SOLMAX

# Foreword

This Sixth International Conference on Geosynthetics, held in Atlanta in 1998, celebrated 21 years of international development of the geosynthetics discipline, much of it nurtured by the International Geosynthetics Society (IGS), under whose auspices the conference is held. For the past 15 years, the IGS, through the IGS Officers, the IGS Council, its committees, and the hard work of many individual members and their affiliated organizations, has fostered the development of this regular series of international conferences. The IGS also has been active in the development of chapters that provide local activities, including regional conferences and seminars, the publication of a directory and newsletter (IGS News), and associations with two first class international journals (*Geotextiles and Geomembranes* and *Geosynthetics International*), to name but a few of its many achievements.

The first of these international conferences (called the "International Conference on the Use of Fabrics in Geotechnics") was held in Paris, France in 1977. The subsequent conferences, held in Las Vegas, U.S.A. (1982), Vienna, Austria (1986), The Hague, The Netherlands (1990), and Singapore (1994), had a variety of titles, the most recent being the melodic but lengthy "International Conference on Geotextiles, Geomembranes and Related Products". Since the first conference, the geosynthetics discipline has matured. We have seen the adoption of terms like geotextiles and geomembranes (coined by J.P. Giroud in 1977), then geonets, geogrids, geocomposites, geosynthetic clay liners and geofoam, encompassed by the generic term "geosynthetics." The conference in Atlanta is the first to simply be called the International Conference on Geosynthetics signalling a maturity that fits with the passage of 21 years.

The maturing of the discipline also brings with it changes in the way these international conferences are run. There now are many regional and local conferences on geosynthetics; hence this conference has attempted to focus on papers that are likely to be of broader international interest rather than specific local interests. It is the first international conference on geosynthetics where all the final papers were peer-reviewed. This has involved a great deal of work for the Secretariat and the Session and Workshop Chairs, who coordinated the reviews of all the papers. Of the initial 428 papers for which abstracts were received, 185 were eventually accepted after peer review of the final papers. It was a challenge getting so many papers from so many parts of the world reviewed, corrected, and finally collected together in these proceedings. Many thanks to all those who contributed to this process; to the extent that the quality of papers has been improved by the review process, it is due to the diligence of the reviewers and the cooperation of the authors.

This is also the first conference in which there was no page limit on contributions. All papers had to be a minimum of four pages, but longer papers were accepted where the author and the reviewers agreed that a longer paper was appropriate. By providing this flexibility, we hope that the key details so often omitted from short conference papers have not been omitted here.

In another break with tradition, the first Giroud Lecture and the three Keynote Lectures all are contained in the proceedings available at the conference, and there will be no post-conference volume. The first volume of the proceedings includes the special lectures and the papers associated with the Environmental Applications theme. The second volume contains the papers relating to the two other primary conference themes: Soil Reinforcement Applications and Geotechnical and Hydraulic Applications.

In addition to the usual parallel sessions, we also have introduced a series of workshops, in which fewer papers are presented so as to allow more time for discussion of the topic by a smaller group of individuals keenly interested in the specific technical area. As usual, we have included some papers as posters where the author(s) can interact on a one-to-one basis with those interested in the topic. Finally, we will have three panel sessions dealing with "Users' Questions - Industry's Response" in the fields of Environmental Applications, Reinforcement Applications, and Hydraulic & Geotechnical Applications. The moderators of these sessions have been invited to write an article on their sessions to appear in the IGS News.

More than 100 people—including the Technical Committee members, the Sessions Chairs and Co-Chairs, the Workshop Chairs and Co-Chairs and numerous other individuals—reviewed papers and provided constructive advice to authors. Special thanks are due to the Conference Chair, Dr. R. M. Koerner, the Chairman of the International Advisory Board, Dr. J.P. Giroud, and the Intermediary to NAGS, Dr. B. Christopher, for their assistance to the Technical Committee. Special thanks are also due to Mr. S. Warner for the support of IFAI and to the IFAI staff, Ms. D. Fettig, Ms. J. McGovern and Ms. S. Kuehl, who were responsible for handling all the papers, correspondence and communications with reviewers and authors. Finally, thank you to the authors, for without your intellectual contributions, hard work and patience there would be no conference proceedings and no conference.

# Analysis and Design of Veneer Cover Soils

Robert M. Koerner

Professor and Director, Geosynthetic Research Institute, Drexel University, Philadelphia, Pennsylvania, USA

Te-Yang Soong

Research Engineer, Geosynthetic Research Institute, Drexel University, Philadelphia, Pennsylvania, USA

**ABSTRACT:** The sliding of cover soils on slopes underlain by geosynthetics is obviously an unacceptable situation and, if the number of occurrences becomes excessive, will eventually reflect poorly on the entire technology. Steeply sloped leachate collection layers and final covers of landfills are situations where incidents of such sliding have occurred. Paradoxically, the analytic formulation of the situation is quite straightforward. This paper presents an analysis of the common problem of a veneer of cover soil (0.3 to 1.0 m thick) on a geosynthetic material at a given slope angle and length so as to arrive at a FS-value. The paper then presents different scenarios that create lower FS-values than the gravitational stresses of the above situation, e.g., equipment loads, seepage forces and seismic loads. As a counterpoint, different scenarios that create higher FS-values also are presented, e.g., toe berms, tapered thickness cover soils and veneer reinforcement. In this latter category, a subdivision is made between intentional reinforcement (using geogrids or high strength geotextiles) and nonintentional reinforcement (cases where geosynthetics overlay a weak interface within a multilayered slope). Hypothetical numeric examples are used in each of the above situations to illustrate the various influences on the resulting FS-value. In many cases, design curves are also generated. Suggested minimum FS-values are presented for final closures of landfills, waste piles, leach pads, etc., which are the situations where veneer slides of this type are the most troublesome. Hopefully, the paper will serve as a vehicle to bring a greater awareness to such situations so as to avert slides from occurring in the future.

**KEYWORDS:** Analysis, Design, Limit Equilibrium Methods, Steep Slopes, Veneer Stability.

## 1 INTRODUCTION

There have been numerous cover soil stability problems in the past resulting in slides that range from being relatively small (which can be easily repaired), to very large (involving litigation and financial judgments against the parties involved). Furthermore, the number of occurrences appears to have increased over the past few years. Soong and Koerner (1996) report on eight cover soil failures resulting from seepage induced stresses alone. While such slides can occur in transportation and geotechnical applications, it is in the environmental applications area where they are most frequent. Specifically, the sliding of relatively thin cover soil layers (called "veneer") above both geosynthetic and natural soil liners, i.e., geomembranes (GM), geosynthetic clay liners (GCL) and compacted clay liners (CCL) are the particular materials of concern. These situations represent a major challenge due (in part) to the following reasons:

- (a) The underlying barrier materials generally represent a low interface shear strength boundary with respect to the soil placed above them.
- (b) The liner system is oriented precisely in the direction of potential sliding.
- (c) The potential shear planes are usually linear and are essentially uninterrupted along the slope.
- (d) Liquid (water or leachate) cannot continue to percolate downward through the cross section due to the presence of the barrier material.

When such slopes are relatively steep, long and uninterrupted in their length (which is the design goal for landfills, waste piles and surface impoundments so as to maximize containment space and minimize land area), the situation is exacerbated.

There are two specific applications in which cover soil stability has been difficult to achieve in light of this discussion.

- Leachate collection soil placed above a GM, GCL and/or CCL along the sides of a landfill before waste is placed and stability achieved accordingly.
- Final cover soil placed above a GM, GCL and/or CCL in the cap or closure of a landfill or waste pile after the waste has been placed to its permitted height.

For the leachate collection soil situation, the time frame is generally short (from months to a few years) and the implications of a slide may be minor in that repairs can oftentimes be done by on-site personnel. For the final cover soil situation, the time frame is invariably long (from decades to centuries) and the implications of a slide can be serious in that repairs often call for a forensic analysis, engineering redesign, separately engaged contractors and quite high remediation costs. These latter cases sometime involve litigation, insurance carriers, and invariably technical experts, thus becoming quite contentious.

Since both situations (leachate collection and final covers) present the same technical issues, the paper will address them simultaneously. It should be realized, however, that the final cover situation is of significantly greater concern.

In the sections to follow, geotechnical engineering considerations will be presented leading to the goal of establishing a suitable factor of safety (FS) against slope instability. A number of common situations will then be analyzed, all of which have the tendency to decrease stability. As a counterpoint, a number of design options will follow, all of which have the objective of increasing stability. A summary and conclusions section will compare the various situations which tend to either create slope instability or aid in slope stability. It is hoped that an

increased awareness in the analysis and design details offered herein, and elsewhere in the published literature which is referenced herein, leads to a significant decrease in the number of veneer cover soil slides that have occurred.

## 2 GEOTECHNICAL ENGINEERING CONSIDERATIONS

As just mentioned, the potential failure surface for veneer cover soils is usually linear with the cover soil sliding with respect to the lowest interface friction layer in the underlying cross section. The potential failure plane being linear allows for a straightforward stability calculation without the need for trial center locations and different radii as with soil stability problems analyzed by rotational failure surfaces. Furthermore, full static equilibrium can be achieved without solving simultaneous equations or making simplified design assumptions.

### 2.1 Limit Equilibrium Concepts

The free body diagram of an *infinitely* long slope with uniformly thick cohesionless cover soil on an incipient planar shear surface, like the upper surface of a geomembrane, is shown in Figure 1. The situation can be treated quite simply.

Figure 1. Limit equilibrium forces involved in an infinite slope analysis for a uniformly thick cohesionless cover soil.

By taking force summation parallel to the slope and comparing the resisting force to the driving or mobilizing force, a global factor of safety (FS) results;

$$FS = \frac{\sum \text{Resisting Forces}}{\sum \text{Driving Forces}} = \frac{N \tan \delta}{W \sin \beta} = \frac{W \cos \beta \tan \delta}{W \sin \beta}$$

hence:

$$FS = \frac{\tan \delta}{\tan \beta} \quad (1)$$

Here it is seen that the FS-value is the ratio of tangents of the interface friction angle of the cover soil against the

upper surface of the geomembrane ( $\delta$ ), and the slope angle of the soil beneath the geomembrane ( $\beta$ ). As simple as this analysis is, its teachings are very significant, for example:

- To obtain an accurate FS-value, an accurately determined laboratory  $\delta$ -value is absolutely critical. The accuracy of the final analysis is only as good as the accuracy of the laboratory obtained  $\delta$ -value.
  - For low  $\delta$ -values, the resulting soil slope angle will be proportionately low. For example, for a  $\delta$ -value of 20 deg., and a required FS-value of 1.5, the maximum slope angle is 14 deg. This is equivalent to a 4(H) on 1(V) slope which is relatively low. Furthermore, many geosynthetics have even lower  $\delta$ -values than 20 deg.
  - This simple formula has driven geosynthetic manufacturers to develop products with high  $\delta$ -values, e.g., textured geomembranes, thermally bonded drainage geocomposites, internally reinforced GCLs, etc.
- Unfortunately, the above analysis is too simplistic to use in most realistic situations. For example, the following situations cannot be accommodated:
- A finite length slope with the incorporation of a passive soil wedge at the toe of the slope
  - The consideration of equipment loads on the slope
  - Consideration of seepage forces within the cover soil
  - Consideration of seismic forces acting on the cover soil
  - The use of soil masses acting as toe berms
  - The use of tapered covered soil thicknesses
  - Reinforcement of the cover soil using geogrids or high strength geotextiles

These specific situations will be treated in subsequent sections. For each situation, the essence of the theory will be presented, followed by the necessary design equations. This will be followed, in each case, with a design graph and a numeric example. First, however, the important issue of interface shear testing will be discussed.

### 2.2 Interface Shear Testing

The interface shear strength of a cover soil with respect to the underlying material (often a geomembrane) is critical so as to properly analyze the stability of the cover soil. This value of interface shear strength is obtained by laboratory testing of the project specific materials at the site specific conditions. By project specific materials, we mean sampling of the candidate geosynthetics to be used at the site, as well as the cover soil at its targeted density and moisture conditions. By site specific conditions we mean normal stresses, strain rates, peak or residual shear strengths and temperature extremes (high and/or low). Note that it is completely inappropriate to use values of interface shear strengths from the literature for final design.

While the above list of items is formidable, at least the type of test is established. It is the direct shear test which has been utilized in geotechnical engineering testing for many years. The test has been adapted to evaluate geosynthetics in the USA as ASTM D5321 and in Germany as DIN 60500.

In conducting a direct shear test on a specific interface, one typically performs three replicate tests with the only

variable being different values of normal stress. The middle value is usually targeted to the site specific condition, with a lower and higher value of normal stress covering the range of possible values. These three tests result in a set of shear displacement versus shear stress curves, see Figure 2a. From each curve, a peak shear strength ( $\tau_p$ ) and a residual shear strength ( $\tau_r$ ) are obtained. As a next step, these shear strength values, together with their respective normal stress values, are plotted on Mohr-Coulomb stress space to obtain the shear strength parameters of friction and adhesion, see Figure 2b.

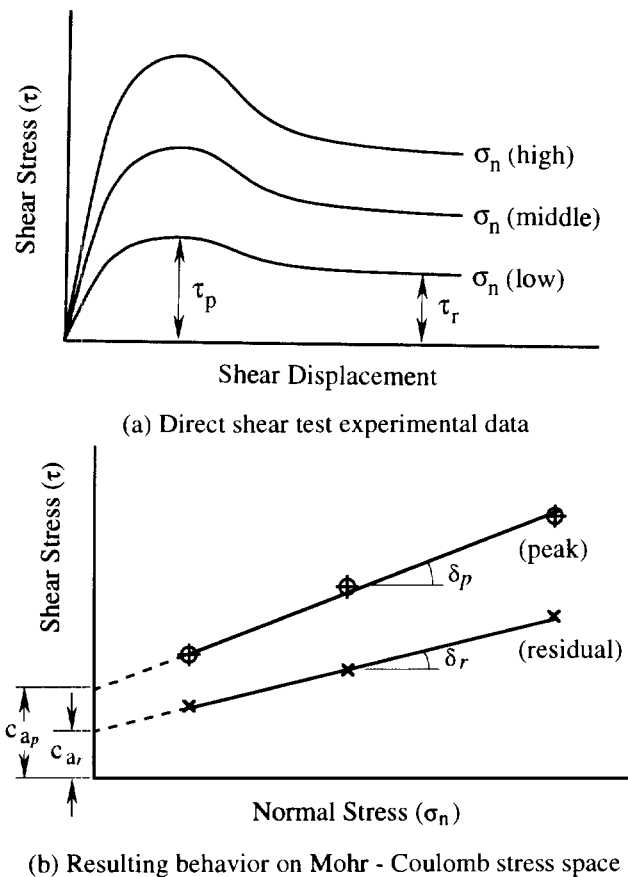

Figure 2. Direct shear test results and analysis procedure to obtain shear strength parameters.

The points are then connected (usually with a straight line), and the two fundamental shear strength parameters are obtained. These shear strength parameters are:

$\delta$  = the angle of shearing resistance, peak and/or residual, of the two opposing surfaces (often called the interface friction angle)

$c_a$  = the adhesion of the two opposing surfaces, peak and/or residual (synonymous with cohesion when testing fine grained soils against one another)

Each set of parameters constitute the equation of a straight line which is the Mohr-Coulomb failure criterion common to geotechnical engineering. The concept is readily adaptable to geosynthetic materials in the following form:

$$\tau_p = c_{ap} + \sigma_n \tan \delta_p \quad (2a)$$

$$\tau_r = c_{ar} + \sigma_n \tan \delta_r \quad (2b)$$

The upper limit of “ $\delta$ ” when soil is involved as one of the interfaces is “ $\phi$ ”, the angle of shearing resistance of the soil component. The upper limit of the “ $c_a$ ” value is “ $c$ ”, the cohesion of the soil component. In the slope stability analyses to follow, the “ $c_a$ ” term will be included for the sake of completeness, but then it will be neglected (as being a conservative assumption) in the design graphs and numeric examples. To utilize an adhesion value, there must be a clear physical justification for use of such values when geosynthetics are involved. Some unique situations such as textured geomembranes with physical interlocking of soils having cohesion, or the bentonite component of a GCL are valid reasons for including such a term.

Note that residual strengths are equal, or lower, than peak strengths. The amount of difference is very dependent on the material and no general guidelines can be given. Clearly, material specific and site specific direct shear tests must be performed to determine the appropriate values. Further, each direct shear test must be conducted to a relatively large displacement to determine the residual behavior, see Stark and Poepfel (1994). The decision as to the use of peak or residual strengths in the subsequent analysis is a very subjective one. It is both a materials specific and site specific issue which is left up to the designer and/or regulator. Even further, the use of peak values at the crest of a slope and residual values at the toe may be justified. As such, the analyses to follow will use an interface  $\delta$ -value with no subscript thereby concentrating on the computational procedures rather than this particular detail. However, the importance of an appropriate and accurate  $\delta$ -value should not be minimized.

Due to the physical structure of many geosynthetics, the size of the recommended shear box is quite large. It must be at least 300 mm by 300 mm unless it can be shown that data generated by a smaller device contains no scale or edge effects, i.e., that no bias exists with a smaller shear box. The implications of such a large shear box should not be taken lightly. Some issues which should receive particular attention are the following:

- Unless it can be justified otherwise, the interface will usually be tested in a saturated state. Thus complete and uniform saturation over the entire specimen area must be achieved. This is particularly necessary for CCLs and GCLs, Daniel, et al. (1993). Hydration takes relatively long in comparison to soils in conventional (smaller) testing shear boxes.
- Consolidation of soils (including CCLs and GCLs) in larger shear boxes is similarly affected.
- Uniformity of normal stress over the entire area must be maintained during consolidation and shearing so as to avoid stress concentrations from occurring.
- The application of relatively low normal stresses, e.g., 10, to 30 kPa simulating typical cover soil thicknesses, challenges the accuracy of some commercially available shear box setups and monitoring systems, particularly the accuracy of pressure gages.

- The issue of appropriate normal stress is greatly complicated if gas pressures are generated in the underlying waste. These gas pressures will counteract some (or all) of the gravitational stress of the cover soil. The resulting shear strength, and subsequent stability, can be significantly decreased. See Liu et al (1997) for insight into this possibility.
- Shear rates necessary to attain drained conditions (if this is the desired situation) are extremely slow, requiring long testing times.
- Deformations necessary to attain residual strengths require large relative movement of the two respective halves of the shear box. So as not to travel over the edges of the opposing shear box sections, devices should have the lower shear box significantly longer than 300 mm. However, with a lower shear box longer than the upper traveling section, new surface is constantly being added to the shearing plane. This influence is not clear in the material's response or in the subsequent behavior.
- The attainment of a true residual strength is difficult to achieve. ASTM D5321 states that one should "run the test until the applied shear force remains constant with increasing displacement". Many commercially available shear boxes have insufficient travel to reach this condition.
- The ring torsion shearing apparatus is an alternative device to determine true residual strength values, but is not without its own problems. Some outstanding issues are the small specimen size, nonuniform shear rates along the width of the specimen, anisotropic shearing with some geosynthetics and no standardized testing protocol. See Stark and Poepfel (1994) for information and data using this alternative test method.

### 2.3 Various Types of Loadings

There are a large variety of slope stability problems that may be encountered in analyzing and/or designing final covers of engineered landfills, abandoned dumps and remediation sites as well as leachate collection soils covering geomembranes beneath the waste. Perhaps the most common situation is a uniformly thick cover soil on a geomembrane placed over the soil subgrade at a given and constant slope angle. This "standard" problem will be analyzed in the next section. A variation of this problem will include equipment loads used during placement of cover soil on the geomembrane. This problem will be solved with equipment moving up the slope and then moving down the slope.

Unfortunately, cover soil slides have occurred and it is felt that the majority of the slides have been associated with seepage forces. Indeed, drainage above a geomembrane (or other barrier material) in the cover soil cross section must be accommodated to avoid the possibility of seepage forces. A section will be devoted to this class of slope stability problems.

Lastly, the possibility of seismic forces exists in earthquake prone locations. If an earthquake occurs in the vicinity of an engineered landfill, abandoned dump or remediation site, the seismic wave travels through the solid waste mass reaching the upper surface of the cover. It then

decouples from the cover soil materials, producing a horizontal force which must be appropriately analyzed. A section will be devoted to the seismic aspects of cover soil slope analysis as well.

All of the above actions are destabilizing forces tending to cause slope instability. Fortunately, there are a number of actions that can be taken to increase the stability of slopes.

Other than geometrically redesigning the slope with a flatter slope angle or shorter slope length, a designer can add soil mass at the toe of the slope thereby enhancing stability. Both toe berms and tapered soil covers are available options and will be analyzed accordingly. Alternatively, the designer can always use geogrids or high strength geotextiles within the cover soil acting as reinforcement materials. This technique is usually referred to as veneer reinforcement. Cases of both intentional and nonintentional veneer reinforcement will be presented.

Thus it is seen that a number of strategies influence slope stability. Each will be described in the sections to follow. First, the basic gravitational problem will be presented followed by those additional loading situations which tend to decrease slope stability. Second, various actions that can be taken by the designer to increase slope stability will be presented. The summary will contrast the FS-values obtained in the similarly crafted numeric examples.

## 3 SITUATIONS CAUSING DESTABILIZATION OF SLOPES

This section treats the standard veneer slope stability problem and then superimposes upon it a number of situations, all of which tend to destabilize slopes. Included are gravitational, construction equipment, seepage and seismic forces. Each will be illustrated by a design graph and a numeric example.

### 3.1 Cover Soil (Gravitational) Forces

Figure 3 illustrates the common situation of a *finite* length, uniformly thick cover soil placed over a liner material at a slope angle " $\beta$ ". It includes a passive wedge at the toe and has a tension crack of the crest. The analysis that follows is after Koerner and Hwu (1991), but comparable analyses are available from Giroud and Beech (1989), McKelvey and Deutsch (1991), Ling and Leshchinsky (1997) and others.

Figure 3. Limit equilibrium forces involved in a finite length slope analysis for a uniformly thick cover soil.

The symbols used in Figure 3 are defined below.

- $W_A$  = total weight of the active wedge  
 $W_P$  = total weight of the passive wedge  
 $N_A$  = effective force normal to the failure plane of the active wedge  
 $N_P$  = effective force normal to the failure plane of the passive wedge  
 $\gamma$  = unit weight of the cover soil  
 $h$  = thickness of the cover soil  
 $L$  = length of slope measured along the geomembrane  
 $\beta$  = soil slope angle beneath the geomembrane  
 $\phi$  = friction angle of the cover soil  
 $\delta$  = interface friction angle between cover soil and geomembrane  
 $C_a$  = adhesive force between cover soil of the active wedge and the geomembrane  
 $c_a$  = adhesion between cover soil of the active wedge and the geomembrane  
 $C$  = cohesive force along the failure plane of the passive wedge  
 $c$  = cohesion of the cover soil  
 $E_A$  = interwedge force acting on the active wedge from the passive wedge  
 $E_P$  = interwedge force acting on the passive wedge from the active wedge  
 $FS$  = factor of safety against cover soil sliding on the geomembrane

The expression for determining the factor of safety can be derived as follows:

Considering the active wedge,

$$W_A = \gamma h^2 \left( \frac{L}{h} - \frac{1}{\sin \beta} - \frac{\tan \beta}{2} \right) \quad (3)$$

$$N_A = W_A \cos \beta \quad (4)$$

$$C_a = c_a \left( L - \frac{h}{\sin \beta} \right) \quad (5)$$

By balancing the forces in the vertical direction, the following formulation results:

$$E_A \sin \beta = W_A - N_A \cos \beta - \frac{N_A \tan \delta + C_a}{FS} \sin \beta \quad (6)$$

Hence the interwedge force acting on the active wedge is:

$$E_A = \frac{(FS)(W_A - N_A \cos \beta) - (N_A \tan \delta + C_a) \sin \beta}{\sin \beta (FS)} \quad (7)$$

The passive wedge can be considered in a similar manner:

$$W_P = \frac{\gamma h^2}{\sin 2\beta} \quad (8)$$

$$N_P = W_P + E_P \sin \beta \quad (9)$$

$$C = \frac{(c)(h)}{\sin \beta} \quad (10)$$

By balancing the forces in the horizontal direction, the following formulation results:

$$E_P \cos \beta = \frac{C + N_P \tan \phi}{FS} \quad (11)$$

Hence the interwedge force acting on the passive wedge is:

$$E_P = \frac{C + W_P \tan \phi}{\cos \beta (FS) - \sin \beta \tan \phi} \quad (12)$$

By setting  $E_A = E_P$ , the resulting equation can be arranged in the form of the quadratic equation  $ax^2 + bx + c = 0$  which in our case, using FS-values, is:

$$a(FS)^2 + b(FS) + c = 0 \quad (13)$$

where

$$a = (W_A - N_A \cos \beta) \cos \beta$$

$$b = - \left[ (W_A - N_A \cos \beta) \sin \beta \tan \phi + (N_A \tan \delta + C_a) \sin \beta \cos \beta + \sin \beta (C + W_P \tan \phi) \right]$$

$$c = (N_A \tan \delta + C_a) \sin^2 \beta \tan \phi \quad (14)$$

The resulting FS-value is then obtained from the solution of the quadratic equation:

$$FS = \frac{-b + \sqrt{b^2 - 4ac}}{2a} \quad (15)$$

When the calculated FS-value falls below 1.0, sliding of the cover soil on the geomembrane is to be anticipated. Thus a value of greater than 1.0 must be targeted as being the minimum factor of safety. How much greater than 1.0 the FS-value should be, is a design and/or regulatory issue. The issue of minimum allowable FS-values under different conditions will be assessed at the end of the paper. In order to better illustrate the implications of Eqs. 13, 14 and 15, typical design curves for various FS-values as a function of slope angle and interface friction angle are given in Figure 4. Note that the curves are developed specifically for the variables stated in the legend of the figure. Example 1 illustrates the use of the curves in what will be the standard example to which other examples will be compared.

Example 1:

Given a 30 m long slope with a uniformly thick 300 mm cover soil at a unit weight of 18 kN/m<sup>3</sup>. The soil has a friction angle of 30 deg. and zero cohesion, i.e., it is a sand. The cover soil is placed directly on a geomembrane as shown in Figure 3. Direct shear testing has resulted in a interface friction angle between the cover soil and geomembrane of 22 deg. with zero adhesion. What is the FS-value at a slope angle of 3(H)-to-1(V), i.e., 18.4 deg?

Solution:

Substituting Eq. 14 into Eq. 15 and solving for the FS-value results in the following which is seen to be in agreement with the curves of Figure 4.

$$\left. \begin{aligned} a &= 14.7 \text{ kN / m} \\ b &= -21.3 \text{ kN / m} \\ c &= 3.5 \text{ kN / m} \end{aligned} \right\} \text{FS} = 1.25$$

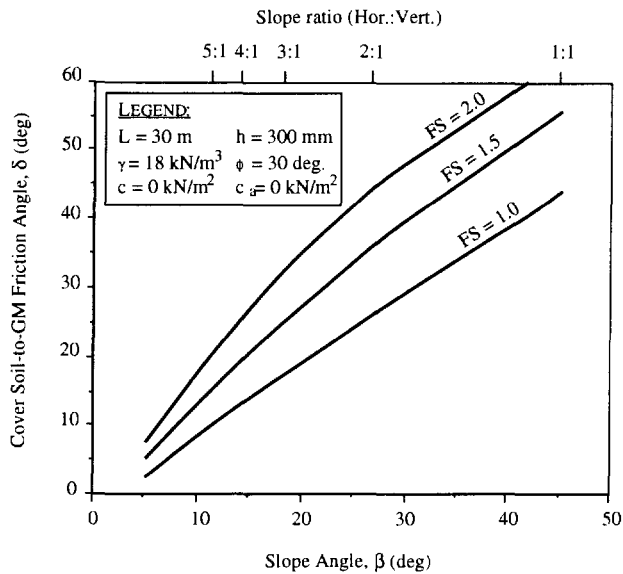

Figure 4. Design curves for stability of uniform thickness cohesionless cover soils on linear failure planes for various global factors-of-safety.

Comment:

In general, this is too low of a value for a final cover soil factor-of-safety and a redesign is necessary. While there are many possible options of changing the geometry of the situation, the example will be revisited later in this section using toe berms, tapered cover soil thickness and veneer reinforcement. Furthermore, this general problem will be used throughout the main body of this paper for comparison purposes to other cover soil slope stability situations.

### 3.2 Tracked Construction Equipment Forces

The placement of cover soil on a slope with a relatively low shear strength inclusion (like a geomembrane) should always be from the toe upward to the crest. Figure 5a shows the recommended method. In so doing, the gravitational forces of the cover soil and live load of the construction equipment are compacting previously placed soil and working with an ever present passive wedge and stable lower-portion beneath the active wedge. While it is necessary to specify low ground pressure equipment to place the soil, the reduction of the FS-value for this situation of equipment working up the slope will be seen to be relatively small.

For soil placement down the slope, however, a stability analysis cannot rely on toe buttressing and also a dynamic stress should be included in the calculation. These conditions decrease the FS-value and in some cases to a great extent. Figure 5b shows this procedure. Unless absolutely necessary, it is not recommended to place cover soil on a slope in this manner. If it is necessary, the design must consider the unsupported soil mass and the dynamic force of the specific type of construction equipment and its manner of operation.

Figure 5. Construction equipment placing cover soil on slopes containing geosynthetics.

For the first case of a bulldozer pushing cover soil up from the toe of the slope to the crest, the analysis uses the free body diagram of Figure 6a. The analysis uses a specific piece of tracked construction equipment (like a bulldozer) characterized by its ground contact pressure and dissipates this force or stress through the cover soil thickness to the surface of the geomembrane. A Boussinesq analysis is used, see Poulos and Davis (1974). This results in an equipment force per unit width as follows:

$$W_e = qwI \quad (16)$$

where

$$\begin{aligned} W_e &= \text{equivalent equipment force per unit width at the} \\ &\quad \text{geomembrane interface} \\ q &= W_b / (2 \times w \times b) \end{aligned}$$

- $W_b$  = actual weight of equipment (e.g., a bulldozer)
- $w$  = length of equipment track
- $b$  = width of equipment track
- $I$  = influence factor at the geomembrane interface  
see Figure 7

Figure 6. Additional (to gravitational forces) limit equilibrium forces due to construction equipment moving on cover soil (see Figure 3 for the gravitational soil force to which the above forces are added).

Upon determining the additional equipment force at the cover soil-to-geomembrane interface, the analysis proceeds as described in Section 3.1 for gravitational forces only. In essence, the equipment moving up the slope adds an additional term,  $W_e$ , to the  $W_A$ -force in Eq. 3. Note, however, that this involves the generation of a resisting force as well. Thus, the net effect of increasing the driving force as well as the resisting force is somewhat neutralized insofar as the resulting FS-value is concerned. It should also be noted that no acceleration/deceleration forces are included in this analysis which is somewhat optimistic. Using these concepts (the same equations used in Section 3.1 are used here), typical design curves for various FS-values as a function of equivalent ground contact equipment pressures and cover soil thicknesses are given in Figure 8. Note that the curves are developed specifically for the variables stated in the legend. Example 2a illustrates the use of the formulation.

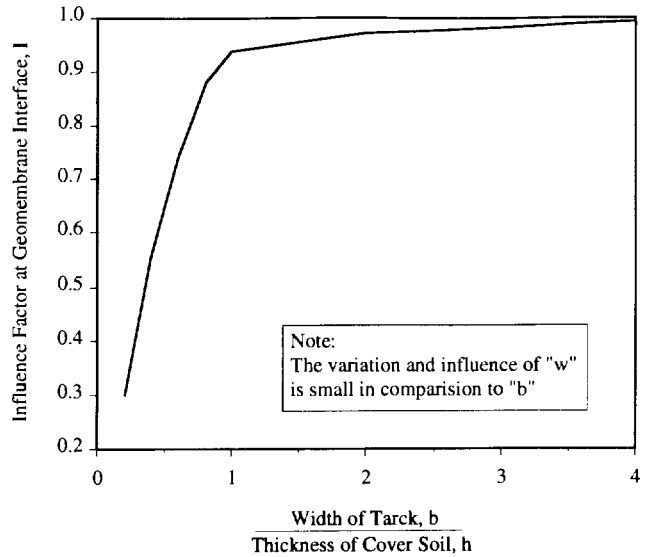

Figure 7. Values of influence factor, "I", for use in Eq. 16 to dissipate surface force of tracked equipment through the cover soil to the geomembrane interface, after Poulos and Davis (1974).

Figure 8. Design curves for stability of different thickness of cover soil for various values of tracked ground contact pressure construction equipment.

Example 2a:

Given 30 m long slope with uniform cover soil of 300 mm thickness at a unit weight of 18 kN/m<sup>3</sup>. The soil has a friction angle of 30 deg. and zero cohesion, i.e., it is a sand. It is placed on the slope using a bulldozer moving from the toe of the slope up to the crest. The bulldozer has a ground pressure of 30 kN/m<sup>2</sup> and tracks that are 3.0 m long and 0.6 m wide. The cover soil to geomembrane friction angle is 22 deg. with zero adhesion. What is the FS-value at a slope angle of 3(H)-to-1(V), i.e., 18.4 deg.

Solution:

This problem follows Example 1 exactly except for the addition of the bulldozer moving up the slope. Using the additional equipment load Eq. 16, substituted into Eqs. 14 and 15 results in the following.

$$\left. \begin{aligned} a &= 73.1 \text{ kN / m} \\ b &= -104.3 \text{ kN / m} \\ c &= 17.0 \text{ kN / m} \end{aligned} \right\} \text{FS} = 1.24$$

Comment:

While the resulting FS-value is low, the result is best assessed by comparing it to Example 1, i.e., the same problem except without the bulldozer. It is seen that the FS-value has only decreased from 1.25 to 1.24. Thus, in general, a low ground contact pressure bulldozer placing cover soil up the slope with negligible acceleration/deceleration forces does not significantly decrease the factor-of-safety.

For the second case of a bulldozer pushing cover soil down from the crest of the slope to the toe as shown in Figure 5b, the analysis uses the force diagram of Figure 6b. While the weight of the equipment is treated as just described, the lack of a passive wedge along with an additional force due to acceleration (or deceleration) of the equipment significantly changes the resulting FS-values. This analysis again uses a specific piece of construction equipment operated in a specific manner. It produces a force parallel to the slope equivalent to  $W_b (a/g)$ , where  $W_b$  = the weight of the bulldozer,  $a$  = acceleration of the bulldozer and  $g$  = acceleration due to gravity. Its magnitude is equipment operator dependent and related to both the equipment speed and time to reach such a speed, see Figure 9. A similar behavior will be seen for deceleration.

The acceleration of the bulldozer, coupled with an influence factor "I" from Figure 7, results in the dynamic force per unit width at the cover soil to geomembrane interface, "F<sub>e</sub>". The relationship is as follows:

$$F_e = W_e \left( \frac{a}{g} \right) \tag{17}$$

where

F<sub>e</sub> = dynamic force per unit width parallel to the slope at the geomembrane interface,

Figure 9. Graphic relationship of construction equipment speed and rise time to obtain equipment acceleration.

- W<sub>e</sub> = equivalent equipment (bulldozer) force per unit width at geomembrane interface, recall Eq. 16.
- β = soil slope angle beneath geomembrane
- a = acceleration of the bulldozer
- g = acceleration due to gravity

Using these concepts, the new force parallel to the cover soil surface is dissipated through the thickness of the cover soil to the interface of the geomembrane. Again, a Boussinesq analysis is used, see Poulos and Davis (1974). The expression for determining the FS-value can now be derived as follows:

Considering the active wedge, and balancing the forces in the direction parallel to the slope, the following formulation results:

$$E_A + \frac{(N_e + N_A) \tan \delta + C_a}{FS} = (W_A + W_e) \sin \beta + F_e \tag{18}$$

where

$$\begin{aligned} N_e &= \text{effective equipment force normal to the failure plane of the active wedge} \\ &= W_e \cos \beta \end{aligned} \tag{19}$$

Note that all the other symbols have been previously defined.

The interwedge force acting on the active wedge can down be expressed as:

$$E_A = \frac{(FS) [(W_A + W_e) \sin \beta + F_e]}{FS} - \frac{[(N_e + N_A) \tan \delta + C_a]}{FS} \tag{20}$$

The passive wedge can be treated in a similar manner. The following formulation of the interwedge force acting on the passive wedge results:

$$E_P = \frac{C + W_P \tan \phi}{\cos \beta (FS) - \sin \beta \tan \phi} \quad (21)$$

By setting  $E_A = E_P$ , the following equation can be arranged in the form of Eq. 13 in which the "a", "b" and "c" terms are as follows:

$$\begin{aligned} a &= [(W_A + W_e) \sin \beta + F_e] \cos \beta \\ b &= -\{[(N_e + N_A) \tan \delta + C_a] \cos \beta \\ &\quad + [(W_A + W_e) \sin \beta + F_e] \sin \beta \tan \phi \\ &\quad + (C + W_P \tan \phi)\} \\ c &= [(N_e + N_A) \tan \delta + C_a] \sin \beta \tan \phi \end{aligned} \quad (22)$$

Finally, the resulting FS-value can be obtained using Eq. 15. Using these concepts, typical design curves for various FS-values as a function of equipment ground contact pressure and equipment acceleration can be developed, see Figure 10. Note that the curves are developed specifically for the variables stated in the legend. Example 2b illustrates the use of the formulation.

#### Example 2b:

Given a 30 m long slope with uniform cover soil of 300 mm thickness at a unit weight of  $18 \text{ kN/m}^3$ . The soil has a friction angle of 30 deg. and zero cohesion, i.e., it is a sand. It is placed on the slope using a bulldozer moving from the crest of the slope down to the toe. The bulldozer has a ground contact pressure of  $30 \text{ kN/m}^2$  and tracks that are 3.0 m long and 0.6 m wide. The estimated equipment speed is 20 km/hr and the time to reach this speed is 3.0 sec. The cover soil to geomembrane friction angle is 22 deg. with zero adhesion. What is the FS-value at a slope angle of 3(H)-to-1(V), i.e., 18.4 deg.

#### Solution:

Using the design curves of Figure 10 along with Eqs. 22 substituted into Eq. 15 the solution can be obtained:

- From Figure 9 at 20 km/hr and 3.0 sec. the bulldozer's acceleration is 0.19g.
- From Eq. 22 substituted into Eq. 15 we obtain

$$\left. \begin{aligned} a &= 88.8 \text{ kN / m} \\ b &= -107.3 \text{ kN / m} \\ c &= 17.0 \text{ kN / m} \end{aligned} \right\} FS = 1.03$$

#### Comment:

This problem solution can now be compared to the previous two examples:

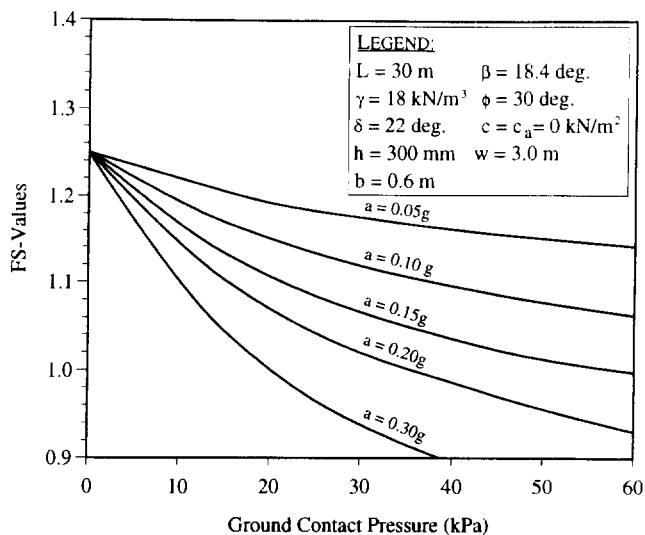

Figure 10. Design curves for stability of different construction equipment ground contact pressure for various equipment accelerations.

- |         |   |           |
|---------|---|-----------|
| Ex. 1:  | cover soil alone with no bulldozer loading  | FS = 1.25 |
| Ex. 2a: | cover soil plus bulldozer moving up slope   | FS = 1.24 |
| Ex. 2b: | cover soil plus bulldozer moving down slope | FS = 1.03 |

The inherent danger of a bulldozer moving down the slope is readily apparent. Note, that the same result comes about by the bulldozer decelerating instead of accelerating. The sharp breaking action of the bulldozer is arguable the more severe condition due to the extremely short times involved when stopping forward motion. Clearly, only in unavoidable situations should the cover soil placement equipment be allowed to work down the slope. If it is unavoidable, an analysis should be made of the specific stability situation and the construction specifications should reflect the exact conditions made in the design. The maximum allowable weight and ground contact pressure of the equipment should be stated along with suggested operator movement of the cover soil placement operations. Truck traffic on the slopes can also give as high, or even higher, stresses and should be avoided unless adequately designed. Additional detail is given in McKelvey (1994). The issue of access ramps is a unique subset of this example and one which deserves focused attention due to the high loads and decelerations that often occur.

### 3.3 Consideration of Seepage Forces

The previous sections presented the general problem of slope stability analysis of cover soils placed on slopes under different conditions. The tacit assumption throughout was that either permeable soil or a drainage layer was placed above the barrier layer with adequate flow capacity to efficiently remove permeating water safely way from the cross section. The amount of water to be removed is obviously a site specific situation. Note that in extremely

arid areas, or with very low permeability cover soils drainage may not be required although this is generally the exception.

Unfortunately, adequate drainage of final covers has sometimes not been available and seepage induced slope stability problems have occurred. The following situations have resulted in seepage induced slides:

- Drainage soils with hydraulic conductivity (permeability) too low for site specific conditions.
- Inadequate drainage capacity at the toe of long slopes where seepage quantities accumulate and are at their maximum.
- Fines from quarried drainage stone either clogging the drainage layer or accumulating at the toe of the slope thereby decreasing the as-constructed permeability over time.
- Fine, cohesionless, cover soil particles migrating through the filter (if one is present) either clogging the drainage layer, or accumulating at the toe of the slope thereby decreasing the as-constructed outlet permeability over time.
- Freezing of the drainage layer at the toe of the slope, while the soil covered top of the slope thaws, thereby mobilizing seepage forces against the ice wedge at the toe.

If seepage forces of the types described occur, a variation in slope stability design methodology is required. Such an analysis is the focus of this subsection. Note that additional discussion is given in Cancelli and Rimoldi (1989), Thiel and Stewart (1993) and Soong and Koerner (1996).

Consider a cover soil of uniform thickness placed directly above a geomembrane at a slope angle of “β” as shown in Figure 11. Different from previous examples, however, is that within the cover soil exists a saturated soil zone for part or all of the thickness. The saturated boundary is shown as two possibly different phreatic surface orientations. This is because seepage can be built-up in the cover soil in two different ways: a horizontal buildup from the toe upward or a parallel-to-slope buildup outward. These two hypotheses are defined and quantified as a horizontal submergence ratio (HSR) and a parallel submergence ratio (PSR). The dimensional definitions of both ratios are given in Figure 11.

When analyzing the stability of slopes using the limit equilibrium method, free body diagrams of the passive and active wedges are taken with the appropriate forces (now including pore water pressures) being applied. The formulation for the resulting factor-of-safety, for horizontal seepage buildup and then for parallel-to-slope seepage buildup, follows.

**The Case of the Horizontal Seepage Buildup.** Figure 12 shows the free body diagram of both the active and passive wedge assuming horizontal seepage. Horizontal seepage buildup can occur when toe blockage occurs due to inadequate outlet capacity, contamination or physical blocking of outlets, or freezing conditions at the outlets.

Figure 11. Cross section of a uniform thickness cover soil on a geomembrane illustrating different submergence assumptions and related definitions, Soong and Koerner (1996).

All symbols used in Figure 12 were previously defined except the following:

- $\gamma_{sat'd}$  = saturated unit weight of the cover soil
- $\gamma_t$  = total (moist) unit weight of the cover soil
- $\gamma_w$  = unit weight of water
- $H$  = vertical height of the slope measured from the toe
- $H_w$  = vertical height of the free water surface measured from the toe
- $U_h$  = resultant of the pore pressures acting on the interwedge surfaces
- $U_n$  = resultant of the pore pressures acting perpendicular to the slope
- $U_v$  = resultant of the vertical pore pressures acting on the passive wedge

The expression for finding the factor-of-safety can be derived as follows:

Considering the active wedge,

$$W_A = \left( \frac{\gamma_{sat'd}(h)(2H_w \cos \beta - h)}{\sin 2\beta} \right) + \left( \frac{\gamma_t(h)(H - H_w)}{\sin \beta} \right) \quad (23)$$

$$U_n = \frac{\gamma_w(h)(\cos \beta)(2H_w \cos \beta - h)}{\sin 2\beta} \quad (24)$$

$$U_h = \frac{\gamma_w h^2}{2} \quad (25)$$

$$N_A = W_A(\cos \beta) + U_h(\sin \beta) - U_n \quad (26)$$

Figure 12. Limit equilibrium forces involved in a finite length slope of uniform cover soil with horizontal seepage buildup.

The interwedge force acting on the active wedge can then be expressed as:

$$E_A = W_A \sin \beta - U_h \cos \beta - \frac{N_A \tan \delta}{FS} \quad (27)$$

The passive wedge can be considered in a similar manner and the following expressions result:

$$W_P = \frac{\gamma_{sat} d h^2}{\sin 2\beta} \quad (28)$$

$$U_V = U_h \cot \beta \quad (29)$$

The interwedge force acting on the passive wedge can then be expressed as:

$$E_P = \frac{U_h (FS) - (W_P - U_V) \tan \phi}{\sin \beta \tan \phi - \cos \beta (FS)} \quad (30)$$

By setting  $E_A = E_P$ , the following equation can be arranged in the form of  $ax^2 + bx + c = 0$  which in this case is:

$$a(FS)^2 + b(FS) + c = 0 \quad (13)$$

where

$$\begin{aligned} a &= W_A \sin \beta \cos \beta - U_h \cos^2 \beta + U_h \\ b &= -W_A \sin^2 \beta \tan \phi + U_h \sin \beta \cos \beta \tan \phi \\ &\quad - N_A \cos \beta \tan \delta - (W_P - U_V) \tan \phi \\ c &= N_A \sin \beta \tan \delta \tan \phi \end{aligned} \quad (31)$$

As with previous solution, the resulting FS-value is obtained using Eq. 15.

