  = stiffness matrix ;  $[\Delta F_1]$  = load increment matrix per unit volume ;  $[\Delta F_2]$  = constant matrix solved

using know value of hydraulic head ;  $[Q]$  = coupled seepage-stress matrix ;  $[s]$  = compression coefficient matrix of fluid ;  $[h]$  = hydraulic head matrix ;  $[R]$  = permeability matrix ; and  $[\Delta u]$  = displacement increment matrix .

##### 4.1.2 Modeling Reinforcement Geotextile

Tensile loads can be expected to develop in the geotextile as a result of deformations in the embankment body , One approach to model the relationship between load and strain is to assume a simple linear elastic model described by the following stiffness matrix :

$$k = \frac{AE}{l_e} \begin{bmatrix} \alpha^2 & \alpha\beta & -\alpha^2 & -\alpha\beta \\ \alpha\beta & \beta^2 & -\alpha\beta & -\beta^2 \\ -\alpha^2 & -\alpha\beta & \alpha^2 & \alpha\beta \\ -\alpha\beta & -\beta^2 & \alpha\beta & \beta^2 \end{bmatrix} \quad (2)$$

Where:  $l_e$  = length of linear element ; A = cross-sectional area of the linear element ;  $\alpha = \cos\theta$  ;  $\beta = \sin\theta$  ;  $\theta$  = orientation of the composite liner ; and  $E$  = elastic modulus of the reinforcement geotextile composite .

#### 5 The INTERNAL STABILITY OF REINFORCEMENT EMBANKMENT

There are a number of methods the model the internal stability of a slip surface in a steep-faced embankment. We adopt to the circular slip analysis methods of Bishop in which the tensile forces induced in the geotextile are assumed to generated an additional tensile power ( Ingold.I.S,1992 ) .

When calculating the geotextile vertical spacing , it should be assured that the tensile force acting on each geotextile layer does not exceeding the design tensile strength of the geotextile for that layer ( N.W.M. John,1987 ) .

#### 6 ANALYTICAL EXAMPLE

##### 6.1 Background

An example illustrating the application of these theories is taken from Zha-Jia-Su shipping line, it is a fourth-grade waterway, its typical cross-section and design results are shown in Fig 1.

Fig 1. Zha-Jia-Su shipping line typical section and design results

### 6.2 Design of the Wrap-around Reinforcement Embankment Section

We Adopt to “ Limit Equilibrium Concepts ” and design the wrap-around reinforcement embankment in the Zha-Jia-Su shipping line. The design parameters in this example are summarized in table 2., and design results are shown in table 3.

Table 2. Design parameters for this example

H	H <sub>w</sub>	γ	μ <sub>1</sub>	μ <sub>2</sub>	φ'	Ta
3.8	4.2	19.3	21.9	30.0	24.0	52.2

Notes: H = height of embankment ( m ) ; H<sub>w</sub> = height of water level in waterway ( m ) ; γ = unit weight of soil-filled ( kN/m<sup>3</sup> ) ; φ' = internal frictional angle ( ° ) ; Ta = allowance tensile in the reinforcement geotextile (kN/m) .

Table 3. Design results for this example

H	β <sub>l</sub>	L	H <sub>sp</sub>	L <sub>f</sub>
3.8	80.0	4.0	0.6	1.5

Notes: β<sub>l</sub> = slope of embankment to the horizontal ( ° ) ; L = reinforcement length ( m ) ; H<sub>sp</sub> = vertical spacing of the reinforcement geotextile ( m ) ; L<sub>f</sub> = the fold-over length ( m ) .

### 6.3 Seepage-Stress Coupling Calculation

#### 6.3.1 Calculation Parameters and Conditions

In the case of seepage-stress coupling calculation of Zha-Jia-Su shipping line, the material parameters in this example are shown in table 4 and 5. The construction of embankment is divided six grades, each grade height of construction is 0.6 m, time of construction is six days, in addition to add two grades to fill water in waterway, so there are eight grades in calculation. In this example the calculations were based on 812 four-nod isoparametric elements with 884 nodes.

Table 4. Seepage parameters for example calculations

H <sub>up</sub>	H <sub>down</sub>	k <sub>s</sub>	k <sub>g</sub>
3.90	2.20	7.0×10 <sup>-6</sup>	1.49×10 <sup>-3</sup>

Notes: H<sub>up</sub> = The design water level ( m ) ; H<sub>down</sub> = the low water level ( m ) ; k<sub>s</sub> = permeability of soil-filled ( cm/s ) ; k<sub>g</sub> = permeability of geotextile ( cm/s ) .

Table 5. Soil-filled parameters for coupled calculations

R <sub>f</sub>	K	m	r	k <sub>b</sub>	k <sub>ur</sub>	c	φ

#### 6.3.2 Calculation Results

The soil-filled is homogeneous clays, and the geotextile permeability coefficient is much more than that of soil-filled, the isotonic lines is well-distributed in seepage zone, so the figures of contour lines of water head are omitted.

Since the geotextile liner is flexible and its deforms with the embankment, when tensile stress are developed in the embankment, they will be partially transmitted to the geotextile that in turn will mobilize tensile force. These tensile forces can then be expected to modify the distribution of stress and strain in the body of embankment. The calculation results using period of embankment are shown in Fig 2.

Fig 2 (a) and (b) show the distribution of major and minor principal stress of seepage-stress coupling calculation, the maximum values of them is respectively 7.85

kPa and 5.36 kPa , major and minor principal stress in

Fig. 2. The calculation results . ( a ) Contour lines of equal major principal stress ( kPa ) ; ( b ) Contour lines of equal minor principal stress ( kPa ) ; ( c ) Contour lines of horizontal displacement ( cm ) ; ( d ) Contour lines of vertical displacement ( cm ) .

reinforcement is respectively 3.24kPa and 1.66kPa, both of them are much less than  $T_a$  ( allowance tensile in the reinforcement geotextile ), but both of major and minor principal stress have a phenomenon of stress centralization in one-third height of reinforcement embankment , it indicted that it should lay the reinforcement in this position. Fig 2 ( c ) and ( d ) summarize horizontal and vertical displacement for seepage-stress coupling calculation , both of them are small , the maximum value of them is respectively 2.10cm and 2.74cm , the tensile stress which the deformation generated would not break off the reinforcement geotextile .

## 6.4 Stability Analysis

We Adopt to above theories to calculate the stability safety factor of embankment, including two kinds of reinforcement and non-reinforcement , the safety factor of each kind is respective 2.12 and 1.82 . Obviously ,the safety factor of reinforcement is larger than that of non-reinforcement , and the safety factor of reinforcement is satisfied with the civil engineering specification of China .

## 7 CONCLUSIONS

We prove the feasibility of using roughened woven geotextile to wrap-around reinforce embankments in a fourth-grade waterway . The seepage-stress coupled calculations and analyses show that woven geotextile can ensures that the reinforcement was laid the rational position and the less horizontal and vertical displacement of the embankment , stability calculations show that the reinforcement can increase the stability of embankment . some studies in this aspect are being performed to improve design methods and assess level and show advantages of this way.

# Alternative Design and Construction of an Under Seawater Road Tunnel Using Geosynthetics in Greece

A. Kollios

Dr. Civil Engineer, Edafomichaniki Ltd, Athens, Greece

**ABSTRACT:** The construction of a 2,7 km length road tunnel and its approaches for the junction of two caps was designed with a net off-shore length of 700 m below sea-bed level. An extensive geological and geotechnical campaign was performed for the complexed foundation design. At this context an alternative water-proofing design concerning the immersed part of the tunnel sections was performed involving a special geomembrane type with hangers, that obviously offered a cost-effective solution and was approved for construction by the project Owner.

**KEYWORDS:** Case - Study, Design - by - Function, Geomembranes, Tunnel Construction.

## 1 INTRODUCTION

On the written instruction of a European contracting Joint-Venture, a detailed geological and geotechnical campaign was carried out as the basis for the detailed foundation design of an immersed tube tunnel crossing the Preveza - Aktion sea strait at the area of Western Greece. The investigations included geological mapping of the approaches to the tunnel and geotechnical drilling boreholes, both on-shore and off-shore, aiming at the determination of a detailed longitudinal geological soil section along the tunnel axis. The contractual design referred to separate tunnel sections as a girder box of 12,0 m width and 7,5 m effective height, incorporating base and roof slabs and side walls of 1,0 m thickness each. The immersed tunnel sections were to be placed immediately below sea-bed level and the maximum seawater height was approximately 26,0 m. Each tunnel section referring to the immersed part had a length of 135,0 m and was to be preconstructed on a dry dock, then by floating to reach the specific placement location.

The stratigraphy along the immersed tunnel axis presented the following geotechnical formations:

- I. The upper geological unit referred to rather loose, contemporary sea deposits involving grey silty sands and silts, with lenses and pockets of soft brown clays, extending to an average depth of 15 - 22 m below sea-bed level, being significantly deeper at the center part of the strait (reaching 40 m depth).
- II. The lower formation consisted of plioptiocene hard marls with intercalations of dense sandy and gravelly layers.

The tunnel immersed sections were designed to be founded by means of stone columns used for sub-soil improvement, in order to minimize the expected large settlements of the initially very loose alluvial deposits. The girder box section was originally designed to bear a 6-mm thick metal plate placed within the bottom slab, acting as a water-proofing element of the sensible tunnel section. An alternative design involving the use of geomembranes was then proposed to the contracting group, replacing successfully the metal plate and offering an interesting solution to the emerged problems. The geomembrane proposal was adopted and is actually under application of the project, to be finished by the end of the year 1998.

## 2 GEOMEMBRANE DESIGN

Water proofing of underground road tunnels under important hydrostatic pressures by geosynthetics involves the determination of the most involved property for geomembranes, the thickness of the liner. This property is directly related to the resistance to tear, to the puncture resistance and to the impact damage resistance. In fact a linear and sometimes exponential increase in resistance to the above mentioned actions is related to the geomembrane thickness increase.

In order to determine the minimum necessary operational geomembrane thickness, a rough estimate of the stress-strain conditions applied on the contractual girder box structure was performed using simple static analysis by a finite element method. The results of this analysis

allowed the determination of the most critical vertical stress applied on the geomembrane (Figure 1).

For the calculation, it was assumed that each preconstructed section of the tunnel was separately isolated by the proposed system, since the in-between joints were to be sealed by the contractually foreseen system of water stops.

The initial design of the minimum necessary function thickness of the geomembrane to be applied at the bottom of the tunnel sections referred to the determination of a cost-effective safety factor  $F$  considered as the ratio of the minimum necessary thickness to the allowable design thickness. This factor of safety  $F$  ranged from  $F=1,5$  to  $5,0$  depending on the polymere type, the special

construction conditions of the project, the method and the effectiveness of the quality control of the water - proofing system. The design of the allowable thickness of the liner was based upon the deformations to occur to the geomembrane during the construction and the life - time of the project. These deformations would mainly be construction deformations that would directly influence the relative displacements of the geomembrane during placement, since the presence of stone piles assured for a practically non - deformable foundation interface.

The allowable thickness design was performed according to R.M. Koerner, 1990 theoretical principles and the results were plotted at the following Figure 2.

Figure 1. Indicative results of initial and deformed mesh of a typical tunnel section.

Figure 2. Correlation of the allowable thickness of the liner to the design safety factor

Based upon the final results, the alternative design for geomembrane selection proposed:

- a. A high density polyethylene geomembrane with a minimum thickness of 2,5 mm, corresponding to a safety factor of  $F_1 = 4$ , or
- b. A low density polyethylene geomembrane with a minimum thickness of 1,5 mm, corresponding to a safety factor of  $F_2 = 2$ .

All calculations were performed according to Eurocode 7, taking into consideration a seismic factor of  $a=0,30$ . g. As deduced by the analysis, the maximal vertical stress applied on the bottom geomembrane was calculated at the level of 300 KPa approximately.

### 3 CONSTRUCTION PROPOSALS

#### 3.1 General Considerations

The main factor of concrete desintegration in saline water is the influence of remaining chlorides within the concrete mass that create reinforcement corrosion. To avoid any such risks at the bottom of each tunnel section, the proposed use of a geomembrane, according to the design presented above, placed at the lower part of the concrete slab, exactly replacing the metal plate of 6 mm thickness initially planned, offers an interesting and rather cost-effective solution. In addition to that, water-proofing of also the walls and the roof of each section might also be adopted by the contractor, in conjunction with a high quality concrete mix, adequate for sea-water tunnelling purposes. The technical advantages of the proposal were evident in terms of quality control during construction, provided that the main geosynthetic placement rules would be completely respected.

#### 3.2 Construction Details

The geomembrane to replace the metal plate of 6 mm should be placed exactly at the same location, as contractually foreseen, i.e. at the lower limit of the concrete slab. For doing so, special conditions and care involved the following points:

- a. In order to assure a perfect adhesion of the geomembrane to the concrete slab (so that no detachment during construction and navigation of the sections occurred), the geomembrane should present the special section indicated at Figure 3.  
For this section, values of  $D$ ,  $d$  and  $H$  were such to assure for a perfect adhesion and that no lateral displacement of the geomembrane to the lower part of the slab might occur. The design called for  $D = H = 10 - 20$  mm and  $d = 5 - 10$  mm.
- b. The lower interface of the geomembrane would be in contact with the specially constructed bases placed on

the stone - piles levelled surface. Those specially constructed bases should be covered by plastic materials (such as teflon, thin plastic sheets) that did not need to present any life - time performance, but they should be applied only for the moment of placement. In this way, during placement, any wrong movement of the tunnel section would not transduce any secondary harmful friction of the membrane to the foundation bases (because of the protection provided).

Figure 3. Special section of geomembrane to assure adhesion to the concrete slab.

- c. The remaining space between the foundation bases and the lower interface of the geomembrane should be filled with cement grout under pressure, according to the contractual specifications. Therefore, a life - time protection of the geomembrane was assured.
- d. Concreting of the slab over the geomembrane should be carefully executed, especially where the reinforcement is placed, so as not to create any short of damage due to scratches on the geomembrane.

In order to combine a complete waterproofing of all the design section of the tunnel according to the specifications used for geomembranes in underground constructions, the geomembrane protection of the bottom slab might also be placed over a 20 cm thick concrete base that would extend all around the section of the bottom, the walls and the roof of the section (outer girder box). This alternative proposal was not finally accepted and the contractually imposed water - proofing system was applied on site (sprayed polyurethane).

### 4 CONCLUSIONS

The use of a special type of geomembrane allowed a most interesting alternative solution for water proofing

the bottom slab of an under sea-water road tunnel, actually under construction, replacing the contractually foreseen metal plate and offering an important cost benefit (estimated at the level of 10% approximately over the total foundation cost). The existing geomembranes installation experience (mostly acquired during construction of multiple store - garages below ground level and the underground tube train and stations at the broader Athens area) combined with the strictly applied supervision, create the assurance for obtaining the most efficient water-proofing method for the final stage of function of the project, which is set to be fully realised by the end of 1998.

## ACKNOWLEDGMENTS

The author would like to thank Mr. S. Papaspyrou of Edafomichaniki Ltd for his review of the original manuscript as well as the site engineers Mr. S. Zafiratos and G. Kilimis from the contracting group for their help concerning the follow-up of the project. Special thanks are also due to Mr. G. Dernikos, project manager at the time of issue of the present alternative proposal for his directive ideas.

# Application and Testing of Geotextiles in Deep-draft Quays

Fengwu Liang

Senior Engineer, China Nanshan Development (Group) Incorporation, Shenzhen, China

**ABSTRACT:** Eight berths capable of taking ships up to 25000 DWT and 50000 DWT respectively were completed in Shenzhen port, in 1985 and 1995 separately. The berths are deep-draft quays of 11, 12.5 and 13.1 meters, behind which woven geotextiles were successfully placed as filters for trial. The durability of the geotextile requires further investigations since it was the first time that geotextiles were used in a large quantity in quay construction, instead of the conventional Crushed-stone filter courses. A blind shaft was built at one end of the quays. Field investigations and observation, a research institute has been commissioned to carry out the observation and investigation for ten successive years. In the shaft, synthetic bags, filled with the same quarry-run fills were placed at three different locations as the filter layers, i.e. underwater, intertidal zone and above water level.

**KEYWORDS:** Case Study, Geotextiles, Design, Walls, Filtration

## 1 THE CHANGES OF THE FILTER COURSES IN GRAVITY TYPE BLOCK QUAY

In a conventional gravity type block quay, the bulkhead wall is often a kind of retaining concrete block wall in a concrete stair type or gravity type. The block size is designed based on the lifting capacity of the crane held by the contractor. A large crushed stone riprap prism as filter courses is often used to keep the fills from leaking through the joints between the blocks to the front of the quay (Fig. 1). The quantity of works for construction of the quay is divided roughly into following parts:

Fig 1. A Conventional Gravity Type Block

The two main factors affecting the cost and the construction period are item 2 and item 3. Usually, 20 percent of total cost and 50 percent of whole construction period will be spent on item 3. As new type construction materials are springing up in the wake of development in science and technology, scientist, after several decades hard work, eventually found out a new effective structure of gravity type quay to replace the conventional one. Eight berths each with capability of taking ships varying from 10,000 DWT to 50,000 DWT, had been successively built in Shenzhen China during the 10 years from 1985 to 1995. The structure of the quays was reformed not only on its blocks size but also on its filter courses by replacing crushed-stone riprap with woven synthetic fabrics. As a result of the reformation, the construction works were simplified enormously.

## 2 DESIGN OF THE FILTER COURSE IN BLOCK QUAYS

A gravity type solid-filled block quay, of good durability and flexibility to working loads as its advantages, is made up of many blocks which form many joints cross and down over the back of the blocks. In order to keep fills from leaking through the joints into the port, a reliable crushed-stone riprap filters should be built. If we want to adopt woven fabrics instead of crushed-stone riprap as filters, we need to reduce the number of joints, and to make the distribution of joints regular. According to our many years experience, a reinforced concrete hollow block in large size, which simplifies the distribution of joints, has been used in a deep-draft quay for 25,000 DWT in Chiwan harbour. The woven fabrics as filter courses were first time adopt in deep-draft quay with overall height 15m and draft 11m. As local soil and rock materials are easily accessible, it is convenient to unguarded quarry run rocks from Chiwan area as fills behind the hollow block quays. Closed H type reinforced concrete hollow blocks, weighing 200 t each, were designed for the quays. On top of the blocks are hollow relieving platforms with wave absorbing chambers. The longitudinal length of the hollow block along the quay is 3.5 m, and the width of the relieving platform which sits directly on top of the block is the same as that of the block, with no alternate joint between the two, thus leaving a vertical through joint every 3.5 m behind the quay. To facilitate placing synthetic fabrics and cut down their consumption, an independent strip of synthetic fabric was placed at every joint and the strip had a 1.00 m overlap on each side of the joint over the back of the block. Since the overall height of the block was about 10.00 m, the levelled foundation bed for the blocks would surely develop some irregularity, thus the joints between installed blocks would be far larger than the stipulated 5 cm in the construction code. Therefore, the largest allowable joint width was stipulated to be 10 cm -15 cm in the design. However, to prevent differential settlement of blocks causing excessive tension in the synthetic fabric strips, the designed width of the synthetic fabric strips was 25 cm.

Fig 2. A Sectional View of A Gravity Type Hollow Block Quay with Wave Absorbing Chambers (Unit: m)

Synthetic fabric strip locking latch seat were embedded in the back walls of the blocks beside the joint. In order to lock the fabric to the back of the blocks, prepared holes were placed on the synthetic fabric strips in line with the position of the locking latch seat. To minimise difficulties of underwater operations, the connection of the locking latch seat and bolts with the synthetic fabric strips should be as simple as possible. The structure of a locking device is shown in Fig. 2.

Three types of woven synthetic fabric strips were designed and used at the cross section of the quays.

Type A: woven synthetic fabric strips of 2.25m x 12.00 m were used behind the hollow blocks.

Type B: woven synthetic fabric strips of 2.25 m x 4.50 m were placed on the cantilever extension of the relieving platforms.

Type C: woven synthetic fabric strips of 4.50 m wide were used beneath the stone prism placed behind the wave absorbing chambers to eliminate residual wave energy. The geotextiles were placed continuously with an overlap of 1.00 m.

As shown in Fig. 2c, loops were arranged both at the top end of type A and at the lower end of Type B to prevent soil grains from being washed out locally. The total consumption of geotextiles used for the 264m long berth accommodating ships up to 25000 DWT is 12000 m<sup>2</sup>.

In 1988 and 1995, 6 light weight gravity type quays each capable of taking ships up to 50,000 DWT were successively constructed in Chiwan Harbour and Mawan Harbour. This further developed and extended the application of Woven fabrics in deep-draft quays and make their section more economical and reasonable.

The light weight gravity type quay is a new type structure, specially designed for uneven distribution of geology, with bent structure upper and hollow blocks underwater. The combination of the upper bent with the railway can make over-water fills as a slope. This greatly releases the fills pressure upon the vertical bulkhead wall, and make filter courses set only behind the blocks for underwater all year long while the protection of filter courses for the over-water fills is unnecessary.

As is well known, the perfect way to extend the woven fabrics service life is to shelter it from ultraviolet

radiation. The light weight gravity type block quay in Chiwan, with its double ribbed upper bent, is an ideal method resolving this problem, with each hollow block weight under the relieving platforms within the crane lifting capacity 500 Ton. Joints are set every 7 metres covered with woven fabrics. The permeable bent and slope type bank protection are constructed above the relieving platforms. Thus, it not only provide a stable berthing condition, but also, due to the riprap being replaced and with no worry about the penetration through the stone and damage to filter course, simplifies the construction of stake foundation under the crane railway. And also, with the fills pressure and weight reduced, the pressure on the ground is released enormously. The woven fabrics make the construction easier and faster and cut down the cost by replacing the complicated crushed-stone filter courses. The quay, built with lower cost and higher quality using new materials and new technology, and with the tangled ground treatment problem resolved, was awarded a national silver medal on its perfect designing.

### 3 SELECTION AND PROTECTION OF WOVEN GEOTEXTILES

The woven geotextiles used as filters behind the quays should have the following properties:

1. Good in soil retention property and that in separating water and soil;
2. High water permeability to protect woven synthetic fabrics from being blocked up to form a detrimental water head;
3. Sufficient strength: tensile strength, impact strength, tear and puncture resistance;
4. Sufficient durability: good ultraviolet resistance, chemical corrosion resistance and sea water resistance.

The durability of geotextiles should not be affected by moulds eating rats and termites and by atmospheric temperature.

A new woven synthetic bag factory in Chiwan, manufacturing woven synthetic bags for chemical fertiliser, was completed and put into production at the time when the designs were completed. A research institute was then commissioned to carry out various tests for the physic-mechanical and chemical properties of the synthetic textile produced in the factory. It was finally decided to use the synthetics produced in this factory instead of the originally selected T7W7 woven geotextiles.

The main features of the woven geotextiles manufactured in this factory are as follows:

Longitudinal strength 2.5t/m

Latitudinal strength 2.5t/m

Impact resisting strength: Crushed when placed on concrete floor and stone of 30 kg dropped from a height of 2.00 m.

Chemical composition polypropylene

Unit weight 190g/m<sup>2</sup>

Permeability: No evident water head was observed during flume tests under sea flood and ebb condition simulated.

Laboratory tests showed that, no change in the tensile strength of the synthetic fabric was observed when the synthetic fabric was exposed to corrosive media of acid, alkali, salt and sea water. The resistance of the fabric against moulds was stable and their properties were also stable when they were subjected to oxygen blasting in normal atmospheric temperature: and no loss of weight was observed. From the outer appearance of the fabric, the colour, lustre and softness remained the same as that before the test. It was smooth surfaced, transparent and no abnormality had been observed in the texture of the fabric.

As the strength of the synthetic fabrics couldn't meet the designed requirements, it was decided to use two layers of the synthetic textile at each joint. Since anti-ageing agent was added to the polypropylene fabric, the synthetic fabric had a poor ultraviolet resistance. Practice proved that the textile would soon become brittle when they were exposed to sunshine. To prevent the textile from being exposed to sunshine, it is requested that the processed synthetic fabric strips should first be stored in dark rooms and then placed at night time or in cloudy days whenever it is possible, in order to prevent geotextile from being damaged by the dumping of rocks, a  $\Phi = 2\text{mm}$  wire netting with grids of  $3 \times 3\text{cm}$  was placed against the textile behind the quays as protection. A layer of rubble stone was ripped over the geotextile on the slope and then larger stones were placed.

#### 4 IMPORTANT REMARKS

Woven synthetic fabrics used as filters should first possess a porosity matching the permeability of the backfills so as to ensure an unimpeded drainage and the geotextile should not be liable to blocking. As a matter of fact, the permeability of commonly used woven synthetic fabric is usually higher than that of the adjacent soils. However, special attention should be paid to the gradual blockage of pores of geotextiles during their service.

A filter course is not formed by geotextiles themselves but formed when fine particles in the fills behind the fabric are washed off through the pores of the fabric and the remaining coarse grains form arch type structures around the pores while the soil beyond forms another granular filter course with different graded grains. The further away the soils is from the geotextile, the lower the permeability of soils becomes. A new natural filter course is thus formed, behind which are natural soils, and after such a natural filter is formed, soil grains will not be washed off any more as the soils behind it becomes stable (Fig. 3). Therefore, geotextiles don't work directly as a filter but help backfills forming a

Fig. 3. Forming Process of A Filter Course

stable natural filter course. Proper selection of woven or non-woven synthetic fabrics according to the permeability requirement of a structure and the grain sizes of the fills is of great importance to a stable and effective filter course. The backfills for marine ports usually consist of rather coarse grains. Though the backfills are influenced by the complex alternating currents and waves during flood and ebb and the arch type structures behind the geotextiles are sometimes liable to failure. The squeezing action of the fills behind the geotextiles can generally keep the natural filter course stable and the pores and draining passages are not liable to salutation and blockage.

Geotextiles suitable should meet the requirements as follows:

- (1) For natural soils when the weight of soil particles passing sieves with a screen size of  $0.074\text{mm}$  (U.S. standard sieve #200) Accounts for less than 50% of the total weight;  $D_{85}(\text{soil})/E_{OS}(\text{geotextile}) \geq 1$  ( $E_{OS}$ : The effective pore size)
- (2) For soils other than above mentioned soil:  $E_{OS}(\text{geotextile}) < 0.211\text{mm}$  (U.S. standard sieve #70) But, when  $D_{85} < 0.074\text{mm}$ , it is not advisable to use geotextiles.
- (3) Geotextiles with  $E_{OS}$  smaller than  $0.149\text{mm}$  (U.S. standard sieve #100) should not be used as they are liable to blocking.
- (4) Within the limits stipulated in the criterion, geotextiles with larger pores should be used.

The above requirements only apply to specified soils and steady flow, and the influence of soil density has not been taken into account. However, those requirements can be considered properly in the case of soft and loose soils.

When geotextiles are used in quay structures, the following requirements have also to be followed.

- (1) The permeability ( $K$ ) of geotextiles should be greater than  $10K$  of soils, where  $K$  is the permeability parameter.
- (2) the slope ratio should be less than 3 so as to prevent the geotextile from blocking and corresponding tests should be carried out.
- (3) Unstable geotextiles or geotextiles with poor ultraviolet resistance should not be exposed to direct sunshine for more than 5 d.

## 5 LABORATORY TEST AND SITE OBSERVATION

In the national harbour engineering code, the service life of a gravity type quay should be more than 50 years. The polypropylene woven fabrics, instead of crushed-stone riprap, are applied in a quay structure for the first time. Its durability requires further investigation and observation. Some scientific research institutions have been commissioned to study the loss of its tensile strength and weight, and the changes of its outer appearance by submerging the fabrics into an acid liquid made up of artificial sea water and lactate for 6 month. In the middle of the quay, an observation well in which 2 series of samples, one series of soil and the other plate, were laid on both the place beneath low water and well ground to observe behavior of the fabrics in a long term of 10 years.

The results from both laboratory and observation are shown in Fig. 4:

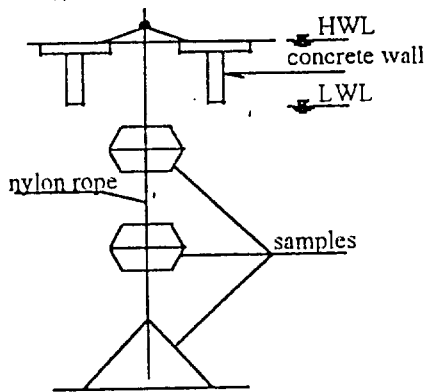

Fig 4. Samples Installation  
View on Testing Ground

The results from both laboratory and observation are shown in Fig 5.

Fig 5. Relative Curve of Strength Loss  
and Exposing Period

From the above results, we can see:

1. In the laboratory test the polypropylene woven fabrics are not sensitive to sea water, acid, alkali, and bacterial corrosion at all.
2. The 10 years' observation demonstrates that the polypropylene woven fabrics corrosion and erosion by

nature sea water and mud is not serious.

3. In the water level changing area, due to the contact of fabrics with flls, the fabrics tensile strength decreased by 33.5 percent of which, by 26.5 percent in the first 3 years, and by 7 percent in the later 7 years in a slow decreasing rate. Under the low water level area, the tensile strength of the polypropylene woven fabrics decreased by 23.5 percent of which, 18 percent in the first 3 years and 5.5 percent in the later 7 years. The tensile strength-time diagram shows that the curve rate is more and more even at the time of 10 years later. By extension of the curve, we can calculate that the tensile strength of over water woven fabrics will have decreased by 50 percent while that of under water by 40 percent by the time in 50 years.

4. The above results also show that woven fabrics filter course and the concrete block with 50 years service life in gravity quays can match very well. When a type of anti-ageing woven fabrics with a longer durability are applied, the service life of a gravity quay is usually more than 70 years if it locates in a no accidents environment, especially in a no ice environment.

5. Woven fabrics filter course in a gravity quay should be set under water as fully as possible to shelter it from damage of the atmosphere and sunshine to extend its service life.

## 6 ECONOMIC BENEFITS

The economic benefits of woven synthetic fabrics used as filters for the quay for 25000 DWT ships in Chiwan Port are given in Table 1 as compared with that of filter drains and riprap prism filter course.

From the table, it can be seen that the filter course comprising synthetic fabrics produce a remarkable economic benefit which saved investment by 74% compared with the crushed-stone filter drains and by 76.1% compared with the riprap prism with crushed stone filter course and construction period is cut down by 1 to 4 times when geotextiles are used as a filter. Thanks to the using of geotextiles which are very easy to handle, the two hollow block deep-water quays were completed in just 9 months in spite of the complicated joints handled at the two ends of the quays, the time consuming bag-and concreting on the riprapped rock foundation bed and the special requirement for wave absorbing chambers on the upper part of the quay. Both quays have therefore been evaluated as excellent projects by the relevant authorities.

# Jute Geotextiles

U. Datta & P.K. Chatterjee

Indian Jute Industries' Research Association (IJIRA), 17 Taratola Road, Calcutta 700088, India.

B. Chottopadhyay & A. Ghosh

Civil Engineering Department, B.E. College (Deemed University), Howrah 711103 India.

**ABSTRACT:** A heavy duty open mesh woven jute fabric is perhaps the first geotextile, which has been in use for protection of slopes from erosion by rain and wind in Europe and America since early fifties. Lighter fabrics have been developed and their performance has been evaluated under various soil and climatic conditions. The results reveal that the fabrics reduce soil loss by about 90% and comparable with the performance of the existing product.

Woven jute fabrics for separation and filtration have been developed and found to be cost effective in river bank protection work replacing conventional granular filter. In this application the fabrics need chemical treatment for enhancement of durability. After successful trials under different soil and river conditions, the treated fabrics are being commercially used. Similarly treated fabrics have also been tried for construction of roads on soft soil as separator and found to be cost effective with encouraging results.

Jute non-wovens have been found suitable for filtration and drainage.

**KEYWORDS:** Erosion Control, Filtration, Separation, Embankments, Geotextiles

## 1 INTRODUCTION

Jute as a geotextile material is well known in Europe and America for protection of slopes from erosion by rain and wind. A heavy duty open mesh woven fabric in the name of Soil Saver/Geojute/Anti-Wash has been in use since fifties and the jute producing countries have been exporting the item since then. The demand of the product went up to as high as 100 M m<sup>2</sup>. In mid-sixties, when concept and application of geotextiles started, other natural and synthetic materials entered in this field of application. At present global demand of natural geotextiles is about 86.6 M m<sup>2</sup> - a recent survey reveals. Among the products, straw based products claim about 60% of the market, while jute and coir together claim about 37% and the rest 3% by others like wood-wool, synthetic etc. (Rickson et al. 1996). It has been reported that the decline in the demand of jute is due to nonavailability of the product in the market because of the fact that a few mills produce the product, which requires special type of processing equipment. For involvement of more number of mills in supply of the product, two products have been developed in consultation with the experts in this field. The products are of different open areas and their performance has been studied extensively. The results of the studies have been discussed in this paper.

The synthetic geotextiles are very expensive in the third world countries and so its application is limited. The civil engineers of the countries are looking for low cost alternatives for geotechnical constructions. Jute being one of the cheap fibres having good strength, structural stability, abrasion resistance etc. its properties for civil engineering applications have been evaluated by many

workers (Thomson 1985, Kabir 1988, Aziz 1991) and found to be useful for specific applications. A prefabricated fibre drain using jute fabric and coir rope was developed for consolidation of silty subsoil and used commercially in Singapore (Ramaswamy et al. 1984). Treated Jute Geotextiles for separation and filtration developed by IJIRA was used for protection of bank of the river Hooghly at Nayachar, opposite to Haldia Port (Datta et al 1990, Sanyal et al. 1993). The product is being used by the engineers of Irrigation & Waterways Directorate, Govt. of West Bengal for river bank protection work after extensive trials under various conditions of soil and river under their control. Results of the trials have been discussed here.

Similar fabrics were tried for construction of roads on soft soil as separator and encouraging results were reported. Jute nonwovens were also tried for construction of unpaved roads as well as for filtration and drainage of roads. The results are satisfactory (Rao et al. 1996).