**The Case of Parallel-to-Slope Seepage Buildup.** Figure 13 shows the free body diagrams of both the active and passive wedges with seepage buildup in the direction parallel to the slope. Parallel seepage buildup can occur when soils placed above a geomembrane are initially too low in their hydraulic conductivity, or become too low due to long-term clogging from overlying soils which do not have a filter. Identical symbols as defined in the previous cases are used here with an additional definition of  $h_w$  equal to the height of free water surface measured in the direction perpendicular to the slope.

Figure 13. Limit equilibrium forces involved in a finite length slope of uniform cover soil with parallel-to-slope seepage buildup.

Note that the general expression of factor-of-safety shown in Eq. 15 is still valid. However, the a, b and c terms given in Eq. 31 have different definitions in this case owing to the new definitions of the following terms:

$$W_A = \frac{\gamma_t(h - h_w)(2H \cos \beta - (h + h_w))}{\sin 2\beta} + \frac{\gamma_{sat}d(h_w)(2H \cos \beta - h_w)}{\sin 2\beta} \quad (32)$$

$$U_n = \frac{\gamma_w h_w \cos \beta (2H \cos \beta - h_w)}{\sin 2\beta} \quad (33)$$

$$U_h = \frac{\gamma_w (h_w)^2}{2} \quad (34)$$

$$W_p = \frac{\gamma_t(h^2 - h_w^2) + \gamma_{sat}d(h_w^2)}{\sin 2\beta} \quad (35)$$

In order to illustrate the behavior of these equations, the design curves of Figure 14 have been developed. They show the decrease in FS-value with increasing submergence ratio for all values of interface friction. Furthermore, the differences in response curves for the parallel and horizontal submergence ratio assumptions are seen to be very small. Note that the curves are developed specifically for variables stated in the legend. Example 3 illustrates the use of the design curves.

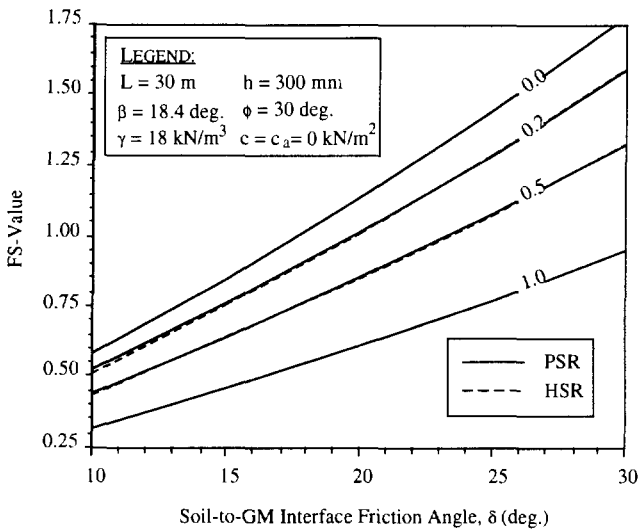

Figure 14. Design curves for stability of cohesionless, uniform thickness, cover soils for different submergence ratios.

**Example 3:**

Given a 30 m long slope with a uniform thickness cover soil of 300 mm at a dry unit weight of 18 kN/m<sup>3</sup>. The soil has a friction angle of 30 deg. and zero cohesion, i.e., it is a sand. The soil becomes saturated through 50% of its thickness, i.e., it is a parallel seepage problem with PSR = 0.5, and its saturated unit weight increases to 21 kN/m<sup>3</sup>. Direct shear testing has resulted in an interface friction angle of 22 deg. with zero adhesion. What is the factor-of-safety at a slope of 3(H)-to-1(V), i.e., 18.4 deg.

Solution:

Solving Eqs. 31 with the values of Eqs. 32 to 35 for the a, b and c terms and then substituting them into Eq. 15 results in the following.

$$\left. \begin{aligned} a &= 51.7 \text{ kN/m} \\ b &= -57.8 \text{ kN/m} \\ c &= 9.0 \text{ kN/m} \end{aligned} \right\} \text{FS} = 0.93$$

Comment:

The seriousness of seepage forces in a slope of this type are immediately obvious. Had the saturation been 100% of the drainage layer thickness, the FS-value would have been even lower. Furthermore, the result using a horizontal assumption of saturated cover soil with the same saturation ratio will give identically low FS-values. Clearly, the teaching of this example problem is that adequate long-term drainage above the barrier layer in cover soil slopes must be provided to avoid seepage forces from occurring.

### 3.4 Consideration of Seismic Forces

In areas of anticipated earthquake activity, the slope stability analysis of a final cover soil over an engineered landfill, abandoned dump or remediated site must consider seismic forces. In the United States, the Environmental Protection Agency (EPA) regulations require such an analysis for sites that have a probability of  $\geq 10\%$  of experiencing a 0.10 g peak horizontal acceleration within the past 250 years. For the continental USA this includes not only the western states, but major sections of the midwest and northeast states, as well. If practiced worldwide, such a criterion would have huge implications.

The seismic analysis of cover soils of the type under consideration in this paper is a two-part process:

- The calculation of a FS-value using a pseudo-static analysis via the addition of a horizontal force acting at the centroid of the cover soil cross section.
- If the FS-value in the above calculation is less than 1.0, a permanent deformation analysis is required. The calculated deformation is then assessed in light of the potential damage to the cover soil section and is either accepted, or the slope requires an appropriate redesign. The redesign is then analyzed until the situation becomes acceptable.

The first part of the analysis is a pseudo-static approach which follows the previous examples except for the addition of a horizontal force at the centroid of the cover soil in proportion to the anticipated seismic activity. It is first necessary to obtain an average seismic coefficient ( $C_s$ ). The bedrock acceleration can be estimated from a seismic zone map, e.g., Algermissen (1991), using the procedures embodied in Richardson, et al (1995). Such maps are available on a worldwide basis. The value of  $C_s$  is nondimensional and is a ratio of the bedrock acceleration to gravitational acceleration. This value of  $C_s$  is modified using available computer codes such as "SHAKE", see

Schnabel, et al. (1972), for propagation to the site and then to the landfill cover. The computational process within such programs is quite intricate. For detailed discussion see Seed and Idriss (1982) and Idriss (1990). The analysis is then typical to those previously presented.

Using Figure 15, the additional seismic force is seen to be  $C_S W_A$  acting horizontally on the active wedge. All additional symbols used in Figure 15 have been previously defined and the expression for finding the FS-value can be derived as follows:

Figure 15. Limit equilibrium forces involved in pseudo-static analysis including use of an average seismic coefficient

Considering the active wedge, by balancing the forces in the horizontal direction, the following formulation results:

$$E_A \cos \beta + \frac{(N_A \tan \delta + C_a) \cos \beta}{FS} = C_S W_A + N_A \sin \beta \quad (36)$$

Hence the interwedge force acting on the active wedge results:

$$E_A = \frac{(FS)(C_S W_A + N_A \sin \beta)}{(FS) \cos \beta} - \frac{(N_A \tan \delta + C_a) \cos \beta}{(FS) \cos \beta} \quad (37)$$

The passive wedge can be considered in a similar manner and the following formulation results:

$$E_P \cos \beta + C_S W_P = \frac{C + N_P \tan \phi}{FS} \quad (38)$$

Hence the interwedge force acting on the passive wedge is:

$$E_P = \frac{C + W_P \tan \phi - C_S W_P (FS)}{(FS) \cos \beta - \sin \beta \tan \phi} \quad (39)$$

Again, by setting  $E_A = E_P$ , the following equation can be arranged in the form of  $ax^2 + bx + c = 0$  which in this case is:

$$a(FS)^2 + b(FS) + c = 0 \quad (13)$$

where

$$\begin{aligned} a &= (C_S W_A + N_A \sin \beta) \cos \beta + C_S W_P \cos \beta \\ b &= -[(C_S W_A + N_A \sin \beta) \sin \beta \tan \phi \\ &\quad + (N_A \tan \delta + C_a) \cos^2 \beta \\ &\quad + (C + W_P \tan \phi) \cos \beta] \\ c &= (N_A \tan \delta + C_a) \cos \beta \sin \beta \tan \phi \end{aligned} \quad (40)$$

The resulting FS-value is then obtained from the following equation:

$$FS = \frac{-b + \sqrt{b^2 - 4ac}}{2a} \quad (15)$$

Using these concepts, a design curve for the general problem under consideration as a function of seismic coefficient can be developed, see Figure 16. Note that the curve is developed specifically for the variables stated in the legend. Example 4a illustrates the use of the curve.

Figure 16. Design curve for a uniformly thick cover soil pseudo-static seismic analysis with varying average seismic coefficients.

**Example 4a:**

Given a 30 m long slope with uniform thickness cover soil of 300 mm at a unit weight of 18 kN/m<sup>3</sup>. The soil has a friction angle of 30 deg. and zero cohesion, i.e., it is a sand. The cover soil is on a geomembrane as shown in Figure 15. Direct shear testing has resulted in an interface friction angle of 22 deg. with zero adhesion. The slope angle is 3(H)-to-1(V), i.e., 18.4 deg. A design earthquake appropriately transferred to the site's cover soil results in an average seismic coefficient of 0.10. What is the FS-value?

**Solution:**

Solving Eqs. 40 for the values given in the example and substituting into Eq. 15 results in the following FS-value.

$$\left. \begin{aligned} a &= 59.6 \text{ kN / m} \\ b &= -66.9 \text{ kN / m} \\ c &= 10.4 \text{ kN / m} \end{aligned} \right\} \text{FS} = 0.94$$

Note that the value of FS = 0.94 agrees with the design curve of Figure 16 at a seismic coefficient of 0.10.

**Comment:**

Had the above FS-value been greater than 1.0, the analysis would be complete. The assumption being that cover soil stability can withstand the short-term excitation of an earthquake and still not slide. However, since the value in this example is less than 1.0, a second part of the analysis is required.

The second part of the analysis is directed toward calculating the estimated deformation of the lowest shear strength interface in the cross section under consideration. The deformation is then assessed in light of the potential damage that may be imposed on the system.

To begin the permanent deformation analysis, a yield acceleration, "C<sub>sy</sub>", is obtained from a pseudo-static analysis under an assumed FS = 1.0. Figure 16 illustrates this procedure for the assumptions stated in the legend. It results in a value of C<sub>sy</sub> = 0.075. Coupling this value with the time history response obtained for the actual site location and cross section, results in a comparison as shown in Figure 17a. If the earthquake time history response never exceeds the value of C<sub>sy</sub>, there is no anticipated permanent deformation. However, whenever any part of the time history curve exceeds the value of C<sub>sy</sub>, permanent deformation is expected. By double integration of the time history curve (which is acceleration), to velocity (Figure 17b) and then to displacement (Figure 17c), the anticipated value of deformation can be obtained. This value is considered to be permanent deformation and is then assessed based on the site-specific implications of damage to the final cover system. Empirical charts, e.g., Makdisi and Seed (1978) can also be used to estimate the permanent deformation. Example 4b continues the previous pseudo-static analysis into the deformation calculation.

Figure 17. Hypothetical design curves to obtain permanent deformation utilizing (a) acceleration, (b) velocity and (c) displacement curves.

**Example 4b:**

Continue Example 4a and determine the anticipated permanent deformation of the weakest interface in the cover soil system. The site-specific seismic time-history diagram is given in Figure 17a.

**Solution:**

The interface of concern is the cover soil-to-geomembrane for this particular example. With a yield acceleration of 0.075 from Figure 16 and the site-specific (design) time history shown in Figures 17a, integration produces Figure 17b and then 17c. The three peaks exceeding the yield acceleration value of 0.075, produce a cumulative deformation of approximately 54 mm. This value is now viewed in light of the deformation capability of the cover soil above the particular interface used at the site. Note that current practice limits such deformation to either 100 or 300 mm depending on site-specific situations, see Richardson et al (1995).

**Comments:**

An assessment of the implications of deformation (in this example it is 54 mm) is very subjective. For example, this problem could easily have been framed to produce much higher permanent deformation. Such deformation can readily be envisioned in high seismic-prone areas. In addition to an assessment of cover soil stability, the concerns for appurtenances and ancillary piping must also be addressed.

#### 4 SITUATIONS CAUSING THE ENHANCED STABILIZATION OF SLOPES

This section represents a counterpoint to the previous section on slope destabilization situations, in that all situations presented here tend to increase the stability of the slopes. Thus they represent methods to increase the cover soil FS-value. Included are toe berms, tapered cover soils and veneer reinforcement (both intentional and nonintentional). Not included, but very practical in site-specific situations, is to simply decrease the slope angle and/or decrease the slope length. These solutions, however, do not incorporate new design techniques and are therefore not illustrated. They are, however, very viable alternatives for the design engineer.

##### 4.1 Toe (Buttress) Berm

A common method of stabilizing highway slopes and earth dams is to place a soil mass, i.e., a berm, at the toe of the slope. In so doing one provides a soil buttress, acting in a passive state thereby providing a stabilizing force. Figure 18 illustrates the two geometric cases necessary to provide the requisite equations. While the force equilibrium is performed as previously described, i.e., equilibrium along the slope with abutting interwedge forces aligned with the slope angle or horizontal, the equations are extremely long. Due to space limitations (and the resulting trends in FS-value improvement) they are not presented.

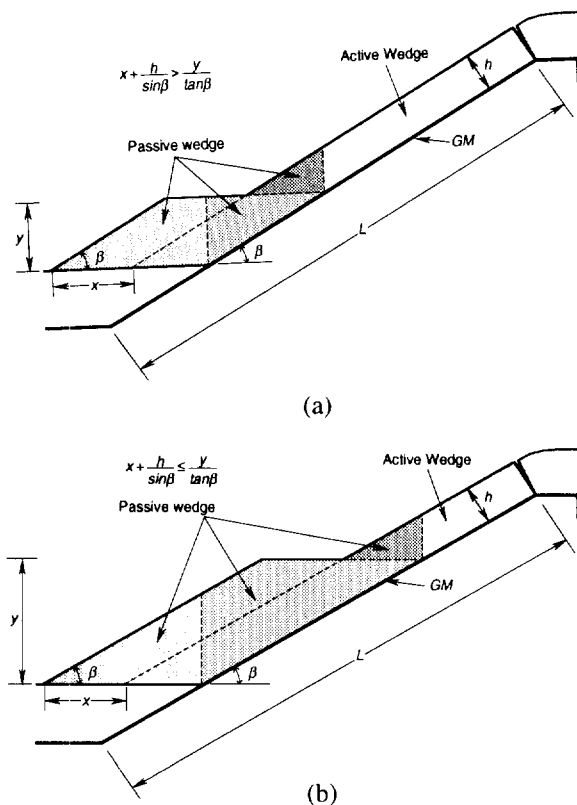

Figure 18. Dimensions of toe (buttress) berms acting as passive wedges to enhance stability.

##### Example 5:

Given a 30 m long slope with a uniform cover soil thickness of 300 mm and a unit weight of  $18 \text{ kN/m}^3$ . The soil has a friction angle of 30 deg. and zero cohesion, i.e., it is a sand. The cover soil is on a geomembrane as shown in Figure 18. Direct shear testing has resulted in a interface friction angle between the cover soil and geomembrane of 22 deg. and zero adhesion. The FS-value at a slope angle of 3(H)-to-1(V), i.e., 18.4 deg., was shown in Section 3.1 to be 1.25. What is the increase in FS-value using different sized toe berms with values of  $x = 1, 2$  and 3 m, and gradually increasing  $y$ -values?

##### Solution:

The FS-value response to this type of toe berm stabilization is given in two parts, see Figure 19. Using thickness values of  $x = 1, 2$  and 3 m, the lower berm section by itself is seen to have high FS-values initially, which decrease rapidly as the height of the toe berm increases. This is a predictable response for this passive wedge zone. Unfortunately, the upper layer of soil above the toe berm

Figure 19. Design curves for FS-values using toe (buttress) berms of different dimensions.

(the active zone) is only nominally increasing in its FS-value. Note that at the crossover points of the upper and lower FS-values (which is the optimum solution for each set of conditions), the following occurs:

- For  $x = 1 \text{ m}$ ;  $y = 6.0 \text{ m}$  (63% of the slope height) and  $FS = 1.35$  (only an 8% improvement in stability)
- For  $x = 2 \text{ m}$ ;  $y = 6.8 \text{ m}$  (72% of the slope height) and  $FS = 1.37$  (only a 12% improvement in stability)
- For  $x = 3 \text{ m}$ ;  $y = 7.3 \text{ m}$  (77% of the slope height) and  $FS = 1.40$  (only a 16% improvement in stability)

##### Comment:

Readily seen is that construction of a toe berm is not a viable strategy to stabilize relatively thin layers of sloped cover soil of the type under investigation. Essentially what is happening is that the upper section of the cover soil (the

active wedge) above the berm is sliding off of the top of the toe berm. While the upper slope length is becoming shorter (as evidenced by the slight improvement in FS-values), it is only doing so with the addition of a tremendous amount of soil fill. Thus this toe berm concept is a poor strategy for the stabilization of forces oriented in the slope's direction. Conversely, it is an excellent strategy for embankments and dams where the necessary resisting force for the toe berm is horizontal thereby counteracting a horizontal thrust by the potentially unstable soil and/or water mass.

#### 4.2 Slopes with Tapered Thickness Cover Soil

An alternative method available to the designer to increase the FS-value of a given slope is to uniformly taper the cover soil thickness from thick at the toe, to thin at the crest, see Figure 20. The FS-value will increase in approximate proportion to the thickness of soil at the toe. The analysis for tapered cover soils includes the design assumptions of a tension crack at the top of the slope, the upper surface of the cover soil tapered at a constant angle " $\omega$ ", and the earth

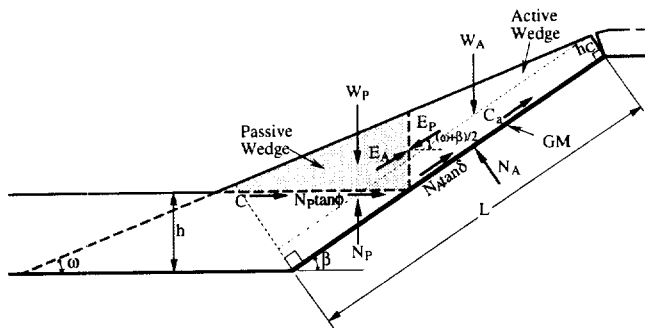

Figure 20. Limit equilibrium forces involved in a finite length slope analysis with tapered thickness cover soil from toe to crest.

pressure forces on the respective wedges oriented at the average of the surface and slope angles, i.e., the E-forces are at an angle of  $(\omega + \beta)/2$ . The procedure follows that of the uniform cover soil thickness analysis. Again, the resulting equation is not an explicit solution for the FS, and must be solved indirectly.

All symbols used in Figure 20 were previously defined (see Section 3.1) except the following:

- $h$  = thickness of cover soil at bottom of the landfill, measured perpendicular to the base liner
- $h_c$  = thickness of cover soil at crest of the slope, measured perpendicular to the slope
- $y$  = see Figure 20

$$= \left( L - \frac{h}{\sin \beta} - h_c \tan \beta \right) (\sin \beta - \cos \beta \tan \omega)$$

$\omega$  = finished slope angle of cover soil, note that  $\omega < \beta$

The expression for determining the FS-value can be derived as follows:

Considering the active wedge,

$$W_A = \gamma \left[ \left( L - \frac{h}{\sin \beta} - h_c \tan \beta \right) \left( \frac{y \cos \beta}{2} + h_c \right) + \frac{h_c^2 \tan \beta}{2} \right] \quad (41)$$

$$N_A = W_A \cos \beta \quad (42)$$

$$C_a = c_a \left( L - \frac{h}{\sin \beta} \right) \quad (43)$$

By balancing the forces in the vertical direction, the following formulations result:

$$E_A \sin \left( \frac{\omega + \beta}{2} \right) = W_A - N_A \cos \beta - \frac{N_A \tan \delta + C_a}{FS} (\sin \beta) \quad (44)$$

Hence the interwedge force acting on the active wedge is:

$$E_A = \frac{(FS)(W_A - N_A \cos \beta) - (N_A \tan \delta + C_a) \sin \beta}{\sin \left( \frac{\omega + \beta}{2} \right) (FS)} \quad (45)$$

The passive wedge can be considered in a similar manner:

$$W_P = \frac{\gamma}{2 \tan \omega} \left[ \left( L - \frac{h}{\sin \beta} - h_c \tan \beta \right) (\sin \beta - \cos \beta \tan \omega) + \frac{h_c}{\cos \beta} \right]^2 \quad (46)$$

$$N_P = W_P + E_P \sin \left( \frac{\omega + \beta}{2} \right) \quad (47)$$

$$C = \frac{\gamma}{\tan \omega} \left[ \left( L - \frac{h}{\sin \beta} - h_c \tan \beta \right) (\sin \beta - \cos \beta \tan \omega) + \frac{h_c}{\cos \beta} \right] \quad (48)$$

By balancing the forces in the horizontal direction, the following formulation results:

$$E_P \cos \left( \frac{\omega + \beta}{2} \right) = \frac{C + N_P \tan \phi}{FS} \quad (49)$$

Hence the interwedge force acting on the passive wedge is:

$$E_P = \frac{C + W_P \tan \phi}{\cos\left(\frac{\omega + \beta}{2}\right)(FS) - \sin\left(\frac{\omega + \beta}{2}\right) \tan \phi} \quad (50)$$

By setting  $E_A = E_P$ , the following equation can be arranged in the form of  $ax^2 + bx + c = 0$  which in our case is

$$a(FS)^2 + b(FS) + c = 0 \quad (13)$$

where

$$\begin{aligned} a &= (W_A - N_A \cos \beta) \cos\left(\frac{\omega + \beta}{2}\right) \\ b &= -\left[ (W_A - N_A \cos \beta) \sin\left(\frac{\omega + \beta}{2}\right) \tan \phi \right. \\ &\quad \left. + (N_A \tan \delta + C_a) \sin \beta \cos\left(\frac{\omega + \beta}{2}\right) \right. \\ &\quad \left. + \sin\left(\frac{\omega + \beta}{2}\right) (C + W_P \tan \phi) \right] \\ c &= (N_A \tan \delta + C_a) \sin \beta \sin\left(\frac{\omega + \beta}{2}\right) \tan \phi \end{aligned} \quad (51)$$

As usual, the resulting FS-value can then be obtained using Eq. 15. To illustrate the use of the above developed equations, the design curves of Figure 21 are offered. They show that the FS-value increases in proportion to greater cover soil thicknesses at the toe of the slope with respect to the thickness at the crest. This is evidenced by a shallower surface slope angle than that of the slope of the geomembrane and the soil beneath, i.e., the value of " $\omega$ " being less than " $\beta$ ". Note that the curves are developed specifically for the variables stated in the legend. Example 6 illustrates the use of the curves.

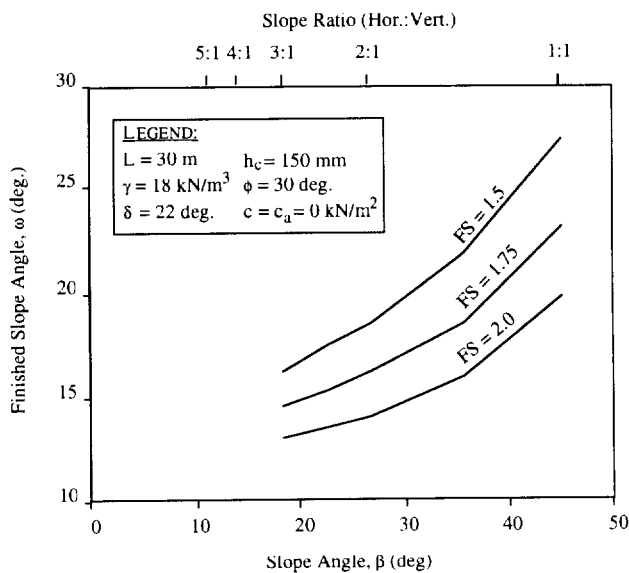

Figure 21. Design curves for FS-values of tapered cover soil thickness.

Example 6:

Given a 30 m long slope with a tapered thickness cover soil of 150 mm at the crest extending at an angle " $\omega$ " of 16 deg. to the intersection of the cover soil at the toe. The unit weight of the cover soil is 18 kN/m<sup>3</sup>. The soil has a friction angle of 30 deg. and zero cohesion, i.e., it is a sand. The interface friction angle with the underlying geomembrane is 22 deg. with zero adhesion. What is the FS-value at an underlying soil slope angle " $\beta$ " of 3(H)-to-1(V), i.e., 18.4 deg.?

Solution:

Using Eqs. 51, substituted into Eq. 15 yields the following:

$$\left. \begin{aligned} a &= 37.0 \text{ kN/m} \\ b &= -63.6 \text{ kN/m} \\ c &= 8.6 \text{ kN/m} \end{aligned} \right\} FS = 1.57$$

Comment:

The result of this problem (with tapered thickness cover soil) is FS = 1.57, versus Example 1 (with a uniform thickness cover soil) which was FS = 1.25. Thus the increase in FS-value is 24%. Note, however, that at  $\omega = 16$  deg. the thickness of the cover soil normal to the slope at the toe is approximately 1.4 m. Thus the increase in cover soil volume used over Example 1 is from 8.9 to 24.1 m<sup>3</sup>/m ( $\approx 170\%$ ) and the increase in necessary toe space distance is from 1.0 to 4.8 m ( $\approx 380\%$ ). The trade-offs between these issues should be considered when using the strategy of tapered cover soil thickness to increase the FS-value of a particular cover soil slope.

#### 4.3 Veneer Reinforcement - Intentional

A fundamentally different way of increasing a given slope's factor of safety is to reinforce it with a geosynthetic material. Such reinforcement can be either intentional or non-intentional. By *intentional*, we mean to include a geogrid or high strength geotextile within the cover soil to purposely reinforce the system against instability, see Figure 22. Depending on the type and amount of reinforcement, the majority, or even all, of the driving, or mobilizing, stresses can be supported resulting in major increase in FS-value. By *non-intentional*, we refer to multi-component liner systems where a low shear strength interface is located beneath an overlying geosynthetic(s). In this case, the overlying geosynthetic(s) is inadvertently acting as veneer reinforcement to the composite system. In some cases, the designer may not realize that such geosynthetic(s) are being stressed in an identical manner as a geogrid or high strength geotextile, but they are. The situation where a relatively low strength protection geotextile is placed over a smooth geomembrane and beneath the cover soil is a case in point. Intentional, or non-intentional, the stability analysis is identical. The difference is that the geogrids and/or high strength geotextiles give a major increase in the FS-value, while a protection geotextile (or other lower strength geosynthetics) only nominally increases the FS-value.

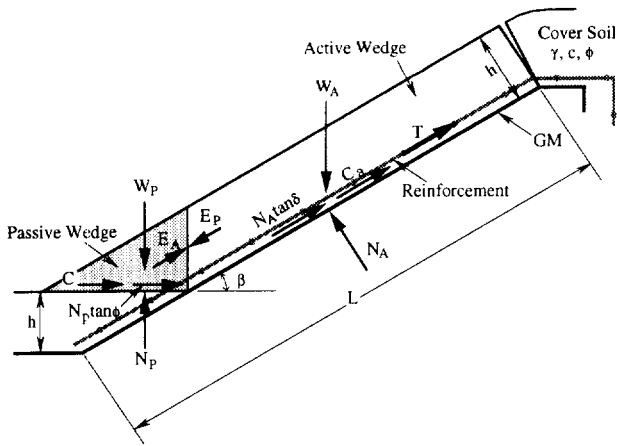

Figure 22. Limit equilibrium forces involved in a finite length slope analysis for a uniformly thick cover soil including the use of veneer reinforcement.

Seen in Figure 22 is that the analysis follows Section 3.1, but a force from the reinforcement “T”, acting parallel to the slope, provides additional stability. This force “T”, acts only within the active wedge. By taking free body force diagrams of the active and passive wedges, the following formulation for the factor of safety results. All symbols used in Figure 22 were previously defined (see Section 3.1) except the following:

$T = T_{allow}$ , the allowable (long-term) strength of the geosynthetic reinforcement inclusion

Consider the active wedge and by balancing the forces in the vertical direction, the following formulation results:

$$E_A \sin \beta = W_A - N_A \cos \beta - \left( \frac{N_A \tan \delta + C_a}{FS} + T \right) \sin \beta \quad (52)$$

Hence the interwedge force acting on the active wedge is:

$$E_A = \frac{(FS)(W_A - N_A \cos \beta - T \sin \beta)}{\sin \beta (FS)} - \frac{(N_A \tan \delta + C_a) \sin \beta}{\sin \beta (FS)} \quad (53)$$

Again, by setting  $E_A = E_P$  (see Eq. 12 for the expression of  $E_P$ ), the following equation can be arranged in the usual form in which the “a”, “b” and “c” terms are defined as follows:

$$\begin{aligned} a &= (W_A - N_A \cos \beta - T \sin \beta) \cos \beta \\ b &= - \left[ (W_A - N_A \cos \beta - T \sin \beta) \sin \beta \tan \phi \right. \\ &\quad \left. + (N_A \tan \delta + C_a) \sin \beta \cos \beta \right. \\ &\quad \left. + \sin \beta (C + W_P \tan \phi) \right] \\ c &= (N_A \tan \delta + C_a) \sin^2 \beta \tan \phi \end{aligned} \quad (54)$$

Again, the resulting FS-value can be obtained using Eq. 15.

As noted, the value of T in the design formulation is  $T_{allow}$  which is invariably less than the as-manufactured strength of the geosynthetic reinforcement material. Considering the as-manufactured strength as being  $T_{ult}$ , the value should be reduced by such factors as installation damage, creep and long-term degradation. Note that if seams are involved in the reinforcement, a reduction factor should be added accordingly. See Koerner, 1998 (among others), for recommended numeric values.

$$T_{allow} = T_{ult} \left( \frac{1}{RF_{ID} \times RF_{CR} \times RF_{CBD}} \right) \quad (55)$$

where

- $T_{allow}$  = allowable value of reinforcement strength
- $T_{ult}$  = ultimate (as-manufactured) value of reinforcement strength
- $RF_{ID}$  = reduction factor for installation damage
- $RF_{CR}$  = reduction factor for creep
- $RF_{CBD}$  = reduction factor for long term chemical/biological degradation

To illustrate the use of the above developed equations, the design curves of Figure 23 have been developed. The reinforcement strength can come from either geogrids or high strength geotextiles. If geogrids are used, the friction angle is the cover soil to the underlying geomembrane, under the assumption that the apertures are large enough to allow for cover soil strike-through. If geotextiles are used, this is not the case and the friction angle is the geotextile to the geomembrane. Also note that this value under discussion is the required reinforcement strength which is essentially  $T_{allow}$  in Eq. 55. The curves of Figure 23 clearly show the improvement of FS-values with increasing strength of the reinforcement. Note that the curves are developed specifically for the variables stated in the legend. Example 7 illustrates the use of the design curves.

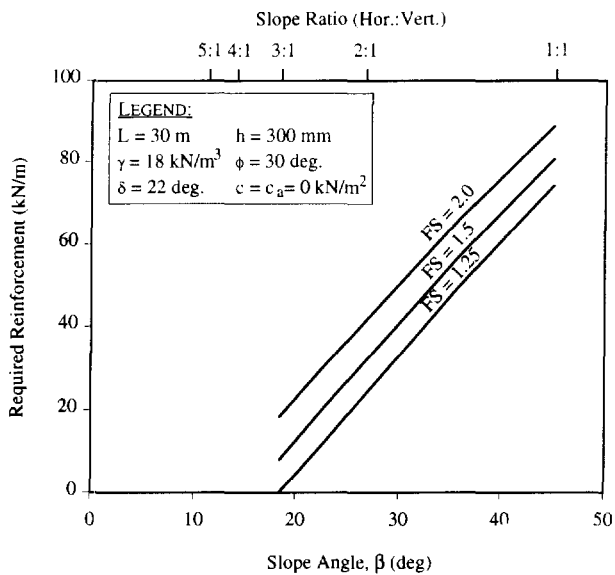

Figure 23. Design curves for FS-values for different slope angles and veneer reinforcement strengths for uniform thickness cohesionless cover soils.

**Example 7:**

Given a 30 m long slope with a uniform thickness cover soil of 300 mm and a unit weight of 18 kN/m<sup>3</sup>. The soil has a friction angle of 30 deg. and zero cohesion, i.e., it is a sand. The proposed reinforcement is a geogrid with an allowable wide width tensile strength of 10 kN/m. Thus reduction factors in Eq. 55 have already been included. The geogrid apertures are large enough that the cover soil will strike-through and provide an interface friction angle with the underlying geomembrane of 22 deg. with zero adhesion. What is the FS-value at a slope angle of 3(H)-to-1(V), i.e., 18.4 deg.?

Solution:

Solving Eqs. 54 and substituting into Eq. 15 produces the following:

$$\left. \begin{aligned} a &= 11.8 \text{ kN / m} \\ b &= -20.7 \text{ kN / m} \\ c &= 3.5 \text{ kN / m} \end{aligned} \right\} \text{FS} = 1.57$$

Comments:

Note that the use of  $T_{\text{allow}} = 10 \text{ kN/m}$  in the analysis will require a significantly higher  $T_{\text{ult}}$  value of the geogrid per Eq. 55. For example, if the summation of the reduction factors in Eq. 55 were 4.0, the ultimate (as-manufactured) strength of the geogrid would have to be 40 kN/m. Also, note that this same type of analysis could also be used for high strength geotextile reinforcement. The analysis follows along the same general lines as presented here.

**4.4 Veneer Reinforcement - Nonintentional**

It should be emphasized that the preceding analysis is focused on intentionally improving the FS-value by the inclusion of geosynthetic reinforcement. This is provided by geogrids or high strength geotextiles being placed above the upper surface of the low strength interface material. The reinforcement is usually placed directly above the geomembrane or other geosynthetic material.

Interestingly, some amount of veneer reinforcement is often nonintentionally provided by a geosynthetic(s) material placed over an interface with a lower shear strength. Several situations are possible in this regard.

- Geotextile protection layer placed over a geomembrane
- Geomembrane placed over an underlying geotextile protection layer
- Geotextile/geomembrane placed over a compacted clay liner or geosynthetic clay liner
- Multilayered geosynthetics placed over a compacted clay liner or a geosynthetic clay liner

Each of these four situations are illustrated in Figure 24. They represent precisely the formulation of Section 4.3 which is based on Figure 22. On the condition that the geosynthetics above the weakest interface are held in their respective anchor trenches, the overlying geosynthetics provide veneer reinforcement, albeit of a nonintentional type. In the general case, such designs are not recommended although they can indeed provide increased resistance to slope instability of the weakest interface.

In performing calculations of the situations shown in Figure 24, the issue of strain compatibility must be considered. For the slopes shown in Figure 24 a and b, the issue is not important and the full wide width strength of the geotextile and geomembrane, respectively, can be used in the analysis. For the slopes shown in Figure 24 c and d, however, the complete stress vs. strain curves of each geosynthetic layer over the weak interface are necessary. The lowest value of failure strain of any one material dictates the strain at which the other geosynthetics will act. This will invariably be less than the full strength of the other geosynthetics. At this value of strain, however, the allowable strengths are additive and can be used in the analysis. Some detail on this issue is available in Corcoran and McKelvey (1995).

To illustrate the use of the above concepts, examples are given for the four situations shown in Figure 24.

**Example 8:**

Given four 3(H)-to-1(V), i.e., 18.4 deg. slopes with cover soils as shown in Figures 24 a to d. In each case, the slope is 30 m long with 300 mm of uniformly thick cover soil at a unit weight of 18 kN/m<sup>3</sup>. The soil has a friction angle of 30 deg. and zero cohesion, i.e., it is a sand. The friction angle of the critical interface is 10 deg. What are the FS-values using the geosynthetic tensile strength data provided in the following table?

(a) Geotextile sliding on geomembrane

(b) Geomembrane sliding on geotextile

(c) Geotextile and geomembrane sliding on CCL or GCL

(d) Double liner system sliding on CCL or GCL

Values used for numeric examples of nonintentional veneer reinforcement.<sup>1</sup>

Slope type (figure)	GT strength <sup>2</sup> (kN/m)	GM strength <sup>3</sup> (kN/m)	GC strength <sup>4</sup> (kN/m)
24a	25	n/a	n/a
24b	n/a	15	n/a
24c	25	13	n/a
24d	25	13+13	36

Notes:

1. Strengths are product-specific and have been adjusted for strain compatibility.
2. Nonwoven needle punched geotextile of 540 g/m<sup>2</sup>
3. Very flexible polyethylene geomembrane 1.0 mm thick
4. Biaxial geonet with two 200 g/m<sup>2</sup> nonwoven needle punched geotextiles thermally bonded to each side

Solution:

Substituting Eqs. 54 into Eq. 15 results in the following data and respective FS-values.

Slope type (figure)	a (kN/m)	b (kN/m)	c (kN/m)	FS-value
24a	7.3	-9.7	1.5	1.15
24b	10.3	-10.3	1.5	0.82
24c	3.4	-9.0	1.5	2.45
24d	-11.0	-6.2	1.5	>10.0

Comments:

While the practice illustrated in these examples of using the overlying geosynthetics as nonintentional veneer reinforcement is not recommended, it is seen to be quite effective when a number of geosynthetics overlying the weak interface are present. On a cumulative basis, they can represent a substantial force as shown in Figure 24d. If one were to rely on such strength, however, it would be prudent to apply suitable reduction factors to each material, and to inform the parties involved of the design situation.

## 5 SUMMARY

This paper has focused on the mechanics of analyzing slopes as part of final cover systems on engineered landfills, abandoned dumps and remediated waste piles. It also applies to drainage soils placed on geomembrane lined slopes beneath the waste, at least until solid waste is placed against the slope. Numeric examples in all of the sections have resulted in global FS-values. Each section was presented from a designer's perspective in transitioning from the simplest to the most advanced. It should be clearly recognized that there are other approaches to the analyses illustrated in the various examples. References available in the literature by Giroud and Beech (1989), McKelvey and Deutsch (1991), Koerner and Hwu (1991), Giroud et al (1995a), Giroud et al (1995b), Liu et al (1997), and Ling and Leshchinsky (1997) are relevant in this

regard. All are based on the concept of limit equilibrium with different assumptions involving particular details, e.g.,

- Existence of a tension crack at the top of slope (filled or unfilled with water)
- Orientation of the failure plane beneath the passive wedge (horizontal or inclined)
- Specific details of construction equipment movement on the slopes in placing the cover soil, particularly the acceleration or deceleration, and the type of equipment itself (e.g., tracked versus wheel equipment)
- Specific details on seepage forces within the drainage layer, including the amount and its orientation
- Specific details on seismic forces, particularly the magnitude and the selection of interface strengths
- Specific details on the geometry of the toe berms or tapered cover soils
- Specific details on the strength and reduction factors used for intentional veneer reinforcement
- Specific details on the strain compatibility issues used with nonintentional veneer reinforcement.

When considering all of these site-specific details, it is readily seen that veneer cover soil analysis and design is a daunting, yet quite tractable, task. For example, one of the reviewers of this paper reanalyzed one of the examples presented herein and another reviewer reanalyzed all of the examples. Both used the analyses of Giroud et al (1995a) and (1995b). They found good agreement in all cases except the nonintentional veneer reinforcement with multiple geosynthetic layers, i.e., the last example presented. It is likely in this regard that different values of mobilized composite strength were being used.

Table 1 summarizes the FS-values of the similarly framed numeric examples presented herein so that insight can be gained from each of the conditions analyzed. Throughout the paper, however, the inherent danger of building a relatively steep slope on a potentially weak interface material, oriented in the exact direction of a potential slide, should have been apparent.

The standard example was purposely made to have a relatively low factor of safety, i.e.,  $FS = 1.25$ . This FS-value was seen to moderately decrease for construction equipment moving up the slope, but seriously decrease with equipment moving down the slope, i.e., 1.24 to 1.03. It should be noted, however, that the example problems were hypothetical, particularly the equipment examples in the selection of acceleration /deceleration factors. There are an innumerable number of choices to select from, and we have selected values to make the point of proper construction practice. Also, drastically decreasing the FS-value were the influences of seepage and seismicity. The former is felt to be most serious in light of a number of slides occurring after heavy precipitation. The latter is known to be a concern at one landfill in an area of active seismicity.

The sequence of design situations shifted to scenarios where the FS-values were increased over the standard example. Adding soil either in the form of a toe berm or tapered cover soil both increase the FS-value depending on the mass of soil involved. The tapered situation was seen to be more efficient and preferred over the toe berm. Both

Table 1. Summary of numeric examples given in this paper for different slope stability scenarios.

Exam- ple No.	Situation or condition	Control FS-value	Scenarios decreasing FS-values	Scenarios increasing FS-values
1	standard example*	1.25		
2a	equipment up-slope		1.24	
2b	equipment down-slope		1.03	
3	seepage forces		0.93	
4	seismic forces		0.94	
5	toe (buttress) berm			1.35-1.40
6	tapered cover soil			1.57
7	veneer reinforce- ment (intentional)			1.57
8	veneer reinforce- ment (non intentional)			varies

\* 30 m long slope at a slope angle of 18.4 deg. with sandy cover soil of 18.4 kN/m<sup>3</sup> dry unit weight with  $\phi = 30$  deg. and thickness 300 mm placed on an underlying geosynthetic with a friction angle  $\delta = 22$  deg.

designs, however, require physical space at the toe of the slope which is often not available. Thus the use of geosynthetic reinforcement was illustrated. By intentional veneer reinforcement it is meant that geogrids or high strength geotextiles are included to resist some, or all, of the driving forces that are involved. The numeric example illustrated an increase in FS-value from 1.25 to 1.57, but this is completely dependent on the type and amount of reinforcement. It was also shown that whenever the weakest interface is located beneath overlying geosynthetics they also act as veneer reinforcement albeit nonintentionally in most cases. The overlying geosynthetic layers must physical fail (or pull out of their respective anchor trenches, see Hullings, 1996) in order for the slope to mobilize the weakest interface strength layer and slide. While this is not a recommended design situation, it does have the effect of increasing the FS-value. The extent of increase varies from a flexible geomembrane to a nonwoven needle punched protection geotextile (both with relatively low strengths) to a multilayered geosynthetic system with 2 to 8 layers of geosynthetics (with very high cumulative strengths).

We conclude with a discussion on factor of safety (FS) values for cover soil situations. Note that we are referring to the global FS-value, not reduction factors which necessarily must be placed on geosynthetic reinforcement materials when they are present. In general, one can consider global FS-values to vary in accordance with the site specific issue of required service time (i.e., the anticipated lifetime) and the implication of a slope failure (i.e., the concern). Table 2 gives the general concept in qualitative terms.

Table 2. Qualitative rankings for global factor-of-safety values in performing stability analysis of final cover systems, after Bonaparte and Berg (1987).

Duration→ ↓Concern	Temporary	Permanent
Noncritical	Low	Moderate
Critical	Moderate	High

Using the above as a conceptual guide, the authors recommend the use of the minimum global factor-of-safety values listed in Table 3, as a function of the type of underlying waste for *static* conditions.

Table 3. Recommended global factor-of-safety values for static conditions in performing stability analyses of final cover systems.

Type of Waste→ ↓Ranking	Hazard- ous waste	Non- hazardous waste	Aban- doned dumps	Waste piles and leach pads
Low	1.4	1.3	1.4	1.2
Moderate	1.5	1.4	1.5	1.3
High	1.6	1.5	1.6	1.4

It is hoped that the above values give reasonable guidance in final cover slope stability decisions, but it should be emphasized that engineering judgment and (oftentimes) regulatory agreement is needed in many, if not all, situations.

## ACKNOWLEDGMENTS

The opportunity of writing and presenting this paper on behalf of IGS and its Nominating Committee as the 1998 Giroud Lecture is sincerely appreciated. Financial assistance in its preparation by the consortium of Geosynthetic Institute members is gratefully acknowledged.

**ABSTRACT:** Geosynthetics play a very important role in modern barrier systems designed to control contaminant migration from waste disposal sites. This paper discusses the effect of temperature, the importance of consideration of clogging of filters and drainage layers, the service life of compacted clay liners beneath geomembranes, the hydraulic conductivity and service life of geosynthetic clay liners (GCLs), diffusion through GCLs, the service life of geomembranes and composite liner systems in the design of these systems. It discusses why any evaluation of equivalence of liner systems should go beyond simple hydraulic equivalency and should consider issues such as diffusive transport and service life. Finally, it highlights the importance of considering conventional stability issues in addition to contaminant transport issues in the design and construction of landfill barrier systems.

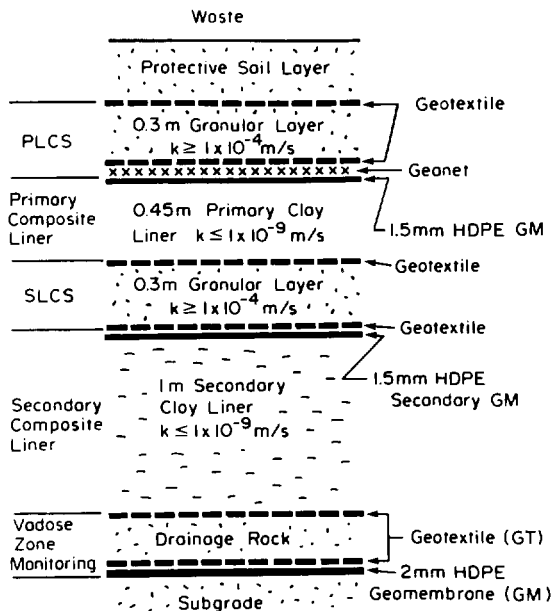

**KEYWORDS:** Liners, Geomembranes, GCLs, Leakage, Diffusion, Service life, Stability, Leachate collection

## 1 INTRODUCTION

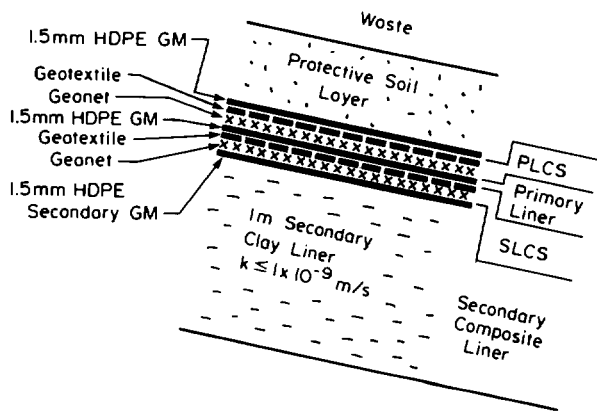

The protection of groundwater and surface water is now a major consideration in the design of waste disposal facilities in many countries. Typically, modern facilities will have a barrier system intended to limit contaminant migration into the surrounding environment to levels that will result in negligible impact. This system will generally include a primary leachate collection system intended to (a) control the leachate head acting on the underlying liner and (b) collect and remove leachate. The leachate collection system will typically incorporate a geotextile filter, a granular layer or geonet, and perforated collection pipes. The liner may range from a thick natural clay deposit to engineered liner systems involving one or more geomembrane (GM) and/or compacted clay liner (CCL) or geosynthetic clay liner (GCL). For example, Figure 1 shows a double composite liner system at the landfill base and a single geomembrane primary liner and composite secondary liner on the side slopes. Not all liner systems are this complicated. Many regulatory systems have both prescriptive designs (minimum) and also permit performance based design with appropriate justification (e.g. Germany 1993; USEPA 1994; MoEE 1996; and see Rowe 1997a for a discussion of the differences in these approaches). Figure 2 shows two simple composite liners involving a geomembrane (GM) over either a compacted clay liner (CCL) or a geosynthetic clay liner (GCL). It is assumed here that there is an attenuation layer (AL) between the base of the composite liner and an underlying aquifer. Since an aquifer is a geologic formation capable of yielding usable quantities of groundwater to wells or springs and since flow in the aquifer is principally in a horizontal direction, the aquifer that is present at some depth beneath many landfill sites often represents the

primary means by which contaminated groundwater can move off-site and impact on public health and safety. Thus a primary objective of the barrier system design is to minimize the escape of contaminants to groundwater and, in particular, to any underlying aquifer. Frequently, questions are raised concerning the equivalency of different systems such as those shown in Figure 2, or the need for double composite liners such as that shown in Figure 3. As discussed in Section 10, these questions should be addressed in terms of the objective of controlling the potential impact on groundwater quality to acceptable levels. However, this first requires consideration of the long term performance of the barrier system components, the different potential transport mechanisms such as advection (the movement of contaminants with flowing water/leachate) and diffusion (the movement of molecules or ions from regions of high concentration to regions of lower concentration), and the potential attenuation mechanisms such as biodegradation, sorption and dilution.

There are numerous factors requiring consideration in the design and construction of landfill barrier systems and there have been a number of excellent papers which provide an overview of many of these factors (e.g. Giroud & Cazzuffi 1989; Koerner 1990; Cazzuffi & Cancelli 1994; Gourc 1994; Bonaparte 1995; Gartung 1996; Daniel & Bowders 1996). The reader is referred to these papers for background on the different types of geosynthetics used in landfills, factors influencing their selection and factors to be considered in construction. This paper does not attempt to cover all of these issues but, rather, will focus in some greater detail on a number of important issues that have received limited attention in the literature and previous keynote lectures. In particular, attention will be focussed on (1) temperature in landfills; (2) the clogging of filters in leachate collection systems

(a) Base

and their influence on collection system service life; (3) service life issues related to compacted clay liners, geosynthetic clay liners and geomembrane liners; (4) diffusion and attenuation of contaminants in liner systems; (5) leakage through composite liners; (6) equivalence of liner systems (in the context of items 3, 4 and 5 above); and (7) stability of barrier systems.

Figure 2. Schematic showing two single composite liner systems: (a) Geomembrane (GM) over 0.6 m compacted clay liner (CCL) over a 3 m thick attenuation layer (AL) over an aquifer; and (b) GM over a geosynthetic clay liner (GCL) over a 3.6 m thick attenuation layer.

## 2 LANDFILL TEMPERATURE

The temperature in a leachate collection system can have a significant effect on the rate of clogging of the leachate collection system (Rowe et al. 1997g). The temperature of the liner can have a significant effect on the service life of geopipes in the collection system and any geomembrane liner (see Section 7 and Koch et al. 1988; Koerner et al. 1992; Hsuan & Koerner 1995). Temperature also has implications with respect to potential fluid movement and moisture content decrease in a compacted clay liner (Collins 1993), especially below a geomembrane (see Section 4). Finally, it has implications with respect to the rate of contaminant diffusion through low permeability liners (i.e. geomembrane, compacted clay or geosynthetic clay liners) (see Section 10).

The literature contains a wide range of reported temperatures in landfills. High temperatures (50°C to 70°C) have been reported in a number of European landfills (Ramke 1989; Lechner & Lahner 1991). For example, Brune et al. (1991) reported (Figure 4) temperatures ranging from 24°C to 38°C in a leachate drain beneath 4-6 year old waste at the Altwarmbüchen Landfill. This landfill had been rapidly filled (10-20 m/a) and although it was in a methane forming phase after 4-6 years, the leachate was still acidic and very strong. In contrast, at the Venneberg Landfill the temperature in the drain only ranged from 14°C to 20°C. This landfill had been filled much slower (2 m/a) than the Altwarmbüchen Landfill and the leachate was only lightly loaded with both organic and inorganic contaminants. In both cases, the temperature was measured about 4 years after the landfill was completed over the drains.

Figure 4. Temperature in drains at two German landfills approximately 4 years after last waste placed above the drains (modified from Brune et al. 1991).

High temperatures are often attributed to aerobic conditions, however, in both cases the generation of CO<sub>2</sub> and CH<sub>4</sub> provided evidence of anaerobic conditions. The primary differences between the two cases appear to have been (a) the rate of landfilling; (b) the thickness of waste; and (c) there had been pre-composting of the waste at the Venneberg Landfill. This illustrates that there is a relationship between the nature of the waste, landfilling practice and temperature.

There is also a relationship between location in the landfill and temperature. Figure 5 shows that the

Figure 5. Temperature variation with distance in gas and leachate collection pipe at an operating landfill in Germany (modified from Collins 1993).

temperature increases with distance into the landfill and above the landfill base at an operating German landfill. Again, the temperatures at the level of the collection pipe are high (20-37°C). The temperature and the elevation of the gas collectors exceeded 60°C.

Figure 6 shows the variation in temperature with depth at two locations in an old German landfill (1936-1980). There is clear evidence of increasing temperature with depth from surface with the peak temperature being reached at a depth of about 30 m below the surface. The temperature then decreases towards the base of the landfill. The base temperature in 1990 (i.e. 10 years post-closure) ranged from 30° to 60°C in this landfill where the leachate level is reported to be 4-6 m above the base of the landfill.

The temperature profiles noted above are not restricted to Germany. Figure 7 shows a similar profile in a 30 m deep Japanese landfill. The landfill was filled very quickly (~10 m/a between 1976-1979). Trends similar to that noted above for the German landfill can be observed. The peak temperature, observed in 1985, was almost 70°C. The temperature generally decreased

Figure 6. Temperature variation with depth at two locations in an old landfill (1936-1980) in Hannover, Germany (waste circa 1938 at bottom).

Figure 7. Temperature variation with depth in Tokyo Port Landfill (modified from Yoshida et al. 1996).

between 1985 and 1988. At the base of the landfill the temperature reached 50°C. The leachate mound is typically 20-25 m above the base of the landfill.

At the Brock West Landfill in Canada (Bleiker 1992), temperatures were found to increase from about 20°C near the surface to 60°C at a depth of about 20 m.

Conditions were anaerobic. Sludge had been disposed of at this landfill and the leachate mound was 22-25 m above the base.

However, not all researchers have encountered the high temperatures noted above. Koch et al. (1988) report temperatures above a landfill liner of between 20°C and 25°C. Haxo and Haxo (1989) report temperatures of 5°-20°C under anaerobic conditions.

Koerner et al. (1996a) have monitored the temperature above the liner at three different landfills in Pennsylvania, Florida and California, U.S.A. over periods of 6, 3 and 5 years respectively. Over the period monitored, the temperature on the liner has remained relatively constant within the following ranges: Pennsylvania 18-23°C; Florida 20-30°C; and California 10-30°C. The Pennsylvania landfill is in a humid area (mean annual precipitation of 1045 mm; mean annual temperature 12.6°C). There is an operational (0.6 m thick gravel) leachate collection system above the thermocouples on the liner and about 50 m of waste over the collection system. The Florida landfill is in a near tropical area (mean annual precipitation of 1920 mm; mean annual temperature 22.5°C). The landfill has a composite liner with a 0.7 m thick sand leachate collection system above the thermocouples on a 1.5 mm HDPE geomembrane. The California landfill has a mild, semi arid climate (mean annual precipitation of 450 mm; mean annual temperature 15.9°C). There is a geonet leachate collection layer and 0.3 m thick soil "operating layer" above the geomembrane being monitored. There is 3-11 m of waste over the thermocouple sensors (based on Figure 2, Yazdani et al. 1995). The Pennsylvania and California landfills have composite, low permeability final covers. The Florida landfill does not yet have a final cover. It would appear that these landfills are giving rise to temperatures at the base of the landfill much less than observed in the landfills previously discussed, although it remains to be seen whether this will continue.

It may be hypothesized that the limited amount of water in the waste combined with an operational leachate collection system, may be responsible for slowing biological activity which, in turn, is keeping the temperature low for at least the first five years. One can hypothesize several other possible reasons for the lower temperatures. Firstly, the waste in the U.S.A. may have a lower organic content than in other countries. While possible, it is unlikely that there is a significant difference in the nature of waste in large urban areas in the U.S.A. and Toronto, Canada where higher temperatures have been recorded at both the Brock West and Keele Valley Landfills. Secondly, thermocouples were directly on the geomembranes and measured temperatures over longer time periods than, say, spot measurement at other landfills. However, this is an unlikely explanation since at the Keele Valley Landfill discussed in the following

paragraph, similar but longer term monitoring above the clay liner has revealed a gradual increase in temperature with time as the water content of the waste increased. Finally, all three landfill liner systems were only 3-4 m above the water table that could provide a heat sink as groundwater movement removes heat from below the site. While possible, this also seems an unlikely explanation when one compares the conditions at these U.S. landfills with those at both the Brock West and Keele Valley Landfills in Toronto, Canada. For example, in the Keele Valley Landfill discussed in the following paragraph the water table was originally 2-3 m below the base of the pit (Reades et al. 1989) and hence 3-4 m below the top of the liner but the temperature in parts of the landfill has now risen to over 40°C as shown in Figure 8. The water table has now dropped to 4-6 m below the liner due to the reduced recharge after landfilling (Barone, personal communication) however, even so, it is likely that the groundwater at this landfill would be a greater heat sink than at the other sites due to the lower groundwater temperature in Toronto. Because of the likely similarity of the Keele Valley waste to U.S. waste, the longer term monitoring (13 years of data) and the similar proximity to groundwater, the Keele Valley Landfill provides an excellent contrast to the three U.S. landfills examined by Koerner et al. (1996a) since the major difference would appear to be the level of leachate mounding.

The Keele Valley Landfill (KVL) is located in an old sand and gravel pit in Maple, Ontario and is operated by the Municipality of Metropolitan Toronto. It became operational in 1983 and has recently been constructed to its maximum approved footprint of approximately 99 ha. It is still active and has an original estimated mass capacity of approximately 20 Mt. No sewage sludge has been disposed of at Keele Valley. The highest refuse contours are about 60 m above the liner and the proposed average thickness is about 30 m for the currently approved final contours. The average annual precipitation is 780 mm and the annual average temperature is 8.1°C. At the end of 1997 there was an intermediate 0.15 m thick sand cover over 60% of the site and a final cover (0.15 m of topsoil and 0.9 m of silty sand) over the remaining 40%. The leachate has mean annual COD of between 8,698 to 17,116 mg/L, mean annual BOD<sub>5</sub> of 3,641 to 12,367 mg/L and BOD<sub>5</sub>/COD ratio of 0.47-0.88 (Rowe 1995).

The KVL has an approximately 1.2 m thick compacted clayey till liner with a hydraulic conductivity of less than 10<sup>-10</sup> m/s (King et al. 1993). It has been constructed in four stages. In each stage, the liner is covered by about 0.3 m of sand intended to provide desiccation protection to the liner. In Stages 1 and 2, the primary leachate collection system consists of lateral french drains (50 mm, nominal diameter, stone) at spacings of about 65 m sloping towards the main collection pipes (spacing 200 m).

Figure 8. Variation in temperature, leachate head and waste thickness above base of landfill - Keele Valley Landfill, Canada (modified from Barone et al. 1997).

In Stages 3 and 4, there is a 0.3 m thick continuous stone drainage blanket of 50 mm clear dolomitic limestone over an approximately 0.3 m thick sand protection layer and clayey liner. A woven geotextile is placed between the stone and the sand. The waste is placed directly on the stone drainage layer.

At the Stage 3 monitor shown in Figure 8, the waste is up to 7 years old and over the 7 year period the leachate head has been at or below about 0.1 m and the temperature above the liner has been relatively constant at about 12°C (Barone et al. 1997) which is fairly consistent with the average leachate temperature (Fleming et al. 1997).

Examining the data for one Stage 1 monitor (Figure 8) it can be seen that for the first 8 years the head remained low and the temperature increased from a few degrees to about 12°C. However, since 1992 the leachate head has increased to 5.4 m and the temperature is now over 40°C. Based on five monitoring locations in Stage 1, the average temperature at the base of the landfill is 33.4°C and the average leachate head is 4-6 m. In contrast, based on thirteen monitors in Stage 3, the average temperature is 13.6°C and the average leachate head is less than 0.4 m. The relatively rapid increase in head in Stage 1 in the 1990s is attributed, at least in part, to attempts to rapidly stabilize the waste by injection of groundwater into the waste (now discontinued) and in part due to the nature of the collection system in this part of the site.

The data presented to this point would suggest that the temperature may vary depending on the rate of landfilling but that a significant factor affecting temperature is the water content of the waste and, in particular, the saturated thickness of the waste.

Apart from isolated saturated zones due to perching of leachate, the saturated thickness is related to the leachate head above the base. Figure 9 shows the data presented by Barone et al. (1997) plus some additional data. It shows a strong correlation between the temperature at the base of the landfill and the leachate head above the base.

As will be discussed in subsequent sections, potentially, the temperature at the liner can have a significant effect on diffusion through composite liner systems, the service life of the liner system, and the service life of plastic pipes in the leachate collection system. In turn, the temperature appears to be related to the water content of the waste and the level of leachate mounding. During the early life of the landfill, the temperature appears to be low if the water content of the waste is low. As the moisture content of the waste increases (e.g. due to moisture movement through the landfill cover or enhanced infiltration), the temperature appears to rise. However, as evidenced by the Keele Valley Landfill, the most significant factor appears to be the level of leachate mounding (the primary difference between Stages I and II, and III and IV). Thus the control of the leachate head may be important until the landfill is biologically stabilized. This highlights the importance of the design, construction and operation of the leachate collection system.

### 3 FILTERS IN LEACHATE COLLECTION SYSTEMS

Leachate collection systems may typically take the form of perimeter drains around the edge of the waste

Figure 9. Variation in temperature at landfill base with leachate head for a number of landfills (modified from Barone et al. 1997).

and/or underdrain systems below the waste which may include either french drains (typically perforated pipes embedded in granular material; e.g. see Figure 10), at some spacing, granular drainage blankets with perforated pipes at some specified spacing (see Figure 11), and geosynthetic (geonet) drainage layers (e.g. see Figure 1b). Geotextiles are often used as filters between the waste and the drainage layer - especially when either coarse drainage material (e.g. gravel) or geonets are used to provide a drainage blanket (see Figures 1, 10 and 11). Key issues in the design of these systems is the need to provide adequate drainage, prevent structural failure (e.g. crushing, or other pipe failure) and to minimize clogging. Of these, the greatest challenge is minimizing clogging and prolonging the life of the leachate collection system.

Figure 10. Schematic showing examples of poor leachate collection system designs (a) problematic; (b) even worse. Schematic also shows a leachate mound developed once there is excessive clogging of the geotextile filter and/or the drainage stone and/or the pipe. For details regarding calculation of mound height see Rowe et al. (1995b). Note: there would also be a mound to the left and to the right of the section shown and the mound would only be symmetric as a special case; generally, it would not be symmetric due to factors such as variability of clogging, hydraulic conductivity of waste etc. (modified from Rowe 1992).

### 3.1 Clogging of Leachate Collection Systems

Leachate typically flows down through the waste and into a granular layer (sand, gravel or crushed stone). It is usually intended that it will then flow through the void space between the solid particles in the granular media to plastic (usually High Density Polyethylene HDPE) collector pipes. These pipes are an essential component of the collection system and are perforated to allow leachate entry. The pipes typically conduct the leachate

Figure 11. Schematic showing examples of blanket leachate collection system designs including a geotextile filter layer (modified from Rowe 1992).

to pumps that are used to remove the leachate from the landfill for treatment.

Leachate contains nutrients that will encourage bacterial growth within the waste, in geotextile filters, in granular drainage layers and around the perforations in the leachate collection pipes. Clogging of the leachate collection system involves the filling of the void space between solid particles as a result of a combination of biological, chemical and physical events. Particulate clogging can be a problem in some cases, but can be controlled by appropriate design (e.g. see Giroud 1996a). There is a growing body of evidence that a major component of the clogging is microbiologically related. For example, microbiological and chemical studies (Brune et al. 1991; Rowe et al. 1995c, 1997f,g and Rittmann et al. 1996) have shown that the clogging of drainage systems is the result of a mobilization process involving fermentative bacteria together with iron and manganese reducing bacteria, followed by precipitation processes involving primarily methanogenic- and sulfate-reducing bacteria. The clog typically has a soft (organic) and hard (predominantly  $\text{CaCO}_3$ ) component. The rate of clogging is related to the flow through the critical component of the system, the void size, the temperature in the collection system (generally higher temperature implies faster clogging) and the leachate chemistry (especially  $\text{BOD}_5$ , COD, TSS and Ca). The reduction in void space caused by biofilm growth and chemical precipitation (Brune et al. 1991; Vandevivere & Baveye 1992; Rowe et al. 1995c, 1997g; Fleming et al. 1997) results in a concurrent reduction in the hydraulic conductivity of these drainage systems and hence a reduction in their capacity to laterally transmit leachate. For example, Figure 12 shows the relationship between reduction in porosity (due to clogging) and the reduction in hydraulic conductivity of a granular medium with 6 mm diameter particles. This data was obtained by passing leachate

Figure 12. Variation in measured hydraulic conductivity of a granular medium (6 mm diameter particles) with decreasing drainable porosity due to biologically induced clogging resulting from permeation with landfill leachate.

through columns of glass beads. Different column tests were performed using actual Keele Valley Landfill leachate and synthetic leachate with a similar chemical composition (see Rowe et al. 1997f, g) and both gave a similar relationship between hydraulic conductivity and drainable porosity. The clog composition was typical of that encountered in the field by Brune et al. (1991) and Fleming et al. (1997) and more than 50% of the clog material (by dry weight) was calcium carbonate when the tests were terminated.

It must be recognized that "clogging" of a drainage layer is not synonymous with it becoming impermeable (Rowe et al. 1995b). On the contrary, a clogged sand blanket may still be substantially more permeable than, say, an underlying clay liner. "Clogging" of a drainage layer becomes significant when the hydraulic conductivity of the blanket drops to or below the hydraulic conductivity of the overlying waste. At this point, the reduction in hydraulic conductivity will result in the buildup of a leachate mound within the landfill that may subsequently result in increased temperature and decreased service life of any composite liner (see Sections 4 and 7) as well as potential impacts on surface water due to leachate seepage from the sideslopes of the landfill and increased contaminant migration through the barrier system and into the groundwater (see Section 10).

### 3.2 Field Examples of Clogging

Examples of clogging of leachate collection systems can be found in a number of existing landfills including Toronto's large Brock West Landfill where a 20 m high leachate mound built up during the first 11 years of operation (Dames & Moore 1992). Here, the primary leachate collection system consists of leachate collection

pipes at spacings ranging between 50 m (newer portions of the landfill) and 200 m (older portions of landfill). The collection system is reported to involve "french drains" with a perforated pipe in a pea gravel (5-10 mm diameter) pipe bedding. No geotextile was used. The landfill has accepted a significant quantity of sewage sludge in addition to MSW.

Another example of clogging of the drainage material around leachate collection pipes in the drain around a landfill has been reported by McBean et al. (1993), who noted that extensive clogging had resulted in excessive leachate mounding and leachate seeps. This design also involved french drains at wide spacing.

The Keele Valley Landfill provides two different examples of clogging. Firstly, there is a sand "protection" layer over the liner. Field exhumations (Reades et al. 1989) have shown that this sand blanket has become clogged and does not contribute to the hydraulic performance of the collection system, but rather, has become part of the "diffusion barrier" with the diffusion profile beginning at the interface between the more permeable waste (where lateral flow dominates) and the less permeable (clogged) sand blanket. Koerner and Koerner (1995b) reported similar clogging of a sand protection layer (Case 3, Table 1) where after 10 years the hydraulic conductivity dropped three orders of magnitude from  $4 \times 10^{-4}$  m/s to  $2 \times 10^{-7}$  m/s and leachate was flowing through the waste rather than the sand.

Exhumation of portions of the leachate collection system at the Keele Valley Landfill after four years (see Table 1 and Rowe et al. 1995c, 1997g; Fleming et al. 1997) indicated a three order of magnitude drop in the hydraulic conductivity of relatively uniform 50 mm stone near the leachate collection pipe (although the hydraulic conductivity was still sufficient to transmit leachate). Clogging was observed to be substantially less (Case 2, Table 1) in areas where a geotextile filter was used between the waste and the stone.

Koerner and Koerner (1994, 1995b) have described exhumations of three leachate collection systems (see Table 1, Cases 3, 4 and 5) and found excessive clogging of the geotextile in two cases where the geotextile was wrapped either around the perforated pipe or around the stone in a drainage trench. The reduction in hydraulic conductivity for these three cases and a fourth case (Case 6) involving geotextiles around well casing from a gas extraction system are summarized in Table 2.

### 3.3 Implications for Design

Research by Koerner et al. (1994) suggested that the hydraulic conductivity of geotextile decreased with increasing leachate flow rate. More generally, recent research by Rowe et al. (1998b) has indicated that clogging is directly related to the leachate mass loading

Table 1. Summary of observations from exhumation of collection systems in North America.

Waste Type <sup>1,2</sup> Age; Leachate	Collection System Design <sup>3</sup>	Key Observations
1.MSW & LI ~4 years COD=14,800 mg/L BOD <sub>5</sub> =10,000mg/L pH=6.3 Performance: ·Adequate at time of exhumation	·Blanket underdrain: Waste over 50 mm relatively uniform stone; 200 mm,SDR 11 HDPE pipe; 8 mm holes ·Pipe never cleaned ·No geotextile between waste and stone	·30-60% loss of void space in upper stone ·50-100% loss of void space near pipe ·Permeability of stone decreased from ~10 <sup>-1</sup> m/s to ~10 <sup>-4</sup> m/s ·All lower holes in pipe blocked; majority of upper holes blocked ·Large clog growth inside pipe
2.MSW & LI As for #1 above	·Blanket underdrain: waste over geotextile over 50 mm stone (rest as above) (GT: W;M <sub>A</sub> =180 g/m <sup>2</sup> , AOS=.475 mm, t <sub>GT</sub> =0.6 mm, ψ=0.04 s <sup>-1</sup> )	Substantially less clogging than observed in #1 above where there was no GT ·0-20% loss of void space in upper stone below geotextile
3.MSW & LI; LR ~10 years COD=31,000mg/L BOD <sub>5</sub> =27,000mg/L pH ~ 6.9 Performance: · No flow in LCS · High leachate mound	·Toe drain only ·Trench with 600 mm of crushed stone (6 to 30 mm) around geotextile wrapped 100 mm SDR 41 perforated PVC pipe (GT:HBNW; M <sub>A</sub> =150 g/m <sup>2</sup> , AOS=.15 mm; t <sub>GT</sub> =0.30 mm, ψ=1.1 s <sup>-1</sup> )	·Flow reduction noted after 1 year ·Pipe crushed (likely due to construction equipment) ·Substantial reduction in void space and cementing of stone. k reduced from 2.5×10 <sup>-1</sup> m/s to 1.2×10 <sup>-4</sup> m/s ·Sand (SW; AASHTO #10) layer above GM was clogged and leachate drained on top (not through this layer). k reduced from 4×10 <sup>-4</sup> m/s to 2×10 <sup>-7</sup> m/s ·Excessive clogging of GT (see Table 2)
4.MSW & LI; LR 6 years COD=10,000mg/L BOD <sub>5</sub> =7,500mg/L pH ~ 7.5 Performance: · Drain function- ing adequately	·Perimeter drain to control leachate seeps geotextile wrapped trench with 6-18 mm gravel and 100 mm SDR 30 HDPE perforated pipe (GT: W, M <sub>A</sub> =170 g/m <sup>2</sup> ; POA=7%, AOS=.25 mm; t <sub>GT</sub> =0.41 mm; ψ=0.9 s <sup>-1</sup> )	·Only small reduction in k of gravel from 5.3×10 <sup>-1</sup> m/s to 2.8×10 <sup>-1</sup> m/s ·Marginal clogging of GT (see Table 2)
5.ISS (included slurried fines 70% finer than 150 μm) 0.5 years COD=3,000 mg/L BOD <sub>5</sub> =1,000mg/L pH=9.9 Performance: · No flow in LCS	·Blanket underdrain: Waste over protection sand (0.075-4 mm) over geotextile (AOS=.19 mm) over pea gravel (1-20 mm) drainage layer; 100 mm diameter geotextile wrapped HDPE perforated pipe; 12 mm dia. holes (GT: NPNW, M <sub>A</sub> =330 g/m <sup>2</sup> , AOS = .19 mm; t <sub>GT</sub> =2.7 mm, ψ=1.8 s <sup>-1</sup> )	·High leachate mound ·Upper geotextile functioning (see Table 2, Case 5a) ·Pea gravel relatively clean ·Geotextile wrapping around perforated pipe excessively clogged (see Table 2, Case 5b) ·Once geotextile sock removed, leachate flowed freely ·Heavy geotextile sock clogging at location of perforations in pipe

in terms of the mass of COD (Chemical Oxygen Demand) and calcium per unit area perpendicular to leachate flow. The leachate mass loading is a function of (a) the concentration of volatile fatty acids (represented in terms of COD) and metals (especially calcium) in the leachate; (b) the flow rate per unit area; and (c) elapsed time. Thus when leachate that is generated over a large area of the landfill is directed through a filter surrounding isolated drainage stone (french drains) (Figure 10a) or even worse, a filter wrapped around the pipe itself (Figure 10b), there is a confluence of flow across the filter and the confluence factor is approximately equal to the area of the landfill divided by the area of the filter material through which the leachate must flow. Since clogging depends on flow rate per unit area, this confluence of flow increases the mass loading per unit time and hence increases the rate of clogging of the geotextile and the drainage stone (it is assumed here that clogging of pipes is mitigated by regular cleaning). However, even more important is the effect that clogging has when it does occur. When the resistance to flow into the drainage pipe is increased, a leachate mound will develop in the waste between the drains (see Figure 10). This mound will maintain some flow to the pipe but will also increase flow out through the underlying liner. Based on this, Rowe (1992) cautioned against designs such as that shown in Figure 10. The field investigation discussed in the previous subsection confirms the soundness of this recommendation. Geotextile used to wrap drains or pipes showed a drop of hydraulic conductivity of between two and five orders of magnitude (to as low as  $4 \times 10^{-8}$  m/s: Case 5b, Table 2).

Rowe (1992) recommended the use of a suitably selected geotextile as a blanket filter above a blanket stone underdrain layer (Figure 11) and the findings of both Rowe et al. (1995c: Cases 1 and 2, Table 1) and Koerner and Koerner (1995b: Case 5a, Table 1) provide some evidence that a suitable blanket geotextile will

function adequately. These investigations demonstrated (Cases 2, 4 and 5) that the geotextile provided good protection to the stone, which experienced relatively little clogging compared to that observed when there was no geotextile filter between the waste and stone drainage medium (Cases 1 and 3). Geotextiles used as shown in Figure 11 will experience some clogging, however, even if a perched leachate mound developed above the geotextile, there would be no effect in terms of contaminant transport through the underlying liner. The level of leachate perching above the geotextile will depend on the leachate generated per unit area of the landfill and the hydraulic conductivity of the geotextile filter as discussed below.

In addition to these field examples, clogging of geotextiles in MSW leachate has been demonstrated by numerous laboratory studies (Cancelli & Cazzuffi 1987; Koerner & Koerner 1990, 1995b; Cazzuffi et al. 1991; Brune et al. 1991; Fourie et al. 1994 etc.). These studies show that the magnitude of the decrease in hydraulic conductivity  $k_n$  (and permittivity  $\psi$ ) will depend on the geotextile (e.g. openness of the pore structure), the flow rate, and the concentration of the leachate. Koerner and Koerner (1995b) provided data from a series of tests where mild leachate was passed through a number of different geotextiles yielding a decrease in hydraulic conductivity of between about two to five orders of magnitude at the highest flow rate examined. The worst hydraulic conductivity observed for nonwoven needle punched geotextile was similar to or higher than that observed in the field ( $6 \times 10^{-8}$  m/s in Table 3 vs  $4 \times 10^{-8}$  m/s in Table 2) under the most extreme conditions. Generally, the level of decrease was similar (four orders of magnitude) to that in the field under severe conditions. Koerner and Koerner (1995b) recommended that for mild leachate, a geotextile in contact with the waste should have the properties given in Table 4.

Giroud (1996a) has discussed the issue of geotextile

Table 3. Decrease in hydraulic conductivity of geotextiles permeated with leachate (average COD: 3000-4000 mg/L; BOD: 2000-2500 mg/L; TSS: 300-600 mg/L) at a rate of  $2 \times 10^{-5}$  m/s ( $620 \text{ m}^3/\text{a}/\text{m}^2$ ) (modified from Koerner et al. 1994).

Type of Filter	Unit Mass $M_A$ ( $\text{g}/\text{m}^2$ )	POA (%)	AOS (mm)	Thickness $t_{GT}$ (mm)	Initial $k_n$ (m/s)	Initial Permittivity $\psi$ ( $\text{s}^{-1}$ )	Equilibrium $k_n$ (m/s)	Flow to Equilibrium ( $\text{m}^3/\text{m}^2$ )
Uniform Sand					$4 \times 10^{-3}$		$2 \times 10^{-6}$	119

burst strength, kPa	1300	1700

clogging as part of a broad review of filter design. He tentatively recommends that sand and nonwoven geotextile filters should not be used even if the waste has been stabilized to produce low strength leachate by pretreatment. Rather, he recommends the use of monofilament woven geotextiles with a minimum filtration opening size (AOS) of 0.5 mm and a minimum relative open area (POA) of 15%, with a preference for a POA greater than 30%. The rationale for these recommendations arises from the observations that (a) the specific surface area for monofilament woven geotextile is much smaller than for nonwoven geotextiles and this decreases the surface area for biofilm growth; (b) the woven filter allows more effective and rapid

movement of fine material (i.e. material not intended to be retained) and leachate through the filter; and (c) due to their compressibility, the filtration characteristics of a nonwoven geotextile vary with applied pressure and the critical filtration characteristics should be assessed under design pressures which could be up to 500 kPa. There is some evidence to suggest that geotextiles selected in accordance with Giroud's (1996a) recommendations are likely to experience less clogging and reduction in hydraulic conductivity with time (e.g. see Table 3) than geotextiles that simply meet the requirements of Koerner and Koerner (1995b and Table 4).

It is important to recognize that Giroud's (1996a) recommendations are based on the premise that we wish to minimize clogging of the filter. This may indeed be the case for some design situations (e.g. if one insists on using a design such as is shown in Figure 10a). However, the writer would argue that while excessive clogging is undesirable, the processes that cause clogging also provide leachate treatment and, in so doing, (a) decrease the potential for clogging at more critical zones (e.g. near collection pipes) and (b) reduce the level of leachate treatment required after removal of leachate from the landfill. Although the subject of ongoing research, it appears desirable to design the leachate collection system to maximize leachate treatment while maintaining its design function (see Fleming et al. 1997). Under these circumstances, and using a design such as the one shown in Figure 11, a sand or nonwoven geotextile filter may actually be desirable provided that the hydraulic conductivity did not drop to such a point as to cause perching of leachate that would have negative effects such as side seeps.

Based on published data, it appears unlikely that the

hydraulic conductivity of the geotextile selected in accordance with either Giroud's (1996a) or Koerner and Koerner's (1995) recommendations would be below  $4 \times 10^{-8}$  m/s (1.3 m/a) for normal conditions and more likely it would be of the order of  $1 \times 10^{-7}$  m/s or higher. If the geotextile was used in a blanket drain (e.g. see Figure 11), one can quickly establish that there would be negligible perched leachate on the geotextile for typical rates of leachate generation (less than  $3 \times 10^{-8}$  m/s or  $1 \text{ m}^3/\text{a}/\text{m}^2$ ). Thus, while recognizing that geotextiles will clog, based on the available data it appears that an appropriately selected geotextile used to protect gravel in a blanket drain will improve the performance and the service life of the drainage stone and not cause excessive perched leachate mounding.

The design and service life predictions for leachate collection pipes and drainage stone is beyond the scope of the present paper. The interested reader is referred to Rowe et al. (1994, 1997c,g) for more information. This is the subject of ongoing research.

#### 4 SERVICE LIFE OF COMPACTED CLAY LINERS BELOW GEOMEMBRANES

Composite liners consisting typically of a geomembrane over compacted clay have been widely adopted in "standard" landfill designs (e.g. Germany 1993; USEPA 1994, MoEE 1996). However, for the composite liner to perform adequately, it is essential that both the compacted clay and geomembrane meet the design specifications for the design life of each component.

The clay liner is intended to limit leakage through any holes in the geomembrane, act as a partial diffusion barrier and to provide attenuation of certain (e.g. organic) contaminants. To meet these requirements, it must maintain a hydraulic conductivity of less than or equal to the design value for the contaminating lifespan of the landfill (i.e. period of time during which the escape of contaminant due to a failure of the engineered system would have an adverse impact on the environment).

For a clayey liner, the service life is the period of time during which the bulk hydraulic conductivity of the liner may be expected to fall within the design range. Provided that a clayey liner has been properly designed and constructed and appropriate attention has been given to clay-leachate compatibility (see Rowe et al. 1995b), there is no reason to believe that it would not perform within the design range of hydraulic conductivity for thousands of years provided that it is not allowed to desiccate after placement. Desiccation can be related to a change in water content in the clay that could occur (a) after construction of the clay liner and before placing the geomembrane; (b) after placing the geomembrane and before covering with waste; and (c) after placement of

waste. These will be discussed below.

#### 4.1 Desiccation Before Placement of Waste

Desiccation can occur within hours after liner placement if the clay is not kept moist. The extent of desiccation cracking will depend on the mineralogy of the clay, the compaction water content and the degree and length of exposure to drying conditions. For example, in an experiment at the Keele Valley Landfill a compacted clay liner containing 20% clay size (clay minerals, mostly illite and chlorite) was found to crack to a depth of 120 mm (maximum width 12 mm) over a five week period (mostly in June) (Rowe et al. 1994). However, this form of desiccation is readily prevented by adopting appropriate construction procedures and, if it does occur, can be observed and rectified by removal and replacement of the cracked portion of the clay liner prior to placement of the geomembrane provided there is a good construction quality assurance program in place.

It has been shown that the temperature of a geomembrane exposed to the sun may rise to 80°C (Felon et al. 1992) and temperatures of 60°-70°C are not unusual. It has been shown (Pierson et al. 1993; Koerner & Koerner 1995a) that the temperature can be reduced by the use of a white coated geomembrane (see Table 5).

Table 5. Maximum temperature (°C) of exposed geomembrane in Philadelphia, U.S.A., Latitude 40° in different regions (after Koerner & Koerner 1995a).

Season of Year	Ambient Temperature	Black Geomembrane	White Geomembrane
Winter	5	13	2
Spring	22	46	38
Summer	30	70	57
Fall	18	35	28

However, Pelte et al. (1994) have also shown that while a white, glossy, reflecting coating adhering to the geomembrane surface effectively decreases the geomembrane temperature (relative to a black geomembrane) for given solar conditions, the placing of a thick white geotextile over the geomembrane only delays the heating of the underlying geomembrane and does not reduce the final temperature.

A high temperature at the geomembrane has the potential to cause (a) evaporation of water from the compacted clay liner into any air space between the clay and the geomembrane and (b) moisture movement from the region of higher temperature to the region of lower temperature. Mechanism (a) is significant in the context of heating and cooling cycles while mechanism (b) is most significant when there is a sustained temperature gradient

(Döll 1996). Both mechanisms cause a decrease in water content in the clay below the geomembrane which in turn can cause shrinkage and consequent desiccation. This is particularly likely to be a concern on side slopes where there can be condensation and movement of previously evaporated water downslope during the cooler portions of the cycle. Basnett and Bruner (1993) give an example where a compacted clay liner on a side slope was observed to desiccate through the full (0.3 m) depth with cracks of 12-25 mm width. This liner had been exposed to daily cycles of heating and cooling for a period of 3 years. Rowe et al. (1998a) also report severe desiccation cracking of a compacted clay liner below a geomembrane in a leachate lagoon. Here the geomembrane had been exposed to temperature cycles for 14 years. Cracking was restricted to the side slopes above the leachate level.

Corser et al. (1992) report results from a test liner/cover left exposed for six months (April-October; temperature of geomembrane reaching 43°C). The section where the geomembrane was in intimate contact with the clay (where a moisture content increase was observed) was found to have performed well. However, in areas where there was an air space between the geomembrane and clay (i.e. at wrinkles/waves) the clay had dried and cracked with cracks up to 6 mm wide extending to a depth of about 75 mm. In another section where there had been a 0.6 m thick soil cover over the geomembrane only very minor hairline cracks (many of which formed after the geomembrane was removed) were observed.

Bowders et al. (1997) performed laboratory simulations of heating cycles for two clays. In these tests there was the potential for some water loss as water vapour. It was found that steady state temperatures were established in the clay at depths of 0.2 and 0.3 m after about 7 days of heating. After 30 days, there was significant moisture drop in the highly plastic clay (PI ~42-48%) to a depth of about 0.17 m with a black geomembrane (average peak temperature ~ 64°C) but only minor moisture loss below the white geomembrane (average peak temperature ~ 59°C). After 60 days, the zone of significant desiccation had extended to 0.21 m and 0.07 m (black and white respectively) and cracks extended to depths of 0.3 m (full thickness) and 0.06 m for the black and white geomembranes respectively. Similar tests with a lower plasticity clay (PI ~ 28%) conducted for about 110 days showed less moisture loss in a given time period than the higher plasticity clay for both geomembranes and again the moisture loss and cracking were less for the white geomembrane, however some cracks extended to a depth of 0.3 m for both geomembranes. While these tests do not fully simulate field conditions, combined with the field observations noted earlier they serve as a warning that there can be significant desiccation of the upper 0.15 m of liner in 2 to 8 weeks and that while a white

geomembrane allows a little longer exposure before serious cracking (maybe 4 weeks), there is still a need to cover the geomembrane quickly.

Both the field cases and laboratory tests noted above illustrate that cracking of the clay liner does occur due to exposure to high temperature and that problems will be greatest on side slopes where there are wrinkles. The available evidence would suggest that provided the geomembrane is covered relatively quickly the depth of desiccation cracking is going to be limited to the upper portion of the clay liner. However, the presence of cracks in even the upper few centimeters could still be significant (especially on the base of the landfill) if these cracks were beneath a hole in the geomembrane since the cracked clay liner would more readily allow movement of leachate through the hole and along the crack. There is no evidence to suggest that the cracks will necessarily close up and even if they do there would still likely be an increase in hydraulic conductivity (due to the macrostructure that has been induced) relative to the original design value. The foregoing suggests that there is a need to cover the geomembrane with the protection layer and the leachate collection layer as soon as possible after placement of the geomembrane.

#### 4.2 Desiccation After Placement of the Waste

Holzlohner (1989, 1995) has suggested that the risk of desiccation of clay liners that have been covered and are no longer subject to solar heating depends on five prime factors: properties of the clay liner, properties of the underlying subgrade, overburden pressure, temperature gradient across the liner and the depth to groundwater. There is still much unknown about the potential for desiccation due to landfill induced thermal effects. As indicated in Section 2, high temperature can be achieved in landfills and this can be expected to create a thermal gradient to the groundwater that has the potential to move moisture away from the heat source (i.e. the landfill). When the clay is overlain by a geomembrane, there is no additional source of water from above and hence there is greater potential for desiccation of a clay liner as part of a composite liner due to thermal effects than for a clay liner used alone. Since there also appears to be a correlation between temperature (at the liner) and the leachate mound (see Figure 9), it would appear to be desirable to keep the leachate mound low and hence control the rate of biological degradation and consequent heat generation. This would minimize the potential for desiccation. This indicates the need to carefully monitor landfill temperature and performance when landfill operators cease leachate collection. If a significant increase in temperature was observed, consideration should be given to resuming leachate removal since a significant rise in temperature may (a)

increase the potential for desiccation cracking of the clay liner, (b) decrease the service life of the geomembrane liner (see Section 7) and (c) increase diffusion through the liner (see Section 10).

The risk of desiccation may be expected to be decreased in situations where there is a high overburden stress. Holzlöhner (1992) reported that cracking may be prevented if the soil suction  $S$  satisfies the expression

$$S \leq \kappa \sigma \quad (1)$$

where

$$\kappa = (K_r / (1 - K_r)) / \chi \quad (2)$$

and  $\sigma$  is the applied vertical pressure,  $K_r$  is the coefficient of earth pressure at rest and  $\chi$  ( $0 \leq \chi \leq 1$ ) controls the distribution of stress between pore water and pore air based on Bishop's (1959) extended effective stress principle. However, this approach has come under severe criticism by Heibrock (1997) who has developed an alternative approach based on the models of unsaturated soil behaviour proposed by Fredlund (1978) and an extension of shear strength concepts of Morris et al. (1992). Heibrock (1997) performed analyses to illustrate that the potential for cracking depends on the temperature rise at the top of the liner, the characteristics of the clayey liner, the unsaturated hydraulic conductivity of the subsoil below the liner and the depth to the water table below the liner. In one example, he predicts no cracking in 50 years with a temperature at the top of the liner of 25°C but predicts cracking to a depth of 1 m in 20 years with a temperature at the top of the liner of 40°C (all other things being constant). In a second example where the subsoil was changed from a silt loam to a loess with a much higher unsaturated hydraulic conductivity, there was no cracking predicted because the calculated downward vapour flux of water was much smaller than the suction induced upward liquid flux from the water table and hence no drying occurs and the water content approached the distribution of static isothermal equilibrium conditions. It should be cautioned that these predictions are soil specific and even so are based on many assumed and hard to determine parameters. However, the results do underline the need to carefully consider the potential for temperature induced cracking and the desirability of limiting the temperature at the top of the liner to the extent possible by the design and operation of the landfill.

Holzlöhner (1995) suggests that the potential water movement due to temperature gradient could be controlled by installing a geomembrane below the compacted clay (as well as above it). This can certainly be expected to reduce water loss from the compacted

clay liner but there may still be some movement of water and it may be anticipated that in this case there would be an increase in water content in the clay at the lower geomembrane and a decrease below the upper geomembrane. This may be expected to limit desiccation of the liner but care would be needed to assess the effect of the higher water content on the lower soil-geomembrane interface strength and design to avoid instability due to sliding at this interface (see Section 11).

Holzlöhner (1995) also claims that a drainage layer below the composite liner will increase the potential for desiccation. Although no evidence is presented to support this claim, one can anticipate that a drainage layer may have two potentially negative effects. Firstly, vapour would be transported from the soil to the drainage layer and then out of the drainage layer due to changes in atmospheric temperature and pressure. This would be expected to result in the removal of moisture from the adjacent soil and increase the chance of desiccation of the liner. Secondly, the drainage layer either alone or in combination with an underlying geomembrane may be expected to prevent any movement of water upward into the clay from the underlying groundwater table. Much more research is required to understand and improve designs for this situation. However, it would seem prudent to design systems such that the potential for moisture loss from the secondary drainage layer due to atmospheric pumping is minimized and to have a thick rather than thin compacted clay component to the composite primary liner. From the perspective of minimizing the effects of temperature on the hydraulic performance of the clay in these composite double liner systems, GCLs may provide a viable alternative to compacted clay as the clay component of a composite primary liner due to their capacity to (a) hold moisture and (b) rehydrate to gain much (but not all) of their initial hydraulic conductivity. However, there are a number of other factors that also need to be considered as discussed in Section 5.

## 5 HYDRAULIC CONDUCTIVITY AND SERVICE LIFE OF GCLs

There is growing interest in the use of geosynthetic clay liners (GCLs) as part of the base seal/bottom liner system in landfills. As part of a composite liner, a GCL may be expected to have a very long service life (hundreds/thousands of years) provided that:

(a) There is no significant loss of bentonite from the GCL during placement. This means that care will be required to avoid loss of bentonite into underlying drainage layers. An additional geotextile filter may be required to avoid bentonite loss for some GCLs (e.g. see Estornell & Daniel 1992). Care is also required to adopt

construction procedures that will maintain a uniform distribution of the bentonite in the GCL (the potential for bentonite movement may vary from one product to another and construction specifications should recognize this fact). This involves consideration of both loss of powdered or granular bentonite as well as scraping off of bentonite (e.g. due to physical or thermally induced movement).

(b) There is no significant lateral movement (thinning) of bentonite during and following hydration that would cause an uneven distribution of the bentonite in the GCL during the contaminating life of the facility. For example, wrinkles in a geomembrane may create a void or area of reduced stress into which bentonite in an underlying GCL could migrate (see Stark 1998). Likewise, care is needed on side slopes (especially steep side slopes) to avoid bentonite migration downslope both in the "dry" and hydrated state (as noted above, the potential for bentonite movement may vary from one product to another).