## 2 FABRICS FOR CONTROL OF SURFACE SOIL EROSION

A heavy duty open mesh jute fabric is perhaps the first natural geotextile used in this field of application scientifically in early fifties in Europe and America. The fabric is made of thick yarns of 5 mm diameter, which requires special type of machinery for processing. Ludlow Jute Mills, an American firm in India set up a separate plant in their mills for manufacture of the product and developed special machinery in collaboration with a jute machine manufacturer. Other

mills also entered into the business to cater to the demand of the product. But from mid-sixties with the advent of other geotextiles of natural and synthetic origin in this field with the concept and application of geotextiles, its demand gradually declined to the present level. A recent market survey of the product revealed that nonavailability of the product in the market was one of the reasons for decline of demand. The experts suggested products, which could be produced by any mill having conventional jute processing machinery. For the purpose, IJIRA developed two varieties of Jute Mesh (JM) type I&II and tested the properties and performance in India and abroad. The specifications of the products including Soil Saver have been furnished in Table 1 below.

Table 1 Specification of Jute Geotextiles for Control of Surface Soil Erosion.

Jute Geotex tiles	Weight (g/m <sup>2</sup> )	Yarn diameter (mm)		No. of threads/dm		Width (Cm)
		Warp	Weft	Warp	Weft	
Soil Saver	500	5	5	6.5	4.5	122
Jute Mesh						
Type I	400	2	3	34	15	122
Type II	300	3	3	12	11	122

### 2.1 Properties

The physical properties of the materials tested by Soil Management Division, Silsoe College, U.K. and IJIRA are given in Table 2 along with the properties of the products available in the market for similar application.

Table 2 Physical properties of Jute and other geotextiles for Control of Surface Soil Erosion.

Properties	W O V E N				N O N W O V E N	
	Soil Saver	Jute Type I	Mesh Type II	Coir	Straw based	Synthetic
Weight (g/m <sup>2</sup> )	500	400	300	700	250	450
Thickness (mm)	5	3	3	4	8.5	18
Coverage (%)	55	60	40	60	100	85
Tensile Strength (KN/m)						
Warp	20	16	12	25	-	3.2
Weft	9.5	6	11	12	-	-
Water holding capacity(%)						
	600	500	400	280	700	90

### 2.2 Functions

When installed they act in two ways - 1. Arrest movement of soil particles, seeds and nutrients on the surface of the soil and 2. Help fast growth of vegetation, which covers the surface with a canopy of living mass as well as reinforces the soil with roots, protecting the surface from erosion by rain and wind permanently.

### 2.3 Trials and Results

The functional performance of Soil Saver is well known to the users for more than four decades; however, that of the new products has been studied by Silsoe College in UK and Tea Research Association as well as the Directorate of Forests, Govt. of West Bengal, in India in collaboration with IJIRA. Silsoe College studied the performance and compared it with the others while Tea Research Association studied soil loss of the hillocks of Cachar district in Assam, after plantation of tea using Jute Mesh Type I & II and compared it with that of bare plots. Forest Directorate used Soil Saver for protection of hill slopes in the district of Darjeeling in West Bengal through vegetation. The results of Silsoe College are shown graphically in Figure 1 & 2, while those carried out by Tea Research Association in Figure 3. The comparison of vegetation densities on treated and untreated areas of Darjeeling is given in Table 3. Vegetation density was measured six months after installation.

Figure 1 Soil loss (%) for different geotextiles treatment under different rain fall (Soil - Sandy loam)

Figure 2 Vegetation cover (%) under different geotextiles with time (Soil-Sandy loam).

Figure 3 Soil loss under treatment of Jute Mesh Type I & II in different months of rainy season (Total rainfall - 2304 mm, Soil composition - Sand : 73%, Silt : 18% and Clay : 9%)

Table 3 Vegetation densities of treated and untreated areas

Plant species	Slope (60-65) <sup>o</sup>		Slope (30-45) <sup>o</sup>	
	Treated	untreated	Treated	untreated
Chipley	43	48	27	11
Kash*	45	21	58	30
Vimsing				
Patay	5	1	2	-
Guelo	1	1	17	1
Unio	9	12	12	2
Banmara	4	6	12	7
Amlisho	5	6	-	2
Kalimontey 10	-	-	-	6
Bansho	43	-	-	-
Raikhaney	-	2	6	1
Bhakatey	-	-	5	-
Total	165	97	139	60

\* Planted; Plant species (local names)

Soil composition - Sandy loam mixed with small stones;

Rain fall - above 3000 mm.

## 2.4 Selection of Fabrics

Selection of suitable fabric depends on the site conditions like gradient of the slope, intensity of rain fall, wind velocity and soil composition.

## 2.5 Installation

It is very easy to install. Any unskilled person can lay after training at site. After cleaning the surface and making it as smooth as possible the fabrics are laid after anchoring at the top of a slope and rolling down to the bottom, where it is anchored again and cut. The layers are to be overlapped by 10 cm side by side. The overlaps are fixed with the surface with the help of iron pegs of suitable size or living pegs made of tree branches, which may grow with time at intervals of one metre. End to end overlapping should be 15 cm and fixed with the ground keeping the finishing end on the top and starting end under. After installation, seeds of suitable plant/bush/legume may be spread over the treated area. Sapling/tree cutting may also be planted through the open areas if necessary. The treated area should be restricted from stamping and grazing till vegetation takes firm roots. Damage caused by chance should be repaired immediately placing fresh fabric on it and fixing it with the ground.

## 2.6 Discussion

It is evident from the above results that Soil Saver as well as the fabrics of type I & II are capable of reducing soil loss by around 90%, in spite of its less coverage compared to nonwovens as well as cover the surface with vegetation within three months. It is due to the fact that it is highly flexible, which increases by about 25% when wet. So, after first shower, it can establish intimate contact with soil surface reducing soil loss significantly. Moreover, it can absorb water to the extent of four to six times of its weight and helps reduce run off velocity considerably. The water is released in dry spell creating a moist atmosphere, which helps vegetation to grow fast. Apart from these properties jute has good insulation property, which again helps control the extremes of temperature for healthy growth of vegetation. After a period of one and a half years to two years it loses its strength while the biomass, which remains on the surface is not toxic, but increases water permeability of the soil.

### 3 FABRICS FOR SEPARATION AND FILTRATION

Development of such fabrics was initiated by Calcutta Port Trust in late eighties, when the trust was searching for low cost fabrics for protection of bank of the river Hooghly opposite to Haldia, a riverine port in Eastern India. Erosion of the bank was creating navigation problem for big ships. As synthetic geotextile for river bank protection is expensive in India, the Calcutta Port Trust approached IJIRA to develop fabrics for the purpose with specific properties like pore size, water permeability and durability for a reasonable period till siltation starts. For the purpose a twill woven fabric was designed and developed and treated with rot resistant chemicals and bitumen to enhance durability. Bitumen treatment was developed so that it maintains the pores of the fabric for filtration and water permeability across the plane of the fabric. The enhancement of durability of the fabric was measured in laboratory using standard methods IS:1623-1992 (BIS Hand Book 1996). The test results are given in Table 4.

Table 4 Results of Soil Burial Test

Incubation period (Week)	Loss in strength (%)		
	Control	Treated	
		Rot resistant chemicals	Rot resistant + Bitumen
3	90	5	2
6	100	50	20
9	-	90	50
12	-	100	80

A pilot trial on the bank observed strength loss around 30% after a year, when siltation was to the extent of 30 cm on the lower part of the bank. The engineers accepted the fabric for the bank protection work, and applied it commercially for protection of the bank to a stretch of 1.5 Km in 1992. The specification of the fabric is shown in Table 5.

Table 5 Specification of Jute Geotextile for Separation and Filtration

Physical properties		
Weight (g/m <sup>2</sup> )	-	760
No. of threads/dm Warp	-	102
No. of threads/dm Weft	-	47

at water column of 10 cm.		

#### 3.1 Further Trials:

Directorate of Irrigation and Waterways, Govt. of West Bengal wanted to replace the conventional filter material for river bank protection work by geotextile due to the fact that quality filter material is not always available particularly in remote areas. They tried jute geotextile (filter) for protection of the banks of the Padma at Hasanpur, embankment of the river Phulahar at Ramayanpur as well as the banks of the river Hooghly at Barrackpore. Sunderban Development Board, Govt. of West Bengal has also used the material for protection of the approach road connecting a jetty constructed in a river subject to high tidal action in Patharpratima. The object of the trials was to compare its performance with that of conventional granular filter material. The above projects were completed in June'95, July'96, February '97 and August '96 respectively following the approved designs of the respective divisions. In these designs only the filter materials were replaced by Jute Geotextile (filter). The Civil Engineering Department of B.E. College tested soil of the sites and made necessary adjustment in the design for proper anchorage of the fabrics with overlapping. B.E. College is also monitoring the sites at regular intervals of time to assess the condition of the structures.

#### 3.2 River Characteristics and Soil Composition of the Sites

##### 3.2.1 Hasanpur

The Padma is a unidirectional river carrying about 30,000 cumec. of water during peak period July to October. From November water recedes and becomes stagnant during March to June. Right bank of the river at Hasanpur was subject to erosion. The bank was regraded to a slope of 2:1. The fabrics were anchored in a trench of 0.5m x 0.5m at the top and at the bottom it was anchored under a sausage of size 1 m x 3 m made of boulders of size 0.45m. A rip rap layer was placed on the fabric with two layers of boulders. The soil composition of the site is cited below.

Whitish grey sandy SILT (Sand - 30%, Silt-59% and Clay - 11%).

### 3.2.2 Ramayanpur

The river Phulahar becomes active from June to October, when it erodes its banks and sometimes causes flood. The embankment at Ramayanpur protects the villages and agricultural land nearby from the flood water. For protection of the embankment the project work was carried out to a stretch of 400 m, which is on a bend of the river and subject to erosion. The fabrics were anchored at the top in a trench of 0.5m x 0.5 m and at the bottom it was anchored under an apron of size 8m x 1m made of boulders of size 0.45 m. Two layers of boulder were placed on the fabrics as rip-rap. Soil composition of the site is given below.

Sandy grey SILT with little clay (Sand - 29%, Silt - 63% and Clay - 8%). Standard Proctor Test, OMC(%) - 12.4,  $\gamma_d$  Max ( $Mg/m^3$ ) - 1.7

### 3.2.3 Barrackpore

The Hooghly is a tidal river. In August-September the tidal waves rise upto 3 m when the river is full of water. The site is a bathing place, which was damaged with the time. Bank length of 20 m was repaired using Jute Filter on the slope after repairing. Jute Filter was laid on the slope with proper anchorage at the top and bottom and cement mortar blocks of size 0.5m x 0.5m x 0.10m were placed on the filter fabric. The soil composition of the site is given below.

Grey clayey SILT (Sand - 4.5%, Silt - 82% and Clay - 13.5%). LL-30.5, PL-19.5; Bulk density ( $Mg/m^3$ ) - 1.94, Water content (%) - 31, UC Strength ( $KN/m^2$ ) - 0.66.

### 3.2.4 Patharpratima

A jetty was constructed in the river Matla in Sunderban for water transport for benefit of the people of the area. The river is a tidal one and the tidal actions are severe in the spring (August-September). For protection of the approach road to the jetty, on the slopes of the road Jute Filter was applied with proper anchoring and brick blocks of size 0.5 m x 0.5m x 0.25m were placed on the fabrics. The soil composition of the site is highlighted below.

Grey clayey SILT with little sand (Sand - 0.4%, Silt - 78.6% and Clay - 21%) LL - 33.8, PL - 17.6, Standard Proctor Test, OMC(%) - 20.5,  $\gamma_d$  Max ( $Mg/m^3$ ) - 1.7.

### 3.3 Inspection Results

Hasanpur - No subsidence on the rip-rap on Jute Filter, while subsidence upto 15 cm was observed at places of that on the conventional filter materials after the flood of '95

Ramayanpur - No damage was observed after the severe flood in October'96

Barrackpore - It has been completed recently and it is too early to comment on it.

Patharpratima - No sign of displacement of the blocks is visible after seven months of tidal actions on the slopes.

### 3.4 Discussion

In bank protection work normally 150 mm thick layer of ballast of size 10 mm to 15 mm is used as filter, which does not function properly on all types of soil particularly on silty soft soil, as observed in Hasanpur bank protection work, which developed subsidence of the rip-rap structure at places. One of the disadvantages of granular filter is - it is difficult to maintain uniform thickness of the ballast over the length and breadth of the area under treatment, particularly when it is spread manually. Moreover, it is difficult to procure quality filter material in remote areas like Sunderban, where the Jetties constructed using available filter are damaged frequently under the tidal action of the rivers of the region.

The filter fabric is cheaper than the conventional filter material. Moreover, procurement and installation are very easy. Only care is to be taken during installation so that it is not ruptured. If it is damaged by chance, it may be repaired placing a piece of material on the damaged portion. It is a renewable resource and available in plenty. It is very cheap in comparison to synthetic geotextiles particularly in the third world countries.

After the above trials and realising the advantages, the Directorate has decided to apply the material commercially for bank protection work under their control and requisitioned materials for protection of both banks of a canal under Tista Barrage Project in Jalpaiguri to a stretch of 1.2 Km. The work will be completed by June, 1997. Further material for protection of bank of the river Mahananda is under negotiation.

Engineers sometimes expressed doubt about durability of the structures using Jute Geotextiles. In this context, it may be mentioned that the bank length of the Hooghly at Haldia treated in 1992 with Jute Geotextile is still in a good shape. It implies that though the strength of the fabric is not there the biomass which remains is acting as a filter or a natural filter has developed in the soil adjacent to the fabric and is working.

The fabric for separation and filtration has also been applied for construction of roads on soft soil by Kakinada Municipality in Andhra Pradesh in India. The site was a reclaimed area in the port of Kakinada, which is an

important port in South India. The road was made for moving trucks carrying cargo materials to port godowns. In this application width was increased by stitching the fabrics side by side. Construction of the road was designed by Central Road Research Institute, Delhi.

After one year the condition of the road satisfied the authorities, who has decided to increase the road length using similar fabric.

#### 4 CONCLUSION

Jute geotextiles are very cheap in comparison to synthetic geotextiles particularly in the third world countries and may find a big outlet. The jute producing countries may utilise their spare capacities of sacking product lines for the purpose with some modifications in machinery and structure of the fabrics to suit the requirements of geotextiles. Durability may be enhanced by chemical treatments in specific applications like bank protection work, road construction etc. While for protection of surface soil through establishment of vegetation, short durability is an advantage since the fabric becomes superfluous after growth of vegetation.

In India application of geotextiles is in an experimental stage and it is the right time to explore the ideas of application of Jute geotextiles to the practicing engineers in their respective fields. For the purpose, the Ministry of Textiles, Govt. of India and United Nations Development Programme (UNDP) have come forward to assist a project on development of Jute geotextiles for specific end uses under the leadership of the Indian Jute Mills Association. A number of Research and Development organizations and educational institutions are working in the project in their respective fields of expertise.

Object of geotextiles is to reduce cost of construction with good serviceability. In this context, Jute geotextiles have been found to be effective for protection of slopes, river bank protection, consolidation of silty sub-soil as well as roads on soft soil.

#### ACKNOWLEDGEMENTS

The authors are grateful to the Ministry of Textiles, Govt. of India and UNDP for funding the project activities. They are also grateful to the Indian Jute Mills Association, Calcutta for monitoring the project activities efficiently.

The authors acknowledge with thanks the co-operation extended by the engineers of Irrigation & Waterways Directorate, Forests Directorate, Sundarban Development

Board, Govt. of West Bengal for application of Jute Geotextiles.

Thanks are also due to the managements of the jute mills, who supplied materials as per specification and helped during development of the products as well as chemical treatments.

Thanks are due to the colleagues of the authors, who helped the project work directly and indirectly and also to the Directors of the institutions for their permission to present the paper.

# ABRASION PROPERTIES OF GEOTEXTILES SUBJECT TO DYNAMIC LOADING

W.S.Alexander  
Business Development Manager, Amoco Australia

**ABSTRACT:** In many civil engineering applications geotextiles are subjected to dynamic loadings. These applications include use as a filter fabric beneath rock beaching, (rip-rap), and particularly in marine or tidal applications, which are subject to storm events. Also, to a lesser extent, dynamic loadings occur in railway and logging haul road applications.

This paper reviews the performance of commonly used geotextiles in these applications by exhuming geotextiles from a range of projects after a number of years. A testing program was undertaken to compare properties of geotextiles. Simple testing of geotextiles was carried out in mechanical agitators as well as in actual marine environment. The properties of a range of geotextiles, spun-bond, heat-bonded, continuous filament and staple-fibre non-wovens were compared before and after testing to establish the relative abrasion resistance of different geotextiles subjected to dynamic loading.

**KEY WORDS:** abrasion, geotextiles, case study, dynamic mechanical analysis testing

## 1 INTRODUCTION

Abrasion resistance is not widely considered an important characteristic of geotextiles. The proof of this statement is borne out by the lack of any abrasion performance parameters in commonly used geotextile specifications around the world. In civil engineering applications for geotextiles such as sub-soil drainage, roadway separation and liner protection abrasion is a secondary consideration. There are, however, applications where abrasion resistance is important to the long-term performance of the geotextile. These applications include the use of geotextiles as filters behind rock revetments as well as, to a lesser extent, in dynamic loading situations such as in railway track applications (ref.1) and unsealed haul roads.