(c) The geosynthetic component of the GCL is not critical to the long term performance of the bentonite component of the GCL.

(d) Seams are installed to ensure intimate contact and the design and the construction procedures are such that the seams can not, and do not, open up during or following placement.

(e) The choice of GCL and the design are such that there is no significant long term loss of bentonite due to migration (internal erosion) through the GCL under the hydraulic gradients that may occur either during or after termination of the operation of the leachate collection system.

(f) The design hydraulic conductivity is selected based on tests that examine the equilibrium (i.e. long term) hydraulic conductivity of the GCL to the proposed leachate under conditions that simulate likely field conditions (i.e. similar hydrating conditions, applied stress, GCL and leachate characteristics).

Items (a), (b) and (c) can be addressed by appropriate design, specifications and construction procedures. If the geosynthetic component of the GCL is critical to the long term performance of the GCL then the service life of the GCL can not exceed the service life of the geosynthetic component. The service life of the geosynthetic component will depend on the polymer and additives used. Some polymers have the potential to degrade due to biological action. For example, Giroud (1996a) reports that there are fungi and bacteria that catalyze hydrolysis of polyester. In situations where the service life of the geosynthetic component is critical, it may be argued that HDPE should be used with additives (especially antioxidants) similar to that used in a geomembrane (see Section 7). However, if a long service life of the GCL is required, it would be better, where

practical, to adopt a design such that the geosynthetic component of the GCL is not critical to the long term performance of GCL. For example, one could avoid situations where the geotextile component is necessary to prevent movement of bentonite into underlying open void space in drainage stone. Likewise, one could avoid situations where one was relying on needle punching to provide long term shear resistance or where the geosynthetic component is required to prevent lateral migration of bentonite into areas of reduced stress (e.g. beneath a wrinkle).

The level of control of wrinkles (waves) in the geomembrane may need to be much higher when a GCL is used as part of the composite liner than when a CCL is used due to much thinner clay and the potential for clay movement within the GCL. If GCLs are going to be used in a base seal and are critical to system performance, it would seem prudent to develop and apply a technique for non-destructive checking of seam integrity following placement of the overlying layers to address item (d). It is noted the geotextile overlaps have been observed to move (open up) more than 0.5 m in some cases (Rowe et al. 1993) and hence it is certainly possible that movement could occur for GCLs (e.g. due to the construction practice adopted).

Items (e) and (f) can be addressed by appropriate hydraulic conductivity tests as will be discussed in the following subsection.

## 5.1 Hydraulic Conductivity of GCLs

A number of researchers (e.g. Schubert 1987; Shan & Daniel 1993; Daniel et al. 1993; Dobras & Elzea 1993; Ruhl & Daniel 1997; Petrov et al. 1997a,b; Petrov & Rowe 1997) have addressed the issue of GCL-leachate compatibility and the hydraulic conductivity and performance of GCLs in contact with various permeants under high gradient conditions that could occur in a base seal/bottom liner application. Table 6 describes the various GCLs that have been examined. Table 7 summarizes the published hydraulic conductivity values for a range of GCLs, leachate, applied stresses, and hydrating conditions. In the case of GCLs that include a geomembrane, the results presented in Table 7, and the following discussion, relate only to the bentonite component of the GCL.

The hydraulic conductivity of a GCL is highly dependent on the hydrating conditions and the applied effective stress during permeation. These factors combined with the method of manufacture, water content prior to hydration and mass of bentonite all significantly influence the GCL thickness and while there is some correlation between hydraulic conductivity,  $k$ , and thickness,  $H$  there is a great deal of scatter. Petrov et al. (1997b) showed that by plotting the bulk void ratio,  $e_B$ ,

rather than thickness, H, against hydraulic conductivity, k, one obtains a much better correlation and much less scatter of the data for a given permeant (e.g. see Figure 13). This is consistent with the conventional geotechnical engineering concept of a strong correlation between the void ratio and hydraulic conductivity.

Figure 13. Final bulk GCL void ratio versus hydraulic conductivity for permeation of synthetic MSW leachate (modified from Petrov & Rowe 1997).

As shown in Table 7, the hydraulic conductivity to water of a number of commercially available GCLs ranges between about  $5 \times 10^{-11}$  m/s at "low" (3-4 kPa) confining stress to  $1 \times 10^{-11}$  m/s at "intermediate" (34-38 kPa) confining stress, and  $7 \times 10^{-12}$  m/s at "high" (109-117 kPa) confining stress. It is of interest to note that at a

confining stress of about 35 kPa the six products tested had a very similar hydraulic conductivity to water ( $7 \times 10^{-12}$  m/s to  $1 \times 10^{-11}$  m/s). Also, the test tended to be quite repeatable. For example, Petrov et al. (1997b) performed four tests with distilled water giving a mean value of  $1.28 \times 10^{-11}$  m/s with a range of  $1.4 \times 10^{-11}$  to  $1.2 \times 10^{-11}$  m/s. Four tests on the same product using tap water give a mean hydraulic conductivity of  $1.58 \times 10^{-11}$  m/s and a range of  $1.6 \times 10^{-11}$  to  $1.5 \times 10^{-11}$  m/s. The hydraulic conductivity values given for BF1 and water in Table 7 represent average values of between 4 and 7 tests. All other values given are individual values for a single test.

The confining stress at the time of hydration and the hydrating fluid can have a significant effect on the final hydraulic conductivity. A sample of BF1 that is hydrated at a low stress level (e.g. 3-4 kPa) and subsequently permeated with a 0.1 N NaCl solution ( $\text{Na}^+ \equiv 2300$  mg/L) at a low stress level has a hydraulic conductivity of  $1 \times 10^{-10}$  m/s whereas the same GCL (BF1) hydrated at 3-4 kPa but permeated at high stress (112 kPa) has a hydraulic conductivity of  $1.5 \times 10^{-11}$  m/s (almost one order of magnitude lower) and a sample hydrated with water and permeated at high stress (108 kPa) had a hydraulic conductivity of  $0.7 \times 10^{-11}$  m/s. This indicates the need to carefully consider the hydrating conditions and final stress level in any testing or selection of the hydraulic conductivity of the GCL to be used on a given project.

The permeating fluid can have a profound effect on the hydraulic conductivity of a GCL (see Table 7). Samples permeated with tap water and distilled water give very similar results but samples permeated with a real or synthetic landfill leachate may have a hydraulic conductivity an order of magnitude larger than that of

Table 7. GCL hydraulic conductivities under different testing conditions.

water. Figure 14 shows an increase in the hydraulic conductivity of the BF1 GCL when permeated with synthetic leachate SL1 (see Table 7). At a low confining stress (3-4 kPa) the increase is by almost an order of magnitude. At an intermediate confining stress (30-35 kPa) the increase is by a factor of six.

Figure 14. Hydraulic conductivity and hydraulic conductivity ratio versus static confining stress for permeation of synthetic MSW leachate (modified from Petrov & Rowe, 1997).

The increases in hydraulic conductivity evident in Figure 14 are not a problem if the barrier system has been designed based on the higher values that reflect interaction with leachate. However, it also should be recognized that the change in hydraulic conductivity will be highly dependent on the leachate. This is particularly evident when one compares the results given in Table 7 for the BF2 product at intermediate stress (30-35 kPa) for tap water ( $k \approx 7 \times 10^{-12}$  m/s), real leachate ( $k < 1 \times 10^{-12}$  m/s) and synthetic leachate SL2 ( $k \sim 2 \times 10^{-8}$  m/s) based on the tests of Ruhl and Daniel (1997). This clearly indicates the need to select the hydraulic conductivity giving due consideration to both the GCL and the leachate that it is likely to encounter. As indicated in Table 7, the hydraulic conductivity increases with the concentration of salts in the permeating solution. This needs to be considered when comparing the results for the two synthetic leachates and the "real leachate". The real leachate studied by Ruhl and Daniel (1997) (see Table 7) had a low concentration of cations ( $\text{Na}^+ \equiv 368$  mg/L;  $\text{Ca}^{2+} \equiv 112$  mg/L;  $\text{Mg}^{2+} \equiv 100$  mg/L) and actually gave a hydraulic conductivity lower than that with tap water. This may be due to the presence of bacteria that

can change the characteristics of the leachate during the test, typically causing an increase in pH and a consequent "dumping" or precipitation of some inorganic constituents (see Rowe et al. 1995b). This in turn can reduce the hydraulic conductivity due to (a) a reduction in pore space due to precipitation and bacterial clogging (see Rowe et al. 1995b) and (b) the formation of gas bubbles (typically methane or carbon dioxide) during anaerobic degradation of leachate. These gas bubbles can lodge in pore space and reduce the hydraulic conductivity unless special efforts are made to maintain the sample in a saturated state during the test. Both these mechanisms can occur in field applications, however it is not known to what extent this will occur and hence it is more conservative to use a chemically similar synthetic leachate. Since at typical laboratory temperatures it usually takes about 100 days for significant biological activity to be induced (see Rowe et al. 1997d, f), there is also the potential for changes in leachate characteristics and gas formation even using synthetic leachate in very long term tests.

Not all "synthetic" leachates are similar. The synthetic leachate used by Petrov and Rowe (1997) was modelled on Keele Valley Landfill leachate and has a very similar chemical composition to the real leachate. In contrast, the synthetic MSW leachate used by Ruhl and Daniel (1997) was not modelled on any specific leachate but was deliberately "designed" to have a high  $\text{Na}^+$  and  $\text{Ca}^{2+}$  content knowing that this would have a significant impact on Na-bentonite.

Considering the BF product, there is a clear trend in increasing hydraulic conductivity with increasing ionic strength of the leachate with Ruhl and Daniel's "real" leachate having the least effect ( $k < 1 \times 10^{-12}$  m/s), Petrov and Rowe's Keele Valley simulated leachate (SL1) having a modest effect ( $k \sim 7.3 \times 10^{-11}$  m/s) and Ruhl and Daniel's synthetic leachate (SL2) having the greatest effect ( $k \sim 2 \times 10^{-8}$  m/s) for samples hydrated and permeated with the same fluid at ~35 kPa. The value obtained by Ruhl and Daniel with synthetic leachate is very similar to that obtained by Petrov and Rowe with a 2N NaCl ( $\text{Na}^+ \equiv 46$  g/L) solution. Thus the high value obtained by Ruhl and Daniel is a little surprising compared to the other data in Table 7. Nevertheless, these results emphasize the need to perform tests on leachate with a composition similar to that expected in the actual landfill in order to obtain a realistic estimate of the GCL hydraulic conductivity in contact with leachate.

## 5.2 Hydration of GCLs

Since the hydration of GCLs with water prior to permeation with leachate generally results in a lower hydraulic conductivity, the level of hydration that can be

achieved prior to contact with leachate is an important question. Unfortunately, there is very little documented research on this topic. Daniel and Shan (1992) indicated that in contact with soil at the wilting point, bentonite can be expected to have a water content rise to about 50%. They performed a number of tests where the bentonite from a GCL (GS) was in contact with sand at different water contents. Table 8 summarizes the bentonite-water content after 40-45 days for bentonite placed in contact with (0.1-0.2 mm) sand at different water contents (at 14 kPa pressure). It can be seen that under these circumstances, the bentonite is very efficient in its uptake of water from the underlying soil. It may be expected that there would be less uptake of water if the GCL is placed on a dry geosynthetic drainage layer or on a drainage layer of stone at a typical (very low) water content, although test results would also be useful in these cases.

Table 8. Uptake of water by bentonite (interpreted from Daniel & Shan 1992).

Sand Initial Water Content (%)	Bentonite Water Content at 40-45 Days (%)
1	50
2	75
3	88
5	128
10	156
17	193

Bonaparte et al. (1996) performed hydration tests on three different GCL products in contact with a compacted clay (PL=22%, PI=19%,  $\omega_{opt}$ =20%) placed at three different water contents ( $\omega_{opt}$  -4%,  $\omega_{opt}$ ,  $\omega_{opt}$  +4%). Even for the driest soil ( $\omega \sim 16\%$ ) the GCL moisture content increased from initial values of 15-20% up to about 40% within 20 days. At the higher water content there was greater hydration. For compacted soil at  $\omega=24\%$ , after 75 days the GCL water content had increased to 70-90% depending on the product. Their test suggested that the uptake of moisture over a period of 25 days was not significantly affected by the applied pressure over the stress range of 5 to 390 kPa.

Daniel et al. (1993) examined the effect of partial hydration on the hydraulic conductivity of GCL:GS. They found that when the partially saturated GCL was permeated with concentrated hydrocarbons, the hydraulic conductivity was high (see Table 9) for a low initial water content (17% and 50%) but was close to that of water (except for TCE) at a water content of 100% and less than that due to water at higher water contents. Thus it was not necessary for the GCL to be fully saturated to have a low hydraulic conductivity.

Table 9. Summary of results of permeability tests on partially saturated bentonite (after Daniel et al. 1993)

Permeating Liquid	Hydraulic Conductivity (m/s)			
	17%	50%	100%	125%
Benzene	$3 \times 10^{-7}$	$2 \times 10^{-7}$	$5 \times 10^{-11}$	No Flow
Gasoline	$4 \times 10^{-7}$	$4 \times 10^{-7}$	$4 \times 10^{-11}$	No Flow
Methanol	$3 \times 10^{-7}$	$3 \times 10^{-7}$	$3 \times 10^{-11}$	No Flow
Tertbutylethylether	$2 \times 10^{-7}$	$3 \times 10^{-7}$	$< 1 \times 10^{-11}$	No Flow
Trichloroethylene	$4 \times 10^{-5}$	$4 \times 10^{-7}$	$3 \times 10^{-10}$	No Flow
Water	$1-2 \times 10^{-11}$	--	--	--

### 5.3 Effect of Holes in GCL

Shan and Daniel (1991) examined the effect of puncturing a CL type GCL by cutting out three holes in each 152 mm diameter specimen. The samples were allowed to hydrate under a confining stress of 14 kPa. The hydraulic conductivity to water was then measured as summarized in Table 10. Under these test conditions the bentonite swelled to completely fill the 12 and 25 mm diameter holes. However, two out of the three 75 mm holes were reported to have not sealed and left an opening of 12 mm diameter giving a hydraulic conductivity greater than  $2 \times 10^{-6}$  m/s (the upper limit measurable with the equipment used). These tests suggest that the GCL had the capacity to effectively self-heal small holes but not large holes or tears.

Table 10. Effect of punctures in a GCL:CL (after Shan & Daniel 1993)

Diameter of Punctures	Hydraulic Conductivity to Water (m/s)
No punctures	$2 \times 10^{-11}$
12 mm	$3 \times 10^{-11}$
25 mm	$5 \times 10^{-11}$
75 mm	$> 2 \times 10^{-6}$

## 6 DIFFUSION THROUGH GCLs

As will be discussed in more detail later, contaminants can migrate through a geomembrane by (a) diffusion through the geomembrane (see Section 8) and (b) advection through holes (see Section 9). The clay component of the composite liner serves two purposes: (a) it acts as a diffusion barrier and (b) it minimizes leakage through holes in the geomembrane. The growing interest in the use of GCLs as a replacement for

compacted clay liners raises the need to address the "equivalence" of the GCL and compacted clay liner with respect to both functions. This will be addressed in Section 10, however in order to make this assessment one must first have a knowledge of the diffusive and sorptive characteristics of GCLs as well as the hydraulic conductivity. Hydraulic conductivity was discussed in Section 5. In this section, the diffusion through GCLs will be addressed. Advection will be discussed in Sections 9 and 10.

Diffusion involves the movement of molecules or ions (in air, water or solid) as a result of their own random kinetic activity from areas of higher activity (concentration) to areas of lower activity (concentration). The movement of molecules or ions in porous media (including GCLs) is given by Fick's Law

$$f = -n_e D_e \frac{\partial c}{\partial z} \quad (3)$$

in which  $f$  is the mass flux [ $ML^{-2}T^{-1}$ ],  $n_e$  is the effective porosity [-],  $D_e$  is the effective diffusion coefficient [ $L^2T^{-1}$ ],  $c$  is the concentration in the GCL [ $ML^{-3}$ ] and  $z$  is the distance parallel to the direction of diffusion [L]. To date, little has been published concerning diffusion through GCLs. Rowe et al. (1997b) have developed an apparatus that can be used to measure the diffusion of various contaminants through a GCL. Details regarding the apparatus and test procedure are given in that paper and will not be repeated here. Briefly, the test involves placing a contaminant source on one side of a hydrated GCL and an uncontaminated receptor solution on the other side of the GCL (see insert to Figure 15). The change in concentration in both the source and receptor solution is then monitored with time as contaminant diffuses (with a hydraulic gradient of zero) from the source to the receptor solution.

Figure 15 shows the data obtained for a needle punched GCL BF2 (see Table 6 for nominal characteristics) for a sample confined to a hydrated thickness of 7.1 mm. By adjusting the effective diffusion coefficient and porosity, it is possible to obtain a theoretical fit to the source and receptor concentration using a computer program (Rowe & Booker 1983, 1997a). Based on this procedure, and using the total bentonite porosity,  $n=0.71$ , an effective diffusion coefficient,  $D_e$ , for chloride of  $1.5 \times 10^{-10} m^2/s$  was inferred giving a product  $nD_e = 1.05 \times 10^{-10} m^2/s$ . Due to the scatter of data inevitable in this type of test, there is some uncertainty and more than one combination of  $n$  and  $D_e$  could be used to fit the data shown in Figure 15. However, for the range of uncertainty, the value of  $nD_e$  only varies between 1.0 and 1.08  $m^2/s$ . It should also be noted that during a diffusion test there will be mechanisms other than molecular diffusion influencing

Figure 15. Variation in source and receptor concentration with time for a diffusion test on a needle-punched GCL BF2 (modified after Rowe et al. 1997b).

the movement of ions (see Rowe et al. 1995b) and  $D_e$  is really more a mass transfer coefficient than a true coefficient of molecular diffusion. A more detailed examination of anion exclusion and osmosis, and their potential effect on the effective porosity and diffusion coefficient is currently in progress and will be reported in a subsequent paper.

Similar tests have been performed for different products and different hydrated thicknesses of the GCL (see Table 11) and the diffusion coefficient and porosity is found to be a function of the void ratio which, in turn, is related to the confining stress and hydrating conditions. Similar tests to those reported in Table 11 can be performed for other contaminants (both inorganic and organic) and these tests are ongoing at the University of Western Ontario.

Diffusion can be an important consideration with respect to contaminant impact of well designed and operated landfill facilities. It can also impact on laboratory hydraulic conductivity tests. For example, Figure 16 shows the salinity ratio of various pore volumes of permeant in a hydraulic conductivity test on a GCL (BF1). As can be seen, the effluent is at 50% of the influent salinity after only 0.3 pore volumes. This early "breakthrough" could be misinterpreted as indicating a macro-structure and preferential flow paths however, in reality, it is diffusion of chloride ahead of the advective contaminant front and can be readily predicted using a diffusion coefficient of about  $4 \times 10^{-10} m^2/s$ .

The observation that there will be an "early" diffusive

Table 11. Chloride diffusion characteristics of some GCLs.

GCL	Applied Stress $\sigma_v'$ (kPa)	Hydrated Thickness $t_{GCL}$ (mm)	Effective Diffusion Coefficient $D_e$ ( $m^2/s$ )	Porosity $n$ (-)
BF3	20	11.1	$3 \times 10^{-10}$	0.80
	65	9.1	$2 \times 10^{-10}$	0.77
	100	7.1	$1.5 \times 10^{-10}$	0.71
	350	5.6	$0.4 \times 10^{-10}$	0.51
BF2	25	9.1	$2.5 \times 10^{-10}$	0.77
	140	7.1	$1.6 \times 10^{-10}$	0.68
	280	5.6	$0.7 \times 10^{-10}$	0.64
BF4	29	11.1	$2.9 \times 10^{-10}$	0.83
	100	7.1	$1.3 \times 10^{-10}$	0.74

movement of contaminant ahead of the advective front in hydraulic conductivity tests can be used to obtain an estimate of diffusion characteristics. For example, Lo (1992) used the program POLLUTE (Rowe & Booker 1983; 1997a) to fit the concentration profile in the effluent for tests performed using the GCL "CL" and obtained diffusion coefficients as summarized in Table 12. Separate batch tests were used to obtain the sorption coefficients given in Table 13. It was inferred that the diffusion coefficient for lead was greater than that for chloride while the diffusion coefficient for 1,2 dichlorobenzene was reported to be less than for

Table 12. Diffusion coefficient inferred by Lo (1992).

Liner Material	Effective Diffusion Coefficient $D_e$ ( $m^2/s$ )		
	Chloride	Lead	1,2 DCB
CL	$2.4 \times 10^{-10}$	$5.9 \times 10^{-10}$	$9.8 \times 10^{-11}$
Organo-Clay	$4.9 \times 10^{-10}$	$9.0 \times 10^{-10}$	$1.5 \times 10^{-10}$
HA-ALOH-Clay	$3.6 \times 10^{-10}$	$7.6 \times 10^{-10}$	$1.2 \times 10^{-10}$

chloride. Diffusion coefficients for the modified clays were up to 50% greater than for conventional bentonite. Compared to the modified clays, conventional bentonite gave the greatest sorption for lead (which was strongly retarded) but the sorption of the chlorobenzenes was very low. In contrast, the modified clays allowed substantial sorption of the chlorobenzenes. Finally, it should be noted that "sorption" of heavy metals is strongly pH dependent.

Table 13. Linear sorption coefficient  $K_d$  inferred by Lo (1992).

Liner Material	$K_d$ value (mL/g)			
	Lead (pH-7)	1,2 DCB	1,2,4 TCB	1,2,4,5 TECB
CL	6000	1.4	2.2	10
Organo-Clay	140	609	1320	4500
HA-ALOH-Clay	417	20	38	254

## 7 SERVICE LIFE OF GEOMEMBRANE LINERS

The exposure conditions of a geomembrane may be expected to be different depending on whether it is part of a composite primary or secondary liner. As a component of the primary liner, the geomembrane is subject to direct contact with leachate and temperatures higher than normal groundwater temperatures. As part of a secondary liner it is in contact with less leachate than the primary liner and this leachate will likely have experienced some attenuation due to cation exchange, precipitation and biodegradation as it migrates through the primary clay liner. The secondary geomembrane is also likely to be closer to natural groundwater temperature. However, depending on the design and operation of the secondary system, there is potential for exposure to atmospheric oxygen. Thus the service life of primary and secondary geomembrane liners may be expected to be different (Rowe et al. 1994).

## 7.1 Potential Failure Mechanisms

The two most important factors that affect the short-term performance of a geomembrane barrier are engineering design (including liner/leachate compatibility verification) and geomembrane manufacturing/installation CQC/CQA. Provided adequate engineering design is carried out and appropriate CQC/CQA procedures are followed during the manufacture and installation of the geomembrane, the geomembrane barrier component may be expected to perform satisfactorily in the short term. The design life (i.e. long-term performance) of the geomembrane is influenced primarily by the synergistic effects of chemical and physical stresses over an extended period of time. Primary considerations are the effect of temperature and the effect of tensile stresses over and above calculated design values (e.g. due to contact stresses that are related to the level of geomembrane protection, and stresses induced due to wrinkles/waves).

## 7.2 Geomembrane Protection

The provision of adequate protection to a geomembrane to strains induced by stones in a granular leachate collection layer is the subject of considerable debate. The debate largely hinges on the difference of design philosophy with respect to (a) providing sufficient protection to avoid holes in the geomembrane (i.e. puncture of the geomembrane); and (b) providing sufficient protection to control the strains due to indentation to a negligible (~ 0.25%) level (e.g. see Narejo 1995a,b; and discussion by Bishop 1996). Giroud et al. (1995) have developed a method of analysis for calculating geomembrane puncture resistance and Badu-Tweneboah et al. (1998) have developed an approach for evaluating the effectiveness of HDPE geomembrane liner protection. Reddy et al. (1996) evaluated the damage to a 1.5 mm HDPE geomembrane due to construction loads and concluded that "a geotextile as light as 270 g/m<sup>2</sup>...completely protects the geomembrane from construction loading". Wilson-Fahmy et al. (1996), Narejo et al. (1996) and Koerner et al. (1996b) provide an extensive examination of puncture protection of geomembranes. They showed that there is a linear increase in protection resistance with increasing thickness (mass per unit area) of the protection layer. However, the German approach (Brummermann et al. 1995; Saathoff & Sehrbrock 1995; Bishop 1996; Seeger & Müller 1996) goes beyond providing puncture protection and focuses on minimizing the contribution of indentation (and subsequent sensitivity to stress cracking) due to collection stones under long term loading condition to a very low strain level (~ 0.25%).

The differences between the U.S. and German approaches is partly a difference in philosophy.

However, there is also room to question the relatively arbitrary choice of 0.25% as a limiting strain (see Bishop 1996). Furthermore, the allowable strain can not be considered in isolation but, rather, must be considered in the context of the method of measurement used to assess whether this objective has been met for a given form of geomembrane protection. For example, Giroud (1996b) has quoted a case where the measured strain in a geomembrane that had been damaged, but not punctured, by stones was approximately 0.3% using a 5 mm scanning grid and an order of magnitude larger (3%) using a finer 0.5 mm scanning grid. Based on this, he argued that a limit of strain of say 0.5% with a scanning grid of 5 mm may really be equal to an allowable strain of 5%. By analogy, an allowable strain of 0.25% with a 5 mm scanning grid may really be an allowable strain of 2.5%. Notwithstanding these uncertainties, it would appear that the German approach is more likely to minimize tensile strains in the geomembrane than the U.S. approach; the need for the additional conservatism of the German approach remains an open question and may depend on the required service life of the geomembrane.

## 7.3 Wrinkles (Waves)

Wrinkles (also called waves in some papers) in a geomembrane are a source of considerable concern. It is well recognized that the high coefficient of thermal expansion and heating by the sun during construction play an important role in wrinkle formation. Conversely, these factors are important with respect to the development of potentially significant tensile stresses in the geomembrane if it is placed without wrinkles at a temperature significantly above its long-term ambient temperature. White geomembranes have been shown to lessen (but do not eliminate) the problem (Pelte et al. 1994; Koerner & Koerner 1995a). Giroud and Morel (1992) and Giroud (1995) showed that in addition to temperature, colour and the coefficient of thermal expansion, factors such as roughness and flexibility can also influence the size of wrinkles. Some have thought that wrinkles will "go away" due to applied pressure once the waste is placed, however findings by Stone (1984), Koerner et al. (1997) and Soong and Koerner (1998) cast doubt on that assumption and suggest that wrinkles may exist under even high pressure. In a series of laboratory tests conducted with normal stresses as high as 1100 kPa, they found that although there was a reduction in wrinkle height, the wrinkles remained. As a result of the wrinkle geometry and the applied stress, tensile strains of up to 3.2% were induced in the 1.5 mm thick HDPE geomembrane for an 80 mm high wrinkle at 23°C. In no case was intimate contact achieved in their tests even for the smallest wrinkle height studied (14 mm). Most

interestingly, it was found that even an increase in temperature up to 55°C (e.g. to simulate a high temperature in the landfill leachate) and an applied pressure of 700 kPa did not eliminate wrinkles and that the tensile strains for a 60 mm initial wrinkle increased from 3% at 23°C to 4.9% at 42°C and 55°C.

The presence of wrinkles (waves) in the geomembrane raises several concerns. Firstly, there is increased potential for contaminant migration through a hole in the geomembrane at or near the wrinkle (see Section 9). Secondly, there is increased potential for stress cracking due to the tensile strains that are induced by the wrinkle and these may be compounded by other tensile strains. This suggests the need for greater attention to reducing/avoiding wrinkles, possibly following the lines presently being advocated in Germany (Averesch & Schicketanz 1998). However, care is required to ensure that the elimination of wrinkles is not at the expense of inducing significant tensile strains in the geomembrane that could ultimately contribute to long term stress cracking, particularly at the toe of slopes. One may expect that in this situation, stress relaxation will play an important role but the long term stress in a geomembrane subject to tensile strain remains an open question and hence it would be prudent to minimize the tensile strains.

#### 7.4 Existing Long Term Performance Data

The relatively short history of geomembrane use in waste containment applications makes it rather difficult to predict a definitive service life for geomembranes. In Europe, polyethylene geomembranes were developed in the 1960s. Therefore, there is about 30 years of actual field experience with geomembranes used in canal and pond lining applications. Geomembranes have been extensively used as liners for landfills since the early 1980s. A study by Brady et al. (1994) examined the behaviour of HDPE in different environments over a period of 30 years. The results of tests on unaged and 30 year old specimens showed that there were no substantial changes in density, water adsorption value, and water extractable matter content. There was a small change in resistivity which was judged to be of no practical importance. There was no significant change in impact resistance after 15.5 years however a reduction of about 50% was observed over a 30 year period. The data from tensile tests showed that over the 30 year period the tensile strength remained essentially constant but there was a reduction in the strain at the peak (yield) strength and the HDPE became stiffer with time.

The oldest case histories which provide information on the field performance of geomembranes come from their use as canal/pond liners. Schmidt et al. (1984) carried out a series of physical index tests (yield, elongation,

break, and tear properties) on samples of polyethylene geomembranes from exposed and submerged geomembranes that had been in use for up to 16 years. The test results were compared with the original geomembrane material properties specified at the time of the geomembrane installation. The study concluded that there is typically a stiffening of the geomembrane with time, but that this is less significant for buried (unexposed) material. The major causes of failure to the liners was from physical/mechanical damage, rather than weathering/aging effects. The authors conclude that when polyethylene geomembranes are buried (i.e. protected), they showed only minor changes in physical performance over the observation period of 16 years.

Rollin et al. (1994) reported results obtained for samples of HDPE geomembrane that had been used in a contaminated soil containment facility for 7 years. Aging was found to increase the yield strength, decrease the tensile force required for rupture and lower the elongation at rupture. Aging was more severe for samples from the bottom of the cells than for samples from the slopes or cover.

In a study by Hsuan et al. (1991), HDPE geomembrane samples were taken from a 7 year old solid waste leachate lagoons. The samples were obtained from four different locations in the lagoons, ranging from areas continuously exposed to the atmosphere to those at the bottom of the impoundment, continuously covered by liquid. It was concluded that: (1) there was no substantial macroscopic change in the geomembrane sheets or seams after 7 years exposure at the site; (2) an evaluation of the stress crack resistance of the materials indicated that constant outdoor exposure had not caused substantial changes in the internal structure of the material; and (3) changes in the geomembrane were observed only on the molecular level and they did not affect the engineering/hydraulic containment properties of the geomembranes.

In contrast, Rowe et al. (1998a) conducted a similar study of a leachate lagoon liner after 14 years of operation. They observed very low standard oxidative induction (OIT) values for exposed geomembrane accompanied by a reduction in tensile break properties and stress crack resistance of the geomembrane. The results of the Melt Index test suggest that the degradation was induced by a chain scission reaction in the polymers. The geomembrane was severely cracked indicating that the material was highly susceptible to stress cracking. This was confirmed by SP-NCTL tests.

For geomembranes that were either covered by soil or leachate, the depletion of antioxidant was slower than for the exposed and partially exposed geomembranes. The amount of antioxidant present in these geomembranes seems to have been sufficient to protect the geomembrane from oxidation degradation over the 14 year

exposure period.

The results of the Rowe et al. (1998b) investigation substantiate the importance of the type and amount of antioxidant and stress crack resistance to the longevity of the geomembrane and suggest that these two properties should be evaluated and incorporated in the specification of a HDPE geomembrane to assure their quality.

## 7.5 Predictions of Service Life

While the most reliable method of determining the service life of geomembranes would be from exposure under the actual field conditions, this is not presently feasible due to the length of time that would be required to obtain useful results. Consequently, several "accelerated aging" tests have been developed which attempt to simulate long-term exposure of HDPE. However, in order to use these results one also needs an understanding of the mechanism of geomembrane aging and failure.

As discussed by Hsuan and Koerner (1995), there are two types of aging: physical and chemical. Physical aging involves a change in the crystallinity of the material but, by definition, there is no breaking of covalent bonds. Chemical aging involves degradation where there is breaking of covalent bonds and, eventually, a reduction in the engineering properties of the geomembrane. Conceptually, chemical aging can be considered to have three distinct stages: (a) depletion time of antioxidants; (b) induction time to the onset of polymer degradation; and (c) degradation of the polymer to decrease some property (or properties) to an arbitrary level (e.g., to 50% of the original value).

There are two key issues with respect to chemical breakdown: (a) the amount of antioxidant and its consumption and/or removal (e.g. by diffusion/leaching) from the geomembrane, and (b) the presence of an environment where oxidation can occur. Generally, conditions at the base of a landfill (i.e. above the primary liner) are anaerobic except for the first few years of operation. There is likely to be more persistent oxygen in the secondary leachate collection system (and hence above the secondary geomembrane) due to its separation from the biological processes ongoing in the landfill. Hsuan and Koerner note that the oxidation reaction of polyethylene can be increased in the presence of transition metals (e.g. Co, Mn, Cu, Pd and Fe). Since these are all potentially present in leachate, there is potential for the reduced presence of oxygen above the primary geomembrane liner to be at least partly offset by increased reactions due to the presence of the transition metals (amongst other things).

There is the potential for debate regarding the property(s) to be assessed with respect to the degree of polymer breakdown. In landfill base liner applications,

the real service life depends on the hydraulic and diffusive properties of the geomembrane. Provided that stress cracking does not occur, it is conceivable (and likely) that a geomembrane may lose strength and become brittle while still performing satisfactorily as a barrier. Therefore, the "hydraulic and diffusive service life" of a geomembrane may exceed the service life as determined by the degradation of physical properties such as tensile strength. This issue is the subject of current research by the writer and his coworkers at UWO. However, based on available information, it is also clear that it is desirable to minimize the physical degradation (by appropriate use of antioxidants) and to use geomembranes with adequate stress crack resistance since the most likely long term cause of loss of hydraulic resistance would be due to the formation of stress cracks in the geomembrane.

Koerner et al. (1993b) have recommended that geomembranes used as liners should not fail in 200 hours in a single point notched constant load test (SP-NCLT; ASTM D5397) at 30% of the yield stress. Studies at GRI have also led them to recommend minimum OIT values of 100 minutes for the standard test (D3895) or 400 minutes in the high pressure test (D5885). After oven aging at 85°C for 90 days (ASTM D5721), the geomembrane should retain 55% of the standard Std-OIT or 80% of the HP-OIT value. In the final assessment of service lives in this section, it is assumed that the geomembrane meets these criteria.

A number of investigators have addressed the issue of trying to assess the service life of geomembrane liners for landfills; these have ranged from "expert opinion" to quantification based on accelerated test data. A U.S. Environmental Protection Agency (USEPA) ad hoc committee considered the durability of polymeric landfill lining materials (i.e. HDPE) in landfills. Haxo and Haxo (1988) summarized the views of these U.S. experts who opined that (subject to numerous qualifications) the service life of geomembranes was likely to be in the order of hundreds of years. Tisinger and Giroud (1993) echo this opinion and state "that in properly designed and constructed facilities, HDPE geomembranes should be able to protect groundwater from leachate for hundreds of years".

Gray (1990) compared two methods of accelerated aging, which both use elevated temperature to simulate long-term HDPE exposure. The paper reviewed work carried out by the wire and cable industry which indicates the service life of HDPE insulation on cables (at a temperature of 40°C) is in the order of several hundred years.

Lord and Halse (1989) reviewed work carried out by the plastic pipe industry on the service life of HDPE pipes used in natural gas pipeline applications. These studies used elevated temperatures and stresses to

determine the ductile/brittle transition point of HDPE pipe, and predicted a service life of greater than 50 years for pipes under relatively high stresses (>7,000 kPa). For a geomembrane at the base of a landfill, the stresses will be much less and it is expected that accelerated aging tests at these lower stresses would indicate a longer service life (likely in the order of several hundred years).

Most of the work on natural gas pipeline service life has been carried out by Hoechst a.g., a German company. They have applied their pipe research expertise to the geomembrane area and conclude that the interaction with leachate is the largest concern in the service life of geomembranes. Although the stress fields in an HDPE pipe are different than those in a geomembrane liner, these studies indicate that the lifetime curves for pipes are applicable to geomembrane sheets with appropriate stress correction factors. Based on this work, Koch et al. (1988) conclude that: (1) The application of the Arrhenius extrapolation technique to predict the service life of HDPE has been confirmed over 30 years of testing. (2) Although various chemicals in landfill leachate have the potential to reduce the durability, since the concentration of organic compounds is low, the durability of HDPE in a domestic waste landfill can be assessed as similar to those in water containing a wetting agent. (3) Based on Arrhenius extrapolation, the time for mechanical/chemical alteration in an aqueous environment at 25°C is between 300 and 400 years assuming that leachate contains the same oxygen content as laboratory bath water. (4) Because of the anaerobic environment, with little or no oxygen, in a landfill environment, the actual time for chemical alteration should be longer than the times suggested by the laboratory data. (5) Considering all of these factors, the service life of these HDPE geomembranes could be expected to be considerably greater than 100 years.

None of the investigations and predictions noted above identified or directly considered the three stages of aging defined by Hsuan and Koerner (1995) although the accelerated aging test and hence the prediction would have incorporated all three components. However, it is useful to consider the three components in an attempt to improve estimates of service life. This can now be attempted based on the work of Hsuan and Koerner (1995) and Hsuan and Guan (1997) who have reported the results from two series of tests directed at assisting in the estimation of the depletion time of antioxidants in geomembranes. In both cases, samples of a single specific geomembrane were incubated at a series of temperatures (55, 65, 75 and 85°C). Samples were retrieved at various time intervals and evaluated by a number of tests for the physical, chemical and mechanical properties. The two test series were: (1) Series I: Nonstressed-Water Incubation: Hsuan and Koerner (1995) indicate that these tests were "designed to simulate

geomembranes that are exposed to liquids (water or leachate) on both sides and are essentially nonstressed". The HDPE samples were fully immersed in four water baths maintained at constant temperatures (as noted above). The data presented in the report for this series of tests spans a period of 30 months (2.5 years). Series III: Compressive Stress-Water/Air Incubation: These tests are said to be "intended to simulate geomembranes situated beneath solid waste landfills". The geomembrane is located between two (100 mm thick) layers of sand. The upper layer appears to be saturated and there is a 0.3 m water head acting on the geomembrane. The soil below the geomembrane is dry. The data presented in the report for this series of tests spans a period of 24 months (2 years). These tests were conducted with the geomembrane subjected to a vertical compressive stress of 260 kPa.

Two different Oxidative Induction Time (OIT) tests were performed and hence there is a (small) range to the interpretation of the results based on the two different methods. Based on the OIT values obtained at the four different temperatures, the results can be extrapolated back to the expected (lower) temperature of a primary geomembrane liner in a (North American) MSW landfill using the Arrhenius equation, assuming that the OIT depletion rate varies exponentially with the inverse of temperature (i.e. 1/T where temperature, T, is in °K). The values deduced by the writer, based on Hsuan and Koerner (1995) for Series I and Hsuan and Koerner (1997) for Series III, are given in Table 14. In their

Table 14. Calculated time for antioxidant depletion based on test data by Hsuan & Koerner (1995). (Original geomembrane had Std-OIT=80.5 min; HP-OIT=210 min; Density=948.8 kg/m<sup>3</sup>; Melt Index=0.23 g/10 min; Yield Stress=19.2 MPa)

Temp. (a) °C	Series I (b) Years	Series III (c) Years	Mean of I & III (d) Years	Mean of (c) & (d) Years
10	111	453	282	368
15	98	299	199	249

55	9	17	13	15
60	7	12	9.5	11

\* Value calculated by Hsuan & Koerner (1997)

\*\* Value calculated by Hsuan & Koerner (1995)

discussion of their experimental results, Hsuan and Koerner (1995) state that: "The shorter depletion time in Series I probably is due to the extraction rate of the antioxidant which is higher in Series I than in Series III conditions. The samples in Series I were exposed to moving water on all of their surfaces, whereas samples in Series III were exposed to stationary water on only one surface. It is known that moving water as in Series I tests actually causes leaching of antioxidants. Hence, the depletion time for incubation Series I probably is a very conservative value, since it is not common for both sides of the geomembrane to be exposed to moving liquids. In this regard, the results of the Series III tests seem to be more similar to HDPE geomembranes in service applications."

Considering the likely conditions in a landfill, the Series I depletion times given in Table 14 would appear to be too conservative since the geomembrane will not be subjected to moving water on both faces (as indicated by Hsuan and Koerner), however there is the potential for the movement of leachate adjacent to one face. This is likely to be less severe than the movement of oxygenated water but may be more severe than the stationary 0.3 m of water case examined in the Series III tests. The present writer averaged the depletion times between the Series I and III values based on the argument that this would correspond (approximately) to fluid movement on one face of the geomembrane and stationary condition on the other face. These depletion times are also given in Table 14. It could be argued that these interpolated depletion times represent a lower estimate of depletion time since the flushing fluid in the landfill environment is likely to be depleted in oxygen relative to the water used in the Series I tests. On this basis, the likely depletion time would lie between the mean value (column (d)) and the Series III value (column (c)) and the mean value is given for each temperature in the last column.

Based on the concept of aging outlined by Hsuan and Koerner and summarized earlier, the "service life" of a geomembrane would be the sum of the time to antioxidant depletion plus the induction time plus the time for degradation of the polymer. Hsuan and Koerner (1995) indicate an induction time of 12 years at 25°C. Hsuan and Koerner (1995) do not provide any information regarding degradation time in this report but indicate that this will be addressed in future reports (over the next decade).

Based on the Series III results, an induction time of 12 years and essentially ignoring the property degradation time, the service life of the geomembrane at 25°C would be about 150 years ( $135 + 12 = 147 \approx 150$  years). Based on the interpolated value of 113 and an induction time of 12 years, the service life would exceed 125 years. Recognizing that unstabilized 25 year old intact plastic has been found in landfills, it is not unreasonable to allow

at least 25 years for the degradation time, giving a service life of  $113 + 12 + 25 = 150$  years for a primary geomembrane at 25°C. If a secondary geomembrane is at a lower temperature, the service life would be expected to exceed 400 years at 10°C and 300 years at 15°C. Taking an intermediate value, the service life of a secondary geomembrane is estimated to exceed 350 years.

The service lives calculated above are reasonably consistent with earlier predictions or, to the extent that they differ, are more conservative at 25°C (or less). However, the rapid decrease in service life for temperatures above 25°C should be noted. As discussed in Section 2, landfill temperatures can increase rapidly to 40°C or more in a few years if leachate mounds to 6 m and this could reduce the service life of an underlying geomembrane to 40-75 years (with the range depending upon how the induction and degradation time decrease at 40°C). A temperature increase to 60°C (see Section 2) could reduce service lives to as little as one or two decades. In short, the service life of the geomembrane may be closely linked to the nature of the waste and the landfill operations and thus these should be carefully monitored.

## 8 DIFFUSION THROUGH GEOMEMBRANES

There are two primary mechanisms for contaminants to migrate through geomembranes: (a) "leakage" through holes and (b) diffusion through the intact geomembrane. Leaks are discussed in Section 9. In this section, attention will be focused on diffusive movement of both water and contaminants.

Geomembranes are not a conventional porous medium in which the pore size is large relative to both water and contaminant molecules. There is no "flow", in the conventional or Darcian sense, through an intact geomembrane. However, there can be movement of water and contaminant through the geomembrane due to molecular diffusion. The diffusive movement of a penetrant (contaminant or water) through a geomembrane where there are no defects such as pores, cracks or holes involves a cooperative rearrangement of the penetrant molecule and the surrounding polymer chain segments. The process requires a localization of energy to be available to allow a diffusive jump of the penetrant molecule in the polymer structure. The penetrant molecule and part of the polymer's molecular chain may share some common volume both before and after the jump. However, this jump will involve the breaking of some van der Waals forces or other interaction between the component molecules and polymer segments (Rogers 1985). Thus the diffusive motion depends on the energy available and the relative

mobilities of the penetrant molecules and polymer chains. This will depend on temperature and concentration, the size and shape of the penetrant, and the nature of the polymer.

### 8.1 Diffusive Transport

The diffusion of penetrant molecules through a geomembrane can be modelled by Fick's Law

$$f = -D_g \frac{\partial c_g}{\partial z} \quad (4)$$

in which  $f$  is the mass flux [ $ML^{-2}T^{-1}$ ],  $D_g$  is the diffusion coefficient in the geomembrane [ $L^2T^{-1}$ ],  $c_g$  is the concentration of the penetrant of interest in the geomembrane [ $ML^{-3}$ ] and  $z$  is the distance parallel to the direction of diffusion [ $L$ ]. Consideration of conservation mass then gives the governing differential equation for transient diffusion:

$$\frac{\partial c_g}{\partial t} = D_g \frac{\partial^2 c_g}{\partial z^2} \quad (5)$$

which must be solved for the appropriate boundary and initial conditions (see Rowe et al. 1995b for discussion of this related to landfills).

### 8.2 Sorption, Solubility and Henry's Law

When a geomembrane is in contact with a fluid (gas or liquid) for sufficient time to reach an equilibrium, there will be a relationship between the final equilibrium concentration in the geomembrane,  $c_g$  [ $ML^{-3}$ ], and the equilibrium concentration in the adjacent fluid  $c_f$  [ $ML^{-3}$ ]. This relationship may often be described by the Nernst distribution function (Rogers 1985) which may take a linear form (Henry's law):

$$c_g = S_{gf} c_f \quad (6)$$

where  $S_{gf}$  is variously called a solubility, partitioning or Henry's coefficient [-]. Alternatively, it may take a non-linear (e.g. Langmuir) form

$$c_g = \frac{S_a b c_f}{1 + b c_f} \quad (7)$$

where  $S_a$  and  $b$  are experimentally determined constants. The coefficients  $S_{gf}$ ,  $S_a$  and  $b$  may all vary with contaminant, phase of the fluid (gas or liquid) and temperature.

In the present context (see Rogers 1985; Naylor 1989),

the term "sorption" is a generalized term for the removal of the penetrant molecules from the fluid and its dispersal on or in the polymer. This may involve numerous processes including adsorption, absorption, incorporation in microvoids, etc. The distribution of penetrant may change with concentration, temperature and time and may change due to potential interaction with the polymer and swelling of the polymer matrix. Although much research has been conducted on sorption relating to plastics, there is limited recognition of its importance with respect to the design of landfills using geomembrane liners.

For the simplest case, where the permeant does not interact with the polymer (often, but not always, the case for HDPE geomembranes) or at low concentrations (Rogers 1985), Henry's law is obeyed and for this "Type I" sorption (Naylor 1989) the relationship between the concentration in the fluid and solid is given by Eq. 6 where, in principle,  $S_{gf}$  is a constant for the given molecule, fluid, geomembrane and temperature of interest (as will become evident later,  $S_{gf}$  will depend on the chemical composition of the fluid). Thus, substituting Eq. 6 into Eq. 4 gives the flux from a fluid on one side of a geomembrane to a similar fluid on the other side

$$f = -D_g \frac{\partial c_g}{\partial z} = -S_{gf} D_g \frac{\partial c_f}{\partial z} = -P_g \frac{\partial c_f}{\partial z} \quad (8)$$

where  $P_g$ , given by

$$P_g = S_{gf} D_g \quad (9)$$

is often referred to in the polymer literature as the permeability. This should not be confused with the old soil mechanics term "coefficient of permeability" (now called hydraulic conductivity) or the intrinsic permeability of a porous medium. It has nothing to do with Darcy's law or flow through the open voids within porous media.

Based on Eq. 9, the mass flux across a geomembrane of thickness  $t_{GM}$  is given by

$$f = S_{gf} D_g \frac{\Delta c_f}{t_{GM}} \quad (10)$$

or

$$f = P_g \frac{\Delta c_f}{t_{GM}} \quad (11)$$

where  $\Delta c_f$  is the difference in concentration in the fluid on either side of the geomembrane. It is possible to experimentally infer the value of  $P_g$  by performing a steady state experiment (see Figure 17) in which the

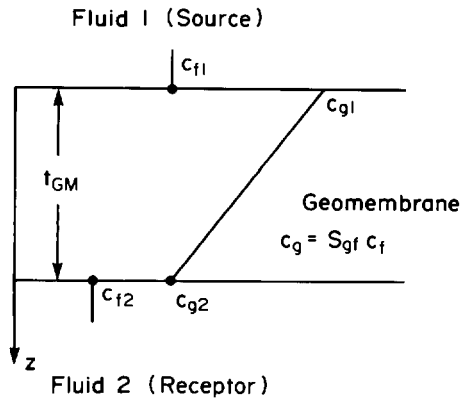

Figure 17. Diffusion across a geomembrane showing partitioning between the concentration in solution and the concentration dissolved in the geomembrane.

concentration is controlled at  $c_{f1}$ ,  $c_{f2}$  in the fluid on either side of the geomembrane and the flux,  $f$ , is measured. Thus

$$P_g = \frac{f t_{GM}}{\Delta c_f} \quad (12)$$

It follows from this that while a steady state test will allow the measurement of  $P_g$ , it does not allow the evaluation of either  $S_{gf}$  or  $D_g$  without additional tests. However transient contaminant transport is controlled by the diffusion coefficient,  $D_g$ , and not the permeability,  $P_g$ . This becomes evident when one substitutes Eq. 6 into Eq. 5 to give

$$S_{gf} \frac{\partial c_f}{\partial t} = S_{gf} D_g \frac{\partial^2 c_f}{\partial z^2} \quad (13)$$

and, on dividing by  $S_{gf}$ , this reduces to

$$\frac{\partial c_f}{\partial t} = D_g \frac{\partial^2 c_f}{\partial z^2} \quad (14)$$

which depends on  $D_g$  but not  $S_{gf}$  or  $P_g$ .

Thus it is important to distinguish between the Henry coefficient  $S_{gf}$  and the diffusion coefficient  $D_g$ . The Henry coefficient,  $S_{gf}$ , provides a measure of the discontinuity in concentration between the fluid and solid phase (as shown in Figure 17). The value of  $S_{gf}$  may be important with respect to mass balance calculations and is established from consideration of mass balance. In a two compartment diffusion test, such as the one shown in Figure 18, one can monitor the diffusion of the

Figure 18. Two compartment diffusion cell used for measuring diffusion through a geomembrane.

contaminant of interest as it migrates from the source to the receptor with time. When an equilibrium is reached, the value of  $S_{gf}$  is given by

$$S_{gf} = \frac{c_{fo} V_s - c_{fF} (V_s + V_r) - \sum V_i c_i}{A t_{GM} c_{fF}} \quad (15)$$

- where
- $c_{fo}$  is the initial concentration of fluid in the source reservoir [ML<sup>-3</sup>]
  - $c_{fF}$  is the final equilibrium concentration in the source and reservoir [ML<sup>-3</sup>]
  - $V_s, V_r$  are the volumes of the source and the reservoir [L<sup>3</sup>]
  - $A$  is the area of geomembrane through which diffusion occurs [L<sup>2</sup>]
  - $t_{GM}$  is the thickness of the geomembrane [L]
  - $\sum V_i c_i$  is the mass removed by sampling events [M] ( $V_i$  and  $c_i$  being the volume and concentration removed at each sampling event).

The diffusion coefficient can then be calculated knowing the value of  $S_{gf}$  by fitting the variation of the source and effluent concentration with time using computer software that models the boundary conditions, phase change and transport through the geomembrane (e.g. Rowe & Booker 1997a). Table 15 summarizes a number of available techniques for obtaining  $D_g$  and  $S_{gf}$ .

It is important to note that there is a difference between phase change at the fluid/geomembrane boundary and sorption that occurs within the geomembrane itself as contaminant migrates through the geomembrane. Because plastic sheets are often very thin, the two have been confused in the literature. While this may be of little importance for very thin membranes, it is potentially important for thicker geomembranes. Sorption may occur, for example, when the contaminant absorbs to sorption sites in the geomembrane such as dispersed porous particles of high surface area (e.g. carbon black or silica gel). For this type of sorption, Eq. 5 is modified to

Table 15. Some techniques for measuring the partitioning and diffusion coefficients for geomembranes.

Technique	Method	Comments
Weight Gain	<p>Monitor increase in mass of geomembrane immersed in fluid of interest from initial value <math>m_o</math> until mass of geomembrane becomes constant at <math>m_\infty</math> (plot <math>(m_t - m_o)/(m_\infty - m_o)</math> vs <math>\sqrt{t}</math>)</p> $S_{gf} = \frac{\rho_{GM}(m_\infty - m_o)}{c_{fF}}$ $D_g = 0.049 t_{GM}^2 / t_{1/2}$	<p>Faster than alternative tests but each chemical must be examined separately. Prone to error due to mass loss when weighing (especially for VOCs).  <math>c_{fF}</math> = final equilibrium fluid concentration  <math>t_{1/2}</math> time to get; <math>(m_t - m_o)/(m_\infty - m_o) = 0.5</math></p>
Time Lag	<p>Monitor mass movement through geomembrane with time for test where <math>c_{t1} = \text{const}</math>, <math>c_{t2} = 0</math> (Figure 17), plot cumulative mass, F, through geomembrane against time and extrapolate steady state value to F=0 to obtain the time lag <math>\tau</math>. Change in source and receptor solution monitored with time. <math>S_g</math> calculated from Eq. 15 at equilibrium, <math>D_g</math> inferred from variation in source and receptor concentration with time.</p>	<p>May be used in conjunction with weight gain method to allow evaluation of parameters prior to equilibrium in the diffusion test.</p>

$$\frac{\partial c_g}{\partial t} = D_g \frac{\partial^2 c_g}{\partial z^2} - \frac{\partial S_g}{\partial t} \quad (16)$$

$\beta$  is an experimentally derived coefficient  $[M^{-1}L^3]$ .

where  $S_g$  may have a number of forms, including linear

$$S_g = K_g c_g \quad (17)$$

where  $S_g$  is the mass sorbed per unit volume  $[ML^{-3}]$   
 $K_g$  is the linear sorption coefficient  $[-]$  and  
 $c_g$  is the dissolved concentration  $[ML^{-3}]$   
 and Langmuir

$$S_g = \frac{\alpha \beta c_g}{1 + \beta c_g} \quad (18)$$

where  $\alpha$  is the limiting sorption mass per unit volume  $[ML^{-3}]$ , and

This sorption is distinct from the partitioning defined by Eq. 7. By combining Eq. 18 with linear partitioning between phases (Eq. 6), one can simulate the case where some of the molecules dissolved in the geomembrane are free to diffuse down the concentration gradient while other molecules are bound at a fixed number of adsorption sites or voids within the polymer.

### 8.3 Factors Affecting Diffusion Through a Geomembrane

The solubility and diffusion of a contaminant in a geomembrane will increase with increasing temperature. The diffusion coefficient tends to decrease with increasing penetrant size (molecular weight, molar volume or molecular diameter; see Berens & Hopfenberg 1982; Park & Nibras 1993). The shape of the molecule is also

important with linear, flexible and symmetrical molecules having higher mobility than rigid or non-symmetrical molecules (Salame 1960; Berens & Hopfenberg 1982; Saleem et al. 1989). For example, Saleem et al. (1989) showed that the diffusion coefficient for o-xylene is much lower than for p-xylene. This is attributed to the symmetrical nature of p-xylene (that has a dipole moment of 0) and the distorted shape of o-xylene with its two adjacent methyl groups (dipole moment = 0.62 debye). Berens and Hopfenberg (1982) showed that the diffusion coefficient for n-alkane and other elongated or flattened molecules are higher, by a factor of up to  $10^3$ , than the diffusion coefficients of spherical molecules of similar molecular weight.

The "permeability" ( $P_g = S_g D_g$ ) is highly dependent on the similarity of the penetrant and polymer. For example, strongly polar penetrant molecules have very low permeabilities through polyethylene (August & Tatzky 1984; Rowe et al. 1995a, 1996a) with the permeability being in the following order: alcohols < acids < nitroderivatives < aldehydes < ketones < esters < ethers < hydrocarbons (August & Tatzky 1984). Rowe et al. (1996a) noted that the diffusion of a number of different contaminants had the following order (lowest to highest): chloride < ethanoic acid < methyl ethyl ketone < 1,1 dichloroethane < dichloromethane < 1,2 dichloroethane. After 4 years there had been negligible diffusion of  $\text{Na}^+$  and  $\text{Cl}^-$  through the geomembrane and only minimal diffusion of ethanoic (acetic) acid. Similarly, August et al. (1992) found that there was negligible diffusion of heavy metal salts ( $\text{Zn}^{2+}$ ,  $\text{Ni}^{2+}$ ,  $\text{Mn}^{2+}$ ,  $\text{Cu}^{2+}$ ,  $\text{Cd}^{2+}$ ,  $\text{Pb}^{2+}$ ) from a concentrated (0.5 M) acid solution (pH=1-2) through HDPE over a 4 year test period.

For crystalline polymers, the crystalline areas act as "diffusion barriers" and diffusion appears to be primarily through the amorphous phase and hence one would expect that, as the crystallinity increases, the diffusion coefficients and solubility will decrease. For example, Park et al. (1995) reported that the permeability ( $P_g = S_g D_g$ ) of xylene in VLDPE was almost twice that through HDPE. Ashley (1985) has indicated that orientation can reduce permeability ( $P_g = S_g D_g$ ) of amorphous polymers by 10-15% and of crystalline polymers by over 50%.

#### 8.4 Diffusion of Water Through HDPE Geomembrane

Eloy-Giorni et al. (1996) performed a detailed study of water movement through intact geomembranes. Based on a series of experiments, they concluded that the concept of hydraulic conductivity (as defined by Darcy's Law) is not appropriate for describing water transport (and by inference the advective transport of contaminants) through hydrophobic geomembranes. In

particular, they demonstrated that a difference in pressure head across a geomembrane of up to 200 m had no significant effect on the movement of water molecules across a 1.7 mm thick HDPE geomembrane ( $\rho_g = 940 \text{ kg/m}^3$ ). Likewise, a head difference of up to 400 m had no significant effect on water movement across a 1 mm and 1.6 mm thick PVC geomembrane ( $\rho_g = 1260 \text{ kg/m}^3$ ). In these experiments, the driven flux of water (i.e. the flow of water across a geomembrane per unit area of geomembrane per unit time under conditions where there is a pressure head difference across the geomembrane) was less than or equal to the limit of accuracy of the apparatus ( $10^{-7} \text{ m}^3/\text{m}^2/\text{day} \leq 3 \times 10^{-5} \text{ m}^3/\text{m}^2/\text{a}$ ) and hence was negligibly small.

These findings, which were verified in several ways, are at variance with earlier results used by Giroud and Bonaparte (1989a) to establish permeation rates for geomembranes. Given the rigour of the recent experiments and the sophisticated techniques used, there is a reasonable likelihood that the 1996 results are more reliable than those used by Giroud and Bonaparte in 1989. If one accepts these results, then the only significant mechanism for water migration through the geomembrane is diffusion.

One may expect negligible water diffusion across a geomembrane in a composite MSW landfill liner for two reasons. Firstly, the permeability ( $P_g = S_g D_g$ ) of the geomembrane to water is extremely low. Based on the parameters given in Table 16 and Equation 10, one can

Table 16. Solubility and diffusion coefficient for water in three types of geomembrane (based on Eloy-Giorni et al. 1996).

	$S_g$ (-)	$D_g$ ( $\text{m}^2\text{s}^{-1}$ )	$\rho_g$ ( $\text{kgm}^{-3}$ )	$t_{GM}$ (mm)
HDPE	$8 \times 10^{-4}$	$2.9 \times 10^{-13}$	940	1.7
PVC	$7 \times 10^{-2}$	$4.4 \times 10^{-13}$	1260	1.0, 1.6
Bituminous	$9 \times 10^{-3}$	$8 \times 10^{-13}$	1150	5

show that the water flux,  $f$ , through a 1.5 mm thick HDPE geomembrane would be  $1.5 \times 10^{-13} \Delta c_f \text{ kg/m}^2/\text{s}$  (where  $\Delta c_f$  is in  $\text{kg/m}^3$  units) ( $1.3 \times 10^{-4} \Delta c_f \text{ L/ha/d}$ ) where  $\Delta c_f$  is the difference in the "concentration" of water on the two sides of the geomembrane. Thus, even with water on one side and zero relative humidity on the other side, the water flux would be very small. Secondly, apart from the low permeability of the geomembrane to water, one would expect there to be very little diffusive flux since the concentration gradient  $\Delta c_f$  is likely to be very small. For compacted clay liners, the soil water potential at the time of construction is typically -10 to -50 kPa and this corresponds to a relative humidity of about 99.5% (Daniel, personal communications). With water

(leachate) on one side of a geomembrane and compacted clay on the other side, the difference in relative humidity (and hence  $\Delta c_t$ ) is negligible. Thus, even with the presence of salts in the MSW leachate to influence the energy difference between the two sides of the geomembrane, the gradient in energy is so close to zero that, for all practical purposes, there will be no diffusion of water or water vapour across the geomembrane. This would appear to be the likely case for most of the service life of a geomembrane used as part of composite liner systems at the base of an MSW landfill. Thus, it would seem appropriate to revise the permeation rates suggested by Giroud and Bonaparte (1989a) to be, for all practical purposes, zero for HDPE geomembrane liners.

### 8.5 Diffusion of Contaminants Through HDPE Geomembranes

Although there is limited data on diffusion through geomembranes, there is enough to identify important issues and to provide a basis for the rational analysis and design of barrier systems that include a geomembrane.

Values of the Henry's coefficient  $S_{gf}$  and diffusion coefficient,  $D_g$ , based on the literature (including the work of the author and coworkers) are summarized in Table 17. These values provide a starting point, however the values should be used with caution since they are temperature and maybe concentration dependent. The values may also vary due to the chemical composition of the contaminant source, the polymer crystallinity, additives etc. and hence published values should only be used as an initial guide and do not replace experimentally determined values for the geomembrane of interest for projects where uncertainty regarding the diffusion coefficient or sorption could have a significant impact.

To illustrate the effect of leachate composition, consider the results for toluene and dichloromethane as summarized in Table 17. It can be seen that the value of  $S_{gf}$  reported for toluene ranges from 0.09 to 192 for pure and aqueous solution respectively and the values of diffusion coefficient range from  $4.4 \times 10^{-12}$  to  $0.18 \times 10^{-12}$ . It is also noted that the values of  $S_{gf}$  and  $D_g$  for aqueous solutions are reported to vary depending on the concentration. Based on the data by Park and Nibras (1993), average values of  $S_{gf}=96$  and  $D_g=0.47 \times 10^{-12}$  m<sup>2</sup>/s will be used in subsequent modelling of toluene in aqueous solution and values of  $S_{gf}=0.09$  and  $D_g=4.4 \times 10^{-12}$  m<sup>2</sup>/s will be used for pure toluene as summarized in Table 18. The variation in values for  $S_{gf}$  for the dichloromethane (DCM) is less than for toluene with  $S_{gf}$  ranging between 0.06 and 5.6 and the reported diffusion coefficients ranging between  $9 \times 10^{-12}$  and  $0.58 \times 10^{-12}$  m<sup>2</sup>/s for pure and aqueous solutions respectively. The values of  $S_{gf}$  and  $D_g$  to be subsequently used in modelling DCM diffusion through an HDPE geomembrane are given in

Table 18.

Fortunately, the variability between diffusion coefficients reported in the literature (see Table 17) is not as critical as it may appear. In essence, for a given contaminant, the geomembrane is either a good diffusion barrier (e.g. to water and hydrated ions such as Na<sup>+</sup>, Cl<sup>-</sup>, Zn<sup>2+</sup>, Ni<sup>2+</sup>, Mn<sup>2+</sup>, Cu<sup>2+</sup>, Cd<sup>2+</sup> and Pb<sup>2+</sup>) or it is not (e.g. organic compounds such as toluene, dichloromethane etc.) with many orders of magnitude difference in the permeability of the geomembrane ( $P_g=S_{gf} D_g$ ) for these two groups. Due to the very low permeation rates, it is very difficult to obtain the values of  $S_{gf}$  and  $D_g$  for hydrated ions however it is possible to obtain an estimate of the parameters. It may be anticipated that the solubility of hydrated ions will be less than unity. One option is to assume  $S_{gf}=1$  and deduce the value of  $D_g$  based on a two compartment diffusion test (see Figure 18). Since  $S_{gf}$  is likely smaller than unity, this approach may lead to some small mass balance error but in a field application it is likely not significant as demonstrated momentarily. The other option is to assume that  $S_{gf}$  is similar to that of water and deduce  $D_g$  from laboratory tests using  $S_{gf}=8 \times 10^{-4}$ . Figure 19 shows parameters deduced in both ways for a diffusion test conducted by Rowe et al. (1995a). Based on 2.5 years of data, they deduced an upper bound on the diffusion coefficient of chloride (assuming  $S_{gf}=1$ ) of  $6 \times 10^{-15}$  m<sup>2</sup>/s and indicated that the value would likely be reduced as more data became available. Figure 19 shows an additional two years of data and it can be seen that the concentration in the receptor remained low (the scatter of the data should be interpreted in the context of the very low concentrations - all lower than 0.2% of the source concentration). Assuming  $S_{gf}=1$ , it is now clear that the diffusion coefficient is less than  $3.2 \times 10^{-15}$  m<sup>2</sup>/s and likely less than  $2 \times 10^{-15}$  m<sup>2</sup>/s. Adopting the partitioning coefficient for water,  $S_{gf}=8 \times 10^{-4}$ , the diffusion coefficient is less than  $4 \times 10^{-13}$  m<sup>2</sup>/s and likely less than  $1 \times 10^{-13}$  m<sup>2</sup>/s. The theoretical fits using  $S_{gf}=8 \times 10^{-4}$  appear to better describe the observation than the fits for  $S_{gf}=1$ . These tests are ongoing and the diffusion coefficient will likely be reduced in the future as more data becomes available. However, there is already sufficient data to address practical issues as shown below.

Figure 20 shows the predicted migration of chloride through a composite liner system assuming no holes and no significant degradation of the geomembrane over the period being examined. It can be seen that the uncertainty regarding the precise parameters ( $S_{gf}=8 \times 10^{-4}$ ,  $D_g=1 \times 10^{-13}$  m<sup>2</sup>/s; versus  $S_{gf}=1$ ,  $D_g=2 \times 10^{-15}$  m<sup>2</sup>/s) is of little practical consequence and that the geomembrane (unlike the clay) is a very good diffusion barrier to Cl<sup>-</sup> (and likely other hydrated ions as already discussed). After 50 years the calculated peak impact is less than 3 mg/L and after 475 years it is less than 16 mg/L for the

predictions using  $S_{gf}=1$  and its corresponding diffusion coefficient.

The tests conducted by Rowe et al. (1995a) were at concentrations of salt typical of landfill leachate. It should be noted that for solutes that dissociate completely to form ions, the mass transfer across a geomembrane may be proportional to concentration squared, and not just concentration as suggested by Ficks law, and hence the apparent "diffusion coefficient" may increase with increasing concentration (remembering the earlier caution that it may really be a mass transfer coefficient rather than a true diffusion coefficient that we use in our models). This is because in the geomembrane, the sodium and chloride (or other similar ion pairs) must diffuse as pseudo-molecules of sodium chloride rather than as ions and the concentration of ion pairs at the surface is proportional to the product of the sodium and chloride ions or the square of the concentration of sodium chloride in the adjacent aqueous solution as discussed by Cussler (1984).

For organic compounds in aqueous solution, the value of  $S_{gf}$  is strongly related to the solubility of the compound of interest in water. Generally, the lower the solubility in water, the greater the affinity for HDPE and the higher the value of  $S_{gf}$  when in aqueous solution. For DCM (see Table 18), the value of  $S_{gf}$  is of the order of unity and a range of values between 1 and 2.3 has only a small effect on the value of  $D_g$  that is deduced ( $0.95$  to  $2.2 \times 10^{-12} m^2/s$ ) (see Figure 21). To illustrate the fact that the precise choice of  $S_{gf}$  and  $D_g$  is not critical, calculations were performed for  $S_{gf} = 1$ ,  $D_g = 2.2 \times 10^{-12} m^2/s$  and  $S_{gf} = 2.3$ ,

Figure 19. Variation in observed and calculated chloride concentrations in a two compartment diffusion test for a range of diffusion parameters  $D_g$ ,  $S_{gf}$ .

conditions examined and these two "likely upper" bound diffusion coefficients. Even for the most conservative interpretation of the current data, the peak increase in the aquifer (assuming no attenuation layer between the liner and aquifer) is less than 5 mg/L at 50 years and the peak is less than 25 mg/L at 475 years. As noted above, the combination of a low solubility ( $S_{gf}=8 \times 10^{-4}$ ) and the corresponding deduced diffusion coefficient gives a better fit to the experimental data shown in Figure 19 and gives much lower predicted impact (see Figure 20) than

Figure 21. Variation in observed and calculated receptor dichloromethane (DCM) concentrations in a two compartment diffusion test for a range of diffusion parameters  $D_g$ ,  $S_{gf}$  (modified from Rowe et al. 1995a).

$D_g = 1 \times 10^{-12} \text{ m}^2/\text{s}$  (both combinations give a similar fit to the experimental data in Figure 21) as shown in Figure 22. The calculated increase in DCM concentration in an

Figure 22. Calculated variation in DCM concentration in an aquifer due to diffusion through an HDPE geomembrane and 0.6 m CCL for different diffusion parameters  $D_g$ ,  $S_{gf}$  and half-lives in the clay.  $t_{1/2}$  (leachate) = 10 years.

aquifer below the composite liner is identical (to plotting accuracy) for the two cases. These calculations assume transport parameters in the clay as shown in the insert to Figure 22. Of particular note is the source concentration and half-life of DCM. The source concentration is based on data from the Keele Valley Landfill in Toronto (Rowe 1995). The half-life of 10 years is considered to be a reasonable value for MSW sites in Canada (see MoEE 1996; Rowe 1995). What is far less certain is the half-life of DCM in the underlying clay. Since the geomembrane acts as a selective barrier and effectively excludes volatile fatty acids that form the primary substrate for biodegradation in the landfill, one would anticipate slower degradation in the clay than in the leachate. This is the topic of current research at the University of Western Ontario. For the purposes of the current modelling, a half-life of 50 years was adopted. For this combination of parameters, and excluding the effects of consolidation, the concentration of DCM in the aquifer would be expected to reach 10-15  $\mu\text{g/L}$  after about 10 years and the Maximum Acceptable Concentration (MAC) of 50  $\mu\text{g/L}$  after 15 years. If the half-life was 10 years in the clay the peak impact at 35 years would be about 1.5 times the MAC for this combination of parameters. Clearly, some caution is required in the selection of half-lives. The impact on the aquifer can be reduced by the presence of either a thicker liner or an attenuation layer between the liner and the aquifer as will be illustrated in Section 10.

The published diffusion parameters for toluene (see Table 18) vary significantly depending on the test conditions, with low values of  $S_{gf}$  and high diffusion,  $D_g$  (e.g.  $S_{gf} = 0.09$ ,  $D = 4.4 \times 10^{-12} \text{ m}^2/\text{s}$ ,  $P_g = 0.4 \times 10^{-12} \text{ m}^2/\text{s}$ ) for pure solvent and high values of  $S_{gf}$  and low  $D_g$  (e.g. average values of:  $S_{gf} = 96$ ,  $D = 0.47 \times 10^{-12} \text{ m}^2/\text{s}$ ,  $P_g = 45 \times 10^{-12} \text{ m}^2/\text{s}$ ) for aqueous solutions. To examine this, Figure 23 shows the calculated variation in concentration with time in an aquifer for these two combinations of diffusion parameters ( $S_{gf}$ ,  $D_g$ ) and it can be seen that the parameters for aqueous contaminants give a much higher impact than those for pure solvent. However, the parameters for sorption ( $K_d$ ) and the half-life in the leachate and the soil are even more important. Results are given assuming no retardation ( $K_d=0$ ) and moderate sorption ( $K_d=3.9$ ) in Figure 23 for infinite half-life. Figure 24 shows similar results assuming a half-life in leachate of 10 years and soil of 50 years. Given that the drinking water objective for toluene is 24  $\mu\text{g/L}$ , it can be seen that the drinking water objective would be met only with moderate retardation and considering the toluene half-life as examined in Figure 24. The impacts for other cases would be reduced if there was an attenuation layer between the compacted clay liner and aquifer (as examined in Section 10). However, it is evident that the most critical liner parameters are the distribution

Figure 23. Calculated variation in toluene concentration in an aquifer due to diffusion through an HDPE geomembrane and 0.6 m CCL for published values of  $D_g$ ,  $S_{gf}$ . Assumed infinite half-life.

Figure 24. Calculated variation in toluene concentration in an aquifer due to diffusion through an HDPE geomembrane and 0.6 m CCL for published values of  $D_g$ ,  $S_{gf}$ . Assumed half-life of toluene: 10 years in leachate; 50 years in soil.

coefficient and the half-life in the clay. As discussed by Rowe et al. (1995b) and Rowe and Weaver (1997), care is required in the selection of  $K_d$  values based on published correlations.

Using computer codes like that used here (Rowe & Booker 1997) to get Figures 20, 22-24, one can establish the importance of diffusion as a transport mechanism through a geomembrane. For hydrated ions such as chloride examined in Figure 20, diffusion is not important for the diffusive service life of geomembrane (i.e. the length of time that it maintains this low diffusion coefficient) and the critical consideration will be leakage through holes. However, for certain organic contaminants (e.g. see Figures 22-24), the diffusive migration may be very significant for a well constructed liner (i.e. one with only a few holes), and should be considered if one is to ensure a safe design.

In the analysis, the migration of organic compounds through composite liners, key factors to be considered include (a) the retardation characteristics of the clayey component of the composite liner (see Rowe et al. 1995b) and (b) biodegradation of the organics as they migrate through the soil (see Rowe 1995; Rowe et al. 1996a, 1997d). Since the geomembrane provides a good barrier to volatile fatty acids and other nutrients in leachate, there is potential that the degradation rates for organic compounds below a geomembrane will be less than when a complete contaminant plume is migrating through soil due to the reduction in substrates.

## 9 LEAKAGE THROUGH COMPOSITE LINERS

### 9.1 Observed leakage Through Liners

Modern landfills typically have a primary leachate collection system (PLCS) intended to collect leachate and control the leachate head acting on the primary liner. A number of landfills have also been constructed with a second drainage layer below the primary liner (see Figures 1 and 3). This secondary drainage layer allows the collection of some or all of the water arising from consolidation of the clay liner as well as leachate that migrates through the primary liner. It also allows the control of the head acting on the secondary liner. The terminology used to describe this layer varies with it often being called either a secondary leachate collection system or a leak detection system. In this paper, the secondary drainage layer will be referred to as the secondary leachate collection system (SLCS).

Monitoring data from a secondary leachate collection system (SLCS) may provide insight regarding the effectiveness of composite primary liners. However, the interpretation of the data from SLCS requires careful consideration of sources of fluid other than leakage from the landfill (Gross et al. 1990). These include (a) water that infiltrated into the SLCS layer during construction; (b) water arising from compression and consolidation of the clay liner; and (c) groundwater water from outside of the landfill.

Bonaparte et al. (1996) examined data for 26 landfill cells containing GCLs as part of the composite primary liner. They identified three periods during which there may be very different flows to the SLCS: (a) the initial period of operation, (b) the active period of operation, and (c) post-closure period (after the final cover has been constructed). Table 19 summarizes the mean and standard deviations of the flows in the PLCS and SLCS. As might be expected, flow rates from the SLCS decrease as flow rates from the PLCS decrease. This is likely, at least in part, due to reduced head acting on the primary composite liner. The mean SLCS flow rates are small during both the active and post-closure period (0.7 and 0.2 lphd respectively). Peak flow rates are about an order of magnitude larger than the average values but are still quite small. If one eliminates construction water from the flows by examining systems with a geonet SLCS, it would appear that for a composite liner with a geomembrane and GCL, the hydraulic efficiency of the liner is in excess of 99.9% and the average flow rates potentially attributable to primary liner leakage are less than 11.2 and 24.3 lphd respectively. Data in the active period is limited but for the two cases reported the maximum mean and peak SLCS flow rates are 0.9 and 3.7 lphd respectively.

The SLCS flow rates reported by Bonaparte et al. (1996) are very low, however there is also potential for diffusive transport of organic compounds through a composite liner involving a geomembrane over a GCL with typical (unmodified) bentonite. Although data relating to potential diffusion through composite liners is limited, there is some evidence to suggest that this requires further evaluation. For example, Othman et al. (1996) report significant levels of 1,1 dichloroethane and dichloromethane (methylene chloride) in the SLCS for a landfill with a 1.5 mm thick HDPE geomembrane and 6 mm thick GCL composite liner and a 5 mm thick geonet SLCS. This same system had exhibited low SLCS flow rates (average value of 3.6 lphd from 14-21 months reducing to 0.7 lphd between 22-31 months) and inorganic chemistry that was not characteristic of leachate. This implies that any leakage through holes

in the geomembrane was very small. However, the concentration of DCM and 1,1 DCA are small but significant over a period of between 6 and 28 months after commencement of waste placement. This suggests possible diffusion through the GM/GCL system. Additional investigation would be required to confirm the hypothesis.

Table 20 summarizes data obtained in the "active operation" period for composite liners involving a geomembrane over compacted clay (CCL). The fluid collected in the SLCS is considerably greater than that obtained for the composite liners involving only a geomembrane and GCL. Othman et al. (1996) attributed much of the fluid collected in the SLCS of these systems to consolidation water from the overlying GCL. This hypothesis is supported by the leachate chemistry that is not similar to leachate. Generally, the volatile organic compound (VOC) concentrations in the SLCS were very low with only DCM being clearly evident at a low concentration and possible trace levels of other compounds for the landfill with a very thin CCL (450 mm thick). For this landfill, the SLCS flow rates were quite small (average value less than 15 lphd reducing to less than 3 lphd after about 3 years). Given (a) the thin liner and (b) the fact that consolidation of the liner increases the rate of contaminant transport and the mass flux across the clay liner (e.g. Smith 1997), there is the potential for organics that readily diffuse through the geomembrane and experience relatively little retardation in clay (such as DCM) to diffuse through the geomembrane and move through the clay in a couple of years.

Workman (1993) has also examined the chemistry of the fluid in the SLCS of a number of cells and detected several VOCs including chloroethane, ethylbenzene and trichloroethene at low concentrations. He hypothesizes that they migrated as gases from the primary to secondary system at the sideslopes. While this may be a reasonable hypothesis, the alternative hypothesis of migration through the primary liner by a combination of diffusion and consolidation induced advection warrants further consideration.

Table 19. Mean and standard deviations of flow in PLCS and SLCS for 6 landfill cells with a GCL as part of a composite primary liner (in lphd) (after Bonaparte et al. 1996).

	Average Flows					Peak Flows			
	Cells	PLCS		SLCS		PLCS		SLCS	
		Mean	sd	Mean	sd	Mean	sd	Mean	sd

Active Operation	18/19	276	165	0.7	1.1	752	590	7.7	13.7
Post-Closure	4	124	-	0.2		266	-	2.3	

Table 20. Average flow rates in PLCS and SLCS for landfills with composite liners involving GM and CCL (in lphd). (modified from Othman et al. 1996) [simple average of data after about 3 years].

Type	Primary Liner		SLCS		PLCS		SLCS		Period	
	GM	Clay	Material	Thick-ness (mm)	Average	Peak	Average	Peak		
Type	Thick-ness (mm)	Type	Thick-ness (mm)	Material	Thick-ness (mm)	(lphd)	(lphd)	(lphd)	(lphd)	(mo.)
CSPE	0.9	CCL	600	sand	450	1120	2076	113	260	41-93
HDPE	2.0	CCL	450	sand	300	4400	5790	59	152	35-54
HDPE	1.5	CCL	900	GN	5	1142	3985	167	275	42-66
HDPE	2.0	CCL	450	GN	5	53	170	1.5	10	34-58
HDPE	1.5	CCL	900	GN	5	1144	1371	60	102	30-37

Bonaparte and Gross (1993) examined the flow through composite primary liners underlain by a SLCS and based on their data it would appear that with Construction Quality Assurance (CQA), 19% of landfills had SLCS flow rates of 50 lphd or less (see Table 21) and 57% of landfills had SLCS flow rates of 200 lphd or less. For those landfills with no CQA, only 20% of landfills had SLCS flow rates of 200 lphd or less. This illustrates the benefits of CQA. The flows reported in Table 21 should be regarded as an upper bound to leakage since Bonaparte and Gross (1993) attribute most of these flows to consolidation water and hence it would not be due to leakage through the geomembrane. A better measure is given by the data in Table 20 where all of the average flows are less than 200 lphd and 60% are less than 100 lphd. In absolute terms, these flows are very small but, as will be discussed in subsequent sections, are generally much larger than would be expected due to leakage through a few holes in the geomembrane.

Table 21. Percentage of landfills with average measured flow rate in the SLCS in specified range for composite primary liners (modified from Bonaparte & Gross 1993).

Flow Rate (lphd)	With CQA	No CQA
<50	19%	-
50-200	38%	20%
200-500	27%	40%
500-1000	8%	40%
>1000	8%	
(Number of landfills)	37	5

## 9.2 Existing Solutions for Assessing Leakage

In the design of composite liner systems consideration needs to be given to the potential for water migration through the liner due to (a) diffusion (permeation) through the intact geomembrane (discussed in Section 8) and (b) flow through holes in the geomembrane. Giroud and Bonaparte (1989a,b) and Giroud et al. (1989) developed a set of equations that have been widely used for estimating the leakage through geomembrane liners underlain by compacted clay liners. These equations provide an approximate solution assuming that the gradient is near unity. This may be a reasonable assumption for low leachate mounds (e.g. design mounds of 0.03-0.3 m) and clay liners that are 0.6-0.9 m, but are not strictly valid for the levels of leachate mounding associated with termination of the operation or excessive clogging of a leachate collection system (e.g. 10-20 m) or even a modest leachate mound over a GCL. Recognizing this limitation, Giroud et al. (1992) extended the approximate solution to consider hydraulic gradients much greater than unity. They also provided a solution for large defects.

These Giroud and Bonaparte (1989a, b) and Giroud et al. (1989, 1992) solutions are all based on leakage experiments that were performed for geomembranes in contact with conventional compacted soil at low confining stress (Brown et al. 1987). They were not developed for the potentially better contact that could be achieved by having a geomembrane in contact with a GCL which itself is placed on a firm foundation layer. Wilson-Fahmy and Koerner (1995) recognized the limitation of the Giroud et al. (1989) solution for geomembranes over GCLs. Specifically, they noted that since the gradients were likely to be much larger than unity, the Giroud et al. (1989) approximations were no longer valid and it was necessary to solve the complete differential equation.

This they did using a numerical (finite difference) technique. They performed a parametric study to examine the leakage through holes of different radii (1, 3, 5 and 7 mm) for a range of transmissivities of the GM/GCL contact ( $10^{-8}$ ,  $10^{-9}$ ,  $10^{-10}$ ,  $10^{-11}$  and  $10^{-12}$  m<sup>2</sup>/s), hydraulic conductivities of the GCL ( $1 \times 10^{-10}$ ,  $1 \times 10^{-11}$ ,  $5 \times 10^{-11}$ , and  $1 \times 10^{-12}$  m/s) and GCL thicknesses (4, 7 and 10 mm).

Walton and Sagar (1990) and Walton et al. (1997) have suggested that for effective stresses corresponding to more than 0.5 m burial of the geomembrane there should be no gap between the geomembrane and the soil (wetted radius  $R=r_o$  in Figure 25) and hence for widely

Figure 25. Schematic showing a hole of radius  $r_o$  in a geomembrane and the underlying strata together with the head distribution between the geomembrane and clay liner.

spaced small holes that are not infilled with soil, the leakage through any such hole would be given by Forchheimer's Equation (1930) for an ideal hole on a semi-infinite soil deposit

$$Q = 4r_o k_L h_w \quad (19)$$

where  $Q$  = leakage per hole (m<sup>3</sup>/s),  $r_o$  = radius of the hole (m),  $k_L$  = hydraulic conductivity of the liner below the geomembrane (m/s), and  $h_w$  = head loss across the geomembrane and the clay, taken here to be equal to the leachate head,  $h_w$ , above the geomembrane. As noted above, this equation represents idealized conductions of no lateral migration at the interface between the geomembrane and the underlying soil. They justify this assumption based on tests performed by Walton et al. (1997) involving fine sand above and below a

geomembrane with a hole. Except for the case where a low permeability soil is deposited as a slurry in contact with the geomembrane and it consolidates with time under a large compressive stress (e.g. see Garlanger et al. 1994; Giroud et al. 1994), Eq. 19 is likely to underestimate the leakage through holes in a geomembrane that is placed below a stone collection layer and protective geotextile and placed above a compacted clay liner or GCL. It also assumes that there are no wrinkles or waves in the geomembrane (after application of stress) near the location of the defect. Rowe and Booker (1998b) have extended this solution to consider a layer of finite depth. They suggest that the solution may be useful for assessing the leakage below a circular (or near circular) "wrinkle" (e.g. around a penetration in the geomembrane).

The scenario considered by Walton et al. (1997) corresponds, in principle, with the perfect contact case examined by Giroud and Bonaparte (1989b) who obtained an approximate expression for the "absolute minimum" leakage with perfect contact that was given by:

$$Q = \pi r_o^2 k_L (h_w + H_L) / H_L \quad (20)$$

where  $H_L$  is the liner thickness and all terms are as defined for Eq. 19 (it being assumed that the head at the base of the liner is zero:  $h_b = H_f$  in Figure 25 and  $k_f \gg k_L$ ). The flow calculated by Eq. 20 is plotted as (MIN) for two cases in Figure 26. They then obtained a second approximate solution for perfect contact:

$$Q = 2\pi r_o k_L (h_w + H_L) / (1 - r_o / H_L) \quad (21a)$$

that, for  $r_o / H_L \ll 1$ , reduced to

$$Q = 2\pi r_o k_L (h_w + H_L) \quad (21b)$$

Giroud and Bonaparte (ibid) argued that it was unreasonable for the flow to increase with increasing  $H_L$  and reduced Eq. 21b to

$$Q = 2\pi r_o k_L h_w \quad (22)$$

Equation 22 was used by Giroud and Bonaparte (1989b) to define flow for "perfect contact" (denoted (P.C.) in Figure 26). Equation 22 can be seen to be very similar to the exact solution for a deep layer (Eq. 19) but giving 57% greater flow. In 1994, Giroud et al. (1994) ceased to use Eq. 22 for perfect contact and adopted, instead, Forchheimer's Equation (Eq. 19).

Most recently Giroud (1997) and Giroud et al. (1997a-g) have published a series of papers addressing liquid migration through defects in a geomembrane (a) overlain by a permeable medium and underlain by a highly permeable medium (Giroud et al. 1997c); (b) underlain

Figure 26. Leakage rate calculation from Giroud and Bonaparte (1989b) showing interpolation method used:  $h_w=0.03$  m;  $r_o=0.00564$  m.

by a saturated permeable medium (Giroud et al. 1997b); (c) underlain by a semi-permeable medium (Giroud et al. 1997g); and (d) underlain by a low permeability clay liner (Giroud 1997).

An excellent summary of these recent developments is given by Giroud et al. (1998). Of particular interest in the context of this present paper are the revised equations for leakage through composite liners due to circular or quasi-circular geomembrane defects given by Giroud (1997) which reduces to

$$Q=1.12C_{qo}[1+0.1(h_w/H_L)^{0.95}]r_o^{0.2}k_L^{0.74}h_w^{0.9} \quad (23a)$$

where  $C_{qo}$ =dimensionless coefficient that characterizes the quality of the contact between the geomembrane and the liner; and it is assumed that there is zero head at the bottom of the liner (i.e.  $h_a=H_f$  in Figure 25 and  $k_f \gg k_L$ ) and all other terms are as previously defined (or see Section 14: Notation). Equation 23 should only be used with the units specified (m for  $h_w$ ,  $H_L$ ,  $r_o$  and m/s for  $k_L$ ). As given above, Eq. 23 has a slightly different appearance than that given by Giroud (1997) due to the use of radius rather than diameter of the basic dimension of the defect. Two values of  $C_{qo}$  are given by Giroud (1997), based on Giroud et al. (1989),

$$C_{qo}=0.21 \text{ for good contact} \quad (23b)$$

$$C_{qo}=1.15 \text{ for poor contact} \quad (23c)$$

Good contact is defined (Giroud 1997) "as conditions where the geomembrane has been installed, with as few wrinkles as possible, on a low-permeability soil layer that has been adequately compacted and has a smooth surface." Poor contact is defined (ibid) as conditions where the geomembrane "has been installed with a certain number of wrinkles, and/or placed on a low-permeability soil that has not been well compacted and does not appear smooth."

Equation 23a represents the latest leakage equation from Giroud and supersedes equations in previous papers (e.g. Eq. 28 to be discussed subsequently). Giroud (1997) clearly identifies the limitations of Eq. 23 as (1) minimum and maximum radius of hole of 0.25 mm and 12.5 mm respectively; (2) liquid head,  $h_w$ , less than or equal to 3 m; (3) hydraulic conductivity of the liner,  $k_L$ , less than the value given by  $k_c$

$$k_L < k_c = (1.355r_o^{1.8} / [C_{qo}(1+0.1(h_w/H_L)^{0.95}h_w^{0.4})])^{1/0.74} \quad (24)$$

This latter condition is likely to be met provided conditions (1) and (2) above are met and  $k_L \leq 7 \times 10^{-9}$  m/s.

### 9.3 Comments on Contact Conditions

The leakage through a defect in a geomembrane overlying a low permeability layer necessarily depends on the contact between the geomembrane and the underlying soil as noted by Brown et al. (1987), Giroud and Bonaparte (1989b) and others. One can envisage three primary sources of imperfect contact as discussed below.

The first relates to protrusions that may exist causing a gap between the geomembrane and the underlying soil. Even for a well compacted soil, there may be protrusions related to particle size distribution (that in turn may be related to hydraulic conductivity) and these protrusions will create some gap in which water may flow. In the development of Eqs. 23, Giroud and Bonaparte (1989b) used Brown et al.'s (1987) test results as the basis of their "spacings",  $s$ , between the geomembrane and soil for "excellent field conditions" (see Table 22).

The second source of imperfection arises from undulations/ruts which result in the surface not appearing smooth. When compacting clay liners to obtain low hydraulic conductivity, it is usually desirable to compact at a water contents 2%-4% above the standard Proctor optimum value, however, this is often close to the plastic limit of the soil and it is difficult to obtain a smooth surface due to rutting that occurs from construction

Table 22. "Spacings",  $s$ , between geomembrane and soil for "excellent" or "best" field conditions as defined by Giroud and Bonaparte (1989b) based on Brown et al. (1987).

Soil Hydraulic Conductivity $k_s$ (m/s)	Geomembrane-Soil Spacing $s$ (mm)
$10^{-6}$	0.15
$10^{-7}$	0.08
$10^{-8}$	0.04
$10^{-9}$	0.02

equipment. This problem can be solved by compacting the upper layer of soil at a lower water content thereby allowing the preparation of a firm smooth surface and also reducing the potential of desiccation cracking. However, it should also be recognized that this layer will have a higher hydraulic conductivity than the rest of the liner and hence any ring infiltrometer tests on this layer may not be representative of the entire liner. However, the hydraulic conductivity of this layer is significant with respect to leakage through holes in the geomembrane. Thus a balance needs to be met between the desire to have the water content low enough to allow the preparation of a smooth surface but at the same time not so low as to increase the hydraulic conductivity of the layer above  $10^{-9}$  m/s under field stress conditions (with landfill loading applied).

The third source of imperfections affecting contact conditions is the presence of wrinkles (waves) in the geomembrane. The reader is referred back to Section 7.3 for a discussion of the need to eliminate wrinkles and the fact that wrinkles likely do not disappear when the waste is placed. The implications of this will be discussed further in Section 9.5.2.