## 2 EXISTING ABRASION TESTS

The ASTM currently has one standardised abrasion test for geotextiles, D4886, "Standard Test Method for Abrasion Resistance of Geotextiles (Sand Paper/ Sliding Block Method)". This test is, however, not widely used for the reasons already stated that abrasion is not widely accepted as being important as well as the general view that these tests are very severe and not a fair reflection of the actual abrasion mechanism in a given engineering application. It is difficult to specify what level of abrasion resistance is appropriate, according to D4886, for a given situation. Australian geotextile standards do not address the issue of abrasion although Austroads (ref.2) describe abrasion as "significant where there is repeated loading such as below rip-rap in shore protection or during placement of the first lift on an embankment/pavement when construction equipment must operate on a thin layer"

In Germany the BAW rotating drum test has been used for some years to carry out abrasion testing of

geotextiles. The author is not aware of further details of this test.

Two other standard textile abrasion tests, the Stolle and the Taber Abrasion test are, likewise, considered severe and inappropriate for testing geotextiles. Other abrasion tests have been put forward by Gray (ref.3) and Dine (ref.4), however these are not known to be widely used.

## 3 REVETMENT APPLICATIONS

Failures of geotextiles in revetment applications have been observed at La Canau, France 1985 and at Somers, Australia 1990. Storm events cause severe turbulent wave action, which has been shown to unravel and damage geotextiles. At Somers a non-woven, needle-punched, continuous-filament polyester geotextile failed after being subjected to wave action over only a few days. A replacement non-woven needle-punched, staple-fibre polyester geotextile was found to perform adequately when used in the same environment. Existing abrasion tests only consider the mechanical abrasion of geotextiles, caused by rock particles abrading the geotextile. Geotextiles should, ideally, be well secured by secondary armour rock however, in practice, when subjected to wave action there is some small movement of the geotextile. In some cases the geotextile will only be secured by large discrete rock units and relatively large movements of the geotextile between these rocks will occur. The structure of the geotextile must be adequate to prevent unravelling of the geotextile from this hydraulic loading as well as be resistant to mechanical abrasion caused by rubbing of the geotextile on rock.

#### 4 HYDRAULIC TESTING

Because of the difficulties of field testing geotextiles subject to wave action in a foreshore environment a simple test was devised to replicate the effects of dynamic wave action on geotextiles.

Geotextiles tested were 3 different commercially available Australian geotextiles, which are commonly used in revetment works. Each geotextile was a non-woven (NW), needle-punched (NP) type. Fibre type was either staple-fibre (SF) or continuous-filament (CF) and polymer was either polypropylene (PP) or polyester (PET). Samples of geotextile were placed in a domestic washing machine and agitated for given periods of time. (See Fig 1) Each agitation cycle was 12 minutes long and samples were tested for 4 and 8 cycles. The samples were visually inspected and Mass, Grab Tensile Strength and Mullens Burst Pressure were measured before and after testing. The results are detailed in Tables 1 and 2, and Fig 2 below:

Fig 1. Photo of Washing Machine Agitator

Table 1. Sample description

A	NW, NP, SF, PP
B	NW, NP, SF, PET
C	NW, NP, CF, PET

Table 2. Test Results

	Mass (gsm)			Grab (N)			Mullens (kPa)		
	B*	4	8	B*	4	8	B*	4	8

C	265	255	255	1100	1100	890	3300	3300	3300

\* Before

Fig. 2 Visual appearance of samples after testing (8 cycles)

#### 5 DISCUSSION OF RESULTS

From the above results it is clear that all geotextiles are subject to damage due to wave action, to varying degrees according to the type of structure of the geotextile. Visual inspection showed severe "fluffing" of samples B and C after 8 cycles (96 minutes in agitator). The structure of the geotextiles had begun to unravel. After 8 cycles sample C had virtually disintegrated. This appears to be due to sample C's lightly needled nature compared to the other more heavily needled staple-fibre fabrics. However, sample A showed little change in its visual appearance, even after 8 cycles, which may be explained by its tightly needled staple-fibre structure. The mechanical properties of each sample were affected to varying degrees. The mullens burst for each was largely unaffected. The grab tensile results for sample A showed a 5% reduction and for sample C showed a 20% reduction, which is a significant reduction and may indicate general strength reduction. Further mechanical strength testing of the sample is needed, such as wide strip tensile strength, trapezoidal tear strength and drop cone test, to determine if the mechanical properties are more broadly affected.

##### 5.1 Limitations of Results

This test should be seen as a useful index test to compare performance of different types of geotextiles. It is also useful to give broad guidance as to a geotextile's suitability for use in this type of application. The severe damage to sample C in this test closely replicates the damage sustained to this fabric at the Somers site and so gives a fair reflection of the damage that may occur in revetment applications. Because of the difficulty of replicating actual field conditions, ie coastal marine environment subject to tidal action, in the laboratory, it is

difficult to more accurately co-relate these results to field conditions and to standardise the test to set minimum acceptable performance limits. It is recognised that this testing regime is very severe and may not be appropriate to test abrasion of geotextiles in other applications such as roading or rail track. This test method only replicates turbulent wave action and does not take into account the mechanical abrasion of rock and soil particles rubbing against the geotextile. One improvement to the method would be to include rock particles in the agitator to help model field conditions more accurately. To this end testing has been conducted by others in Australia using a modified form of the LA Abrasion test, although the results have not been published. In this test, samples of fabric are fixed to the internal walls of a drum, which is filled with water and rocks. The drum is then rotated and the fabric samples are tested for the effects of water borne abrasion. The German BAW rotating drum test may also address this issue.

## 5.2 Recommendations

From this testing it would not be recommended to use geotextile C in revetment applications in marine applications due to the disintegration of the fabric's structure after 8 cycles in the test. The reduction in grab tensile may indicate a broad reduction in the strength properties of the geotextile.

## 5.3 Further Testing

Because of the limited nature of this project it is required to conduct further extensive testing to determine the reproduceability of the test method. Variables such as length of time of testing and addition of, and type of, rock samples need to be investigated.

## 6 CONCLUSIONS

The following conclusions were made based on this testing:

- abrasion is an important consideration in some engineering applications of geotextiles, such as revetment and rail track situations.
- abrasion is inadequately treated by current standard tests
- dynamic wave action causes stresses, other than mechanical abrasion, to occur in the geotextile
- a simple agitation test, using a domestic washing machine, was found to be a useful index test to compare performance of different geotextiles as well as to give broad assessment of suitability of geotextile for application

- field experience, together with agitator testing, show that some lightly needled continuous-filament non-wovens are not suitable for use in revetment applications in tidal environments
- The results of this testing together with field experience, indicate that staple-fibre non-woven geotextiles are most suitable for use in this application.

## ACKNOWLEDGEMENTS

The writer would like to thank Mr. G. Byrne of Vantree Pty Ltd for his assistance.

**ABSTRACT:** Geotextile systems such as bags, mattresses, tubes and containers filled with sand or mortar can be a good and often cheaper alternative for more traditional materials/systems as rock, concrete units or asphalt. These new systems were applied successfully in a number of countries and they deserve to be applied on a larger scale. Because of low price and easy construction these systems can be a good alternative for coastal protection and coastal structures in developing countries. The main obstacle in their application is however the lack of proper design criteria. An overview is presented on stability criteria of the existing geosystems and their limitations.

**KEYWORDS:** Geomattresses, Geobags, Geotubes, Design

## 1 INTRODUCTION

Various structures/systems can be of use in hydraulic and coastal engineering, from traditional rubble or concrete systems to more novel methods as geosystems and others. Within the scope of the research on the stability of rock and block revetments, much knowledge has been developed about the possible failure mechanisms and methodology on development of stability criteria under current and wave load (CUR/RWS, 1995a,b). Until recently, no or unsatisfactory design tools were available for a number of other (open) types of revetment and geosystems. This is why the design methodology for block revetments has recently been extended in applicability by means of a desk-study for a number of geosystems, such as sandbags and sand- and mortar-filled mattresses and tubes/containers. Also other stability aspects, such as soil-mechanical stability and residual strength were taken under consideration.

Geotextile systems utilize a high strength synthetic fabric as a form for casting large units by filling them by sand or mortar, or as curtains collecting sand. At this moment there is a relative large number of products of this type on the market provided by some specialistic companies all over the world. Mattresses are mainly applied as slope and bed protection. Bags are also suitable for slope protection and retaining walls or toe protection but the main application is construction of groins, perched beaches and offshore breakwaters. The tubes and containers are mainly applicable for construction of groins, perched beaches and offshore breakwaters. They can form an individual structure conforming functional

requirements for the project or as a component of the main structure. In general, the sand-filled structure can be used as: temporary structures to learn the natural interactions/responses, permanent structures at locations with relatively low wave attack ( $H < 1.5\text{m}$ ), or submerged structures where direct wave forces are reduced. The mortar-filled systems can resist much higher wave and current loading and, if necessary, can be interconnected by bars or by creating a special interlocking shape.

The main advantages of these systems in comparison with more traditional methods are: a reduction in work volume, a reduction in execution time, a reduction in cost, a use of local materials, a low-skilled labour requirement and possibility of using of locally available equipment.

This paper aims at giving a summary of the increased knowledge, especially that concerning the stability criteria for sand- and mortar-filled mattresses, bags and geotubes that have been made available.

## 2 STABILITY CRITERIA

### 2.1 Wave-load stability

There are two practical design methods available: the black-box model and the analytical model. In both cases, the final form of the design method can be presented as a critical relation of the load compared to strength, depending on the type of wave attack. For revetments, the basic form of this relation is:

$$\left(\frac{H_s}{\Delta D}\right)_{cr} = \frac{A}{\xi_{op}^{2/3}} \text{ with maximum } \left(\frac{H_s}{\Delta D}\right)_{cr} = 8.0 \quad (1)$$

In which: A = revetment (stability) factor (-),  $H_s$  = significant wave height (m),  $\Delta = \rho_s/\rho_w - 1$  = relative density (-),  $\rho_s$  = density of the protection material,  $\rho_w$  = density of water (kg/m<sup>3</sup>), D = thickness of the top layer (m), and  $\xi_{op}$  = breaker parameter (-). For porous top layers, such as sand mattresses and gabions, the relative density of the top layer must be determined, including the water-filled pores:

$$\Delta_m = (1 - n) \cdot \Delta \quad (2)$$

In which:  $\Delta_m$  = relative density including pores (-) and n = porosity of the top layer material (-).

The breaker parameter is defined as follows:

$$\xi_{op} = \frac{\tan \alpha}{\sqrt{H_s/L_{op}}} \quad (3)$$

In which:  $\alpha$  = slope angle (°),  $L_{op} = 1.56 T_p^2$  = deep-water wavelength at the peak period (m), and  $T_p$  = wave period at the peak of the spectrum (s).

The advantage of this black-box design formula is its simplicity. The disadvantage, however, is that the value of A is known only very roughly for many types of structures.

The analytical model is based on the theory for placed stone revetments on a granular filter. In this calculation model, a large number of physical aspects are taken into account. In short, in the analytical model nearly all physical parameters that are relevant to the stability have been incorporated in the "leakage length" factor. The final result of the analytical model may, for that matter, again be presented as a relation such as Eq. 1 where  $A = f(\Lambda)$ . For systems on a filter layer, the leakage length is given as:

$$\Lambda = \sqrt{\frac{b_f D k_f}{k'}} \quad (4)$$

with:  $\Lambda$  = leakage length (m),  $b_f$  = thickness of the filter layer (m),  $k_f$  = permeability of the filter or subsoil (m/s), and  $k'$  = permeability of the top layer (m/s).

With a system without a filter layer (a system placed directly on sand or clay) the permeability of the subsoil (eventually with gullies/surface channels) is filled in. For the thickness of the filter layer it is examined to which depth changes at the surface affect the subsoil. One can

fill in 0.3 m for sand and 0.03 m for clay. The values for D and  $\Delta$  depend on the type of revetment. When schematically representing a block on a geotextile on a gully on sand, the block should be regarded as the top layer and the combination of the geotextile and the small gully as the filter layer. The leakage length can be calculated using:

$$\Lambda = \sqrt{\frac{(k_f d_g + k_g T_g) D}{k'}} \quad (5)$$

with:  $k_f$  = permeability of the filter layer (gully) (m/s),  $d_g$  = gully depth (m),  $k_g$  = permeability of the geotextile (m/s),  $T_g$  = thickness of the geotextile (m), D = thickness of the top layer (m), and  $k'$  = permeability of the top layer (m/s).

To be able to apply the design method for placed stone revetments under wave load to other systems, the following items may be adapted:

- the revetment parameter A;
- the (representative) strength parameters  $\Delta$  and D;
- the design wave height  $H_s$ ;
- the (representative) leakage length  $\Lambda$ ;
- the increase factor  $\Gamma$  on the strength.

Only suchlike adaptations are presented in this summarizing paper. The basic formulas of the analytical model are given in (CUR/RWS, 1995a).

## 2.2 Flow-load stability

Severe flow attack may in practice occur on revetments, such as with flow over a steep slope and flow attack near many kinds of structures (downstream of sills, gates, discharge structures and the like). At these structures, the flow is often specifically determined by the geometry and the boundary conditions. With flow over a steep slope, such as on the downstream slope of a over-flow dam or dike, the situation is less ambiguous.

When the flow velocity is known well, or can be calculated reasonably accurately, Pilarczyk's relation (1990) is applicable:

$$\Delta D = 0.055 \frac{\Phi}{\Psi} \frac{K_T K_h}{K_s} \frac{u_{cr}^2}{2g} \quad (6)$$

in which:  $\Delta$  = relative density (-), D = characteristic dimension (m), g = acceleration of gravity ( $g=9.81 \text{ m/s}^2$ ),  $u_{cr}$  = critical vertically-averaged flow velocity (m/s),

$\Phi$  = stability parameter (-),  $\Psi$  = critical Shields parameter (-),  $K_T$  = turbulence factor (-),  $K_h$  = depth parameter (-), and  $K_s$  = slope parameter (-).

\* The stability parameter  $\Phi$  depends on the application. Some guide values are given below.

	Continuous toplayer	Edges and transitions
Riprap and placed blocks	1.0	1.5
Mattresses, gabions, and washed-in blocks	0.5	0.75

\* With the critical Shields parameter  $\Psi$  the type of material can be taken into account. Some guide values are given below.

Revetment type:	$\Psi$ (-)
riprap	0.035
loose, placed blocks	0.05
blockmats	0.07
gabions	0.07
sand and concrete mattresses	0.07

\* The degree of turbulence can be taken into account with the turbulence factor  $K_T$ . Some guide values for  $K_T$  are given below.

Situation:	$K_T$ (-)
Normal turbulence:	1.0
Increased turbulence (i.e. river bends)	1.5
Heavy turbulence (i.e. hydraulic jump)	2.0
Load due to water (screw) jet:	3.0 to 4.0

\* With the depth parameter  $K_h$ , the water depth is taken into account, which is necessary to translate the depth-averaged flow velocity into the flow velocity just above the revetment. The depth parameter also depends on the measure of development of the flow profile and the roughness of the revetment. The recommended formulas can be found in (Pilarczyk, 1990, Klein Breteler, 1996). The following indicative values for the water depth  $h > 2$  m are given below:

developed profile	:	$K_h = 0.2$
nondeveloped profile	:	$K_h = 0.4$

For shallow water and rough flow ( $h/k_s < 5$ ):  $K_h = 1.0$  ;  
 $h$  = water depth (m) and  $k_s$  = equivalent roughness according to Nikuradse (m);  $k_s \approx 0.05$  m for mattresses.

\* Slope parameter  $K_s$ . The stability of revetment elements also depends on the gradient under which the revetment is applied, in relation to the angle of internal friction of the revetment. This effect on the stability is taken into account with the slope parameter  $K_s$ , which is defined as follows:

$$K_s = \sqrt{1 - \left(\frac{\sin \alpha}{\sin \theta}\right)^2} \quad (7)$$

with:  $\theta$  = angle of internal friction of the revetment material ( $^\circ$ ) (about  $90^\circ$  for concrete mattresses and  $30$  to  $40^\circ$  for sand-filled systems) and  $\alpha$  = transversal slope of the bank ( $^\circ$ ).

With a downward flow along a steep slope it is difficult to determine or predict the flow velocity exactly, because the flow is very irregular (high turbulence, inclusion of air as a result of which the water level cannot be determined very well, etcetera). One is confronted with this when dimensioning the revetment of (the crest and) the inner slope of a dike in the case of flooding. In that case a design formula based on the discharge is preferable (Klein Breteler, 1996).

### 2.3 Soil-Mechanical Stability

The water movement on a revetment structures can also affect the subsoil, especially when this consists of sand. This effect is treated within the framework of the soil-mechanical aspects and can be of importance to the stability of the structure.

There are three aspects that will be discussed within the framework of soil-mechanical aspects:

- elastic storage;
- softening (liquefaction);
- drop in the water level.

These aspects and the accompanying damage mechanisms en design methods are discussed in detail below. Background information can be found CUR/RWS (1995a).

Elastic storage in the subsoil is connected with the permeability and stiffness of the grain skeleton and the compressibility of the pore water (the mixture of water and air in the pores of the grain skeleton). Because of these characteristics, wave pressures on the top layer are passed on delayed and damped to the subsoil of the revetment construction and to deeper layers (as seen perpendicular to the slope) of the subsoil.