When a geomembrane is placed over a geosynthetic clay liner (GCL), there is greater potential for obtaining good contact with a low permeability layer due to the fact that the GCL can be placed flat on a well compacted, smooth and firm foundation (e.g. see Giroud 1997). The factor controlling the leakage of an unwrinkled geomembrane over a GCL is the transmissivity of any geotextile between the geomembrane and bentonite (e.g. see Harpur et al. 1993). Where there are wrinkles in a geomembrane over a GCL, there is potential for the bentonite to "extrude" laterally and establish close contact between the geomembrane and clay provided there is sufficient applied compressive stress (e.g. see Giroud 1997) and the wrinkle is small. However, this also creates potential thinning of the GCL (see Stark 1998) which could impact on the GCL performance if there was significant bentonite movement. Also, for large wrinkles

there may be (a) significant thinning of the GCL adjacent to the wrinkle and (b) failure to fill the gap between the GCL and geomembrane. Thus, avoidance of wrinkles would appear to be important when a GCL is used to replace a compacted clay liner below a geomembrane.

A fundamental difference between the Forchheimer's Equation (1930) (Eq. 19) and Giroud (1997; Eqs. 23) is the potential for lateral fluid flow between the geomembrane and the underlying liner. This is related to the transmissivity between the geomembrane and liner. Walton et al. (1997) implicitly assume  $\theta=0$ .

As discussed by Brown et al. (1987) and Giroud and Bonaparte (1989b), if there is a gap that can be approximated by two smooth parallel plates then, based on Newton's viscosity theory, the transmissivity is given by

$$\theta = \frac{\rho g s^3}{12\eta} \quad (25)$$

where:  $\theta$  = hydraulic transmissivity of the empty space [ $m^2/s$ ];

$\rho$  = density of the liquid [ $kg/m^3$ ];

$g$  = acceleration due to gravity [ $m/s^2$ ];

$s$  = spacing between the geomembrane and the soil [ $m$ ]; and

$\eta$  = viscosity of the liquid [ $kg/m/s$ ].

The challenge is to relate the transmissivity  $\theta$  to the field contact conditions and hence derive leakage equations. In this context, and for the purposes of subsequent discussion, it is important to trace the genesis of the coefficients for "good" and "poor" contact as defined by Giroud (1997) and Giroud et al. (1998) to obtain Eq. 23. Giroud and Bonaparte (1989b) defined four reference conditions: "absolute minimum" leakage (Eq. 20), "perfect contact" (Eq. 22), "best contact" and "geomembrane alone". The "best" case was taken to correspond to "excellent field" conditions and based on the Brown et al. (1987) charts and using the value of spacing "s" given in Table 22 to calculate the transmissivity,  $\theta$ , using Eq. 25. This was then used in conjunction with charts published by Brown et al. (1987) to obtain empirical equations for the leakage rate and wetted radius under "best contact" conditions. For this case the flow was given in  $m^3/s$  for  $r_o$  and  $h_w$  in m units and  $k_L$  in m/s units by

$$Q = 0.785r_o^{0.2} k_L^{0.88} h_w \quad (26)$$

and plotted as "best" in Figure 26 for two cases.

The "maximum" geomembrane alone leakage conditions were taken to correspond to the maximum leakage rate ( $\theta \rightarrow \infty$ ) given by Bernoulli's equation (assuming zero hydraulic resistance below the geomembrane)

$$Q = \pi C_B r_o^2 \sqrt{2gh_w} \quad (27)$$

where  $g$ =acceleration due to gravity ( $m/s^2$ ),  $C_B$ =dimensionless coefficient related to the shape of the edges of the hole with  $C_B=0.6$  for sharp edges (Giroud & Bonaparte 1989a), and all other terms are as previously defined.

The values for the "absolute minimum" (MIN), "perfect contact" (PC), "best contact" (BEST) and "maximum" leakage (MAX) were plotted on a logarithmic scale (for a given soil hydraulic conductivity) as shown in Figure 26 with equal spacing between (MIN; Eq. 20), (PC; Eq. 22), (BEST; Eq. 26), (WORST: no data point) and (MAX; Eq. 27) points along the abscissa and a curve was fitted to these four data points (see Figure 26). The interval between "BEST" and the interpolated "WORST" point was then subdivided (arbitrarily in the absence of better alternatives: Giroud, personal communication) into three equal subintervals and "good" and "poor" contacts were taken as the flows corresponding to these intermediate points as shown in Figure 26.

Giroud et al. (1989) performed the interpolation described above for some 500 combinations of parameters and established the empirical equation:

$$Q = 0.785 C_{qo} r_o^{0.2} k_L^{0.74} h_w^{0.9} \quad (28)$$

where all terms are as defined for Eqs. 23 and  $C_{qo}$  is given by Eqs. 23b,c for "good" and "poor" contact. This equation was originally limited to low values of  $h_w$  and was subsequently extended (Giroud 1997; Giroud et al. 1998) to the most recent form given by Eq. 23.

Since the fundamental basis of a difference in flow (leakage) through the defect over the range between "perfect contact" ( $\theta=0$ ) and maximum flow ( $\theta=\infty$ ) is the difference in transmissivity of the "interface" zone between the geomembrane and the underlying soil (the clay liner in the context of this paper) it follows that it should be possible to relate these flows deduced for the cases of "good" and "poor" contact using Eq. 23 to values of  $\theta$ . It is also likely that leachate heads will exceed 3 m at some point during the service life of the geomembrane (see Sections 2 and 3) and hence it is useful to examine the implications of the empirical equation given by Eq. 23 for these conditions and the conditions associated with a GCL replacing a compacted clay liner. However, to do this one needs an analytical solution for leakage through the geomembrane liner. Such a solution is presented in the following section and this will be applied in Section 9.5 to address the issues raised above.

#### 9.4 General Analytical Solution for Leakage Through a Composite Liner

Consider a composite liner with a hole in the geomembrane as shown in Figure 25. The geomembrane rests on a low permeability layer of thickness  $H_L$  and hydraulic conductivity  $k_L$  (e.g. a compacted clay liner, CCL; or geosynthetic clay liner, GCL) which in turn rests on some more permeable (but not highly permeable) foundation layer (thickness  $H_f$  and hydraulic conductivity,  $k_f$ ) which rests on a highly permeable layer in which there is no significant matric suction. It is assumed that the geomembrane is not in perfect contact with the clay either due to small undulations creating a small gap of nominal thickness,  $s$ , or a geotextile (e.g. as part of a GCL) with transmissivity  $\theta$ .

Provided that the hydraulic conductivity of the liner is low relative to the other soil layers, the flow through the liner and foundation may be approximated as vertical and is given by

$$Q = k_s i_s A \quad (29a)$$

where  $Q$  = vertical flow [ $m^3/s$ ] through an area  $A$  [ $m^2$ ];  $k_s$  = harmonic mean hydraulic conductivity of the liner and foundation layer [ $m/s$ ];  $i_s$  is the mean gradient through the liner and foundation layer over the area  $A$  [-]; and

$$\frac{H_L + H_f}{k_s} = \frac{H_L}{k_L} + \frac{H_f}{k_f} \quad (29b)$$

$$i_s = \frac{H_f + H_L + h_w - h_a}{H_f + H_L} = 1 + \frac{h_w - h_a}{H_f + H_L} \quad (29c)$$

##### 9.4.1 Solution assuming hole is not on a wrinkle: circular hole

Following the rationale given by Giroud and Bonaparte (1989b) one can show that the head distribution beneath the geomembrane and acting on the low permeability liner is given by the solution to the equation

$$\frac{d^2 h}{dr^2} + \frac{1}{r} \frac{dh}{dr} - \alpha^2 h = \alpha^2 C \quad (30a)$$

$$\text{where: } \alpha^2 = \frac{k_s}{(H_L + H_f)\theta} \quad (30b)$$

$$C = H_L + H_f - h_a \quad (30c)$$

Equation 30 is to be solved subject to the boundary

conditions

$$h = h_w \quad \text{when} \quad r = r_o \quad (31a)$$

$$h = 0 \quad \text{when} \quad r = R \quad (31b)$$

and R is the wetted radius.

Extending the work of Jayawickrama et al. (1988), one can obtain the following analytical solution to Eqs. 30 and 31 and for the head h at position r:

$$h = (H_L + H_f + h_w - h_o)\Omega_o + (H_L + H_f - h_o)(\Omega_1 - 1) \quad (32a)$$

where

$$\Omega_o = \frac{K_o(\alpha r)I_o(\alpha R) - K_o(\alpha R)I_o(\alpha r)}{K_o(\alpha r_o)I_o(\alpha R) - K_o(\alpha R)I_o(\alpha r_o)} \quad (32b)$$

$$\Omega_1 = \frac{K_o(\alpha r)I_o(\alpha r_o) - K_o(\alpha r_o)I_o(\alpha r)}{K_o(\alpha R)I_o(\alpha r_o) - K_o(\alpha r_o)I_o(\alpha R)} \quad (32c)$$

and  $K_o$ ,  $I_o$  are modified Bessel functions of zero order that can be easily evaluated (Press et al. 1986). The solution given by Eq. 32 assumes that the wetted radius is known. In fact, R can be evaluated from the knowledge that at  $r=R$ ,

$$\frac{dh}{dr} = 0 \quad (33)$$

so the value of R can be obtained by finding the value that gives  $\frac{dh}{dr} = 0$  where, at  $r=R$ ,

$$\frac{dh}{dr} = (h_w + h_o - H_L - H_f)\Lambda_1 - (H_L + H_f - h_o)\Lambda_2 \quad (34a)$$

where

$$\Lambda_1 = \frac{-\alpha K_1(\alpha R)I_o(\alpha R) - \alpha K_o(\alpha R)I_1(\alpha R)}{K_o(\alpha r_o)I_o(\alpha R) - K_o(\alpha R)I_o(\alpha r_o)} \quad (34b)$$

$$\Lambda_2 = \frac{-\alpha K_1(\alpha R)I_o(\alpha r_o) - \alpha K_o(\alpha r_o)I_1(\alpha R)}{K_o(\alpha R)I_o(\alpha r_o) - K_o(\alpha r_o)I_o(\alpha R)} \quad (34c)$$

and  $K_1$ ,  $I_1$  are modified Bessel functions of order one. It is a simple matter to evaluate Eq. 34 to find the value of R for which Eq. 33 is satisfied.

The flow, Q, through the hole and low permeability

soil within the zone defined by the wetted radius is now given by the following closed form expression.

$$Q = \pi k_s [r_o^2 i_s + 2i_s \Delta_1 + 2i_s \Delta_2 - \frac{2h_w}{H_L + H_f} \Delta_2] \quad (35a)$$

where

$$\Delta_1 = -[R\lambda_1(r_o, R)K_1(\alpha R) + R\lambda_2(r_o, R)I_1(\alpha R)]/\alpha + r_o\lambda_1(r_o, R)K_1(\alpha r_o)/\alpha + r_o\lambda_2(r_o, R)I_1(\alpha r_o)/\alpha \quad (35b)$$

and

$$\Delta_2 = [-R\lambda_1(R, r_o)K_1(\alpha R) - R\lambda_2(R, r_o)I_1(\alpha R) + r_o\lambda_1(R, r_o)K_1(\alpha r_o) + r_o\lambda_2(R, r_o)I_1(\alpha r_o)]/\alpha \quad (35c)$$

$$\lambda_1(X, Y) = \frac{I_o(\alpha Y)}{K_o(\alpha X)I_o(\alpha Y) - K_o(\alpha Y)I_o(\alpha X)} \quad (35d)$$

$$\lambda_2(X, Y) = \frac{K_o(\alpha Y)}{K_o(\alpha X)I_o(\alpha Y) - K_o(\alpha Y)I_o(\alpha X)} \quad (35e)$$

and all other terms are as previously defined. Using Eq. 35, the leakage Q can be readily evaluated for any combination of layer properties, hole size or head. Eqs. 34 and 35 can be easily programmed using published code for Bessel functions (Press et al. 1986) and the results presented in this paper were obtained using the implementation by Rowe and Lake (1997).

#### 9.4.2 Solution assuming hole is on a wrinkle: circular hole

The previous subsection assumed that the defect occurred in an area away from a wrinkle. However, there is no reason that the defect could not be at the location of the wrinkle. In this case, the leakage will be substantially higher than given in the previous section. Here, we again assume a circular defect but in this case it occurs on a wrinkle of length L and width 2b (see Figure 27) where the height of the wrinkle is such that the transmissivity is much greater than between the geomembrane and the soil beyond. It is also assumed that  $L \gg b$  such that the effects of leakage at the ends of the wrinkle can be neglected. For this case, the head distribution beneath the geomembrane and acting on the low permeability liner is given by

Figure 27. Schematic showing a wrinkle (wave) in a geomembrane with a hole in the wrinkle of radius  $r_o$ .

$$\frac{d^2h}{dx^2} - \alpha^2 h = \alpha^2 C \quad (36)$$

where  $\alpha$  and  $C$  are as defined in Eqs. 30b and c.

Equation 36 has the solution:

$$h = (h_w + C)e^{-\alpha(x-b)} - C \quad (37)$$

and the total flow is given by

$$Q = 2Lk_s \left[ b + \frac{1}{\alpha} (1 - e^{-\alpha(x-b)}) \right] \frac{H_L + H_f + h_w - h_a}{(H_L + H_f)} \quad (38)$$

where  $x$  is the wetted distance away from the centre of the wrinkle. If  $L \gg b$  then  $x$  must be established by one of three limits.

The first limit corresponds to the case where the flow is not limited by the hole and  $x$  tends to infinity. For this case, the flow is given by

$$Q = 2Lk_s \left[ b + \left( \frac{H_L + H_f}{k_s} \right)^{0.5} \right] \frac{H_L + H_f + h_w - h_a}{(H_L + H_f)} \quad (39)$$

The second limit recognizes that the flow may be controlled by (a) Bernoulli's equation if the permeability of the overlying layer is high enough or (b) by the capacity of the fluid to drain to the hole. The latter case corresponds to the case examined by Giroud et al. (1997c) where the limiting value of  $Q$  is obtained (iteratively) from

$$h_w = \left( \frac{r_o^2 q_o}{2k_{om}} + \frac{Q}{2k_{om}\pi} \left[ \ln \left( \frac{Q}{\pi r_o^2 q_o} \right) - 1 \right] + \frac{1}{4g^2} \left( \frac{Q}{1.88r_o^2} \right)^{4.5} \right)^{0.5} \quad (40)$$

where  $h_w$ ,  $k_{om}$ ,  $r_o$ ,  $q_o$  and  $g$  are all known,  $q_o$  is the liquid supply (e.g. permeation through the waste per unit area reaching the leachate collection system) in (m/s),  $k_{om}$  is the hydraulic conductivity of the permeable leachate collection layer over the geomembrane (m/s), and all

other terms are as previously defined. This expression reduces to the Bernoulli equation (Eq. 27) as  $k_{om}$  tends to infinity.

In discussing the third limit, we remember that for a circular hole the wetted radius ( $R$ ) is established by the condition  $dh/dr=0$  and corresponds to the point ( $r=R$ ) where the head  $h=0$  (Eq. 31b). For a plane problem  $dh/dx \rightarrow 0$  only as  $x$  tends to infinity, however  $h=0$  for a value of  $x$  which is quite finite and is given by

$$x = b - \ln \left( \frac{C}{C + h_w} \right) / \left( \frac{\theta(H_L + H_f)}{k_s} \right)^{0.5} \quad (41a)$$

$$C = H_L + H_f - h_a \quad (41b)$$

For the purposes of comparing leakage it makes some sense to compare the leakage in the zone where the head on the clay liner is greater than or equal to zero (taking the datum to be at the lower side of the geomembrane and noting that to satisfy the no flow condition a long way away from the hole, the head below the geomembrane tends to  $-C$  as  $x \rightarrow \infty$ ). Under these circumstances, the leakage can be calculated on a hand calculator by first calculating  $x$  from Eq. 41 and substituting this into Eq. 38. This will give a flow less than that given by Eq. 39. The leakage  $Q$  is therefore the minimum of the values calculated from Eqs. 41 and 38, and the value calculated from Eq. 40.

These calculations above assume that wrinkles with holes are spaced far enough apart such that they do not interact. This is valid provided that the distance between wrinkles is greater than  $2x$  (as calculated from Eq. 41). If wrinkles with holes are close enough that they could possibly interact then  $x$  should be taken as half the distance between the wrinkles with holes and the flow  $Q$  can be taken as the minimum of the value calculated from Eq. 38 (for the appropriate value of  $x$ ) and Eq. 40.

The foregoing equations are subject to the limitations that (1) the length of the wrinkle is much longer than its width, (2) the transmissivity of the space below the wrinkle is much higher than that between the geomembrane and the liner outside the wrinkle, (3) if there is more than one wrinkle with a hole, the wrinkles and holes are of similar size.

## 9.5 Calculated Leakage Rates for Composite Liners

### 9.5.1 Geomembrane in intimate contact with clay liner

Based on the equations presented in the previous subsections, it is possible to easily calculate the leakage through holes in a geomembrane for a range of conditions. Giroud's (1997) equations are very useful, however they do have a number of limitations that can be

readily overcome using Eqs. 34 and 35. Since the Giroud and Bonaparte (1989b) (now refined by Giroud 1997) equations have been widely used, it is of interest to infer the "transmissivity" that corresponds to "good" and "poor" contact for use in subsequent applications of Eqs. 34 and 35. Table 23 shows the leakage rate, Q, calculated from

Table 23. Backcalculated transmissivity and wetted radius corresponding to Giroud's (1997) latest equations:  $H_L=0.6$  m,  $H_f=0$ ,  $h_a=0$ ,  $k_L=10^{-9}$  m/s, small and large holes ( $r_o=0.001$  and  $0.00564$  m). Rounded to three significant digits.

Contact Hole	$h_w$ (m)	Q ( $m^3/s$ )	$\theta$ ( $m^2/s$ )	R (m)
Good small	0.003	$6.94 \times 10^{-11}$	$1.66 \times 10^{-8}$	0.149
	0.03	$5.54 \times 10^{-10}$	$1.63 \times 10^{-8}$	0.42
	0.3	$4.61 \times 10^{-9}$	$1.61 \times 10^{-8}$	1.2
	3	$5.08 \times 10^{-8}$	$2.06 \times 10^{-8}$	3.75
Poor small	0.003	$3.80 \times 10^{-10}$	$1.08 \times 10^{-7}$	0.348
	0.03	$3.04 \times 10^{-9}$	$1.03 \times 10^{-7}$	0.982
	0.3	$2.52 \times 10^{-8}$	$0.99 \times 10^{-7}$	2.81
	3	$2.78 \times 10^{-7}$	$1.26 \times 10^{-7}$	8.84
Good large	0.003	$9.82 \times 10^{-11}$	$1.53 \times 10^{-8}$	0.177
	0.03	$7.84 \times 10^{-10}$	$1.66 \times 10^{-8}$	0.499
	0.3	$6.51 \times 10^{-9}$	$1.73 \times 10^{-8}$	1.42
	3	$7.19 \times 10^{-8}$	$2.3 \times 10^{-8}$	4.39
Poor large	0.003	$5.38 \times 10^{-10}$	$1.08 \times 10^{-7}$	0.414
	0.03	$4.29 \times 10^{-9}$	$1.1 \times 10^{-7}$	1.17
	0.3	$3.57 \times 10^{-8}$	$1.11 \times 10^{-7}$	3.33
	3	$3.94 \times 10^{-7}$	$1.44 \times 10^{-7}$	10.4

Giroud's (1997) version of the leakage equation [Eq. 23] for a "small" and "large" hole and "good" and "poor" contact as defined by Giroud and Bonaparte (1989b). Table 23 also gives the transmissivity required in Eq. 35 to get the same flow as Eq. 23 for the contact, hole size and heads considered. Also shown are the corresponding wetted radii calculated from Eq. 34.

For given contact conditions and leachate heads,  $h_w$ , of 0.3 m or less, the transmissivities required to give the Giroud (1997) flows were very similar for both the "small" and "large" hole. This is as one would hope and expect since the hole size should not influence the contact conditions and transmissivity outside the hole. For "good" contact, the transmissivity was about  $1.6 \times 10^{-8}$  m<sup>2</sup>/s which

corresponds to an equivalent value of spacing, s, between the geomembrane and liner of about 0.027 mm. For "poor" contact the transmissivity was  $1.0 \times 10^{-7}$  m<sup>2</sup>/s corresponding to  $s=0.05$  mm. The backcalculated transmissivity for a 3 m leachate mound is about 25% higher than for heads of less than 0.3 m. While not particularly significant, this does indicate the error due to the approximation adopted by Giroud and Bonaparte (1989b) and Giroud (1997) and confirms their judgement in limiting the solution to cases for a head of 3 m or less.

The transmissivities deduced in Table 23 are for a 0.6 m thick compacted clay liner with  $k_L=10^{-9}$  m/s. Table 24

Table 24. Backcalculated (average) transmissivities and spacings corresponding to Giroud's (1997) equations for  $h_w=0.3$  m,  $H_L=0.6$  to 1.2 m; small and large hole ( $r_o=0.001$  &  $0.00564$  m). Rounded to two significant digits.

Liner $k_L$ (m/s)	Transmissivity, $\theta$		Spacing, s	
	Good Con-tact ( $m^2/s$ )	Poor Con-tact ( $m^2/s$ )	Good Con-tact (mm)	Poor Con-tact (mm)
$10^{-10}$	$3.2 \times 10^{-9}$	$2.0 \times 10^{-8}$	0.016	0.029
$10^{-9}$	$1.6 \times 10^{-8}$	$1.0 \times 10^{-7}$	0.027	0.050
$10^{-8}$	$8.6 \times 10^{-8}$	$5.5 \times 10^{-7}$	0.047	0.088

summarizes similar results for a head  $h_w=0.3$  m for a range of liner thicknesses and values of liner hydraulic conductivity. Based on the results presented in Table 25, it is possible to establish the following interpolation formulae for the transmissivity,  $\theta$  (in m<sup>2</sup>/s units), for a given liner hydraulic conductivity,  $k_L$  (in m/s units):

For good contact

$$\log_{10}\theta = 0.07 + 1.036(\log_{10}k_L) + 0.018(\log_{10}k_L)^2 \quad (42a)$$

For poor contact

$$\log_{10}\theta = 1.15 + 1.092(\log_{10}k_L) + 0.0207(\log_{10}k_L)^2 \quad (42b)$$

It is essential that the correct units be used in calculating a transmissivity from this equation.

Using a transmissivity,  $\theta=1.6 \times 10^{-8}$  m<sup>2</sup>/s, for "good" contact, Table 25 gives the calculated wetted radius, flows through a small and large circular hole and the leakage and Darcy velocity for 2.5 holes/ha for heads ranging from 0.003 to 30 m. For a head of 0.3 m, the leakage is quite small (~1 lphd) and even for a 30 m head (due to either a failed leachate collection system or termination of the operation of the collection system), the leakage is 100 lphd (or less). Table 25 also gives the calculated average Darcy flux beneath the wetted area ( $r \leq R$ ). For heads less than 5 m, this is relatively consistent at a value

Table 25. Calculated wetted radius, and leakage from circular holes for GM in good contact with a CCL for a range of head values based on Eqs. 34 and 35;  $H_L=0.6$  m,  $k_L=10^{-9}$  m/s, ( $\theta=1.6\times 10^{-8}$  m<sup>2</sup>/s). Rounded to two significant digits.

\* Assumes 2.5 holes/ha

\*\* Average Darcy velocity below wetted radius

between 0.03 and 0.04 m/a and for typical liner porosity implies an average linearized groundwater velocity of about 0.1 m/a. Neglecting the effects of consolidation, this alone implies that a conservative contaminant transported through a hole would migrate through a 0.6 m thick liner in 6 years and hence one can expect dilute leachate constituents to be detected in the leak detection system relatively quickly. One would expect that these constituents would have been diluted by (a) pore water from the clay liner that has been expelled due to consolidation; (b) any construction water in the secondary collection/leak detection system; (c) other water entering the system (if any). Also, the chemistry will not be a simple dilution of the leachate since (a) it will be combined with the pore chemistry of the clay water that will contribute inorganic constituents (such as Cl<sup>-</sup>, Na<sup>+</sup>, Ca<sup>++</sup>, Mg<sup>++</sup>, SO<sub>4</sub><sup>2-</sup>, etc.) in concentrations that will vary from clay to clay; and (b) inorganic and polar organics will leak through holes at one rate and volatile organic compounds (VOCs) will diffuse through the intact geomembrane at a second rate. Of these, the most telling sign of contaminant migration is likely to be the VOCs.

The use of a GCL in place of the CCL as the clay component of a composite liner can be expected to have some effect on leakage through holes in the geomembrane. Based on the tests performed by Harpur et al. (1993), it would appear that for the GCLs and conditions examined by them the transmissivity,  $\theta$ , between a geomembrane and GCL is in the range of  $6\times 10^{-12}$  m<sup>2</sup>/s to  $2\times 10^{-10}$  m<sup>2</sup>/s for GCLs with a woven or

nonwoven geotextile in direct contact with the geomembrane and  $3\times 10^{-12}$  m<sup>2</sup>/s for bentonite in direct contact with the geomembrane. Based on hydraulic conductivity tests with leachate (see Table 7), the hydraulic conductivity,  $k_L$ , of a GCL could lie within a wide range. For the purposes of the current comparison, three values of  $k_L$  ( $7\times 10^{-12}$  m/s,  $2\times 10^{-10}$  m/s and  $2\times 10^{-8}$  m/s) will be examined. To assess the potential for leakage through holes in a geomembrane underlain by a GCL, calculations were performed using Eqs. 34 and 35 for a range of values of  $k_L$  and  $\theta$  (using  $k_L=2\times 10^{-10}$  m/s;  $\theta=1\times 10^{-10}$  m<sup>2</sup>/s as base values) for a large hole ( $r_o=0.00564$  m,  $a=1$  cm<sup>2</sup>) and the results are presented in Table 26. It can be seen that even with significant clay leachate interaction ( $k_L=2\times 10^{-8}$  m/s) the leakage for 2.5 "large" holes/ha is very small at a design head of 0.3 m (less than 0.1 lphd) and even with a 30 m leachate mound the leakage is less than 5 lphd. It is of particular note that a variation in clay hydraulic conductivity from  $7\times 10^{-12}$  to  $2\times 10^{-8}$  m/s increased the flows by only about a factor of 5 at large heads (3 and 30 m). This is because at these high hydraulic conductivities the wetted radius is substantially reduced.

The implications from Tables 25 and 26 are that, for even large holes in good contact with either a CCL or GCL, the leakage would be very small for 2.5 holes per hectare; these flows are much lower than reported in Tables 19 and 20. Table 27 shows the effect of contact condition and the number of holes per hectare on leakage for large holes and (a) a CCL with good and poor contact and (b) a GCL with different combinations

Table 26. Wetted radius and leakage from circular holes for a GM in good contact with a GCL for a range of head, transmissivity and hydraulic conductivity values based on Eqs. 34 and 35;  $H_L=0.01$  m,  $H_T=0.6$  m,  $h_a=0$ ,  $k_t=10^{-6}$  m/s. Large hole ( $r_o=0.00564$  m). Rounded to two significant digits.

\* Assumes 2.5 holes/ha.

of liner and transmissivity condition. As might be expected, the leakage increases linearly with the number of holes and almost linearly with leachate head for heads of 0.3 m or larger. Of particular interest are the leakages for a "design" head of 0.3 m. Under landfill operating conditions, one would expect the head in the primary leachate collection system to be less than 0.3 m and hence these values should represent an upper bound to the leakage that one would expect to detect in a SLCS under active and post-closure conditions for as long as the leachate collection system is operating to design specifications. Thus it is instructive to compare the numbers in Table 27 with those observed in field monitoring as reported in Tables 19 and 20. The easiest comparison is for systems involving a geomembrane over a GCL since there should not be any significant consolidation water in the flows recorded in the SLCS. From Table 19 it can be seen that under active conditions the mean flow is 7.7 lphd and even under "closed" condition it is 2.3 lphd. These substantially exceed that predicted in Table 27 even for a very large level of clay-leachate interaction and 40 holes per hectare. Indeed, one would need between 65 and 140 holes per hectare to explain the average post-closure

leakage. Since it is highly unlikely that there are this many large holes, an alternative explanation is required as discussed below. For geomembranes over compacted clay liners, the comparison is more difficult due to consolidation water contributing to the flow; however, even so, the flows are large enough to lead one to believe that more than leakage through "large" holes in good contact with the clay is required to explain the flows.

#### 9.5.2 Leakage through holes in a wrinkled geomembrane forming part of a composite liner

Wrinkles (waves) represent a particular concern due to the fact that available evidence suggests that (a) wrinkles remain after placement of waste and (b) local tensile strains are developed in the geomembrane at the wrinkle as discussed in Section 7.3. There is no reason to believe that holes will not occur at the location of wrinkles. On the contrary, given the local stress concentration, it is reasonable to hypothesize that holes would be more likely to occur at the location of a wrinkle. Thus it is of some interest to explore the implications of a hole coinciding with a wrinkle. As discussed in Section 9.4.2, one can develop a solution for a strip wrinkle. Table 28 presents

Table 27. Calculated leakage for different numbers of holes for a large hole ( $r_o=0.0054$  m). Based on Eqs. 34 and 35. Rounded to two significant digits.

	$h_w$ (m)	Leakage for number of holes per ha (lphd)

2. Poor Contact,  $\theta=1.0 \times 10^{-7}$  m<sup>2</sup>/s,  $k_L=1 \times 10^{-9}$  m/s,  $H_L=0.6$  m,  $H_f=0$
3. Fair Condition,  $\theta=2 \times 10^{-10}$  m<sup>2</sup>/s,  $k_L=2 \times 10^{-10}$  m/s,  $H_L=0.01$  m,  $H_f=0.59$  m
4. Poor Condition,  $\theta=1 \times 10^{-10}$  m<sup>2</sup>/s,  $k_L=2 \times 10^{-8}$  m/s,  $H_L=0.01$  m,  $H_f=0.59$  m

the results obtained for a strip wrinkle 3 m long and 0.2 m wide for both a compacted clay liner (CCL) and geosynthetic clay liner (GCL). Calculations were performed assuming a single small hole per wrinkle ( $r_o=0.001$  m), a percolation to the collection system of  $10^{-9}$  m/s and a hydraulic conductivity of the collection system of  $10^{-6}$  m/s unless otherwise noted. In no case did the hole (Eq. 40) limit the leakage and hence the same results would be obtained for  $r_o > 0.001$ . For comparison with Tables 25 and 26, the leakage and Darcy flux ( $v_a$ ) were calculated assuming 2.5 holes coinciding with wrinkles per hectare. (Since not all holes will coincide with wrinkles, this likely corresponds to more than 2.5 holes/ha.) Comparing the results in Table 28 with those in Tables 25 and 26, it can be seen that the coincidence of even a small hole with a wrinkle of the dimensions examined substantially increases

Table 28. Calculated leakage from a small hole ( $r_o=0.001$  m) in a wrinkle:  $L=3$  m,  $2b=0.2$  m,  $h_a=0$ ,  $q_o=1 \times 10^{-9}$  m/s.

\*Assumes 2.5 holes in wrinkles/ha

the leakage. The increase in leakage due to a wrinkle relative to that without a wrinkle is much greater for a GCL than for a CCL, however, for  $h_w \geq 3$  m the absolute magnitudes of the leakages are still smaller with the GCL than with the CCL for the cases considered.

Table 29 summarizes the calculated leakage (for 1 and 2.5 holes in wrinkles per hectare) for a range of wrinkle dimensions contact conditions and CCL and GCL properties. Also shown are the calculated leakage assuming that the area under the wrinkle is the same as for a strip of the dimensions shown but where the wrinkle is "circular" in shape.

For a "design" head of 0.3 m it can be seen that for a GCL with  $k_L \sim 2 \times 10^{-10}$  m/s, only a single hole in a wrinkle 5 m  $\times$  0.2 m is required to explain a leakage of about 2.3 lphd (see Tables 29 and 19) and that a hole in a 30 m  $\times$  0.2 m wrinkle will explain an average leakage of 7.7 lphd observed in field installations. For a greater level of clay-leachate interaction ( $k_L \sim 2 \times 10^{-8}$  m/s) the leakage is substantially higher.

Comparing observed results in Table 20 with calculated leakages in Table 29, it can be seen that one 5 m  $\times$  0.2 m wrinkle with a hole per hectare for a CCL and "good" contact or 3 m  $\times$  0.2 m and "poor" contact with a CCL would explain a leakage of 1.5 lphd, however seven 30 m  $\times$  0.2 m wrinkles with holes and "good" contact or three 30 m  $\times$  0.2 m wrinkles with holes and "poor" contact would be required to explain a leakage of about 60 lphd;

Table 29. Effect of wrinkle geometry on leakage: ( $2b=0.2$  m,  $q_o=10^{-9}$  m/s,  $k_{om}=10^{-2}$  m/s).

- Good Contact:  $\theta=1.6 \times 10^{-8}$  m<sup>2</sup>/s; Poor Contact:  $\theta=1 \times 10^{-7}$  m<sup>2</sup>/s

alternately, with poor contact a single wrinkle would need to be about 85 m  $\times$  0.2 m to explain an average flow of 60 lphd under a leachate head of 0.3.

For the results shown in Table 29, it was assumed that

$k_{om}=10^{-2}$  m/s and it was found that Eq. 40 controlled several cases involving a GCL with  $k_L=2 \times 10^{-8}$  m/s. The effect would be even greater for a lower hydraulic conductivity of the collection layer.

In summary, it appears that wrinkles associated with holes in the geomembrane can explain the observed leakage through composite liners (Table 19) involving a geomembrane over a GCL under both active and post-closure conditions and hence this hypothesis warrants further examination. Likewise, holes in a wrinkle will explain the low leakages observed through a geomembrane over a CCL but probably not the high values of flow rate observed in SLCSs (Table 20); this implies that other mechanisms such as consolidation of the CCL are required to explain the observed flow rates. Consolidation of the CCL may also give rise to earlier (diluted) contaminant arrival times in the SLCS than would otherwise be expected. The theory presented in Section 9.4.2 can be used to estimate the leakage for reasonable numbers of wrinkles. Comparing the results presented in Tables 27 and 29, it is clearly desirable to minimize wrinkles if leakage is to be minimized. It should be noted that the long term performance of geomembranes with wrinkles may be even worse than implied by these calculations due to the potential for the development of stress cracking and increased leakage through the geomembrane at the location of the wrinkle. This provides an incentive to minimize wrinkles.

## 10 CONTAMINANT IMPACT ASSESSMENT AND EQUIVALENCE OF LINER SYSTEMS

### 10.1 Impact Assessment

The assessment of the suitability of a liner system should, in principle, be related to the potential impact on water quality (especially groundwater) due to the proposed landfill and liner system. This assessment typically involves the solution of the advection-dispersion equation subject to appropriate boundary conditions (e.g. see Rowe et al. 1995b for a detailed discussion). Factors that influence the potential impact include (a) the landfill source concentration and its decay characteristics; (b) the advective flux (leakage) across the barrier system; (c) the thickness of any "attenuation" layer between the base of the low permeability liner(s) and the receptor aquifer (or distance to the water table if the liner is constructed in the unsaturated portion of the aquifer); (d) diffusion (especially for VOCs) across the barrier system; (e) sorption/retardation in the liner and underlying soil; (f) biodegradation; (g) dilution in the aquifer, (h) the service life of the engineered components of the landfill (e.g. covers/caps; leachate collection systems; liners); (i) the mode of operation of the landfill; and (j) consolidation of the liner and any underlying compressible soils.

Consolidation (item j) is usually not considered on the

grounds that it is transient and provides water for "dilution" of contaminants, however it should be noted that consolidation may be significant if one is calculating travel times and, in particular, first arrival times. As previously discussed, it may be hypothesized that the "premature" arrival of contaminant in leakage detection systems is, in part, attributable to failure to consider consolidation effects in assessing the expected travel times. More research is required into this aspect.

Items (a)-(i) can be readily modelled using existing contaminant transport theory and codes (e.g. Rowe and Booker 1997a). However, the factors considered in modelling impact tend to be regulatory driven and vary from one country to another and hence the assessment of what represents an "adequate" barrier system will vary from regulatory environment to regulatory environment. Thus one can not generalize about "equivalency" of liner systems since what is "equivalent" depends on what is being compared and how it is being compared.

It is possible to gain insight into how different barrier systems are likely to behave by modelling. In the following subsections, the potential impact of a landfill with two different composite liners (geomembrane over compacted clay; geomembrane over GCL) will be compared including consideration of diffusion, leakage through holes, contaminant biodegradation (for VOCs) and the finite service lives of the leachate collection system and geomembrane liner based on the factors discussed in previous sections of this paper. The comparisons will be limited by the use of assumed parameters that represent one hypothetical site. For any specific project, appropriate parameters should be established for that site. Then analyses such as those described in the following can be readily performed using the same techniques (Rowe & Booker, 1984, 1985, 1995, 1997a,b) to assess equivalency (and potential impact) for that site.

It is noted in passing that in some areas it is not practical to have an "unsaturated" zone below the base of the engineered barrier system and any assumption of the presence of an unsaturated zone must be specific to locations where that is practical. Secondly, when assessing dilution in an aquifer, it may not be reasonable to include the entire thickness of the aquifer in the dilution calculations for thick aquifers. Although beyond the scope of this paper, readers should be aware of the potential for plume localization in the upper few meters of an aquifer and this needs to be considered when assessing the thickness of the aquifer to be used in dilution calculations. In the following comparison, only the upper 3 m of the aquifer are considered to provide significant dilution.

As noted in Section 2, temperature may have an important effect on both hydraulic conductivity and diffusion coefficient. Table 30 gives the ratio of both the

Table 30. Effect of temperature on diffusion coefficient,  $D_T$ , hydraulic conductivity,  $k_T$ , in a liner at temperature  $T$  to values at 10°C.

Temperature, °C	$D_T/D_{10}$	$k_T/k_{10}$
10	1.0	1.0
20	1.4	1.3
25	1.6	1.5
35	2.0	1.8
50	2.7	2.4
65	3.5	2.9

diffusion coefficient and hydraulic conductivity at different temperatures to that at 10°C (see Collins 1993; Rowe et al. 1995b; Barone et al. 1997 for details of method of calculation). Domenico & Schwartz (1990) indicate that the groundwater temperature at a depth of 10-20 m is typically 1-2°C higher than local mean temperature and hence a temperature of 5-10°C would be typical groundwater temperature in the Northern U.S. and Southern Canada. From Table 30, it can be seen that diffusive and advective transport are 40% and 30% higher at 20°C than at 10°C and 100% and 80% higher at 35°C. If the liner temperature is to remain relatively constant, then constant diffusion and hydraulic conductivity parameters relevant to that temperature may be used. However, if the temperature of the liner changes with time (see Section 2) then some consideration may need to be given to the effect of the change in these parameters with temperature on the impact calculations. The approach proposed by Rowe and Booker (1997a) readily models change in  $D$  and the effect of a change in  $k$  with time as appropriate.

In the following examples, it will be assumed that the geomembrane and liner are at 20°C and that by the time the leachate mound begins to develop (30-50 years, or greater, post-closure) the temperature has stabilized. This is not necessarily the case since it is also assumed that the landfill has a low permeability final cover (cap) that is maintained ( $q_e=0.0003\text{m/a}\cong 8\text{ lphd}$ ) for this same period of time. Once the leachate collection system operation and cover maintenance are terminated, a leachate mound will develop and the temperature may increase since the organic waste may not have fully biodegraded in the low infiltration environment (see Section 2). This could be modelled using the Rowe and Booker (1997a) approach but is beyond the scope of the present paper. If the temperature were to increase, the impact would be greater for both systems examined in the following subsections.

## 10.2 Equivalency of Liner Systems

In North America, GCLs have been approved as

replacement for conventional compacted clay liners in at least 45 landfills and both Richardson (1997) and Giroud et al. (1997a) have discussed a number of aspects of equivalency between these systems. Giroud et al. (1997a) focus on the issue of leakage through GCLs and CCLs and steady state advective travel time (i.e. neglecting the effect of consolidation and diffusion on the first arrival time). Richardson (1997) discusses leakage and steady state travel time (also neglecting consolidation and diffusion effects) as well as chemical-absorption capacity and dilution potential. Rowe (1997b) has considered equivalency in terms of impact calculations that include consideration of leakage (in a similar manner to Giroud et al. 1997a and Richardson 1997) but has also examined the effects of diffusion, finite service life and biodegradation in the context of Ontario's draft landfill regulations (MoEE 1996). However, based on the material presented in this present paper, it is possible to go beyond these three recent evaluations. A detailed comparison would require a separate paper (in preparation) and the following is only intended to illustrate how a number of key factors may be incorporated.

Any comparison of equivalency of GCL and CCL as part of a liner system should consider: (a) the potential for clay/leachate interaction, (b) the interaction with the adjacent geomembrane, (c) the leachate head and corresponding gradient, and (d) diffusion and sorption. Inspection of Table 7 shows that the hydraulic conductivity of a GCL could potentially vary over many orders of magnitude, due to clay-leachate interaction, depending on the characteristics of the bentonite in the GCL and the leachate. However, as indicated in Table 27, even with a hydraulic conductivity as high as  $2 \times 10^{-8}$  m/s, a composite liner involving a GCL has the potential to give rise to substantially less leakage than a composite liner with a CCL having  $k_L \sim 10^{-9}$  m/s for a similar number of holes in the geomembrane. The explanation for this lies in the smaller potential for lateral migration between the geomembrane and GCL than for a geomembrane and CCL.

### 10.3 Comparison of Two Liner Systems: CCL versus GCL

For purposes of comparison of a conventional composite liner system and a composite system with a GCL replacing a 0.6 m CCL, the two liner systems shown in Figure 2 were examined using the parameters given in Table 31 and 32. For the cases involving a 0.6 m thick CCL, it was assumed that there was a 3 m thick attenuation layer (AL) between the CCL and the aquifer so that the combined thickness of the CCL and attenuation layer above the aquifer was 3.6 m (see Figure 2a). For cases involving a GCL two situations were examined. In the

basic case (see Figure 2b), the attenuation layer below the GCL was assumed to be 3.6 m thick so that the thickness of soil above the aquifer was essentially the same as for the case with a CCL (see Figure 2a). As a sensitivity analysis, a second GCL case was also examined where the GCL was assumed to be resting on a 3 m thick attenuation layer; this corresponds to a simple replacement of the 0.6 m thick CCL in Figure 2a by a 0.007 m thick GCL. The potentiometric surface in the aquifer was assumed to be 2 m above the bottom of the attenuation layer in all cases.

The long term hydraulic conductivity of the CCL was taken to be  $10^{-9}$  m/s. For the GCL it was assumed that, due to clay-leachate interaction, the hydraulic conductivity increased to  $2 \times 10^{-10}$  m/s.

Three contaminants (chloride, DCM  $\equiv$  dichloromethane, and benzene) were examined. Due to uncertainty regarding organic carbon content of clay liners in a generic calculation, no sorption was considered. A range of half-lives for DCM and benzene was examined in the leachate, liner system and attenuation layer.

All time was measured relative to the mid time of landfill operation for a MSW landfill with an assumed 20 year operating period. Thus to know time relative to the start of landfilling one would add 10 years to the times given in the following discussion. Likewise, to know the time since landfill closure, one would subtract 10 years from the times given. It was assumed that a low permeability landfill cover (cap) will be maintained and the leachate collection system operated for a period  $T_1$  ( $T_1 = 40$  years and 110 years were examined; i.e. 30 and 100 years post-closure). During the period up to time  $T_1$ , the percolation through the waste was assumed to be  $3 \times 10^{-4}$   $m^3/m^2/a$  (8 lphd). The design leachate head during the period was assumed to be 0.3 m and the flows through the liner system for the period 0- $T_1$  are given in Table 33 for the two liner systems assuming 2.5 large (1  $cm^2$ ;  $r_o =$

0.00564 m) holes per hectare. Under assumed design conditions, the leakage through both systems was small; but it was smallest for the system with the GCL.

After time  $T_1$ , the landfill cover was no longer maintained and the percolation was assumed to increase to  $0.15$   $m^3/m^2/a$  (4100 lphd).

Once the operation of the primary leachate collection system is terminated (at time  $T_1$ ), leachate will build up in the waste until an equilibrium is reached wherein the flow in through the landfill cover (cap) is balanced by the outflow through the liner system, leachate seeps from the sides of the landfill, and lateral migration above the intact liner system (if any). The magnitude of the leachate mound and the time needed to develop the mound depend on a number of factors including the porosity of the waste, the water content of the waste at the time of landfill cover (cap) failure, the thickness and hydraulic conductivity of the waste, and the landfill geometry. These factors will vary from site to site and a full discussion of modelling the development and equilibrium value of a leachate mound is beyond the scope of the present paper. For the purposes of illustration, it will be assumed that over a 20 year period following termination

of operation of the leachate collection system (at time  $T_1$ ), a leachate mound develops and at time  $T_2$  ( $T_2 = T_1 + 20$  years) an equilibrium is reached with a mound of 12 m. During the period from  $T_1$  to  $T_2$ , an average mound of 6 m was used to calculate the flow given in Table 33. More sophisticated modelling of this period is possible but not necessary for current purposes.

Between the time  $T_2$  (when the full leachate mound has developed) and a subsequent time  $T_3$  (when the geomembrane was assumed to fail), the leachate head remained at 12 m and the flows through the liner system were as given in Table 33. Both liners were very effective at controlling leakage even with a 12 m leachate mound but the system with the GCL allowed almost 40 times less leakage (43 lphd for CCL versus 1.1 lphd for the GCL) even allowing for some clay leachate interaction with the GCL.

At time  $T_3$  ( $T_3 = 160$  years; i.e. 150 years post-closure) the geomembrane was assumed to fail instantaneously. (One can easily model a gradual degradation however there is presently a paucity of data to justify modelling a gradual variation with time.) The clay component of the liner was assumed to remain intact but could not support a 12 m leachate mound. Thus the leachate mound reduced due to advective transport out of the landfill until an equilibrium was reached where there was sufficient mound to allow the full percolation of  $0.15 \text{ m}^3/\text{m}^2/\text{a}$  ( $4100 \text{ lphd}$  or  $4.7 \times 10^{-9} \text{ m/s}$ ) to migrate through the clay liner. It may be anticipated that when the geomembrane fails, whatever contaminant remains in the leachate will be readily transported down to the aquifer.