This phenomenon takes place over a larger distance or depth as the grain skeleton and the pore water are stiffer. If the subsoil is soft or the pore water more compressible (because of the presence of small air bubbles) the compressibility of the system increases and large damping of the water pressures over a short distance may occur. Because of this, alternately water undertension and overtension may develop in the subsoil and corresponding to this an increasing and decreasing grain pressure.

Elastic storage can lead to the following damage mechanisms:

- lifting of the top layer;
- sliding of the top layer;
- sliding of the subsoil.

For the stability of the top layer, elastic storage could particularly be of importance if the top layer is placed directly on the subsoil without there being small gullies under the top layer and, if the permeability of the top layer is (locally) less than that of the subsoil. These conditions imply that the leakage-length approach according to the analytical model for the stability under wave load cannot be applied.

The stability of the subsoil may be jeopardized if, because of elastic storage, the grain tension decreases so strongly that insufficient shear stress can be absorbed in the subsoil to prevent sliding. The design method with regard to the different damage mechanisms connected with elastic storage are presented in the form of design diagrams. In these diagrams the permissible wave height is plotted against the thickness of the top layer and the slope gradient. If the revetment construction consists of a top layer on a filter layer, the thickness of the filter layer may in these diagrams be partially or completely (depending on the type of revetment) added to the thickness of the top layer.

Also through cyclic generation of water tension, water overtensions may occur in the subsoil, but with impermeable top layers also directly under the top layer. In sand, these watertensions can be calculated using the MCYCLE program developed by Delft Geotechnics. As the top layer becomes more impermeable, the water tension manifests itself closer to the surface of the slope. In the case of a very permeable top layer this is exactly the opposite. Softening (liquefaction) can be defined as follows:

A cyclic variable load causes compaction to occur in a

layer of sand. This leads to a decrease in the pore space. The water in the pores is subjected to pressure and will want to run off. At first, water overtension occurs. This causes a decrease in the contact pressure between the grains and with this the resistance to sliding. Finally, the water overtension might become so large that the contact pressure between the grains falls away completely. This is called softening or liquefaction.

The difference between liquefaction and elastic storage is that with liquefaction, water overtension is connected with a plastic deformation of a grain skeleton instead of an elastic deformation. Water overtension through softening occurs when the grain skeleton deforms plastically to a denser packing. From which follows that the dangers connected with liquefaction are smaller as the subsoil is compacted better during construction.

With regard to liquefaction, the following design rules are suggested for constructions with a reasonably compacted subsoil:

- With a top layer on sand there is no danger of liquefaction, if:
  - the slope gradient is gentler than or equal to 1:3,
  - the slope gradient is gentler than 1:2 and the wave height  $H_s$  is smaller than 2 m, or
  - the slope gradient is gentler than 1:2 and the subsoil is well-compacted.
- With a top layer on clay there is no danger of liquefaction.
- With a top layer on a granular filter there is generally no danger of liquefaction.

In these design rules hardly any distinction is made between types of revetment.

Through a drop in the water level a difference in the rise over the top layer may occur. A drop in the water level may occur as a result of tide or a ship passing through a waterway or canal. As with packed stone revetments, this is only a problem if any possible filter layer and the top layer are sanded up and because of this obtain a low permeability.

No calculations need to be made on this phenomenon if applies:

$$\frac{\Delta \sin \alpha}{2} \leq \Delta D \cos \alpha \quad (8)$$

in which:  $\Lambda$  = leakage length (m),  $\alpha$  = slope angle ( $^\circ$ ),  $\Delta$  = (representative) relative density of the top layer (-),  $D$  = (representative) thickness of the top layer (m).

### 3 TYPES OF STRUCTURES

#### 3.1 Concrete Mattresses

Characteristic of concrete mattresses are the two geotextiles with concrete or cement between them. The geotextiles can be connected to each other in many patterns, which results in each mattress system having its own appearance and properties. An example is given in Figure 1.

Figure 1 Example of concrete mattress

The permeability of the mattress is one of the factors that determine the stability. It is found that the permeability given by the suppliers is often the permeability of the geotextile, or of the so-called Filter Points. In both cases, the permeability of the whole mattress is much smaller. A high permeability of the mattress ensures that any possible pressure build-up under the mattress can flow away, as a result of which the differential pressures across the mattress remain smaller. The stability is there-

fore the largest with a large mattress permeability. In the long term, however, pollution of the Filter Points or the clogging of the geotextile can cause a decrease in the permeability.

##### 3.1.1 Design rules with regard to wave load

In the design rules for concrete mattresses with regard to wave load the calculation of the leakage length is adapted. This consideration, which is closely related to a consideration in accordance with the analytical model, results in a design formula in the form of the black-box formula.

During wave attack, the mattress will be exposed to a differential pressure which is directed upwards, as also is the case with packed stone revetments. This takes place the moment the wave has drawn back, just before the wave impact. Just as with packed stone revetments, the leakage length for this differential pressure is the most important construction-descriptive parameter. The leakage length ( $\Lambda$ ) can be calculated using Eqs. 4 or 5. The values of the leakage length may vary from about 0.5 to 10 m depending on the type (permeability) of the mattress, the permeability and thickness of the filter, and the presence of cavities under the mattress.

The failure mechanism of the concrete mattress is probably as follows:

- First, cavities under the mattress will form as a result of uneven subsidence of the subsoil. The mattress is rigid and spans the cavities.
- With large spans, wave impacts may cause the concrete to crack and the spans to collapse. This results in a mattress consisting of concrete slabs which are coupled by means of the geotextile.
- With sufficiently high waves, an upward pressure difference over the mattress will occur during wave run-down, which lifts the mattress.
- The pumping action of these movements will cause the subsoil to migrate, as a result of which an S-profile will form and the revetment will collapse completely.

The value of stability factor  $A$  in the design formula of the black-box model (Eq. 1) depends on the leakage length and the subsoil:  $A = 2$  to  $4$ . A permeable mattress on sand has a medium-sized or small leakage length and then the value of  $A$  is  $3$  to  $4$ . A low-permeable mattress on a filter has a large leakage length and therefore an  $A$ -

value of 2 to 3 (Figure 2). For the determination of the leakage length, one is referred to the analytical model.

Figure 2 Calculation results for concrete mattresses

The representative relative density  $\Delta$  follows from the standard definition. For the representative thickness  $D$ , the average thickness should be filled in.

It can be concluded that, compared to the available data in literature, the derived stability relations give a safe estimation of the stability. Because the relations have not been verified sufficiently yet, it is not recommended to decrease the existing safety.

In the long run, the permeability of the top layer may diminish as a result of accretion and silting-up. This will have a negative effect on the stability, especially with systems with a leakage length smaller than approximately 2 m. If the leakage length is larger than 2 m, the effect of the permeability of the top layer on the stability is rather small.

### 3.1.2 Design rules with regard to flow load

A number of characteristic values for the critical flow velocity for concrete mattresses is given below.

Thickness	on slope	on bottom
50 mm	2.7 m/s	3.3 m/s
100 mm	3.9 m/s	4.7 m/s
200 mm	5.5 m/s	6.4 m/s

For the application of the design formula (Eq. 6), guide values for the constants are given in Section 2.2. For the representative thickness  $D$ , one should fill in the average thickness of the top layer.

### 3.1.3 Design rules with regard to soil-mechanical stability

The flow through a concrete mattress is concentrated in the Filter Points. The permeability of the systems filled with concrete lies approximately between  $1 \cdot 10^{-4}$  and  $5 \cdot 10^{-3}$  m/s. A concrete mattress is less flexible than a sand mattress and does not connect to the subsoil as well as a sand mattress. In contrast with sand mattresses, it is assumed that only the sliding of the whole mattress can occur and not just part of it.

#### \* Elastic storage

With regard to elastic storage, the following design example for a wave height  $H = 1$  m and a slope 1 on 3 is given. The required thickness of the mattress on sand for various failure mechanisms and wave steepness ( $S_{op}$ ) is equal to:

Failure type	$S_{op} = 0.03$	$S_{op} = 0.05$
Lifting of toplayer	0.35 m	0.25 m
Partial sliding toplayer	0.80 m	0.60 m
Sliding of toplayer	0.30 m	0.25 m
Sliding of subsoil	0.55 m	0.40 m

Concrete mattresses are mostly stiff and anchored at the top. Therefore, not the sliding and/or uplifting of the toplayer but the sliding of the subsoil is the most dangerous (for  $H=1$ m, the required thickness is 0.55m).

If the systems are placed on a filter, one can take into account an increase in the stability with regard to elastic storage. For the total thickness of a concrete mattress on a filter,  $D + b/\Delta$ , can be filled in, where  $b$  is the thickness of the filter.

#### \* Liquefaction

The design rules with regard to liquefaction do not differ from those presented in Section 2.3.

## 3.2 Sand Mattresses

A sand mattress consists of two geotextiles attached onto each other, between which sand is interposed. This way, a mattress is formed of sausages lying next to each other which run from the top to the bottom of the slope and which are interconnected. The lower geotextile is usually flat and the upper geotextile lies on top of it, in arches.

#### \* Construction/design/repair

The edges and connections of sand mattresses are vulne-

nable and must therefore be finished carefully. Mattresses lying next to each other can be sown together and the ends can be secured with for example ground anchors.

In actual practice, mattresses are not only threatened by the hydraulic load. The possibility of vandalism occurring, limits sand mattresses to being applied in places where unauthorized persons do not have access to. The system is also vulnerable to collision, (drifting) ice, floating bulky refuse, sunlight and chemical degradation.

**\* Stability**

Sand mattresses cannot be used when the significant wave height  $H_s$  is larger than 1.0 m (max. 1.5 m in case of properly compacted subsoil). Unfortunately, not much research has been conducted into the stability of sand mattresses. Besides Pilarczyk's design formula (1990), a small-scale model investigation, a desk study and a prototype experiment have been found. Based on these, the following value for A in the design formula (Eq. 1) is recommended according to the black-box model:  $A = 4$  to 5. In this formula the relative density including pores  $\Delta_m$  should be filled in for the representative relative density. For the representative thickness D of the mattress, the average thickness should be filled in:

$$100\% \text{ filled} : \frac{D}{D_d} = 0.7 \text{ to } 0.8$$

$$90\% \text{ filled} : \frac{D}{D_d} = 0.6 \text{ to } 0.7$$

with: D = average thickness of the mattress (m) and  $D_d$  = maximum diameter of the sausages (m).

Above a flow velocity of 1.5 m/s (max. 2 m/s), the sand in the mattresses is no longer internally stable. The design formula on stability against currents is given in section 2.2.

A sand mattress is relatively flexible and connects closely to the subsoil. The geotechnical design criteria are similar to those for the concrete mattresses.

**3.3 Geobags and geotubes**

Geobags or tubes can be filled with sand, gravel or concrete. The bags may have different shapes and sizes, varying from the well-known sandbags for emergency dikes to large flat shapes or elongated "sausages" (see Figure 3). The most common use for sandbags in hydraulic engineering is for temporary structures. The reasons why sandbags are not or hardly used for permanent structures are as follows:

- the resistance against flow load and wave load is relatively small;
- because the geosystems are prone to vandalism and the effect of sunlight, for example, the durability is relatively small;
- good design formulas are lacking;
- a construction made of sandbags looks ugly.

Major advantages of sandbags as construction material are the low costs and the simple processing. Uses for sand- or cement-filled bags are, among other things:

- revetments of relatively gentle slopes;
- temporary toe constructions in places where in due course vegetation should develop;
- (temporary) training walls/groins;
- temporary or permanent offshore breakwaters;
- temporary dikes surrounding dredged material containment areas.

Figure 3 Application of geobags and containers

Because sand is easy to use and cheap, it is extremely suitable for temporary structures. Above a flow velocity of 1.5 to 2 m/s, the sandbags cannot be used for permanent applications because the sand is no longer internally stable.

Sandbags can be placed as follows:

1. *As a blanket:* One or two layers of bags placed directly on the slope. An "interlocking" problem arises if the bags are filled completely. The bags are then too round. A solution is not to fill the bags completely, so that the sides flatten out somewhat, as a result of which the contact area becomes larger.
2. *As a stack:* Bags stacked up in the shape of a pyramid. The bags lie half overlapping with the long side parallel to the shoreline.

When installing geosystems, one should see to it that this

does not take place on a rough foundation. Sharp elements may easily damage the casing of the element. Geosystems must not be filled completely. With a fill ratio of approximately 75% an optimum stability of the elements is reached. A sound soil protection is necessary if gravel (sand) sausages are used in circumstances where they are under attack of flow or waves.

Background information on geobags can be found in Pilarczyk (1995) and Wouters (1995).

New developments concern the large hydraulically filled geotubes and hydraulically or mechanically filled geocontainers (in combination with a split barge). Information on these systems can be found in Leshchinsky (1995), Pilarczyk (1996, 1997) and Den Adel et al (1996).

### 3.3.1 Design rules with regard to wave load

The stability relation of sand, gravel or cement bags which are used as protection elements on a slope appears to deviate somewhat from the formula according to the black-box model. For regular waves the recommended formula is as follows:

$$\left(\frac{H}{\Delta D}\right)_{cr} = \frac{3.5}{\sqrt{\xi_o}} \quad (9)$$

In which  $\Delta$  is the relative density if the pores are completely filled with water ( $\Delta_m$ ). The representative thickness  $D$  is the average thickness of the top layer, measured perpendicularly to the slope.

If this stability relation is combined with the relation found between  $H_s$  and  $H$ , (significant wave height with irregular waves and the wave height with regular waves) this results in the following stability relation:

$$\left(\frac{H_s}{\Delta D}\right)_{cr} = \frac{2.5}{\sqrt{\xi_{op}}} \quad (10)$$

For concrete sausages (tubes) used as a protection element on the crest of a low or underwater breakwater, it is found that the following stability relation for regular waves can be used:

$$\left(\frac{H}{\Delta b}\right)_{cr} = 3.2 \left(\frac{H}{L_0}\right)^{1/3} \quad (11)$$

In which  $b$  is the width of the sausage. Should two sausages be connected, the widths of both sausages together can be filled in for  $b$ .

If the sausage is placed with its longitudinal direction perpendicularly to the axis of the breakwater, the following stability relation applies:

$$\left(\frac{H}{\Delta l}\right)_{cr} = 1.0 \quad (12)$$

In which  $l$  is the length of the sausage.

### 3.3.2 Other design rules

Stability against current should be treated according to the rules given in Section 2.2.

The soil-mechanical stability should be treated according to the criteria mentioned in Section 2.3.

## 4 CONCLUSIONS

The geotextile systems can be a good and mostly cheaper alternative for more traditional materials/systems. These new systems deserve to be applied on a larger scale. Information presented on the stability criteria will be of help in preparing the preliminary alternative designs with geosystems. However, there are still many uncertainties in the existing design methods. Therefore, further improvement of design methods and more practical experience at various loading conditions is still needed.

# Evaluation of Geosynthetic Fabric Containers to Contain Contaminated Dredged Sediment

Horace Moo-Young

Department of Civil and Environmental Engineering, Lehigh University, Bethlehem, PA, USA

Tommy Meyers

Environmental Engineering Division, Waterways Experiments Station, Vicksburg, MS, USA

Dan Townsend

Department of Civil Engineering, Louisiana State University, Baton Rouge, LA, USA

**ABSTRACT:** Recent changes in environmental regulations to protect the water column have prohibited the open water disposal of dredged sediment from the New York Harbor. As a result, the New York Harbor will lose about a foot of depth each year if the contaminated sediments are not dredged. Because of the restrictions and perceived political problems with dredging and open water disposal of the contaminated materials, the New York Port Authority investigated the use of geosynthetic fabric containers (GFC) to reduce the movement of contaminated sediments outside of the boundary of the disposal site and to decrease the impact of the sediment on the water column. This laboratory study investigates the migration of fines and contaminants through GFCs. Contaminated sediment was characterized for the physical and chemical properties. Laboratory filtration tests were conducted on the contaminated sediment and GFC configurations to determine the amount of total suspended solids that would be released to the water column.

**KEYWORDS:** Geotextiles, Filtration, Hazardous Containment, Apparent Opening Size

## 1 INTRODUCTION

The New York Harbor is a major industrial port on the East Coast of the U.S. where 4,500 ships carry \$60 billion per year worth of goods. River borne silts are sifting into the harbor's shipping channels and reduce the depth of the harbor. New York and New Jersey Port Authority continuously dredges to maintain channel depths for cargo ships and tankers. From 1990 to 1994, the average amount of dredged material was approximately 4.3 million cubic yards (5.6 million m<sup>3</sup>). Dredged material was disposed in the Atlantic Ocean, a few miles east of the Jersey Shore at the New York Bight Dredged Material Disposal Site. Recent changes in environmental regulations have restricted open water disposal of the sediment due to contamination. These restrictions on dredging have decreased the average amount of sediment dredged by 70% to 1.3 million cubic yards (1.7 million m<sup>3</sup>) in 1996. As a result, the New York Harbor will lose about a foot of depth each year if contaminated sediments are not dredged. Decreases in the harbor depth will have a severe impact, as larger cargo ships will dock at deeper ports.