The leakage results given in Table 33 suggest that the GCL system is hydraulically as good as, if not better than, the system with a CCL. It should be noted that this comparison assumes that there is a low transmissivity geotextile ( $\theta \leq 2 \times 10^{-10} \text{ m}^2/\text{s}$ ) as part of the GCL in contact with the geomembrane; care is required in selection of the GCL since the uppermost geotextile on the GCL (the one in contact with the geomembrane) may vary considerably from one product to another. The leakage given in Table 33 also assumes that there are no holes in the wrinkles (or no wrinkles!); as illustrated in Section 9.5.2, a hole in a wrinkle can substantially increase leakage.

The initial peak concentration,  $c_o$ , of the various contaminants considered is given in Table 31. This represents the peak annual average value (see Rowe 1995; Rowe & Booker 1995 for a more detailed discussion of landfill leachate history). The finite mass of contaminant in the waste was modelled as described by Rowe et al. (1995b) using the proportion of contaminant mass in the waste and total mass of waste given in Table 31. Consideration of the finite mass of contaminant gives rise to a decrease in concentration in the leachate with time as contaminant mass is removed from the landfill by

leachate collection, by contaminant diffusion and advection through the liner system and, where appropriate, by other mechanisms such as biodegradation of organic compounds. As indicated by Rowe (1991, 1995), the decrease in concentration with time ( $c(t)$ ) can be approximately given by

$$c(t) = c_o \exp\left[-\left(\frac{c_o q_o}{p M_w} + \lambda\right)t\right] \quad (43)$$

where  $c_o$  is the initial (peak) (annual average) concentration in ( $\text{mg/L} \equiv \text{g/m}^3$ ),  $q_o$  is the percolation through the waste ( $\text{m/a}$ ),  $p$  is the proportion of contaminant (chloride here) in waste ( $\text{mg/kg}$ ),  $M_w$  is the mass of waste per unit area ( $\text{t/m}^2$ ),  $t$  is time (years: a),  $\lambda$  is the decay coefficient  $= \ln 2/t_{1/2}$  ( $\text{a}^{-1}$ ) where  $t_{1/2}$  is the contaminant half life (a). Thus the time required for the leachate concentration to reduce to a value of  $c(t)/c_o$  is given by

$$t = -\ln(c(t)/c_o) / \left[\frac{c_o q_o}{p M_w} + \lambda\right] \quad (44)$$

In the case of chloride, the concentration can only reduce due to mass being removed from the system ( $\lambda=0$ ). Since there is a low permeability final cover and a geomembrane primary liner, negligible mass is removed in the period  $0-T_1$  and the concentration in the landfill remains relatively constant. This can be appreciated by substituting the appropriate parameters into Eq. 43 ( $c_o=2500 \text{ mg/L}$ ,  $q_o=0.0003 \text{ m/a}$ ,  $p=1800 \text{ mg/kg}$ ,  $M_w=25 \text{ t/m}^2$  and  $\lambda=0$ ) and it will be found that the annual average concentration after 40 years has only dropped by about  $2 \text{ mg/L}$ . Once the final cover is no longer maintained and the leachate generation,  $q_o$ , increases to  $0.15 \text{ m}^3/\text{a}/\text{m}^2$ , ( $4100 \text{ lphd}$ ) more mass is removed from the landfill (by the collection of leachate at perimeter drains or, failing this, escape to surface water) and there is a much faster decrease in average leachate concentration with time than was the case with a low permeability cover. However, for these parameters it still takes another 280 years after the time  $T_1$  for the source concentration to decrease to 10% of the initial value (i.e. a total of about 320 years for  $T_1=40$  years). The model used to obtain the following results (Rowe & Booker 1997a) adopts a more sophisticated approach but yields a decrease in concentration with time similar to that which can be calculated from Eq. 43. For more details see Rowe et al. (1995b) and Rowe and Booker (1997a).

For contaminants that undergo biodegradation (e.g. DCM, benzene etc.) the time to reduce the concentration to acceptable levels may be much faster than for chloride but will depend on the assumed half-life,  $t_{1/2}$ . For example, for DCM the parameters given in Table 31 and

a DCM half-life in the landfill of 10 years, Eq. 44 can be used (remembering to use  $c_0$  in mg/L units) to predict that it will take about 30 years for the concentration in the leachate to reduce to 10% of the initial value ( $c(t)/c_0=0.1$ ). For a DCM half-life of 2 years (see Rowe 1995 and Rowe et al. 1997d), it would take only 6 years for the leachate concentration to decrease to 10% of the initial value by biodegradation. Thus from these simple hand calculations it can be seen that for a modest sized landfill (25 t/m<sup>2</sup>) and relatively high leachate generation (0.15 m<sup>3</sup>/a/m<sup>2</sup>) flushing out of contaminant (e.g. chloride) is very slow and that for organic contaminants a controlling parameter will be the half-life of that contaminant in the landfill and in the underlying soil as will be illustrated in the following examples.

For the period 0-T<sub>3</sub> (i.e. before the geomembrane fails), the dominant transport mechanism is diffusion although advection does make a measurable contribution for the case of a geomembrane and CCL. There will be a variation in concentration with distance below the geomembrane due to the diffusive resistance of the geomembrane, the clay and the attenuation layer. There is some dilution in the aquifer due to the horizontal flow however the effect of this is limited for the assumed horizontal Darcy velocity in the aquifer,  $v_b=1$  m/a, and the length of the landfill examined here. Thus the concentration calculated in the aquifer reflects the effect of several mechanisms including a decrease in landfill concentration due to flushing (i.e. due to  $q_0$ ) and biodegradation (where considered), the diffusive resistance of the liner system, and some dilution in the aquifer. Retardation of organic contaminants (e.g. due to sorption onto organic matter) is not considered in the following examples but can be readily modelled (as illustrated in Section 8) if the partitioning coefficient,  $K_d$ , is known for the particular contaminant and soil. More details regarding contaminant transport modelling and the controlling mechanism is given by Rowe et al. (1995b) and Rowe and Weaver (1997).

Analyses were first performed for dichloromethane (DCM), a chlorinated solvent often found in MSW leachate (Gibbons et al. 1992; Rowe 1995). In some regulatory environments, one can not include consideration of biodegradation in modelling impact. Assuming an initial source concentration of 3300 µg/L (Rowe 1995; MoEE 1996) and neglecting biodegradation, the calculated concentration in the aquifer (see Figure 28) would increase to about 14 µg/L at about year 40 (i.e. 30 years post-closure) which is well below the maximum acceptable concentration (MAC) in drinking water of 50 µg/L, however by year 110 (100 years post-closure) it would increase to about 250 and 230 µg/L for the CCL and GCL system respectively which exceeds the MAC. The peak impact at about year 180 would be around 1090 and 1070 µg/L for the CCL and GCL systems

respectively (see Figure 28). These values would be considered quite unacceptable in regulatory environments where no time limit exists on the period being examined. In order not to exceed the MAC, the initial concentration would need to be 150 µg/L or less under these conditions. However, these calculated impacts are very conservative (likely unrealistically so) since the calculation did not take account of any biodegradation. It is known that DCM degrades under anaerobic conditions in leachate and as it migrates through soil (Rowe 1995; Rowe et al. 1997). A DCM half-life in the leachate of 10 years can be assumed. Recognizing that the DCM half-life in soil below a geomembrane could be longer, a DCM half-life of 50 years was assumed in the clay and attenuation layer. The resulting contaminant impact curves are shown in Figure 28. In this case, the impact after 40 and 110 years is about 5-6 µg/L and 23-24 µg/L with the peak impact being about 24 µg/L (i.e. half the MAC: see Figure 29) for both systems shown in Figure 2. These calculations indicate that for DCM, the GCL and CCL systems shown in Figure 2 are equivalent with respect to contaminant impact. If the thickness of the attenuation layer below the GCL was reduced from 3.6 m to 3 m, the peak impact would increase to about 40 µg/L (see Figure 29) but this is still less than the MAC for the parameters considered.

Calculations were also performed for benzene assuming an initial source concentration of 20 µg/L. Again, the two systems shown in Figure 2 were equivalent. If one neglects biodegradation, they would both potentially exceed the MAC of 5 µg/L with a peak

Figure 28. DCM impact curves in the aquifer below the composite liner systems shown in Figure 2 for different assumed half-lives ( $t_{1/2}$ ) of DCM.

Figure 29. DCM impact curves in an aquifer below the two composite liner systems shown in Figure 2 for DCM half-lives  $t_{1/2}$  = 10 years in leachate, 50 years in soil.

impact of between 6 and 7 µg/L, however, if one considers half-lives of 25 years in the landfill and 125 years in the soil, the peak impact is less than 1 µg/L in both cases.

The migration of chloride was also examined since it is representative of conservative inorganic contaminants. As previously indicated, the diffusion coefficient for chloride is very low and for the low leakage rates that occur with only a few holes in the geomembrane the impact at the time of geomembrane failure (at  $T_3 = 160$  years) was less than 1 mg/L. However, since contaminants such as chloride do not degrade and the reduction in concentration can only occur due to dilution, there is considerable potential for impact when the primary geomembrane fails. Figure 30 shows the calculated variation in chloride concentration in the aquifer with time assuming the cover and collection system are maintained for (a) 40 years and (b) 110 years respectively, and assuming the service life of the geomembrane is 160 years. In both cases the impact greatly exceeds the typical drinking water objective for chloride of 250 mg/L. The greatest impact is for the case where the cover is maintained for 110 years and the lesser impact is for 40 years maintenance. At first this might seem counterintuitive, however it arises from the fact that cover failure implies increased infiltration into the landfill and even if the landfill underdrain system is not operated, leachate will mound and need to be collected at the perimeter drains (or else it will contaminate surface water). The leaching associated with

Figure 30. Chloride impact curve in an aquifer below the composite liner systems shown in Figure 2 showing the effect of maintaining the cover for periods  $T_1=40$  and 110 years. Geomembrane assumed to have service life to 160 years.

this will reduce the concentration of chloride in the landfill and hence when the geomembrane fails the impact on the aquifer is less. This highlights the desirability of early stabilization of the waste wherein the concentrations of contaminant in the waste (and hence leachate) are reduced to levels that would not cause an unacceptable environmental impact if the leachate was to escape to surface and groundwater without control (e.g. see Delaware 1995).

If one did intend to protect groundwater from contamination by chloride (and similar contaminants that can be leached by slightly acidic rainwater) without accelerating waste stabilization for a landfill of the size and characteristics considered here, it would be necessary to adopt a double lined system using either a CCL or GCL as part of the composite liner. Figure 3 shows one such system. The leachate conditions were the same as assumed previously for the primary collection system and the leakage volumes are as given in Table 33. Some readers may be surprised that the leakage through the primary composite liner shown in Figure 3 is less than through the composite liner shown in Figure 2b. As discussed by Rowe et al. (1995b), the leakage through a multi-layered soil system is controlled by the lowest hydraulic conductivity layer and the suction that may develop in an underlying unsaturated layer can actually increase leakage through a multilayered system relative to what would be obtained for the layer of less permeable soil alone. Thus, as noted by Giroud et al.

(1997a), an unsaturated mineral layer beneath a GCL does not improve the hydraulic performance relative to a GCL alone. On the contrary, the leakage through the system is increased if the soil below the GCL can sustain matric suctions. Typically, clayey and silty soils below a GCL can sustain significant matric suctions and it is generally not valid to adopt the assumption that the pressure head below the GCL in a multilayer system is zero. For calculating the leakage through the secondary composite liner, it was assumed that the head on the secondary liner would be kept to 0.03 m for the service life of the secondary geomembrane; this implies operation of the secondary leachate collection system for 350 years!

Figure 31 shows the calculated variation in

Figure 31. Chloride impact curve in an aquifer below the double composite liner system shown in Figure 3. Secondary geomembrane assumed to have a service life to 360 years.

concentration with time assuming that the secondary collection system is operated for the assumed service life of the geomembrane (i.e. until year 360; 350 years post-closure) and the peak impact is about 150 mg/L (i.e. well below the typical drinking water objective of 250 mg/L). This implies that if one was only required to meet the 250 mg/L objective, one could terminate operations earlier (essentially when the concentration in the leachate reached 250 mg/L); for the parameters adopted here (based on MoEE 1996) and a large landfill, this would be about 325 years. This implies that this landfill has a contaminating lifespan of at least 325 years. Once again, this highlights the desirability of early waste stabilization as an alternative to the long post-closure operating

period otherwise required to protect groundwater below large landfills. Clearly, the contaminating lifespan will change depending on assumed landfill conditions; generally, the larger the landfill (in terms of mass per unit area), the longer will be the contaminating lifespan and the required maintenance period unless there is accelerated stabilization.

#### 10.4 Summary

For landfills with a composite primary liner, the foregoing analyses and other analyses performed by the writer (Rowe et al. 1995b; Rowe 1997b) lead one to conclude that for well constructed liners (with relatively few holes in the geomembrane), contaminant transport of volatile organic compounds is governed by diffusive transport through the composite liner and any underlying soil. The impact of volatile organic compounds on water quality in any underlying groundwater will depend on: the peak source concentration ( $c_0$ ); the variation in source concentration with time; the diffusion coefficient and Henry's coefficient for the geomembrane; the diffusion coefficient and sorption characteristics of the clay component of the liner and the underlying attenuation layer; the biodegradation that occurs in the soil below the geomembrane; and dilution in the aquifer. The combined thickness of the clay component of the composite liner and the attenuation layer may be critical in terms of controlling impact on groundwater quality in any underlying aquifer for these contaminants.

Although data is limited and there is a need for more research, it appears that an HDPE geomembrane may provide a low permeability barrier to contaminants that are relatively soluble in water. For these contaminants, the diffusive transport across an intact geomembrane is low relative to that of the volatile organic compounds with low solubility and a low dipole moment (less than 1 debye). For the relatively soluble organic and inorganic contaminants, the number of holes and, in particular, the holes in contact with wrinkles may control the impact for the service life of the geomembrane. Once the primary geomembrane reaches its service life, many of the contaminants remaining in the leachate at this time will be readily transported across the clay component of the liner and the attenuation layer and impact may be largely controlled by dilution in the aquifer or by a secondary liner and collection system (if present). Thus for these contaminants the potential for concentration decrease with time in the landfill, the number of wrinkles and holes in the geomembrane, the service life of the primary geomembrane, the potential for dilution, and the presence of any secondary composite liner and operation of any secondary collection system will control the impact on groundwater beneath the site.

Finally, it is noted that it is possible that the

construction of a landfill may cause a change in groundwater quality even if there is no contaminant escape from the landfill! This may arise in situations where the construction of the landfill causes a reduction in recharge to an underlying aquifer (the "shadow effect") and/or a change in groundwater direction in the underlying aquifer as discussed by Rowe et al. (1995b). Likewise, construction of a landfill may cause a drop in groundwater levels below the landfill under some circumstances (Rowe et al. 1995b).

Using the modelling techniques adopted in Section 10.3, it is possible to assess equivalency of liner systems with respect to contaminant transport. For the specific cases considered in Section 10.3, it was shown that the composite liner with a GCL gave rise to less impact than a composite liner with a CCL even allowing for an increase in hydraulic conductivity of the GCL to  $2 \times 10^{-10}$  m/s due to clay-leachate interaction. However, it should be noted that in this comparison the total thickness of soil between the primary geomembrane and the receptor aquifer was held constant. In order to control the diffusion flux to a level similar to a CCL, it is necessary to couple the GCL with a soil layer that, while not having the hydraulic characteristics of a CCL, still provides diffusive (and potentially sorptive) resistance to contaminant migration.

It should be emphasized that when comparing liner systems, consideration should be given to factors such as:

- (a) The hydraulic resistance over the contaminating life-span of the landfill including the effects of leachate mounding and clay-leachate interaction for both compacted clays and GCLs. This will typically require clay-leachate compatibility tests (e.g. see Rowe et al. 1995b, Petrov & Rowe 1997). Consideration should also be given to the potential for internal erosion when there may be high gradients.
- (b) The contact conditions between the geomembrane and "clay". The geotextile component of the GCL may control transmissivity at the interface between the GCL and geomembrane and any assessment of leakage using the approach given in Section 9 should be based on experimental data for the proposed geomembrane and GCL under anticipated stress conditions.
- (c) The presence of wrinkles may be a problem with respect to the long term performance of composite liner systems in landfills. This may be particularly true for composite liners that incorporate a GCL due to the potential for clay movement in the GCL under applied pressure (see Section 7.3).
- (d) The level of construction CQA/CQC. The quality of a compacted clay liner is highly dependent on the construction control (e.g. compaction equipment, water content etc.). These CCL liners are also prone to desiccation cracking as discussed in Section 4.

GCLs are easier to place and their long term performance is less sensitive to desiccation effects however care is required to ensure that overlapped seams do not move and open up when overlying layers are placed.

- (e) The stability of the liner system and the potential for shear failure either at the interface between materials or within a layer itself both during construction and during placement of the waste (see Section 11).
- (f) The potential for diffusion, sorption and biodegradation. Since compacted clay liners are often not specified to have a minimum organic carbon content, sorption can not be relied on without independent tests. If sorption is required to control impact to a regulatory driven level, it is possible to specify a minimum organic carbon content and/or use modified clays in the GCL to achieve the desired level of sorption. For both compacted clay and GCL liner systems, some consideration should be given to the migration of metals, organic compounds and organo-metallic complexes that may be encountered in leachate.

From the discussion presented in this paper it is evident that there is potential for use of GCLs as part of composite liner systems in the base liners (base seals) of landfills provided that factors such as those itemized above are considered and addressed in the design and construction.

## 11 STABILITY OF BARRIER SYSTEMS

The preceding sections have focussed on the role of various geosynthetics with respect to reducing and controlling contaminant escape from a landfill. However, it is essential that in addition to contaminant transport considerations, adequate consideration be given to ensuring the stability of the barrier system (a) during liner construction, (b) during landfilling, and (c) after landfill completion. Failure in the barrier system prior to waste placement can occur if insufficient consideration is given to interface strength and/or the development of unanticipated seepage forces. Table 34 summarizes four cases where there were slides on slopes ranging from 4:1 (H:V) to 2.5:1. In three of the four cases, the failure arose due to low permeability of the drainage material. In one case, the as placed material had too low a hydraulic conductivity. In the other two cases, accumulation of fines gave rise to a build-up in seepage forces and subsequent failure. These cases illustrate the need to (a) select suitable materials, (b) have a design and construction plan that will minimize accumulation of fines, and (c) consider the potential climatic effect to impact on performance (e.g. heavy rainfall, freezing conditions). The design of landfill final cover (cap)

Table 34. Case histories involving slides of leachate collection layers before waste placement due to seepage forces (R.M. Koerner, personal communication).

No.	Upper Interface	Lower Interface	Slope Inclination (H:V)	Cover Soil Thickness (mm)	Approx. Slope Length (m)	Approx. Time After Construction (yr)	Cause of Seepage Force

systems is discussed in detail by Giroud and Beech (1989), Giroud et al. (1995a, b) and Koerner and Soong (1998) and the reader is referred to these papers for more details regarding the stability of covers and barrier systems on slopes.

Public aversion to the approval of new landfills has led to a general increase in the size of new landfills being constructed (since this maximizes the amount of waste that can be disposed of on a given footprint) and a tendency, when possible, to expand existing landfills laterally and/or vertically. In the construction of new landfills with complex barrier systems (e.g. see Figure 1), particular attention must be given to the potential for sliding within the barrier system before, during and after landfilling. This is illustrated with reference to the "Kettleman Hills" and "French" Landfills in the following subsections. When existing landfills are being expanded, it is common to include an engineered barrier system in the expanded portion of the landfill, even though the original landfill may not have incorporated any engineered barrier system. Particular care is required to integrate the new and old portions of the landfill and, in particular, to avoid stability problems when excavating at the toe of the existing landfill. This is illustrated with respect to the "Maine Landfill" and "Cincinnati Landfill" discussed subsequently.

#### 11.1 Kettleman Hills Slide as reported by Bryne et al. (1992)

The Kettleman Hills Landfill B-19 is a hazardous waste landfill with an engineered liner system as shown schematically in Figure 1. Construction of this phase had been completed and approximately 490,000 m<sup>3</sup> of waste and other material had been placed with the waste

reaching its maximum height (27 m) above the base when the failure occurred. The waste mass moved horizontally about 11 m and vertical slump of up to 4.3 m was observed along the sideslopes. Shortly after the failure, a study by Mitchell et al. (1990) and Seed et al. (1990) concluded that the failure was likely related due to failure in the liner system. Low shear strengths were identified for both the geomembrane/clay and geosynthetic/geosynthetic interfaces.

A second study was conducted during the removal of waste from the failed area and this study (Byrne et al. (1992) is reported to have established that failure involved: "slip along multiple interfaces within the landfill liner system. The predominant surface of sliding appeared to be the secondary clay/secondary geomembrane interface. In the upper portions of the northwest and southwest basal sideslopes" (see Figure 32), "the sliding surface corresponded to the primary geomembrane/secondary geotextile interface. In the toe regions of the northwest and southwest basal sideslopes, where the waste mass moved either directly or transversely away from those slopes, the failure mechanism was more complex and involved slip on multiple interfaces together with zones of distortion as a result of kinematic constraints to sliding on a continuous liner surface in these areas....The driving or destabilizing forces for the failure mechanism observed came from the waste located above the 2H:1V basal sideslopes located to the northwest and the southwest, and the resisting or stabilizing forces came from the waste located above both the essentially flat base of the landfill and the 3H:1V basal sideslope located to the northeast" (Figure 32). This complicated failure surface may have been caused by the stress dependent nature of the interfaces (Stark & Poeppel 1994).

Figure 32. Displacement vectors for waste blocks during failure of the Kettleman Hills Landfill (modified from Byrne et al. 1992).

The failure appears to have been primarily the result of the low geomembrane/clay interface shear strength in the secondary liner system. The undrained behaviour of the interface about one year after construction is of particular note and was attributed to the fact that there was relatively little excess pore pressure dissipation near or within the geomembrane/clay interface due to the low hydraulic conductivity and coefficient of consolidation, and the length of the drainage path (since the geomembrane prevented drainage). The drainage path may, in part, explain why the secondary liner was more critical than the primary liner. Other interfaces also had low strength including the geomembrane/geonet interface ( $11^\circ$  peak;  $8^\circ$  residual) and geomembrane/geotextile ( $14^\circ$  peak;  $8^\circ$  residual).

This failure, and the subsequent investigations reported by Mitchell et al. (1990), Seed et al. (1990), Byrne et al. (1992) and Stark and Poepfel (1994) highlighted a number of important lessons to be considered in the design of barrier systems for landfills, including:

1. The interface behaviour between a geomembrane and compacted clay may be essentially undrained during landfilling and is quite sensitive to the as placed moisture content and dry unit weight of the clay. In this case, the undrained strength ranged from  $s_u = 26$ – $58$  kPa over the range of water content examined with a value of 45 kPa at the mean secondary liner water content.
2. The mean residual geomembrane/clay shear strength may be considerably lower than peak strength and is a function of the normal stress.
3. The geosynthetic/geosynthetic residual interface strength with conventional (smooth) HDPE geomembranes is quite low ( $8^\circ$  in this case).

4. There was a quite rapid decrease from peak to residual strength on all key interfaces as deformation occurs.
5. Peak strength may only be mobilized over a portion of the failure surface and at the onset of failure a significant portion of the interface may be at or near residual strength. Thus an evaluation of stability based solely on peak strengths is inappropriate. Stark and Poepfel (1994) have suggested that the use of peak strength may only be appropriate on flat or slightly inclined portions of the landfill.
6. Although 3D analyses may aid in interpreting stability of relatively complex geometric configurations (such as in this case), a conventional two-dimensional stability analysis along a representative cross-section provides an indication of potential problems (as in this case).
7. Appropriate laboratory strength tests appear to provide parameters that explain field behaviour provided they are performed for conditions representative of actual field conditions.
8. Particular care is required with compaction control of clay liners below geomembranes. A water content that is too low may lead to macrostructures and higher than specified hydraulic conductivity. A water content that is too high may give good hydraulic conductivity but low shear strength that could give rise to failure.
9. The effect of wetting of a clay liner (e.g. due to rainfall) after construction and before geomembrane placement needs to be considered in developing the design and construction plan.

## 11.2 French Slide as Reported by Ouvry et al. (1995)

A second example of the need to carefully design for barrier stability has been described by Ouvry et al. (1995). This municipal solid waste landfill had a barrier system consisting of at least 3 m of compacted clay ( $k < 1 \times 10^{-9}$  m/s) and 2 mm thick smooth HDPE geomembrane. At the base of the landfill a 190 g/m<sup>2</sup> spunbonded nonwoven geotextile was placed between the smooth geomembrane and the compacted clay (see Figure 33). The leachate collection system included a sand drainage blanket on the base, and sand and tyres (the tyres being to protect the geomembrane during compaction) on the 2:1 sideslope.

After compaction of the liner for Cell 1, the geomembrane was installed (December 1993) during a very wet period (234 mm of rain during the month of installation). Waste was then placed in the cell (see Figure 34) to an average thickness of 12–15 m (maximum 20 m) at the time of the waste slide.

The waste slide occurred in July 1994 and was reported to have occurred along the geomembrane/clay interface along the sideslopes and along the geotextile/clay interface at the base. The geomembrane was pulled out

Figure 33. Schematic showing base and sideslope barrier systems for the French landfill (adapted from Ouvry et al. 1995).

Figure 34. Schematic showing geometry of the base and waste at failure for the French slide (adapted from Ouvry et al. 1995).

of the anchor trench over a length of 60 m. The displacement at the top of the waste slide was 5-6.7 m. The moisture content of the clay from beneath the geomembrane was found to be 5-9% higher than it had been after compaction.

This case highlights a number of points made in the previous subsection, namely:

1. the importance of considering potential waste sliding when designing the landfill and developing its operations plan;
2. the critical nature of the geosynthetic/clay interface and the important role played by water content with respect to the shear strength developed at the interface;
3. the potential for a decrease in design interface strength due to events occurring during construction (heavy rainfall during placing of the geomembrane on the clay in this case).

### 11.3 Maine Slide as Reported by Reynolds (1991)

This landfill was initially developed as an unlined MSW

landfill on a soft marine clay with a soil profile consisting of a 3 m thick crust over 12 to 18 m of soft clay (vane strength 10-30 kPa). Stability calculations performed in 1986, assuming a waste density of 600 kg/m<sup>3</sup>, indicated that the maximum safe height of waste was 17 m. By 1989, the landfill had reached 22 m and it had been determined that the MSW density was about 1250 kg/m<sup>3</sup> (i.e. more than twice that assumed in the stability calculations). The increased density was attributed to the use of (a) more compactive effort, and (b) more daily and intermediate cover to control odour, birds and windblown waste.

As part of a 1989 landfill expansion, work started on constructing a liner system consisting of two layers of HDPE geomembrane over 0.6 m of recompacted clay over the marine clay in the expansion area (see Figure 35). The use of two layers of geomembrane is itself unusual and the rationale for this is not provided by Reynolds (1991). Trees were removed and 1-3 m of the stiff crust was removed to (a) remove some sand seams and (b) increase air space.

Figure 35. Schematic showing plan view of Maine slide (modified from Reynolds 1991).

Since the original landfill had no leachate collection system or engineered liner, a trench was excavated through the stiff clay at the western toe of the old landfill to allow interception of subsurface leachate flow from the landfill (see Figure 35). This combined with the stockpiling of cover soil over the westerly crest of the old landfill further reduced stability (see Figure 35) and following 10 days of rain (0.3 m) a landslide occurred involving some 500,000 m<sup>3</sup> of material (see Figure 35). The movement was reported to have lasted about 15 seconds. Figure 36 shows scale sketches for an east-west section both before and after the slide (Reynolds 1991). The slide was reported (Reynolds 1991) to have begun with a rotational failure under the original landfill slope (see Figure 36) and then retrogressed beneath the entire landfill, exiting at the eastern crest of the old landfill.

Figure 36. Schematic showing cross-section through the Maine slide (modified from Reynolds 1991).

During the slide the waste broke into large blocks which moved to the southwest, west and northwest on the remoulded soft clay which had lost up to 80% of its original strength (Figure 36). The block moved horizontally up to 50 m and at about 60 m from the original toe, the remoulded soft clay began to flow over the undisturbed surficial soil and extended up to 120 m from the original toe. Vertical walled crevasses up to 10 m deep were left between the blocks of waste when movement ceased (Figure 36). The post-failure investigation revealed that the average waste density (including daily and intermediate cover) was  $1520 \text{ kg/m}^3$  (range  $800\text{-}2000 \text{ kg/m}^3$  from  $10 \text{ m}^3$  test pits). The average shear strength parameters for the waste were  $c=24 \text{ kPa}$ ,  $\phi=27^\circ$  however large deformations were needed to mobilize this strength. The soft clay had a normalized strength ratio  $s_u/\sigma'_v=0.2$ .

This case illustrates a number of important points as follows:

1. as with most failures, there were a number of factors contributing to the failure;
2. the major cause of instability was the excavation of the stiff clay crust from the toe of the slope and excavation of the trench at the toe of the old landfill as part of the activity to construct an engineered barrier for the expansion portion of the site;
3. failure to recognize the actual waste densities contributed to the problem;
4. placement of a cover stockpile near the crest of the landfill decreased stability; and
5. heavy rains prior to the slide likely increased the density of the waste providing a trigger for the failure given the other conditions.

#### 11.4 Cincinnati Slide as Reported by Stark and Evans (1997)

This landfill experienced a significant waste slope failure in 1996. As reported by Stark and Evans (1997), the landfill covers about 93.6 ha and accepts an average of about 4,500 tonnes of waste per day. Initial development of the site began in 1945 and consisted of pushing waste over the edge of existing ravines where it came to rest on native soils consisting of a poorly sorted mixture of fine grained soil and angular rock fragments (colluvium). As a result of a 1994 approval for a 48 ha expansion and the requirements of US EPA Subtitle D (USEPA 1994), the operator was required to install a barrier system consisting of a leachate collection system, 1.5 mm HDPE geomembrane liner and a 1.5 m thick compacted liner in the expanded portion of the landfill.

The expansion involved creating a 40 m deep excavation at the toe of the existing landfill to allow installation of the barrier system. As the excavation was nearing completion after eighteen months, a major wasteslide occurred involving about  $1.3 \times 10^6 \text{ m}^3$  of waste. About 8 ha of waste slid into the 44 ha excavation and the toe of the slope moved about 250-300 m to the northern edge of the deep excavation.

At the time of the failure, the slope adjacent to the excavation was 2.6:1 (H:V) but some portions were steeper than 1.85:1 (H:V) and there was a 4.5-6 m nearly vertical excavation through the waste and colluvium at the toe. Stark and Evans report that the translational failure was thought to be due to mobilizing the post-peak shear strength ( $\phi \sim 10\text{-}12^\circ$ ,  $c' \sim 0$ ) in the colluvium, overbuilding of the waste above the approved elevation by about 12 m, excavating the toe that exposed the weak colluvium, and strain incompatibility between the waste and colluvium.

This case provides clear evidence that:

1. care is needed in the operational development of a landfill to avoid situations that could potentially cause overfilling and instability,
2. the interfaces between the waste and adjacent material (e.g. native or engineered liners) may be critical to the stability of waste slopes,
3. it is important to identify the geotechnical characteristics (including shear strength) of the native material on which the landfill is constructed and to calculate the stability of proposed slopes (it appears that the operational strength of the colluvium was the post-peak strength, not the peak strength), and
4. excavation of the toe of a slope can substantially increase the risks of a failure occurring.

## 11.5 Summary

Numerous landfills are safely constructed without stability problems. However, the four examples cited in this section illustrate the need for careful consideration to be given to the potential for sliding (a) during barrier construction, (b) during expansion of existing landfills and (c) during landfilling over the barrier system. Not illustrated here, but of importance nevertheless, is the potential for a failure at (or after) closure. The likelihood of failure occurring can be minimized by:

1. appropriate design and materials selection (including appropriate laboratory tests and stability analyses);
2. good CQC/CQA to ensure that the barrier system is installed as designed;
3. development plans for expanded landfills that limit toe excavation and overfilling and define allowable conditions for construction of the expansion area and a means of monitoring adherence to the development plans;
4. operations plans that include consideration of stability as the waste is placed and means of monitoring adherence to the operations plans;
5. contingency plans in the event of changed conditions occurring during construction (e.g. excessive rain, unexpected foundations conditions etc.); and
6. disposal alternatives so that waste can be diverted if expansion schedules are not met.

Provided that these issues are addressed, the numerous successful landfill construction projects not explicitly cited here illustrate that the well engineered barrier system can be safely constructed to provide a high level of environmental protection.

## 12 CONCLUSIONS

A number of key factors affecting the long term performance of landfill barrier systems (base seals) have been reviewed. It was shown that the temperature at the base of landfills is particularly sensitive to the type of waste, rate of landfilling and the saturated thickness of waste. In particular, leachate mounding on the base of the landfill (e.g. due to clogging of a leachate collection system or failure to remove leachate from the collection system) may result in a significant increase in temperature at the landfill liner. This in turn can increase both diffusive and advective contaminant transport through the liner system and can reduce the service life of both a geomembrane and underlying compacted clay liner.

Geotextile filters in landfill leachate collection systems do clog and may experience a drop in hydraulic conductivity of 2 to 5 orders of magnitude. The key issue is

whether or not they are excessively clogged. Currently, available evidence would suggest that when appropriately used in a drainage blanket, suitable geotextiles may increase the long term performance of the underlying granular drainage blanket without having any negative impact on the performance of the barrier system. However, geotextiles should be used with caution in areas of flow localization (e.g. around french drains, wrapping pipes etc.) in landfill leachate collection systems since excessive clogging can occur and this may cause leachate mounding and increased potential for the escape of contaminants.

Compacted clay liners potentially have a very long service life provided (a) adequate consideration is given to clay leachate compatibility in the selection of the clay and (b) there is no significant desiccation of the liner. Care needs to be given to minimizing/preventing desiccation both in the short term and the long term. Minimizing "short term" desiccation before waste placement can be achieved by appropriate design and construction. Minimizing "long term" desiccation after waste placement will require both appropriate design and landfill operations that limit the temperature at the base of the landfill. Particular care is required for thin (e.g. 0.6 m thick) compacted clay liners and for liners underlain by a secondary leachate collection/leak detection system.

The hydraulic conductivity of GCLs is sensitive to the permeant, the hydrating conditions and the applied stress. The hydraulic conductivity may increase several orders of magnitude for some permeating conditions. Thus the hydraulic conductivity needs to be assessed on a case by case basis (examining the proposed GCL permeated with leachate similar to that anticipated). However, a number of tests with real leachate and synthetic leachate whose chemical composition is based on real MSW landfill leachate have shown only modest increases in hydraulic conductivity (up to an order of magnitude). Calculations performed using the hydraulic conductivity of the GCL after interaction with MSW leachate suggest that a GCL may still be a very effective component of a composite liner system when combined with a well designed and constructed geomembrane liner.

Diffusion may be an important transport mechanism in well designed and operated landfills. Diffusion through geomembranes and GCLs has been discussed and parameters given. The rate of diffusive transport may be both concentration and temperature dependent. It is shown that some organic contaminants (e.g. volatile organic compounds, VOCs) can readily diffuse through HDPE geomembranes and that they may migrate through thin (~0.6 m) composite liners to detectable levels within less than a decade. The long term impact will depend on (a) the level of sorption that occurs in the clay liner and any attenuation layer above any potential

receptor aquifer; and (b) the level of biodegradation of organic contaminants that occurs in the waste and barrier system. Since the geomembrane is a selective barrier (providing considerable resistance to bacteria and primary substrates like volatile fatty acids but relatively little resistance to VOCs) the biodegradation in the soil below a geomembrane may be less than that observed in liners and aquifers where there is no geomembrane. More research is required to establish the magnitude of this effect.

Geomembranes provide an excellent diffusion barrier to inorganic contaminants and many organic contaminants. For these contaminants, the primary mode of contaminant transport is through holes in the geomembrane during the service life of the geomembrane. The leakage through composite liners has been examined. Field experience indicates that the leakage through composite liners is relatively small after waste placement and especially after the final cover has been constructed. However, the leakage is more than one would expect based on a few isolated holes in geomembranes assuming "good" construction. A new analytical solution for modelling leakage through holes in a geomembrane for a wide range of leachate heads and clay liner thicknesses has been presented both for isolated holes and holes in wrinkles (waves). It is shown that the presence of holes in wrinkles could explain the magnitude of the leakage observed in field applications with a leak detection system when allowance is also made for consolidation water arising from compacted clay liners.

The service life of GCLs and geomembranes is discussed. The service life of the geomembrane will be related to the type and amount of antioxidant used in the geomembrane, and the presence of stress concentration (e.g. at wrinkles, due to indentation by stones, etc.) and stress crack resistance. Based on existing data, the service life of a primary and secondary properly formulated HDPE geomembrane is projected to be of the order of 150 and 350 years (or greater) at temperatures of 25°C and 12°C respectively and assuming the conditions stated in Section 7, including (a) good design and construction practice; (b) the specified minimum oxidative induction time (OIT); (c) the specified minimum stress crack resistance; (d) negligible tensile stress concentrations in the geomembrane. It is noted that an increase in the temperature of the liner may substantially reduce the service life of the geomembrane.

Contaminant impact assessment is discussed in the context of the equivalence of liner systems. The use of GCLs as a replacement for a conventional compacted clay liner (CCL) has been discussed. By considering a specific example, it is shown that even allowing for an order of magnitude increase in hydraulic conductivity due to clay-leachate interaction, a GCL could replace a

conventional 0.6 m thick compacted clay liner and it still provides acceptably low impacts on an underlying aquifer. For the example examined, maintaining the same thickness of soil between the geomembrane and the aquifer (i.e. using a GCL and 0.6 m "foundation" layer to replace the 0.6 m CCL), the calculated impacts were less than for the CCL. If the CCL was replaced by a GCL alone, the calculated impacts were greater than for the CCL but with a 3 m attenuation layer between the GCL and aquifer were still acceptable during the service life of the geomembrane. These findings should not be generalized and each landfill should be considered on a case by case basis. The techniques used in Section 10 can be used to perform this assessment.

From the results presented in this paper it is evident that there is the potential for use of GCLs as part of composite liner systems in the base liners (base seals) of landfills provided that factors such as those itemized in the paper are considered and addressed in the design and construction. It should be emphasized that just as clay liners should be evaluated on a case by case basis, so should GCLs. Landfills vary in terms of mass loading and leachate characteristics and not all clays and GCLs have the same characteristics; even for a given GCL manufacturer there may be a range of products some of which are better suited than others for use in base liners.

It is shown that without stabilization of the waste there is the potential for significant impacts on groundwater due to recalcitrant contaminants once the primary geomembrane reaches its service life. These impacts can be minimized using a double composite liner. However, for large landfills the period of operation and maintenance of the leachate collection system may be of the order of hundreds of years.

Although the inclusion of various geosynthetics (e.g. geomembranes, geotextiles and geonets), clay liners, geosynthetic clay liners, and granular drainage layers may improve a landfill's performance by reducing contaminant escape, the implications of each layer and the potential interaction between layers (especially at interfaces) with respect to stability must be considered on a case by case basis. Potential failures may include sliding within the barrier system or general shear failures (landslide/waste slide) through the waste and underlying geological deposit (a) during liner construction, (b) during landfilling, or (c) after landfill completion. The need to carefully assess the stability of landfills is discussed and the lessons learned from four failures have been highlighted.

It is concluded that over the past decade very substantial advances have been made in understanding the behaviour of geosynthetics in barrier systems for landfills and that with appropriate design and construction, geosynthetics can be used to design a system that will provide excellent long term environmental protection.

This paper is dedicated to the memory of Professor John Booker - gentleman, scholar and friend. It was prepared with funding from the Natural Sciences and Engineering Research Council of Canada. The paper attempts to draw together both the author's research and the work of many other investigators. Explicit reference is made in the text to the sources of data (information relied upon). However, many individuals also provided suggestions, information and assistance in the preparation of the paper that can not be easily referenced. The author gratefully acknowledges Drs. J.P. Giroud and R.M. Koerner for their review of the entire manuscript and their constructive comments as well as to the following individuals who kindly offered their advice, information and, in some cases, their review of sections of the paper (in alphabetical order): Drs. F.S. Barone, R. Bonaparte, J.R. Booker, D.E. Daniel, E. Gartung, J.P. Giroud, J.P. Gourc, H. Haxo, Jr., G. Heibroek, Y.G. Hsuan, G.R. Koerner, R.M. Koerner, M. Othman, D. Smith, T. Stark and Messrs. R. Petrov, D. Stewart, K. von Maubeuge and the following graduate students who assisted in various aspects of the research reported herein: M. Armstrong (Section 3.2 and Figure 12), I.R. Fleming (Section 3.2), L. Hrapovic (Figures 19 and 21), C. Lake (Section 6, Table 11 and Figure 15), S. Millward (Table 30), P. Sangam (Sections 7.4 and 8, Table 17, Figures 19 and 21) and J. VanGulck (Figure 12).

## 14 NOTATION

AL	=	Attenuation Layer
AOS	=	apparent opening size (mm)
A	=	area perpendicular to flow and/or diffusion
a	=	area of hole in a geomembrane (cm <sup>2</sup> ; m <sup>2</sup> )
b	=	half width of a wrinkle (see Figure 27) (m)
C	=	H <sub>L</sub> + H <sub>f</sub> - h <sub>a</sub> (m)
CCL	=	Compacted Clay Liner
CSPE	=	Chlorosulphenated Polyethylene
c	=	contaminant concentration (mg/L, μg/L)
c(t)	=	contaminant concentration at time t (mg/L, μg/L)
c <sub>g</sub>	=	contaminant concentration in a geomembrane (mg/L; μg/L)
c <sub>f</sub>	=	contaminant concentration in solution (mg/L; μg/L)
c <sub>FE</sub>	=	final equilibrium concentration in fluid (mg/L; μg/L)
c <sub>IP</sub>	=	initial concentration in fluid (mg/L; μg/L)
c <sub>o</sub>	=	initial concentration (mg/L, μg/L)
D <sub>e</sub>	=	effective diffusion coefficient in soil (m <sup>2</sup> /s; m <sup>2</sup> /a)
D <sub>g</sub>	=	diffusion coefficient in a geomembrane (m <sup>2</sup> /s; m <sup>2</sup> /a)

D <sub>T</sub>	=	diffusion coefficient of temperature T (m <sup>2</sup> /s; m <sup>2</sup> /a)
D <sub>10</sub>	=	diffusion coefficient of temperature T=10°C (m <sup>2</sup> /s; m <sup>2</sup> /a)
e <sub>B</sub>	=	bulk GCL void ratio (-)
f	=	mass flux of contaminant (g/m <sup>2</sup> /a)
GCL	=	Geosynthetic Clay Liner
GM	=	Geomembrane
GN	=	Geonet
g	=	gravitational acceleration (m/s <sup>2</sup> )
HDPE	=	High Density Polyethylene
h	=	hydraulic head (m)
h <sub>a</sub>	=	potentiometric head in an aquifer (m)
h <sub>b</sub>	=	thickness of an aquifer (m)
h <sub>w</sub>	=	leachate head acting on top of a geomembrane (m)
H <sub>f</sub>	=	thickness of an attenuation (foundation) layer (m)
H <sub>L</sub>	=	thickness of a liner (CCL or GCL) (m)
i <sub>s</sub>	=	mean gradient across the liner and attenuation layer (see Eq. 29) (-)
K <sub>d</sub>	=	partitioning or distribution coefficient (mL/g)
K <sub>g</sub>	=	linear sorption coefficient for geomembrane (-)
K <sub>o</sub>	=	coefficient of earth pressure at rest (-)
k	=	hydraulic conductivity (m/s)
k <sub>f</sub>	=	hydraulic conductivity of a foundation/attenuation layer (m/s)
k <sub>L</sub>	=	hydraulic conductivity of clay liner (m/s)
k <sub>n</sub>	=	geotextile normal hydraulic conductivity (m/s)
k <sub>om</sub>	=	hydraulic conductivity of leachate collection layer (m/s)
k <sub>s</sub>	=	harmonic mean hydraulic conductivity of clay liner and attenuation layer (see Eq. 29) (m/s)
k <sub>T</sub>	=	hydraulic conductivity at temperature T (m/s)
k <sub>10</sub>	=	hydraulic conductivity at temperature T=10°C (m/s)
L	=	length of a wrinkle (m)
LCS	=	Leachate Collection System
LDS	=	Leak Detection System (also called a Secondary Leachate Collection System)
M <sub>A</sub>	=	mass per unit area (g/m <sup>2</sup> )
MSW	=	Municipal Solid Waste
M <sub>w</sub>	=	mass of waste per unit area (t/m <sup>2</sup> )
n	=	porosity (-)
n <sub>b</sub>	=	porosity in aquifer
n <sub>e</sub>	=	effective porosity (-)
P <sub>g</sub>	=	"permeability" of a polymer to a given contaminant (P <sub>g</sub> =S <sub>g</sub> D <sub>g</sub> ) (m <sup>2</sup> /s; m <sup>2</sup> /a)
PLCS	=	Primary Leachate Collection System
POA	=	percentage open area (-)
p	=	proportion of contaminant in waste (mg/kg)

Q	=	flow through a hole in a geomembrane (m <sup>3</sup> /s)
q <sub>o</sub>	=	permeation through landfill cover reaching the leachate collection system per unit area (m/s; m/a)
R	=	wetted radius (m)
r <sub>o</sub>	=	radius of a hole in a geomembrane (m)
S	=	soil suction (kPa)
S <sub>g</sub>	=	sorbed mass per unit volume of geomembrane (ms/L)
S <sub>gf</sub>	=	partitioning (solubility, Henry) coefficient (-)
SDR	=	Standard Dimension Ratio for pipes (-)
SLCS	=	Secondary Leachate Collection System (also called a Leak Detection System)
s	=	spacing between geomembrane and clay liner (m)
s <sub>u</sub>	=	undrained shear strength (kPa)
T <sub>1</sub>	=	time at which maintenance of landfill final cover (cap) and operation of the leachate collection system is terminated in example in Section 10.
T <sub>2</sub>	=	time at which equilibrium leachate mound is reached for an unmaintained landfill assuming no leachate collection from the underdrains but a fully functioning liner system in example in Section 10.
T <sub>3</sub>	=	time at which the geomembrane component of the primary composite liner is assumed to fail in the example in Section 10.
t	=	time (s,a)
t <sub>1/2</sub>	=	half-life (unless otherwise noted) (a)
t <sub>GM</sub>	=	thickness of a geomembrane (mm)
t <sub>GT</sub>	=	thickness of a geotextile (mm)
t <sub>GCL</sub>	=	thickness of GCL (mm)
VFA	=	Volatile Fatty Acids
VOC	=	Volatile Organic Compounds
v <sub>a</sub>	=	Darcy velocity (Darcy flux) through a layer (m/s; m/a)
v <sub>b</sub>	=	Darcy velocity (Darcy flux) in an aquifer (m/a)
v <sub>i</sub>	=	average Darcy velocity beneath the wetted radius around a hole in a geomembrane over a clay liner (m/a)
α	=	[k <sub>v</sub> /(H <sub>L</sub> +H <sub>i</sub> )/θ] <sup>0.5</sup> (-)
σ	=	applied vertical stress (kPa)
σ <sub>v</sub>	=	vertical effective stress (kPa)
ψ	=	geotextile permittivity (s <sup>-1</sup> )
ρ	=	density of a fluid (t/m <sup>3</sup> ; kg/m <sup>3</sup> ; g/cm <sup>3</sup> )
ρ <sub>d</sub>	=	dry density of soil (t/m <sup>3</sup> ; kg/m <sup>3</sup> ; g/cm <sup>3</sup> )
ρ <sub>GM</sub>	=	density of geomembrane (t/m <sup>3</sup> ; kg/m <sup>3</sup> ; g/cm <sup>3</sup> )
θ	=	transmissivity between geomembrane and clay liner (m <sup>2</sup> /s)
η	=	viscosity of a liquid (kg/m/s)
λ	=	decay constant = ln2/t <sub>1/2</sub> (a <sup>-1</sup> )

**ABSTRACT:** It is shown that there exists a big gap between the currently used design seismic coefficients  $(k_h)_{design}$  for retaining walls (RWs) and the ratio of the highest peak ground accelerations to the gravitational acceleration experienced during the 1995 Hyogo-ken-nambu Earthquake. It is argued that some factors for the above include; a) the use of conservative soil strength in the design; b) positive aspects of dynamic effects arising from ductility and flexibility of RW that are not considered in the pseudo-static approaches; and c) the use of a global safety factor larger than unity. It is suggested, at the same time, that the currently used  $(k_h)_{design}$  values should be increased appropriately to avoid such collapse of RWs as observed during the earthquake to a larger extent in the order of a) gravity type RWs, b) cantilever reinforced concrete RWs and c) geosynthetic-reinforced soil RWs having a full-height rigid facing. To evaluate dynamic earth pressure and failure zone size in unreinforced and reinforced backfill at high seismic loads more properly than the conventional pseudo-static methods, a modified pseudo-static approach is proposed, which takes into account the progressive process of the active failure in the backfill associated with shear banding and strain softening.