Containing the contaminated sediment in a geosynthetic fabric container (GFC) for placement from split hull barges is one alternative that can reduce the movement of contaminated sediments outside the boundary of the disposal site and decrease the impact on the water column. After placement of the sediment, the

opening of the GFC is closed, transported to an aquatic disposal site where it is then released from the barge. When properly constructed, GFCs have performed well as hydraulic and geotechnical structures. Numerous projects have shown the beneficial uses of GFCs for dikes in shallow and deep-water energy (Fowler and Sprague, 1994; Risco, 1995).

This paper reports the findings on a laboratory study of the GFC performance with respect to the migration of fines and contaminants. In this study, laboratory filtration tests were conducted to provide information on the release of fines through GFCs.

## 2 MATERIALS

### 2.1 Dredged Sediment

Sediment (Category III by U.S. Army Corps of Engineers, New York District (CENAN) classification) from New York Harbor was used in this study. The sediment was mixed in a 250-gallon (1 m<sup>3</sup>) tank for three hours. Samples of the mixed sediment were collected for geotechnical and chemical analysis.

Three samples of the contaminated dredged sediment were analyzed for polycyclic aromatic hydrocarbons (PAHs), NH<sub>4</sub>, Total Organic Carbon, Arsenic, Cadmium, Chromium, Copper, Iron, Manganese, Lead, Mercury

and Zinc. Table 1 summarizes the standard procedures, detection limits, and chemical analysis on the sediment.

According to American Society for Testing and Materials (ASTM) designation D-2487, the sediment classifies as a sandy clay (CH). The initial water content (ASTM procedure D-2974) of the sediment was 207%, and the specific gravity (ASTM procedure D-854) of the sediment was 2.57. Consolidation tests were performed on sediment according to ASTM procedure D-2435 method A, and test results showed that the sediment was highly compressible with a compression index of 1.2.

## 2.2 Geosynthetics

A geosynthetic fabric container (GFC) is constructed by sewing one or more layers of geotextiles together to form a container that will support and contain a measured amount of saturated material. A woven polyester geotextile (fabric A) was used as the strength layer in the GFC. Four polypropylene nonwoven needle punched geotextiles were tested as potential filter layers for the GFC: fabric B (4 ounce/yd<sup>2</sup>), fabric C (8 ounce/yd<sup>2</sup>), fabric D (12 ounce/yd<sup>2</sup>) and fabric E (16 ounce/yd<sup>2</sup>). Physical and hydraulic properties of the geotextiles were determined using ASTM procedures and are shown in Table 2. Geotextiles in this study meet the recommended soil retention criteria which requires the apparent opening size (AOS) to be less than two to three times the soil particle size for which 85% of the total soil is finer (AOS < 2 or 3 d<sub>85</sub> where d<sub>85</sub> = 0.185 mm).

## 3 METHODS

### 3.1 Pressure Filtration Test

Bench top filtration tests were conducted to obtain information on the release of fines from geosynthetic fabrics of varying AOS. The filtration procedure described in this method simulates the migration of fines through a GFC. A vacuum pressure is applied to a filter media to separate liquids from solids. During a dredging operation, cake formation occurs after the GFC is filled with the sediment and is caused by self-weight consolidation. Cake formation also occurs after placement of the GFC in the disposal facility and is caused by consolidation under a hydrostatic pressure.

### 3.2 Apparatus

A Millipore Hazardous Waste Filtration System was used to conduct the pressure filtration tests, and this pressure filtration device is also used for the Toxicity Characteristic Leaching Procedure (TCLP) in hazardous waste testing (U.S. Environmental Protection Agency (EPA), 1982). The geosynthetic fabric was placed on a filter holder that was able to withstand pressures up to 100 psi (690 kPa). Five GFC configurations were tested: A, A + B, A + C, A + D, and A + E.

Three filtration tests were conducted on each fabric configuration at applied pressures of 5 psi (34.5 kPa) and 10 psi (69 kPa). Pressure was applied to the inlet of the filtration device using a compressed nitrogen cylinder. A relief valve on top of the chamber was used to adjust the pressure. A 250 ml graduated cylinder was used to measure the volume of filtrate.

Table 2. Geotextile properties

Fabric Properties	Units	Fabric				
		A	B	C	D	E
Thickness	mm	NP	1.8	2.7	3.7	4.7
	(mils)		70	105	145	185

	(US Sieve)	60	70	70	100	100

Note: NP-Not provided by manufacturer

### 3.3 Procedure

The geosynthetic fabric and filter chamber were initially weighed. The filter was then washed with deionized water, allowed to drip dry, and placed on the filter holder. The lower portion of the filtration apparatus was assembled, and to reduce the potential for migration of fines at the edges, the filter fabric slightly overlapped the filter holder. Approximately 500 grams of the sediment was weighed and placed into the filtration device, whereby the slurry was allowed to settle before running the test. The top plate was placed on top of the chamber and sealed. Silicone grease was used to reduce the loss of pressure between the chamber and the upper and lower plates. Pressure from the nitrogen cylinder was gradually applied on top of the sample, until the desired pressure was achieved. The volume of the filtrate was measured using a 250-ml beaker and recorded with respect to time. Tests were conducted until the pressure began to decrease, and no more filtrate passed through the filter. When consolidation of the sediment at the applied pressure was completed, the filter cake ruptured which caused a decrease in the applied pressure.

Total suspended solids (TSS) tests were conducted on the filtrate in the graduate cylinder using the Standard Method for Water and Wastewater procedure at 209F. The filtration apparatus was disassembled, and the filtered cake was weighed. The final water content of the filtered cake was obtained using ASTM procedure D-2216. Thirty filtration tests were conducted on the contaminated sediment from the New York Harbor; three replications were conducted for the five fabric configurations at filtration pressures of 5 (34.5 kPa) and 10 psi (69 kPa).

## 4 RESULTS

Initial and final TSS data indicate that there is low migration of the fines through the various filter configurations. Table 3 shows the filtration test results for tests conducted at 5 psi (34.5 kPa). The filtering efficiency was determined by comparing the final TSS of the filtrate to the initial TSS of the contaminated sediment as shown in equation 1 (Henry and Hunnewell, 1995; Christopher and Holtz, 1985).

$$FE = \frac{TSS_{initial} - TSS_{final}}{TSS_{initial}} \times 100 \quad (1)$$

where FE = Filtering Efficiency, %  
 $TSS_{initial}$  = initial TSS, mg/l  
 $TSS_{final}$  = final TSS, mg/l

For the filtration tests conducted on the various fabric configurations, the initial water content ranged from 180-

200%. The fabric configurations reduced the TSS migrating to the water column by an average factor of 1000. In all tests, the water flow through the fabric and sediment slowed with time. Initial and final TSS data indicate that there is low migration of the fines through the various filter configurations.

Figure 1 plots the TSS and fabric weight relationships for the filtration tests conducted at 5 psi (34.5 psi) with a minimum TSS concentration occurring at fabric D. Fabric E showed a sharp increase in TSS compared to fabric D. The TSS and fabric weight relationship at 10 psi (69 kPa) has a minimum TSS occurring at fabric D. These data indicate that fabric D has the lowest TSS concentration passing through the material.

Figure 2 plots the apparent opening size and total suspended solids relationship for tests conducted at 5 psi (34.5 kPa) and 10 psi (69 kPa). As the apparent opening size decreases, the total suspended solids concentration decreases.

## 5 SUMMARY AND CONCLUSION

The feasibility of using GFCs to contain contaminated sediment from the New York Harbor was studied. Laboratory filtration tests were conducted to determine the flow rate of suspended solids through a GFC system. Filtration testing provided an index test to determine the migration of fines through the fabrics. From these tests, it was shown that GFCs provide adequate filtration for dredge sediment. Utilizing the GFCs to contain contaminated dredged sediment will reduce the migration of fines in an open water disposal facility.

Table 3 Filtration test data at 5 psi (34.5 kPa)

Fabric Tested	Final	Initial TSS (g/l)	Final TSS (mg/l)	Average Flow (ml/min)	TSS Filtering Efficiency (%)
	Water Content (%)				
A	121	433.3	64.3	0.78	99.98
A + B	132.6	425.8	44.3	0.73	99.99
A + C	126	438.9	33.9	0.69	99.99
A + D	121	442.9	28.5	.68	99.99
A + E	112.7	44.8	68.4	0.87	99.98

# Infrared Thermography of Damage in Geosynthetics

M.P. Luong

Professor, CNRS-LMS, Ecole Polytechnique, F-91128 Palaiseau, France

M. Khay

Civil Engineer, CETE Centre d'Expérimentation Routière, F-76121 Grand Quevilly, France

**ABSTRACT:** This paper aims to illustrate the use of quantitative infrared thermography as a nondestructive, noncontact, and real-time technique to detect the intrinsic dissipation that depicts the physical processes of damage and the mechanisms of geosynthetics failure. The parameter investigated in this experimental work is heat generation due to the energy dissipated by geosynthetics subject to tensile loading, up to failure. This experimental technique subsequently proposes a durability threshold, a loading limit beyond which geosynthetics fail.

**KEYWORDS:** Failure, Laboratory Tests, Materials Tests, Mechanical Properties, Tensile Strength.

## 1 INTRODUCTION

The use of geosynthetics in geotechnical engineering has been steadily increasing these last decades. It was initiated primarily by the manufacturers who sensed the need, developed, and marketed the products. The range of applications of geotextiles (Giroud 1980) is enormous: (i) filtration, drainage, earth dams, canals, coastal works, bank and shore protection, and in erosion prevention and control systems; (ii) stabilization of landslides, parking lots, paved and unpaved roads, roadways, and railroads on soft subgrades; and (iii) reinforcement of retaining structures, earth and waste slopes, and embankments. Geosynthetics (geotextiles, geogrids and geomembranes) can also be used together in a geocomposite system to provide multiple functions. Common applications of geocomposites are in hazardous waste containment systems and as prefabricated drainage layers. With the rapid recent growth in the use of these materials, civil engineers often have difficulty obtaining reliable mechanical characteristics for design, specifications, and construction with geosynthetics.

This paper emphasizes the application of infrared thermography to detect the occurrence of damage and to examine the mechanism and process of geosynthetics failure. Subsequently it proposes a limit of dissipative stability, defined as a drastic change in the rate of intrinsic dissipation.

## 2 THERMOGRAPHY BACKGROUND

Damage theories rely on assumed discontinuous phenomena at the microscopic scale. At the macroscopic scale, damage

parameters, considered as internal variables, are introduced according to the following main approaches: i) effective stress introducing a scalar continuous variable; ii) plasticity formalism suggesting phenomenological constitutive models that are widely used in engineering applications; and iii) micromechanics using micro- and macroscale relationships

Understanding damage requires making a clear distinction between the physical damage, the process of damage, and the manifestation of damage. This experimental work is based on the assumption that intrinsic dissipation and damage present the same evolution under loading up to failure as they occur in traditional strength tests.

The development of the thermo-visco-elastic-plasticity equations requires three types of basic assumptions (Dillon 1963, Kratochvil & Dillon 1969), leading to the following coupled thermomechanical equation:

$$\rho C_v \dot{T} = K \nabla^2 T - (\beta : \overset{4}{D} : \dot{E}^e) T + S : \dot{E}^I + r_0$$

where  $\overset{4}{D}$  denotes the fourth-order elasticity tensor,  $C_v$  ( $J.kg^{-1}.K^{-1}$ : Joule per kilogram per degree Kelvin) the specific heat at constant deformation and  $K$  ( $W.m^{-1}.K^{-1}$ : Watt per metre per degree Kelvin) the thermal conductivity.

This equation shows the potential applications of the infrared scanning technique in diverse engineering domains (detection of fluid leakages, nondestructive testing using thermal conduction phenomena, elastic stress measurements, and localization of dissipative phenomena). The detected temperature change, resulting from four quite different phenomena, must be correctly discriminated by particular test conditions and/or specific data reduction. This is the

main difficulty when interpreting the thermal images obtained from experiments under the usual conditions.

Infrared thermography is a convenient technique for producing heat pictures from the invisible radiant energy emitted from stationary or moving objects at any distance and without surface contact or any perturbation of the actual surface temperature of the objects viewed. The temperature rise ahead of a fatigue crack has been measured and thus proved using an infrared thermographic camera by Attermo & Östberg (1971). Attempts to measure and characterize the heat generated during the cyclic straining of composite materials have also been made. The scanning infrared camera was used to visualize the surface-temperature field on steel and fiberglass-epoxy composite samples (Charles *et al.* 1975) during fatigue tests.

A scanning camera, analogous to a television camera, utilizes an infrared detector in a sophisticated electronics system. It detects radiated energy and converts it into a detailed real-time thermal picture in a video system either in color or monochromatically. Response times are shorter than one microsecond. Temperature differences in the heat patterns are discernible instantly and are represented by several hues. The quantity of energy  $W$  ( $W.m^{-2}.\mu m^{-1}$ ), emitted as infrared radiation, is a function of the temperature and emissivity of the specimen. The higher the temperature, the more important the emitted energy. Differences of radiated energy correspond to differences of temperature. The infrared scanner unit in use comprises:

i.- a set of infrared lenses which focuses the electromagnetic energy, radiating from the object being scanned, into the vertical prism,

ii.- an electro-optical mechanism which discriminates the field of view in  $10^4$  pixels by means of two rotating vertical (180 rpm) and horizontal (18,000 rpm) prisms with a scanning rate of 25 fields per second,

iii.- a set of relay optics containing a selectable aperture unit and a filter cassette unit which focuses the output from the horizontal prism onto a single-element point detector, located in the wall of a Dewar chamber,

iv.- a photovoltaic SW short-wave infrared detector composed of Indium Antimonide InSb which produces an electronic signal output varying in proportion to the radiation from the object within the spectral response  $3.5 \mu m$  to  $5.6 \mu m$ ,

v.- a liquid nitrogen Dewar which maintains the InSb detector at a temperature of  $-196^\circ C$  allowing a very short response time of about one microsecond, and

vi.- an electronic control with preamplifier that produces a video signal on the display screen.

The received radiation has a nonlinear relation with the object temperature, can be affected by atmosphere damping, and includes reflected radiation from the object's surrounding. In consequence, calibration and correction procedures have to be applied. Knowing the temperature of the reference, the view-field temperature can then be calculated with a sensitivity of  $0.1^\circ C$  at  $20^\circ C$ . This infrared device is used to scan the following tests on geosynthetics.

### 3 TENSILE TESTING ON GEOSYNTHETICS

When reinforcing materials are deposited in embankments or slope, not only the deformation conditions of soil, but also the direction of reinforcing materials in soil influences the functions and effects of reinforcing materials. A geotextile may be subjected to various tensile loadings all over its life. The most common cases are caused by local irregularities of soil layer upon which it is placed. Rocks, stones, cracks or settlements in soil mass are frequent, even with a meticulous control of the earthwork. A great number of different tensile tests exist nowadays (Figure 1). Nevertheless there still exists the need for a good understanding of the failure mechanisms in order to specify a test procedure on geotextiles (Fayoux & Loulière 1984, Rollin *et al.* 1984).

A tensile force is gradually applied by a tension hydraulic actuator to a geotextile specimen while its length  $L$  is measured. Generally the nominal stress is expressed by the force  $F$  divided by the width  $b_0$  of the specimen and the strain  $\epsilon$  is obtained by dividing the increment  $\Delta L$  by the initial length  $L_0$ . Different types of tightening system have been devised for specimen gripping (Luong & Habib 1989).

Presently, most of the tensile characteristics (yield and failure, strain at yield and at failure) provided by laboratory tests - and so considered as references in civil engineering - are based on uniaxial standardized tensile tests such as AFNOR NFT 54102, DIN 53455 or ASTM D638. However the great influence of geosynthetic specimen geometry and

Figure 1 - 1D-tension tests on standardized specimens of various geosynthetics.

of the applied strain rate has been shown in literature (Gourc *et al.* 1986, Hoekstra 1988, Steffen 1984, Van Leeuwen 1977). The scattering of results caused by the influence of the specimen geometry and the sliding of the jaws can be reduced by measuring the strain in the central part of the specimen where failure occurs. It complicates the test procedure and needs more expensive equipment. Furthermore, the narrowing in the central part of the specimen may be very prejudicial to the validity of the measured elongation: very large strains occur at failure in contrast to limited lateral strains in reality.

Figure 2 - Thermal images showing the failure process on a specimen of non-woven geotextile subject to 1D-tension test (0.5 °C for each color hue).

The principle of 2D-tension test is similar to the uniaxial tension test. The specimen is simultaneously loaded in two perpendicular directions with a 2D-tension frame. The lateral strain can be controlled, but in certain cases it would be closer to field conditions to maintain the deformation at the same value in the two dimensions. The stress-strain curves obtained in such test conditions would be particularly interesting for the designer. Unfortunately, in consideration to the ease of use and the cost of the required equipment, the generalization of the 2D-tension test seems to be not yet very realistic. The bursting test can be used as a more convenient alternative (Lucng & Bernhard 1990).

The proposed parameter, investigated in strength tests on geosynthetics, is heat generation due to the energy dissipated by the material that has been loaded up to failure (Figure 2). The contribution of the plasticity term is revealed by the rapid evolution of the heat dissipation once the stable reversible domain has been exceeded.

Geotextiles are dense fiber assemblies, usually defined as those in which the mechanics is dominated by fiber deformation predicted from assembly deformation. Thanks to the heat dissipation of the textile at large stresses, infrared thermography provides a ready mean to evidence what happens when the fabric yields: a) the effect of slippage from fiber ends, or false ends where fiber paths curve back on themselves, b) the cause of yielding and failure of bonds, either bond breakage or slippage of fibers through bonds, and c) the relevance of the geometry of fiber paths and binder distribution.

Figure 3 - Intrinsic dissipation evidencing the failure process on a specimen of non-woven geotextile subject to 1D-tension test (Temperature scale is given in °C).

The infrared scanner device displays a ten-color calibrated surface-temperature picture of the specimen. Each color hue corresponds to 0.2 °C. A computer-aided thermography software allowed the data reduction of the thermal images that shows heat generation between two loading levels (Figure 3). These thermal images provided quantitative values of the intrinsic dissipation of geosynthetics specimens subject to loading up to failure. The same procedure has been applied for each load step. The manifestation of the damage mechanism is revealed by a break of the intrinsic dissipation regime of the loaded specimen. Experimental results have been summarized in Figure 4 where it can be seen how a threshold of dissipative stability is determined using a graphical procedure. This provides a simple way to define a durability threshold for the tested material.

Figure 4 - Graphical determination of the durability threshold of a geotextile under tension.

#### 4 CONCLUDING REMARKS

This work has demonstrated that the intrinsic dissipativity of geosynthetics subject to tensile loading is the most sensitive and accurate manifestation of damage occurrence. Owing to the thermomechanical coupling, this useful technique provides a nondestructive real-time test with no contact to observe the physical processes of geosynthetics degradation, to detect the occurrence of intrinsic dissipation, and to estimate the evolution of dissipative behavior. It thus provides a measure of the material damage and permits evaluation of the sharp limit of a low accumulation of damage beyond which the material leads quickly to failure.

Infrared thermography can be used for the validation of new testing methods on geosynthetics, the development of

the mechanics of woven and non-woven geotextiles, particularly the relationships between the mechanical behavior of filaments and the fabric, and between the tensile strength as measured in various tests.

In addition the infrared thermographic analysis of geosynthetics under tension evidences the failure mechanisms of geosynthetics. Consequently it can be applied for the quality assessment and control of geosynthetics products.

# Influence of Reinforcement Damage on the Pull-out Resistance of Geogrids

M.L. Lopes

Assistant Professor, Department of Civil Engineering, University of Porto, Porto, Portugal

T. Ayele

Ph.D. Student, Department of Geological Engineering, University of Bratislava, Bratislava, Slovakia

**ABSTRACT:** This paper studies the influence of reinforcement damage on the soil-reinforcement interaction mechanism by analyzing the results of pull-out tests carried out with pre-damaged reinforcements and a granular soil. The reinforcement tested was HDPE uniaxial geogrid and the soil was a well graded very gravelly sand. Testing equipment is described and soil and reinforcement materials are characterized physically and mechanically. To study the influence of reinforcement damage on its interaction mechanism with the soil, five different configurations of reinforcement damage and two different values of confinement stress were used. The role of damage configuration and of confinement stress on the pull-out behaviour of damaged geogrids is discussed. Finally, some general conclusions are put forward.

**KEYWORDS:** Geogrids, Damage, Interaction, Pull-out test, Pull-out resistance.

## 1 INTRODUCTION

Geosynthetics can be damaged during handling, placement, and construction operations, if enough care is not taken. The degree of reinforcement damage (extension, severity, and type) that can occur during those operations depends also on the types of machinery, soil, and reinforcement used.

Published field and laboratory test results generally consider reinforcement damage in terms of reduction in tensile and burst strength, grab, puncture and tear resistance, and number of holes per square meter (Razaqpur et al. 1993). Lately, some studies have been carried out accounting for reinforcement damage in terms of long term behaviour of geosynthetics (using creep tests for the assessment of damage) (Esteves, 1996).

However, when geogrids are used as soil reinforcement, particularly in walls and slopes, in addition to the short and long term tensile resistance requirements, the pull-out resistance must be sufficient to inhibit the failure by lack of pull-out resistance. To study the influence of a certain amount of damage on the pull-out behaviour of a high density polyethylene (HDPE) uniaxial geogrid, five different types of damage were simulated in the laboratory and the damaged specimens were tested in a pull-out apparatus. The influence of confinement stress on the pull-out behaviour of the damaged specimens was studied by carrying out tests under two different levels of confinement stress.

## 2 EQUIPMENT AND MATERIALS

The pull-out box used to study soil-geogrid interaction has internal dimensions of 1.53 m length, 1.00 m width, and 0.80 m height (Figures 1 and 2). The reduction of the influence of the top boundary on the pull-out resistance of the reinforcement and the uniform distribution of the

applied vertical stresses are achieved by placing over the top of the soil a smooth neoprene slab having a thickness of 0.025 m. To reduce the influence of the front wall on that resistance, a steel sleeve is used which extended 0.20 m inside the box. The pull-out force, obtained by a hydraulic system, is transmitted to the specimen by a clamp (Figure 3). The confinement stress is applied by placing ten small hydraulic cylindrical masses on the top of the box (Figure 2 and 4). The pull-out force and the confinement stress are measured by load cells (Figures 3 and 4). The frontal displacement and the displacements along the length of the reinforcement are measured by six linear potentiometers (Figure 2).

The soil used in the tests is granular as illustrated by the particle size distribution curve shown in Figure 5. The sand had a maximum and minimum dry unit weights of  $18.9 \text{ kN/m}^3$  and  $16.1 \text{ kN/m}^3$ , respectively. The dry unit weight of the sand used in the tests was  $17.5 \text{ kN/m}^3$ . The friction angles, defined by direct shear tests, for this unit weight and the two confinement stresses (24.1 kPa and 48.4 kPa) used in the pull-out tests were  $37^\circ$  and  $35.2^\circ$ , respectively, being zero the cohesion of the soil. The geogrid tested was a HDPE uniaxial geogrid with a tensile strength of 55 kN/m. Each specimen had 0.33 m width and 0.96 m confined length at the beginning of the test and was positioned at the middle of 0.60 m height of sand. The constant displacement rate applied in the tests was 1.8 mm/min. Figure 6 shows the dimensions and the position of the points of measurement of the displacements along the reinforcement for the undamaged specimen. Either, the dimensions and the position of the points of measurement, were the same for all specimens tested during the study.

### 3 ANALYSIS OF RESULTS

To study the influence of reinforcement damage on the pull-out behaviour of the geogrid, six pull-out tests were carried out for each confinement stress. One of the tests performed was with the undamaged geogrid (SPU) (Figure 6) and the others five with the damaged specimens. The various configuration of the damaged specimens (SP1, SP2, SP3, SP4, SP5) and the points of measurement of the displacements along the geogrid are presented in Figure 7. This figure represents only the confined geogrid at the beginning of the test.

The variation of the pull-out force with the front displacement of the reinforcement is presented in Figure 8 for specimens SPU, SP1 and SP5 under a confinement stress of 48.4 kPa. Specimens SP1 and SP5 had the same damage configuration (four ribs were cut adjacent to the mid-width of specimen), but its position along the length of the geogrid was different (SP1 at the middle and SP5 at the front). It can be seen that the pull-out behaviour of specimen SP5 is very similar to that of the undamaged specimen until failure occurs by lack of tensile strength (tensile failure) at a front displacement of 0.096 m. Specimen SP1 fails by lack of pull-out resistance (shear failure) at a front displacement of 0.142 m for a maximum pull-out force of 33.10 kN/m. The maximum pull-out force for the undamaged specimen (SPU) was 36.44 kN/m, at a front displacement of 0.087 m.

The displacements by strain along the geogrid measured in the tests with specimens SPU, SP1 and SP5 under a confinement stress of 48.4 kPa are present in Figure 9. It can be seen that the contribution of the posterior part of specimen SP5 for the pull-out resistance of its interface with the soil is zero. In fact, bars 6, 7 and 8 do not move during the test. The higher strain in the anterior part of the geogrid can be justified by the localization of the damage (just in the entrance of the sleeve). In fact, as the pull

out of the geogrid starts the damaged zone goes inside the unconfined area of the sleeve, deforms more than the undamaged specimen and fails by lack of tensile strength before starting the mobilization of shear stresses in its interface with the soil in the posterior part of the geogrid. As the front part of specimen SP1 was not damaged, during pull-out all the geogrid length contributes for the pull-out resistance of its interface with the soil, failing when this maximum resistance is reached. Specimen SP1 shows lower displacements by strain in bar 6 than in bar 8. The reason is the position of the linear potentiometer in bar 6 (just in the back limit of the damaged area), showing a localized reduction in movements due to damage, suggesting the easier penetration of the soil grains in the larger apertures of the geogrid in the damaged area, with consequent local increase of the interlock mechanism.

Figures 10 and 11 present the results of the pull-out tests in terms of variation of the pull-out force with the front displacement of the reinforcement for confinement stresses of 48.4 kPa and 24.1 kPa, respectively, for an undamaged specimen (SPU) and four damaged specimens (SP1, SP2, SP3 and SP4) (see Figure 7). Table 1 shows, for the two confinement stresses considered, the maximum pull-out force measured for each specimen tested, and the ratio between this force and that measured for the undamaged specimen. Analogous presentation can be seen in Table 2 for the front displacement for the maximum pull-out force.

The influence of the confinement stress in the pull-out resistance of the geogrid is presented in Figure 12. This figure shows the displacements by strain along the undamaged specimen for the two values of the confinement stress used in the tests (48.4 kPa and 24.1 kPa). It can be concluded that the increase in the confinement stress leads to a significant increase in the pull-out resistance of the reinforcement, increasing the maximum pull-out force about 71 % when the confinement stress changes from 24.1 kPa to 48.4 kPa. This behaviour suggests the importance of the skin friction mechanism in the pull-out resistance of the geogrid tested.

Figures 10 and 11 and Table 1 suggest that the behaviour of damage type SP1 and SP2 is distinct from that of SP3 and SP4. In fact, for the less damaged specimens (SP1 and SP2) the failure occurs by lack of pull-out resistance, as in the undamaged specimen (SPU), and for the heavily damaged specimens (SP3 and SP4) the failure mode is lack of tensile strength. In damage type SP1 and SP2, although the extensibility of the reinforcement increases (see Table 2) its stiffness is enough to mobilize shear stresses all along its length. The maximum pull-out force is similar or even greater than that of the undamaged geogrid. The greater values obtained are, probably, due to the local increase in the dimensions of the geogrid with consequent easier penetration of the soil grains in it, leading to a local increase of passive thrust mobilization on the bearing members of the grid (see Figure 9, bar 6). Damage type SP3 and SP4 due to the strong reduction of reinforcement stiffness in the damaged zone inhibits the mobilization of shear stresses in the length of the geogrid located behind that zone.

Figure 7. Geogrid damaged specimens.

Figure 9. Displacements by strain along the geogrid (specimens SPU, SP1 and SP5,  $\sigma_{conf.}=48.4$  kPa).

In these cases only the remaining length contributes for the pull-out resistance of the reinforcement and failure occurs by lack of tensile resistance in the unconfined area of the sleeve.

The front displacement for the maximum pull-out force when the geogrid fails by lack of pull-out resistance (specimens SPU, SP1 and SP2) increases with damage (see Table 2). This is, the geogrid becomes more extensible with damage. This behaviour is more clear under a confinement stress of 48.4 kPa. In fact, for relatively similar values of maximum pull-out forces, the front displacement is about 45% to 63% higher when the specimen is damaged. The increase of confinement stress leads to an increase in maximum pull-out force and in front displacement for the maximum pull-out force. However, for damage configuration SP3 the influence of confinement stress is almost negligible.

The influence of damage is more important for higher confinement stresses. In fact, the extensibility of the damaged reinforcements increases more significantly, decreasing the ratio between the maximum pull-out forces of damaged and undamaged specimens when the confinement stress increases (see Tables 1 and 2).

#### 4 CONCLUSIONS

The study of the influence of reinforcement damage on the pull-out behaviour of a HDPE uniaxial geogrid embedded in a well graded very gravelly sand leads to the following major conclusions:

1. The localization of the same configuration of damage along the length of the geogrid can affect its pull-out behaviour, leading to tensile failure of the reinforcement when its location is near the front.

2. The configuration of damage can lead to a distinct behaviour of the geogrid: small damage leads to pull-out failure; large damage leads to tensile failure.
3. In general, damage increases the displacement at failure, the geogrid becoming more extensible.
4. In general, the increase of confinement stress leads to the increase of the maximum pull-out force and of the front displacement at the maximum pull-out force.
5. The influence of the geogrid damage on its pull-out behaviour increases significantly as the confinement stress increases, increasing the geogrid extensibility and decreasing the ratio between maximum pull-out forces of damaged and undamaged specimens.

# Full-Scale Dynamic Tests on Geocomposites as Waterproof Layer and Reinforcement of the Surface of Embankment

J. ZHANG

Ph. D. Candidate, Department of Civil Engineering, University of Canterbury, Christchurch, New Zealand

D. Y. ZOU

Lecturer, Department of Civil Engineering, Southwest Jiaotong University, Sichuan, P. R. of China

**ABSTRACT:** The paper introduces the four groups of the full-scale dynamic tests which have been done to investigate the effects of the geosynthetic complex layers to behaviors of embankment. The results of system modulus, stresses, and settlements in the embankment for the tests are compared, some conclusions are obtained: the thickness of optimal complex layer is 100mm; special attention should be given to geosynthetics that is directly paid between subgrade surface and ballast. Because geosynthetics is used, mud stone can be used as fill in the embankment.

**KEYWORD:** Composite Material, Embankments, Railroad Applications, Separation

## 1 INTRODUCTION

Mud stone is a kind of poor quality soil that can not be used as filling in the embankment. The reason is that when the mud stone is saturated, its strength will be very low. However, railroad has to pass extensive mud stone areas. Hence, the soil will be improved to suit the design code. Comparing with soil improvement, geosynthetics is an economic method. When ground water, i. e., spring, is not present, geocomposites (geotextiles + geomembrances + geotextiles) not only prevent water above it into mud stone (Selig and Waters 1994), but also improve the stress state of the subgrade. Thus the disadvantage of mud stone can be overcome. When the geocomposites and subballast are used together, their functions will be used completely. However, in the geocomposites, geomembrance is very important to the design. Hence, It is necessary that the second subballast layer is inserted between subballast and subgrade. In this case, The thickness of geocomposites and the second subballast layer (the thickness is called complex thickness) ( Fig. 1) is a key to an economic and safe design.

Figure 1. Confirmation of the embankment

For obtaining the optimal complex thickness, four complex thicknesses were tested. Comparisons of the stresses,

settlements and system moduli illustrate that the optimal complex thickness should be 100mm. The thickness assures the functions of subballast and avoids the abrasion and attrition between geocomposites and big particles..

## 2 MODEL TEST

### 2.1 Model and Material

The tests take 1:1 model to simulate the subgrade, ballast, subballast, sleeper. The size of the model box is 2.5m by 0.9m by 2.3m and it is made by steel frame and thick hard woods. In the analysis, because subgrade, subballast, ballast and superstructures are symmetry, only one-half of its section is taken.

According to measuring pressures on sites which illustrate that a axial weight will be taken by the successive 5 sleepers (Cui et al. 1994), maximum static pressure on the sleeper under the train wheel is 42 KN. However, because of the effects of track, train characteristics, and operating condition, measuring pressures on sites were in the range 45 KN - 60 KN. In terms of the above analysis, the static loading 45 KN and the dynamic maximum loading amplitude 15 KN were taken.

Subgrade clay was got from the site. special gravity  $G_s=2.67$ ; liquid limit  $W_L=36$ ; plastic limit  $W_p=23.1$ ; plasticity index  $I_p=13.5$ ; maximum dry density  $\rho_{dmax}=1.645g/cm^3$ ; optimal water content  $W_{opt}=20.5$ . In the filling, density was controlled by 95% maximum dry density.

The ballast was 250 mm thick. The subballast was 200 mm thick(Cui et al. 1994). The second subballast layer consists of sand and its thickness would be changed from 0 - 300mm.

The geocomposites consist of the two layers of non-woven geotextiles(Polyester) and a layer of geomembrance (PVC-Polyvinyl Chloride). Its weight is  $600g/m^2$  and thickness is about 2mm. Main parameters were measured in

the factory. tensile strength, puncture strength, and permeability strength were 600 N/5CM, 1.5MPa, 0.5 MPa, respectively. Before the tests, the ones were measured again which were 657 N/5CM, 1.92 KN, 0.825MPa, respectively(average value). A number of tests confirmed the parameters had change slightly.

## 2.2 Test Procedure

### 2.2.1 Test Equipment

All tests were done by the servo-hydraulic system. In the system, there are a displacement gauge and a load cell on the loading head. They measure total settlement and pressure. In the subgrade, displacement gauges, earth pressure cells, and acceleration gauges are setup along various height and away the loading center figure 2.

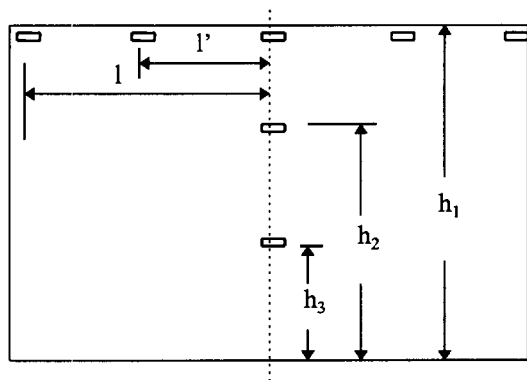

Figure 2. Location of instrument

### 2.2.2 Test Procedure

The test procedure should reflect situations on the site. Therefore, the thickness of the second subballast layer is a key factor, because it should spread stress from wheel load and prevent geomembranes from being punctured by big particles. At the same time, efficiency spreading stress by the second subballast layer was expected to be investigated. The four thicknesses of the second subballast layers which were 0mm, 100mm, 200mm, 300mm, respectively, were selected to the tests. According to different thickness, the location of some instruments were changed as followed: In model 1, the location of instruments were  $l=500\text{mm}$ ,  $h_1=850\text{mm}$ ,  $h_2=500\text{mm}$ ,  $h_3=200\text{mm}$ . In model 2, the location of instruments were  $l'=200\text{mm}$ ,  $h_1=750\text{mm}$ ,  $h_2=550\text{mm}$ ,  $h_3=350\text{mm}$ . In model 3, the locations of instruments were  $l'=200\text{mm}$ ,  $h_1=750\text{mm}$ ,  $h_2=550\text{mm}$ ,  $h_3=350\text{mm}$ . In model 4, the locations of instruments were  $l'=300\text{mm}$ ,  $h_1=75\text{mm}$ ,  $h_2=550\text{mm}$ ,  $h_3=350\text{mm}$  ( $l$  denotes distance from loading center;  $h$  denotes height from the bottom of box)

In the tests, the thickness and density of ballast and subgrade were the same. However, loading times would be

changed according to the cases. The loading times of the model 1 and 2 were one million times, respectively. The loading times of the model 3 and 4 were 500 thousand times, respectively. The different loading times among the models were decided by the total settlement.

## 3 RESULTS

### 3.1 Comparisons of deformation loading modulus

Deformation loading modulus  $E_v$  denotes the ratio of the stress and strain in the static loading. It will reflect the stiffness of system of the embankment (including ballast, subballast, geocomposites, and subgrade). For the new constructed embankment, initial deformation is very important. Therefore,  $E_v$  is important factor. The larger  $E_v$ , the smaller the settlement and the higher the density.

To investigate the change of the deformation loading modulus after the dynamic tests, the  $E_v$  was measured before and after the tests based on load plate test. The result of the model 1 is shown in figure 3.

Figure 3. Relation between load and settlement before and after test in model 1

It denotes that the settlement of the embankment is clearly reduced after dynamic test, hence  $E_v$  increases greatly. The relation between the load and settlement is non-linear before test, but the relation becomes linear after test. Figure 4 reflects the relation between  $E_v$  and the thickness of the second subballast layer. The deformation loading modulus  $E_v$  of the four models are nearly the same before tests. However the  $E_v$  increases when the thickness of the second subballast layer increases from 0 to 200mm, but when the thickness of the one is equal to 300mm, its  $E_v$  has nearly no change. The results show that the thickness of the complex layer made by the second subballast layer and geocomposites will directly affect the stiffness and stability of the embankment and if the complex layer is too thick, its function will be reduced. The stress at the interface between geocomposites and the subgrade will directly affect the settlement of the embankment. Five earth pressure cells were setup on the interface. Figure 5 gives results of model 1 and 2.

Figure 4. Relation between  $E_v$  and the thickness of complex layer

Figure 5. Stress of interface

Figure 6. Relation between maximum stresses and thickness of complex layer

### 3.2 Stress at Interface Between Geocomposites and the Subgrade

These results show that the complex layer reduces the stress peak at the interface between the geocomposites and the subgrade. Figure 6 compares the maximum stress of the four tests which illustrate the complex layer has the function reducing stress, but the efficiency will gradually reduce as the thickness of the complex layer increases. Therefore, the optimum thickness of complex layer is very important in the embankment design.

### 3.3 Distributed Stresses Along the Depth

The distributed stresses along the depth of the embankment causes the settlement of the embankment. The complex layer reduces the stress at the interface between the complex layer and subgrade (figure 5), the layer also affects the distributed stresses. Figure 7 shows the results of the model 1 and 2. In the top of subgrade, the stresses in the model 1 are greater than the ones in the model 2. However, in the low part of subgrade, the stresses in the model 1 are smaller than the ones in the model 2. This result denotes

that although the complex layer reduces the stresses at the interface, the stress attenuation along the depth of the embankment in the model 2 is slower than that in the model 1. Special attention should be given to a high speed train. Geocomposites which affects stresses in the embankment is very interesting. Figure 8 is the result in which stresses were measured above and below geocomposites. It efficiently reduce stresses below geocomposites and change the value of the stresses of distribution along the depth of embankment. At the 100mm range above and below geocomposites, the stresses are reduced by about 30%.

Figure 7. Distributed stresses in model 1 and 2

Figure 8. Effect of geocomposites on stress

### 3.4 Settlement of the Subgrade

The settlement of the surface of the subgrade will affect stability of the embankment and will increase cost of maintenance in the future and if settlement is greater, geocomposites will be in the dynamic extension state. Therefore, reducing settlement will be a key to the research. Figure 9 shows the results of settlement in the four models. These results illustrate that initial settlement is most part of total settlement. For example, initial settlement is 93% and 55% of the total settlement in the model 1 and 2, respectively. The result is conformable to stress analysis. Because the complex layer is on the surface of the subgrade, the settlement of subgrade is reduced greatly. If

the settlement in various models compares with the settlement of the model 1, the percent at model 2, 3, 4 is

Figure 9. Surface settlement of embankment

37%, 52%, and 59%. The efficiency of the complex layer is very clear. Figure 10 shows settlement along the depth of

Figure 10. Distributed settlement along embankment

the embankment. The result shows that the settlement will reduce as the thickness of the complex layer increases. This is also conformable to the distributed stresses.

### 3.5 Situation of the Geosynthetics

After the four model tests, the geocomposites were checked by eyes and tests. In the model 1, the surface of the geocomposites is very rough. The reason is that big particles in the first subballast layer and ballast contact the surface of the geocomposites under dynamic loading. However, in the model 2, 3, 4, the surfaces of the geocomposites were still

new after tests. The reason is that the second subballast layer separates big particles and geocomposites and avoids their contacts.

Comparing geocomposite properties before and after the tests, tensile strength, puncture strength, and tear strength were nearly the same. It illustrates that the geocomposite qualities are well and meet the need of the project.

## 4 CONCLUSIONS

According to the above analysis, some conclusions can be obtained:

1. The static system modulus will increase with the thickness of complex layer. However the efficiency of complex layer will gradually reduce as its thickness increases. Because complex layers are inserted between subgrade and ballast, the amplitude of dynamic stresses is reduced. It illustrates that complex layers have efficiency spreading stress.
2. With respect to the maximum stress in the model 1, the maximum stress in the model 2, 3, and 4 reduce 36%, 38%, and 39%, respectively. With respect to the settlement of subgrade surface in the model 1, the settlement of subgrade surface in the model 2, 3, and 4 reduce 37%, 52%, and 59%. Compared to these results, in practice, the complex layer 100mm in model 2 is optimal thickness.
3. Compared to state of geocomposites after tests, if there is no the second subballast layer (in model 1), the surface of geocomposites become very rough, the reason is that big particles contact the surface of geocomposites under dynamic loading. If the case is taken, the geomembrance in the geocomposites may be punctured out in the future. Therefore, attention must be given that geocomposites are directly laid between subgrade surface and the first subballast layer.

# Performance Test to simulate Geotextile Puncture under dynamic cyclic Loading

G. Mannsbart

Technical Manager, Polyfelt Ges. m. b. H., Linz, Austria

H. Breymann

Head of Geotechnical Department, Testing and Research Institute for Civil Engineering, Salzburg, Austria

**ABSTRACT:** Puncturing is one of the decisive stresses geotextiles are exposed to. For geotextiles used as separators under unpaved roads, the stress elongation behavior under dynamic puncture loading is of crucial importance. Dynamic and cyclic stresses caused by sharp edged aggregate have only been taken into account to a small amount in geotextile testing so far. On the basis of existing test methods (CBR-puncture according to EN 12236, Pyramid puncture according to ASTM 5494 and NFG 38019) a special test has been developed. The main modification is a cyclic up-and-down movement of the pyramid piston, which is pushed slowly into the geotextile.

The deformation and the puncture force are continuously measured, and the envelope of the obtained curves is the main characteristic of the geotextile behavior. Numerous test results have been obtained in the laboratory and will be cross-checked with the results from on-site trials. It is shown that needle punched non wovens perform very well. This is attributed to the rupture resistance and to the resistance to tearability of the product. To be able to withstand the harsh installation stresses, geotextiles have to show a clearly defined force elongation behavior in the dynamic cyclic loading test.

**KEYWORDS:** Dynamic mechanical analysis, Geotextiles, Installation Damage, Puncture Resistance, Separation

## 1 INTRODUCTION

Still the most common use of geotextiles is in road and pavement construction. Geotextiles increase stability and improve the performance of the subgrade by reducing deformations and by increasing the bearing capacity of the soil. (Polyfelt; 1986)

The primary function is separation, but also filtration, drainage, and strengthening of the soil may be regarded as secondary functions in road and pavement construction. The geotextile must prevent the movement of fines from the subgrades into the sub-base course. To be able to fulfill this requirement, it is necessary that the geotextile withstands all stresses during the installation phase.

Stresses occurring during installation are critical in most of the cases and therefore are regarded as decisive for design. Installation stress is understood here as the sum of puncturing, burst, and abrasive forces which occur during placement of the sub-base material as well as during compaction and loading by construction traffic. To simulate the forces exerted on a geotextile by a single sharp edged grain of the fill, a dynamic cyclic loading test has been developed.

## 2 TEST DESCRIPTION OF THE CYCLIC PYRAMID PUNCTURE TEST

### 2.1 Test Setup

When considering international specification tendencies, that aim to guarantee the separation function of geotextiles, one finds the CBR puncture resistance, Mullen Burst strength, and tear strength as essential specification criteria. In only a few standard specifications unit weight is also listed as a requirement. Dynamic and cyclic stresses caused by sharp edged aggregate have only been taken into account to a small amount in geotextile testing so far. (Bräu; 1996).

To be able to simulate the puncturing forces on a geotextile separator, a specific test method has been developed on the basis of existing test methods (CBR-puncture according to EN 12236, Pyramid puncture according to ASTM 5494 and NFG 38019; Werner; 1986). The main modification is a cyclic up-and-down movement of a pyramid-shaped piston, which is pushed slowly into the geotextile. By the use of this test the static and dynamic behavior of geotextiles under a pyramid load can be studied.

Figure 1: Scheme of the test device

The geotextile is positioned and fixed on a test pot. A pyramid shaped piston is used to simulate a sharp edged grain which exerts the stress during installation. The test pot has an inner diameter of 150 mm and a height of 150 mm. The fixing device was made in accordance with EN ISO 12 236.

Dynamic and static forces acting on the test pot due to the movement of the pyramid were measured.

For the dynamic puncture, the maximum value of the loading cycle is registered.

Figure 2: lay-out of the pyramid piston

## 2.2. Test Procedure

The test device offers the possibility to simulate both dynamic as well as static loading. Therefore, the test description is made in two parts.

### 2.2.1 Static Pyramid puncture test

In the static test, the piston is moved downward continuously until rupture occurs. The test is performed in analogy to EN ISO 12236. Instead of the cylindrical piston with 50 mm diameter the pyramid according to ASTM D 5494 is used (see Fig. 2). The velocity of the (upward) movement of the pot is  $10 \pm 1$  mm/min.

### 2.2.2 Dynamic Pyramid puncture test

In the dynamic test, the pyramid is exposed to cyclic up-and-down movement. The same 50-mm diameter cylindrical piston and the pyramid peak according to ASTM D 5494 are used.

The pyramid is moved up and down vertically by the use of an eccentric (see Fig. 3). At the same time, the test pot with the fixed geotextile is moved upwards against the oscillating pyramid. The force-elongation behavior is recorded.

The oscillating movement is achieved by an eccentric, which has an amplitude of  $\pm 5$  mm. The frequency of the vertical movement of the pyramid is 15 Hz.

Figure 3: Principle of dynamic (cyclic) loading.

The stress for the dynamic test is characterized by the following parameters:

- vertical (upward) velocity of the pot (= velocity of the fixed geotextile) [mm/min]. The pot is moved upwards continuously by a special device with a velocity of 10 mm/min. The allowable tolerance is  $\pm 1$  mm/min.
- maximum vertical displacement of the pyramid during it's oscillating movement [mm]
- Frequency (strokes per second) for the movement of the pyramid [Hz]

For every type of geotextile at least five single tests (static, dynamic) at  $23 \pm 2^\circ\text{C}$  should be performed. The mean values  $F_{\text{stat}}$ ,  $F_{\text{dyn}}$  and the standard-deviation are calculated.

### 2.2.3. Test results

The static puncture force  $F_{stat}$  is the maximum value of the forces (in Newtons) measured during puncturing of the fixed geotextile specimen.

The dynamic puncture Force  $F_{dyn}$  is the maximum value of the dynamic forces (in Newtons) measured during puncturing of the fixed geotextile specimen. Here puncturing will be achieved by the superposition of the oscillating movement of the pyramid with the continuous upward movement of the pot.

Figure 4: Graphical evaluation of the test results.

### 2.2.4 Boundary conditions

The test should be performed for at least 5 single specimens at  $23^\circ \pm 2^\circ$ . The curve of the force -elongation behavior is recorded.

The specimen has been prepared with a marking and cutting template and installed without any tension between the clamping rings.

The pot is fixed centered under the pyramid and the start-amplitude is fixed. For the start-amplitude of every test, the peak of the pyramid is lying without any tension on the surface of the fixed geotextile, and the pyramid has been set to the lowest point of the excenter.

The test is finished, if a decisive reduction of the puncture force is observed.

The evaluation is done according to the curves in Figure 4. The envelope curve of the arithmetic mean values is plotted.

The deformation has been determined by an electronic device in millimeters with an accuracy of  $\pm 0.1$  mm. The dynamic and the static puncture forces are given in

Newtons. The maximum of the obtained values is considered the puncture force.

### 2.2.5 Test report

In the test report the values obtained (static and dynamic puncture force) as well as the standard-deviation and the coefficient of variation are stated. A graphic evaluation (force-displacement curve) similar to the one given in figure 4 is enclosed.

## 3 TEST RESULTS

Large series of tests have been performed on various types of products. Thermobonded as well as needlepunched staple fibers and continuous filament nonwovens have been examined.

Among the results which have been obtained, results from a typical range of products are presented in this paper. Results for different grades of a specific polypropylene continuous filament nonwoven geotextile are given. The specimens have been tested with respect to both their static and dynamic puncture resistances. The properties of these products are given in Table 1.

Table 1 Properties of tested products

	Type A	Type B	Type C
CBR test [N]	2300	3500	4200
Tens. Str. [kN/m]	13.5	21.5	26.5
Elongat. MD/CD	80% / 45%	80% / 45%	80% / 45%
Weight [g/m <sup>2</sup> ]	200	315	400

At least 10 single tests have been performed for each of these grades. In Table 2 the mean values for the static puncture force ( $F_{stat}$ ) and the displacements at maximum load (Displ.-stat.) are given. Standard deviations and coefficients of variation obtained from these tests, are also shown in Table 2.

Table 2 Values obtained in the static puncture test

	Type A	Type B	Type C
F-stat. [N]	609.49	941.34	1285.20
Sdev	152.36	234.46	165.51
CVar	25	24.91	12.88
Displ.-stat.[mm]	42.8	42.90	47.60
Sdev	2.0	2.92	1.51
Cvar.	4.90	6.81	3.16

The graphical results for geotextile C are shown in Figure 5.

#### 4 ON SITE TESTS

To be able to show a correlation between laboratory and field tests, it is intended to perform onsite tests with sharp edged granular material on soft and weak subgrades.

For these tests sharp edged diabas granulate will be used and the performance of different geotextiles will be studied.

#### 5 CONCLUSION AND OUTLOOK

By a newly developed test method it is possible to evaluate the performance of a geotextile under dynamic loading. The properties of a product can be described by its behavior under static and dynamic puncturing and the force-deformation behavior can be quantified. By the use of the described test, a clearer more performance-orientated specification can be made possible.

An analysis of the first series of tests has shown the following significant results:

- The values for dynamic puncturing are far below the ones for the static tests.
- The shape of the curve is similar for both the static and the dynamic tests. Differences can mainly be seen in the behavior after rupture; the static tests show a sudden decrease, whereas the dynamic tests show a slow decrease.
- Static as well as dynamic tests show a relation between performance and the weight per unit area for each product type. However, the manufacturing process is of decisive importance for the performance of the geotextile. Therefore weight alone is not an adequate parameter for specification and should (if necessary) only be used as identification parameter.

It seems necessary to continue testing both in the laboratory as well as on full scale trials on site.