**KEYWORDS:** Seismic stability, Retaining walls, Pseudo-static analysis, Case histories, Model tests, Progressive failure

## 1. INTRODUCTION

It has been accepted that under static conditions, properly designed permanent geosynthetic-reinforced soil retaining walls (GRS-RWs) can be more cost-effective than, and can function equivalently to or even better than, conventional type retaining walls (RWs). Good performance of a number of GRS-RWs observed during a couple of recent very severe earthquakes in USA and Japan has shown that it is also the case under seismic conditions (e.g., Collin et al., 1992; White and Holtz, 1996; and Tatsuoka et al., 1996). Results obtained from recent theoretical and experimental works are consistent with the above (e.g., Bathurst and Alfalo, 1996). In this report, first some lessons from the seismic performance of representative types of RWs including GRS-RWs during the 1995 Hyogo-ken-nambu Earthquake will be summarized.

In the current aseismic design, RWs are designed to resist dynamic earth pressure, which is usually obtained by limit equilibrium-based pseudo-static stability analysis, mostly by the Mononobe-Okabe method (the original M-O method; Okabe, 1924; Mononobe and Matsuo, 1929). In such current aseismic design, conservative soil strength is

used (Table 1.1); for example, angles of internal friction, typically 35°, are assigned for cohesionless soils. These values are definitely lower than the actual peak friction angles  $\phi_{peak}$  for such densely compacted cohesionless backfill as realized in most permanent GRS-RWs. Rather, these values are similar to the residual frictional angles  $\phi_{res}$  for usual cohesionless soils. The use of such low design

Table 1.1 Typical soil strength values recommended for aseismic design of soil structures (Railway Technical Research Institute, 1997)

Type of backfill soil	Angle of internal friction, $\phi$
1) Well graded sand, gravel and muck from hard rock	40°
2) Ordinary sand and gravel	35°
3) Poorly graded sand	30°
4) Cohesive soil*	30°

\* For retaining walls not higher than 6 m and embankments not higher than 10m; cohesion is empirically replaced by shear resistance angle.

friction angles as above have been recommended for a reasonable conservatism, covering possible effects of progressive failure in the backfill and uncertainties of compaction level in each project (e.g., Bolton and Steedman, 1985; Jewell, 1991).

In the pseudo-static aseismic design methods that are employed in many countries including Japan, the design horizontal seismic coefficient  $(k_h)_{design}$  for RWs is usually as low as 0.1 - 0.2. On the other hand, after having experienced very serious damage to a great number of civil engineering structures during the 1995 Hyogo-ken-nambu Earthquake, a double-level aseismic design methodology has been proposed and accepted by Japanese civil engineers (JSCE, 1996). In this method, permanent civil engineering structures are first to be designed so as to maintain their serviceability against the specified lower level seismic load (Level 1). Level 1 seismic load is equivalent to the conventional seismic design load as described above, which is considered to be equivalent to the order of 200 - 300 gals in terms of the peak (horizontal) ground acceleration (PGA). At the same time, each structure should be designed against the higher Level 2 seismic load in such that although they are allowed to exhibit some plastic deformation, they should not collapse totally and can be remedied within a short period. Level 2 seismic load is considered to be equivalent to a PGA of the order of 600 - 800 gals. Following this recommendation, a number of Japanese aseismic design specifications and codes for reinforced concrete (RC) and steel civil engineering structures have been revised. Now, RWs cannot be an exception, and it is now required to develop a rational aseismic design method for RWs including GRS-RWs to survive such very high seismic load.

When a value of  $(k_h)_{design}$  equal to as high as 0.5 is employed, however, the seismic active earth pressure for cohesionless backfill obtained by the conventional pseudo-static approaches using the above-mentioned conservative friction angle becomes very high and the failure zone in the backfill becomes unrealistically very large and deep as shown later. Then, conventional type RWs as well as GRS-RWs are very difficult to be designed to have reasonable dimensions when they are to survive Level 2 seismic load. Yet,  $k_h = 0.5$  is still lower than  $PGA/g = 0.6 - 0.8$ , which was experienced by many collapsed and uncollapsed RWs during the 1995 Hyogo-ken-nambu Earthquake (n.b., the response maximum horizontal acceleration in the RWs should have been even higher). In the second part of the paper, reasons other than the use of conservative soil strength for inconsistencies between the conventional  $(k_h)_{design}$  values and the observed high  $PGA/g$  values will be discussed based on field and laboratory observations. The reasons will include positive net dynamic effects and the use of a global safety factor larger than unity.

In addition, the postulates used in the original M-O method will be examined based on field and laboratory observations and some theoretical considerations. Then, a modified pseudo-static approach to obtain reasonable design seismic active earth pressure and failure zone size for unreinforced and reinforced backfill subjected to very high seismic loads will be proposed.

Then, based on the information presented in this report, the values of  $(k_h)_{design}$  for Level 2 seismic load will be tentatively suggested as a function of analysis method, design soil strength and RW type.

## 2. SOME LESSONS FROM THE 1995 HYOGO-KEN-NAMBU EARTHQUAKE

The major lessons obtained from the performance of RWs including GRS-RWs during the 1995 Hyogo-ken-nambu Earthquake could be summarized as follows (Tatsuoka et al., 1996). Fig. 2.1 shows the locations of the RWs referred to below.

The damaged RWs could be categorized into the following three groups;

- a) slightly damaged; the RW deformed and/or displaced slightly, and its reuse was soon started after some remedy work;
- b) moderately damaged; the RW deformed and/or displaced noticeably, but did not totally collapse, and was demolished to be re-constructed, or was substantially repaired before reuse; and
- c) severely damaged; the RW totally collapsed to the ground, and was demolished to be re-constructed.

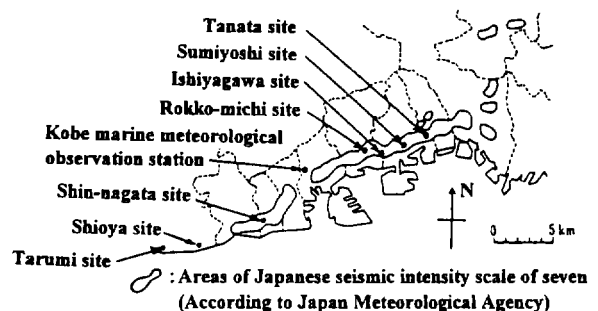

Fig. 2.1 Locations of typical soil retaining walls in Hyogo-ken-nambu referred to in the paper and Kobe Marine Meteorological Observation Station.

- 1) The GRS-RWs having a full-height rigid (FHR) facing at Tanata was slightly damaged; the wall deformed and displaced to some extent by sliding out at its base and overturning about its base (Fig. 2.2a), but it did not show a sign of ultimate failure, despite extremely high seismic loads at the site (the estimated PGA of about 800 gals or more) and use of reinforcement layers truncated to a same short length of  $L/H$  equal to 0.56. A recently constructed

Fig. 2.2 Cross-sections before and after the earthquake of slightly damaged RWs at Tanata; a) a GRS-RW having a FHR facing (n.b., effects of the H-piles on the wall stability are considered to be very small); and b) a RC RW supported with a row of bored piles.

cantilever reinforced concrete (RC) RW supported with a row of bored piles (Fig. 2.2b), located adjacent to the Tanata GRS-RW, was also slightly damaged. Although the seismic load was less severe with an estimated PGA/g of the order of 0.5, similar GRS-RWs having a FHR facing located at Tarumi exhibited a limited amount of deformation and displacement (thus very slightly damaged). Cantilever RC RWs supported with a pile foundation constructed adjacent to these GRS-RWs

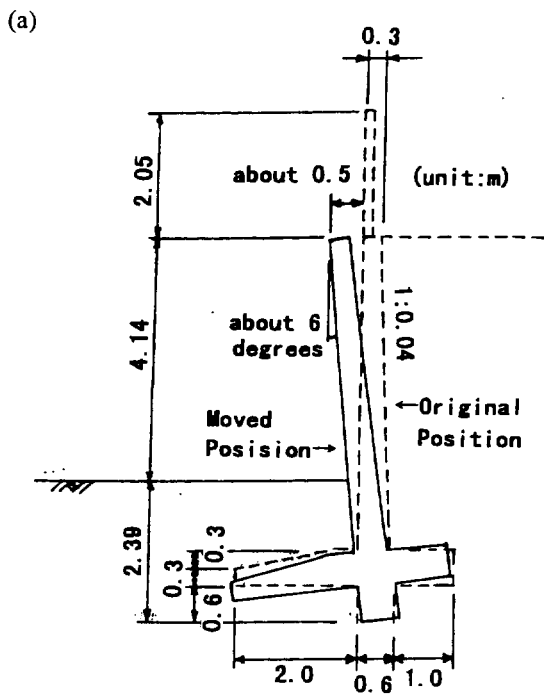

Fig. 2.3 Cross-sections before and after the earthquake of moderately damaged RWs; a) a RC retaining wall located at Rokko-michi; b) a cantilever RC RW at Ishiyagawa Station; and c) cantilever RC RW at Shioya Station

Fig. 2.4 Cross-sections before and after the earthquake of seriously damaged or totally collapsed RWs; a) a masonry RW between Setsu-motoyama and Sumiyoshi Stations; b) a leaning-type RW between Setsu-motoyama and Sumiyoshi Stations; c) a gravity-type RW at Ishiyagawa Station; and d) a poorly designed old cantilever RC RW at Shin-nagata Station

displaced similarly to the GRS-RWs. Subjected to the seismic loads similar to the Tanata GRS-RW, a reversed T-shaped cantilever RC RW at Rokko-michi (Fig. 2.3a) and those at Ishiyagawa (Fig. 2.3b) were moderately damaged. Although the seismic load was less severe, a cantilever RC RW at Shioya (Fig. 2.3c) was also moderately damaged. In comparison, a number of conventional gravity type RWs (masonry RWs and leaning type and gravity type unreinforced concrete RWs) and poorly designed old cantilever RC RWs such as that at Shin-Nagata which were located in the similarly very severely shaken areas were seriously damaged (Figs. 2.4a-d). In summary, the performance of the GRS-RWs with a FHR facing located in the severely shaken areas, particularly the one at Tanata, was satisfactory and equivalent to, or even better than, that of the recently constructed RC RWs. Reasons for these different performances should be understood.

2) The most dangerous failure mode of RW is over-turning about its bottom, because it is abrupt in a brittle and uncontrollable manner, which may result into very serious damage to structures and human beings located on the backfill and in front of the wall. A number of conventional

leaning and gravity type RWs collapsed in the overturning failure mode, triggered by large inertia force of RW and bearing capacity failure in the sub-soil below near the toe of RW, as typically seen in Figs. 2.4c and d. Sliding out of wall at the wall base is not preferable, but some amount should be admitted when subjected to very high seismic loads, because this failure mode is usually in a ductile manner, being not so abrupt as, and more stable than, the overturning failure mode. We need a relevant seismic design method for overturning at high seismic loads.

3) Fig. 2.5 shows the relationships between the safety factor and the  $k_h$  value for the Tanata GRS-RW and the RC RW at Rokko-michi obtained by the above-mentioned conventional pseudo-static design method using a design  $\phi$  value equal to  $35^\circ$  for the backfill. When based on this result, the Tanata GRS-RW should have failed by base sliding at  $k_h = 0.36$ . Despite its good seismic behaviour,  $k_h = 0.36$  is noticeably below the estimated values of PGA/g at the site (i.e., 0.8 or larger). We need an explanation for this large gap. There is a gap also for the cantilever RC RW at Rokko-michi. The gap is, however,

Fig. 2.5 Relationships between the safety factor and the  $k_h$  value for; a) the GRS-RW having a FHR facing at Tanata; and b) the cantilever RC RW at Rokko-michi, obtained using soil strength and simplification methods following the conventional design procedures (see Table 3.1 for calculation details).

smaller than that for the Tanata wall; the calculated critical  $k_h$  for bearing capacity failure in the sub-soil below the RW, leading to the overturning failure of RW, is higher (0.45), while the damage was severer.

4) The failure planes observed in the backfill of failed RWs, such as the gravity type unreinforced concrete RW at Ishiyagawa (Fig. 2.6a) and the leaning type unreinforced concrete RW along JR railway embankment between Setsu-motoyama and Sumiyoshi stations (Fig. 2.6b), were

Fig. 2.6 Observed failure planes in the backfill; a) the gravity-type unreinforced concrete RW at Ishiyagawa Station; and b) the leaning-type RW along JR railway embankments between Setsu-motoyama and Sumiyoshi Stations.

much steeper than those predicted by the original M-O method using a conservative value  $\phi = 35^\circ$  and based on a tentative value of  $k_h$  equal to  $0.65 \cdot \text{PGA}/g = 0.65 \times 0.7 \approx 0.45$ . If the reinforcement layers should be extended well back the failure zone predicted for a high design  $k_h$  value by the original M-O method using a low design soil strength, we should use extremely long reinforcement layers.

5) Effects of facing type on the deformation of reinforced soil RW were observed; subjected to seismic loads which were less severe than that for the Tanata GRS-RW, discrete panel facings of several Terre Armee RWs exhibited relatively large deformation. Due to excessive wall deformation, the upper half of one major Terre Armee wall was rebuilt after the earthquake (Tatsuoka et al., 1996).

### 3. EXISTING PSEUDO-STATIC APPROACHES

In most of the aseismic design specifications, codes and guidelines used in Japan for relatively important RWs, seismic active earth pressure is evaluated by the original M-O method together with the assumption of hydrostatic distribution of dynamic earth pressures (static plus dynamic components). Alternatively, the trial wedge method, which is equivalent to the original M-O method for plane backslopes, is used for backfill having an irregular backslope. As mentioned earlier, conservative soil strength is used in these aseismic design procedures, as typically listed in Table 1.1. These design soil strength values are usually not a function of the degree of compaction, resulting in no differences in calculated stability between loosely and densely compacted backfills. Rather, the required degree of compaction is specified separately, not directly linked to static and seismic stability analyses. Note again that the use of conservative soil strength does not necessarily mean that the conventional aseismic design is conservative, because of the use of conservative  $(k_h)_{\text{design}}$  values.

Fig. 3.1 Outline of the original Mononobe-Okabe method

In the original M-O method, the load equilibrium at the limit state (i.e., failure state) is examined for an assumed failure mechanism, and the maximum earth pressure is sought by trial and error changing the location and size of failure plane (Fig. 3.1). Fig. 3.2 shows the seismic active earth pressure coefficient  $(K_A)_{\text{seismic}}$ , plotted against  $k_h$ , for

Fig. 3.2 Relationships between the seismic active earth pressure coefficient  $(K_A)_{\text{seismic}}$  and the horizontal seismic coefficient  $k_h$  obtained by the M-O method for  $\phi = 30, 35, 40, 45$  degrees for the simplest wall and backfill configuration.

Fig. 3.3 Relationships between the size of failure zone in the backfill and the horizontal seismic coefficient  $k_h$  obtained by the M-O method for  $\phi = 30, 35, 40$  degrees, corresponding to Fig. 3.2.

the simplest wall and backfill configurations as shown in the figure, obtained by the original M-O method using  $\phi = 30^\circ, 35^\circ, 40^\circ$  and  $45^\circ$ , while Fig. 3.3 shows the size of the failure zone in the backfill. It may be seen that at a high  $k_h$  (about 0.5 or more), the use of conservative  $\phi$  values such as  $30^\circ$  results into very high  $(K_A)_{\text{seismic}}$  values with very deep and long failure planes.

The original M-O method is based on several postulates as summarized below:

- 1) The maximum earth pressure is obtained by changing the angle  $\zeta$  of the straight failure plane starting from the heel of the wall. Therefore, the angle  $\zeta_c$  for the critical failure plane is a function of  $k_h$  (and  $k_v$ ), and becomes smaller as the value of  $k_h$  increases.
- 2) The seismic coefficients  $k_h$  and  $k_v$  are usually applied uniformly in both vertical and lateral directions in the backfill (vertically or laterally non-uniform distributions of  $k_h$  (and  $k_v$ ) are used in some modified methods as discussed below).
- 3) The friction angle  $\phi$  is constant along the critical failure plane in homogeneous backfill. That is, the backfill soil is an isotropic and perfectly-plastic material, and the  $\phi$  value mobilized in the failure zone is independent of the previous wall movement which has occurred before the ultimate failure of RW. This is equivalent to not considering the progressive process of active failure associated with shear banding and strain softening in the backfill.
- 4) As a result of postulates 1, 2 and 3, the distribution of dynamic earth pressure is hydrostatic with the center of gravity at one third of the wall height ( $H/3$ ) when the backslope is level without surcharge.

Fig. 3.4 Modified M-O method for GRS-RWs introducing a more realistic non-uniform vertical distribution of  $k_h$  (Bathurst and Cai, 1995); a) static component; b) dynamic increment; and c) dynamic (total) pressure distribution.

We should note, however, that these postulates are not relevant, as examined later in this paper in the light of the recent experimental results. For example, the postulate 3 is not relevant particularly for ductile RWs such as GRS-RWs, which can survive seismic loads largely exceeding the value at which the first active failure takes place in the backfill.

Several modifications have been proposed to alleviate some limitations of the original M-O method. The results of the previous model tests on conventional type RWs, including those by Ichihara and Matsuzawa (1973), revealed that the hydrostatic distribution assumption may be less conservative by itself. To apply to segmental GRS-RWs, Bathurst and Cai (1995) introduced a more realistic vertically non-uniform distribution of  $k_h$  (Fig. 3.4). In their method, however, a single straight failure plane starting from the heel of facing is assumed (as the original M-O method), irrespectively of the presence of reinforcement, and the reinforcement is considered to resist the seismic earth pressure obtained as above.

The two-wedge method (TW method; e.g., Jewell et al., 1984) has been used to design many GRS-RWs. This approach is particularly relevant for GRS-RWs having a FHR facing and short reinforcement (Horii et al., 1994; Fig. 3.5), since for such GRS-RWs, the failure zone consists of two wedges as observed in many model tests (Fig. 3.6a). Furthermore, the TW method can simulate single straight failure planes, thus covering the original M-O method. In the TW method, the pattern and location of failure plane is controlled by the presence of reinforcement.

Fig. 3.5 The two-wedge method (Horii et al., 1994); a) cross-section; and b) force diagram.

Fig. 3.6 a) Two-wedge failure mode observed in a model shaking test of GRS-RW having short reinforcements (see Fig. 4.6b and Fig. 4.7b for “Reinforced type 1”); and b) multiple failure planes observed in a model tilting test of GRS-RW having longer top reinforcement (see Fig. 4.6a and Fig. 4.7a for “Reinforced type 2”) (Koseki et al., 1997).

The design procedure proposed by Leshchinsky et al. (1995) for geosynthetic-reinforced slopes and segmental walls under static loads assumes a log-spiral failure plane in the backfill. Extending the above, Ling et al. (1997) considered seismic effects by introducing a uniformly-distributed horizontal seismic coefficient  $C_s$  for the whole backfill above and below the failure plane for the tieback failure analysis (Fig. 3.7). Log-spiral failure planes cover planar failure planes as assumed in the original M-O method by setting the pole of the log spiral at infinity, but may not sufficiently model such a two-wedge failure mechanism as shown in Fig. 3.6a.

Fig. 3.7 Tie back failure analysis employing log-spiral failure plane and horizontal seismic inertia force (Ling et al., 1997).

Fukuda et al. (1994) analyzed the performance of a geogrid-reinforced slope of road embankment which survived the 1993 Koshiro-Oki Earthquake without any noticeable damage. In the aseismic design method proposed by Public Works Research Institute (1992) (Fig. 3.8a), the entire reinforced zone is regarded as a rigid body and seismic earth pressure acting from the unreinforced

backfill is evaluated by the trial wedge method or its equivalent (i.e., the original M-O method). They reported that when based on the external stability analysis described above, the safety factor of the wall against direct sliding along the wall base during the earthquake was 0.93, which is not consistent with the actual behavior. They considered that in the above method, no phase lag is introduced between the horizontal inertia force of the

(a) Reinforced zone as a pseudo-retaining wall

(b) Reinforced zone as a pseudo-retaining wall

Fig. 3.8 Concept of horizontal inertia force and seismic earth pressure acting on the reinforced zone (Fukuda et al., 1994); a) when they are in the same phase; and b) when they have a phase-lag and increment of the earth pressure is zero at the maximum inertia force.

reinforced zone and the dynamic component of earth pressure acting on the back of the reinforced zone, as in many other design specifications. In order to explain this discrepancy, they assumed that the horizontal inertia force of the reinforced zone and the earth pressure acting on the back of the reinforced zone should have been out of phase. This assumption is consistent with observations in the small-scale model shaking table tests shown later. As an extreme case, they assumed that there was no dynamic component in the earth pressure when the inertia force was at its maximum, as schematically shown in Fig. 3.8b. The obtained safety factor was 1.23, which is more consistent with the actual behavior.

In the design guidelines of FHWA (1990), the value of  $(k_h)_{design}$  value assigned to the reinforced part of backfill is a half of that to be applied in evaluating the seismic thrust of the earth pressure acting from the unreinforced part of backfill by considering that these two forces are unlikely to peak simultaneously. For geosynthetic-reinforced segmental RWs, Bathurst and Cai (1995) proposed a factor of 0.6, instead of 0.5.

The major limitations inherent to the pseudo-static approaches as summarized above include the following:

- 1) Deformation and displacement of RW cannot be evaluated.
- 2) The effects of dynamic effects cannot be fully nor properly accounted for, as discussed by Tatsuoka et al. (1996). The major factors of the dynamic effects include;
  - a) dynamic ductility (the capability of deforming and/or

displacing without exhibiting ultimate failure against dynamic loads exceeding the yield strength of the structure); and b) dynamic flexibility (the property which causes phase lag in a RW reducing earth pressure on the RW in a positive way while it may increase the response acceleration in a negative way). In fact, among RWs having similar seismic safety factors evaluated by the pseudo-static approach, those having a higher dynamic ductility and larger positive effects of flexibility performed better during the Hyogo-ken-nambu Earthquake (Koseki et al., 1996). Fig. 3.9 shows the  $(k_h)_{critical}$  values at which the safety factor becomes unity for the several types of conventional type RWs (Figs. 2.2b, 2.3 and 2.4) and the Tanata GRS-RW (Fig. 2.2a) evaluated by the conventional pseudo-static approaches (i.e., the original M-O method and the conventional TW method) under the following two conditions;

- A) soil strength values and wall configurations are determined following the current design procedures; the  $\phi$  values are conservative, similar to the residual values, and passive pressure on part of the front face of underground part of RW is ignored (see Table 3.1); and
- B) peak soil strength values are used; for cohesionless soils, basically the peak friction angles estimated by relevant triaxial compression tests are used, which are larger than those described above, and the passive earth pressure on the front face of the underground part of RW is evaluated as it was at the time of the earthquake (see Table 3.2).

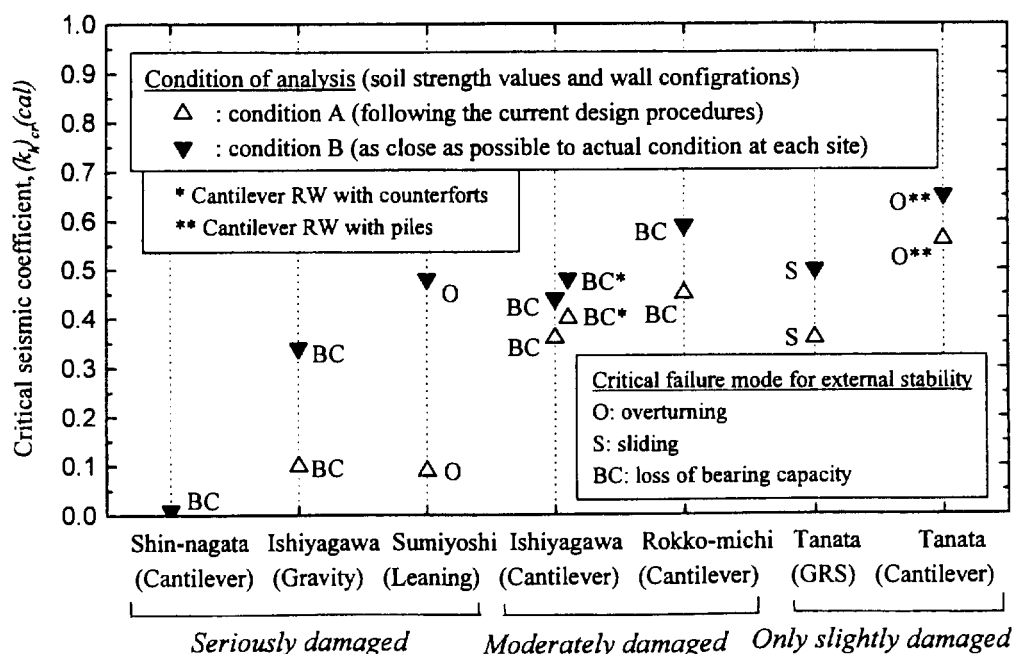

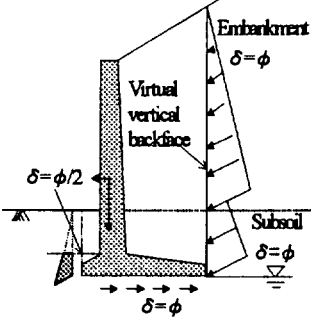

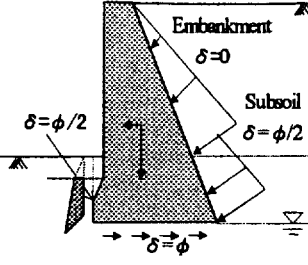

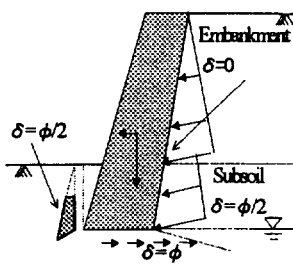

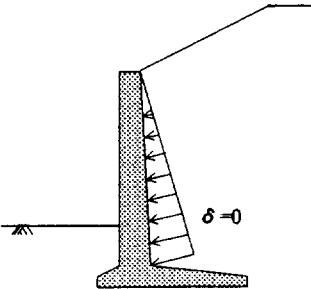

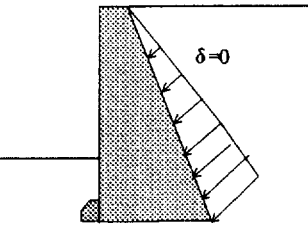

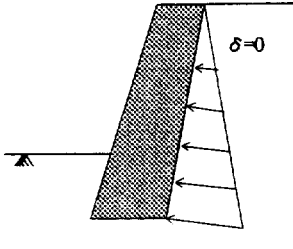

Fig. 3.9  $(k_h)_{crit}(cal)$  values for a safety factor equal to unity for ultimate failure of several conventional type RWs and the Tanata GRS-RW, evaluated by the current design methods (i.e., the original M-O method and the conventional two-wedge method) using two different soil strength values and wall configurations listed in Tables 3.1 and 3.2.

Table 3.1 Detailed calculation conditions used to obtain the  $(k_h)_{cr}(cal)$  values shown in Fig. 3.9 (using soil strength values and simplification methods following the current design procedures).

Condition A (upper line): using soil strength values and simplification methods following the current design procedures (refer to Table 3.1)

Condition B (lower line): using soil strength values and wall configurations as close as possible to those at each site (refer to Table 3.2)

\*At Shin-nagata site, safety factors against sliding and loss of bearing capacity even at  $k_h=0$  on condition A were smaller than 1.

\*\* For cantilever RW with piles at Tanata site, internal stability analyses were conducted on both the facing and the piles, and their results are listed in the table as " $(k_h)_{cr}(cal)$  for facing failure /  $(k_h)_{cr}(cal)$  for pile failure." Furthermore, another set of analyses was conducted by neglecting the presence of a temporary coffer dam in front of the RW, as denoted by conditions A' and B'.

Table 3.3 lists the summary of the results of the analysis with a global safety factor equal to unity. Here, the overturning failure of RW as a rigid body is assumed to occur about its toe. In actuality, overturning failure of RW may have resulted from bearing capacity failure in the subsoil below around the toe of RW, as observed with some RWs in the field (and in the laboratory as discussed later). It may be seen that when based on condition A, using conservative soil strength values, the calculated values  $(k_h)_{cr}(cal)$  of the two conventional gravity type (leaning and gravity types) RWs (Figs. 2.4b and 2.4c) are particularly low when compared with the others. However, for the purpose of evaluating different dynamic effects among these different RWs, the  $(k_h)_{cr}(cal)$  values obtained based on condition B, using more realistic soil strength values, are more informative. Then, it may be seen that except for the cantilever RC RW at Shin-nagata, these  $(k_h)_{cr}(cal)$  values are rather similar, despite their very different levels of damage. It is considered that positive net dynamic effects on the ultimate failure of RW may be one of the major reasons for their different seismic

behaviours. Note also that for many of the RWs (except for three cases), the  $(k_h)_{cr}(cal)$  based on condition A is much higher than 0.2, which is currently used for these types of RW. This difference is largely due to the use of a global safety factor, which is typically 1.5 for these types of RW.

When based on Table 3.3, the seismic stability of the pile-supported cantilever RC RW at Tanata (Fig. 2.2b) had increased largely by the presence of a temporary coffer dam in front of the RW, which was existing at the moment of the earthquake (cases A and B in Table 3.3); seemingly, the weight of the coffer dam have largely increased the overburden pressure in the sub-soil, thus have largely increased the passive earth pressure in the ground. Without these effects (cases A' and B'), the  $(k_h)_{cr}(cal)$  values of the RW becomes much lower, suggesting that the wall would have been damaged much more seriously than the GRS-RW at Tanata. On the other hand, the construction cost per wall length for the RC RW is about 2 - 3 times as high as that for the GRS-RW. These facts

indicate that the GRS-RW having a FHR facing could be much more cost-effective also from a viewpoint of seismic stability.

Note also that the value of  $(k_h)_{cr}(cal)$  for internal stability under condition B are similar to, or larger than, the estimated (PGA/g) values, except for an unusual case of the RC RW at Shin-nagata (see Table 3.3). Therefore, internal stability will not be discussed herein.

#### 4. ACTIVE FAILURE PROCESS IN THE BACKFILL

##### 4.1 Shear banding in PSC tests on sands and gravels

To examine the postulates with respect to soil properties used in the original M-O method, shear banding in granular materials will first be discussed. Densely compacted sand and gravel fails always associated with strain localization into a shear band (or shear bands) exhibiting strain softening. Therefore, the ultimate failure of the RW-backfill system is usually preceded by the active failure in the backfill associated with shear banding. Fig. 4.1 shows relationships between the shear stress level  $R_n$  and the shear deformation  $U_s$  of shear band for a variety of granular materials having a large range of particle size. These results were obtained from detailed observations of local deformation on the specimen's boundary  $\sigma_2$  surface in a series of plane strain compression (PSC) tests.  $R_n$  is defined as;

$$R_n = (R - R_{res}) / (R_{peak} - R_{res}) \quad (4.1)$$

where  $R$  is the principal stress ratio  $\sigma_1/\sigma_3$ , and  $R_{peak}$  and  $R_{res}$  are the peak and residual values of  $R$ .  $R_n$  is equal to 1.0 and 0.0 at the peak and residual states. The following important trends of behaviour have been found from Fig. 4.1 and related observations:

- In the post-peak strain softening regime, the stress level drops associated with yielding in a shear band and elastic rebound outside the shear band.
- The increment  $\Delta U_s$  by which the stress ratio drops from the peak value to the residual value is only about 5 - 10 times  $D_{50}$  for most of the granular materials (or less for Isomi gravel). This amount of shear deformation is very small when compared with the dimensions of usual full-scale RWs; for example, when the wall height  $H$  is 5 m and  $D_{50}$  is 0.2 mm,  $\Delta U_s = (10 - 20) \text{ times } D_{50}$  is only 0.4 - 0.8 % of  $H$ . This small figure suggests that the stress state in the shear band can become the residual state very rapidly after it develops associated with the active failure in the backfill.
- In PSC tests on sufficiently large specimens having height/width ratios larger than about 2.5 with well lubricated top and bottom ends, due to the weakening process inside the shear band, the first developed shear band further deforms without developing the second shear band(s). It would be also the case with the backfill of RW unless increasing seismic loads or backfill deformations or both change largely the principal stress directions in the backfill.

Fig. 4.1 Relationships between the shear stress level  $R_n$  and the shear deformation  $U_s$  of shear band from plane strain compression tests on a variety of granular materials with a large range of particle size (Yoshida et al., 1994; Yoshida and Tatsuoka, 1997).

These three features are relevant particularly for densely compacted backfill as that of reinforced soil RWs.

4.2 Active failure in PSE tests on sand

Yamada and Masuda (1997) performed a series of special plane strain tests in which specimens of Toyoura sand were rotated 90° after specimen preparation by air-pluviation so that the horizontal and vertical stresses  $\sigma_h$  and  $\sigma_v$  during the specimen preparation become, respectively, the axial

stress  $\sigma_a$  and the constant lateral stress  $\sigma_c$  during the plane strain tests (Fig. 4.2). The plane strain compression and extension tests were performed on specimens anisotropically consolidated at  $\sigma_a/\sigma_c (= \sigma_h/\sigma_v) = 0.375$ , which simulated, respectively, the passive and active failures from the  $K_0$  condition in the backfill behind a smooth vertical RW. In the active failure test (i.e., the plane strain extension test, PSE test; Figs.4.2c and d), the minimum earth pressure ( $\sigma_a$ )<sub>min</sub> with  $\phi_{peak}$  being mobilized (i.e., the active earth pressure ( $\sigma_h$ )<sub>a</sub>) was

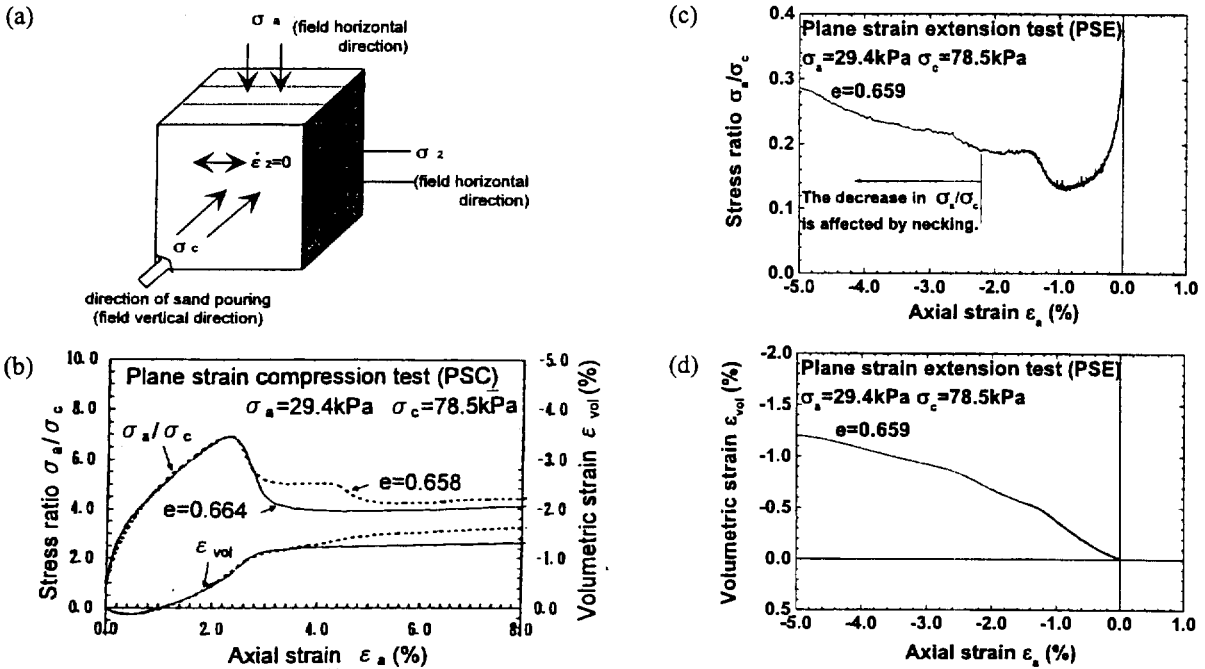

Fig. 4.2 a) Specimen configuration; and b) to d) relationships between the axial stress  $\sigma_a$  and the axial strain  $\epsilon_a$  from monotonic active and passive tests on saturated Toyoura sand at an axial strain rate of 0.125 %/min (Yamada et al., 1996).

Fig. 4.3 Schematic diagram showing the active failure in the backfill and the ultimate failure of the RW.

attained at a very small axial strain of about -1.0 %. The minimum earth pressure state was followed by shear banding with the axial stress  $\sigma_a$  (i.e., the earth pressure  $\sigma_h$ ) increasing towards a larger value at the residual state and  $\phi_{mob}$  decreasing from  $\phi_{peak}$  to  $\phi_{res}$ . The basically same process occurred in the passive failure in the PSC test (Fig.4.2b).

It may also be inferred from Fig. 4.2c that for actual backfill soil, under static conditions or a certain seismic condition with a constant positive  $k_h$ , the pre-peak relationship between  $K$  ( $K_{static}$  or  $K_{seismic}$ ) and  $u$  is non-linear having a negative slope  $dK/du$ , while the post-peak relationship is also non-linear but having a positive slope (see Fig. 4.3). On the other hand, at a constant  $u$  (i.e., at a constant  $\phi_{mob}$ ), the relationship between  $K_{seismic}$  and  $k_h$  has a positive slope  $dK_{seismic}/dk_h$ . The existence of such opposite signs as shown above makes the seismic earth pressure properties very complicated and confusing.

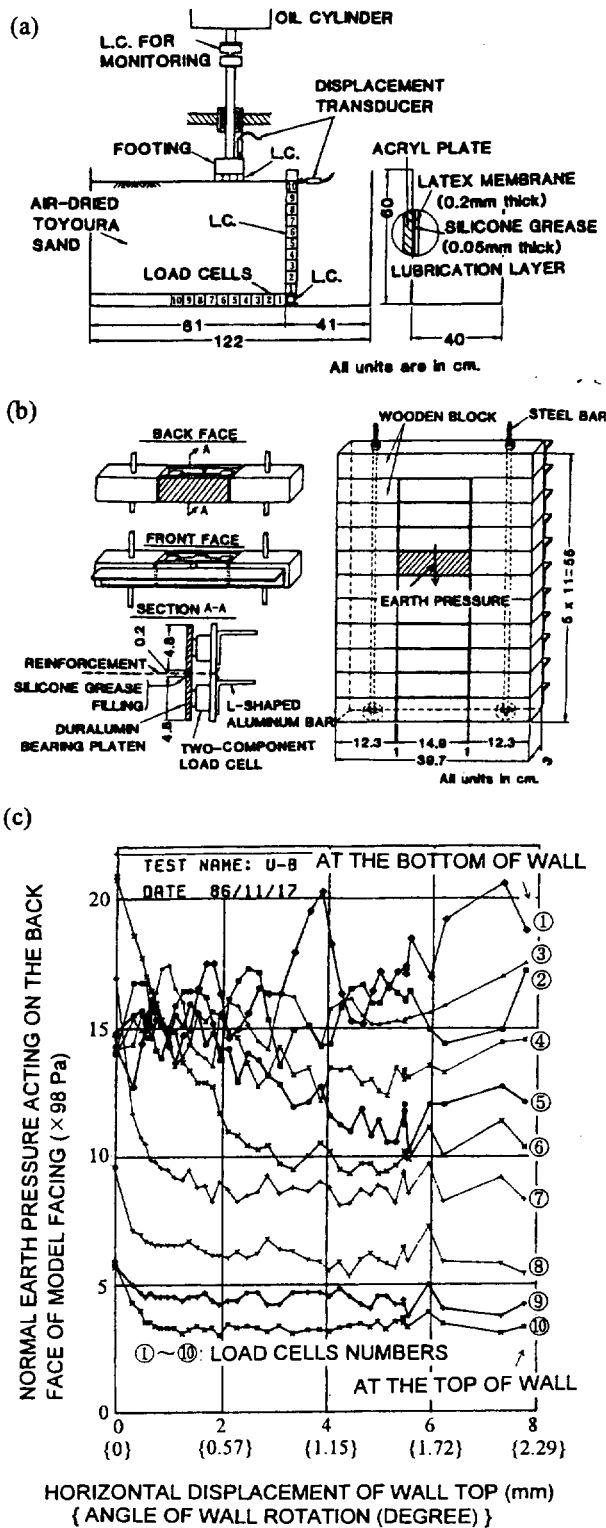

Fig. 4.4 a) Model configuration; b) details of model facing; and c) earth pressure acting on the back face of a 50 cm-high rough vertical retaining wall with backfill of air-dried Toyoura in a static model test controlling the rotation of the wall about its base (Tateyama, 1997).

### 4.3 Active failure in the backfill in model tests

**Static model test:** Tateyama (1997) measured by using ten load cells the earth pressure acting on the back face of a 50 cm-high model of rough vertical rigid RW with the backfill of air-dried Toyoura sand (Fig. 4.4). The model RW was rotated about its base at a controlled displacement rate. Similar to the above-mentioned PSE test, the minimum earth pressure was attained at a very small wall rotation (about 1.0°), which was equivalent to about -0.6 % lateral strain in the uniformly deforming active zone with  $\phi = 55^\circ$ . After this active failure state, at the lower part of the wall (i.e., load cell Nos. 1 to 6), the earth pressure increased associated with shear band development in the backfill. Measurements of strain field in the backfill showed that within the limit of wall rotation examined (about 2.2°), the first developed shear band further deformed without developing the second failure plane, likely due to essentially constant directions of the principal stresses in the backfill.

**Shaking table tests in a centrifuge:** Bolton and Steedman (1985) performed small-scale shaking tests of a 135 mm-high box RW model with the backfill of air-dried SLB sand ( $D_{50} = 0.225$  mm) in a centrifuge (Fig. 4.5a). The initial centrifuging to 80 g (g denotes the gravitational acceleration) and the first earthquake loading using roughly sinusoidal cycles having the maximum amplitude of 21 % of 80 g, which was equivalent to  $k_h = 0.21$ , caused a total rotation of 0.57° and a total base slip of 0.39 mm of the model RW. These wall displacements were seemingly enough to initiate the active failure in the backfill. The second earthquake loading having  $k_h = 0.33$  caused the ultimate failure of the RW with about a further 11 mm base slip and a visible failure plane developed in the backfill from the heel of the RW at an angle of  $(90^\circ - 25.5^\circ) = 64.5^\circ$  relative to the lateral direction. It is likely that the RW exhibited ductile behaviour, surviving higher seismic loads exceeding the value that caused the active failure in the backfill. The observed angle  $\zeta_r$  of the failure plane is slightly larger than the Coulomb failure angle equal to 58.4° at  $k_h = 0.21$  with  $\phi_{peak} = 50^\circ$  and the wall friction angle  $\delta = 2/3(\phi_{peak})$  obtained by;

$$\cot(\zeta_r) = -\tan(\phi + \delta) + \sec(\phi + \delta) \cdot \sqrt{\frac{\cos(\delta + \theta) \cdot \sin(\phi + \delta)}{\sin(\phi - \theta)}} \quad (4.2)$$

where  $\theta = \tan^{-1}(k_h)$ .

By using the ultimate failure seismic load  $k_h = 0.33$ , the failure plane angles predicted by the original M-O method using  $\phi_{peak} = 50^\circ$  and  $\phi_{res} = 34^\circ$  are, respectively, 52° and 36°, which are much smaller than the observed one. In a broad sense, this observation is consistent with the field behaviour (Fig. 2.6).

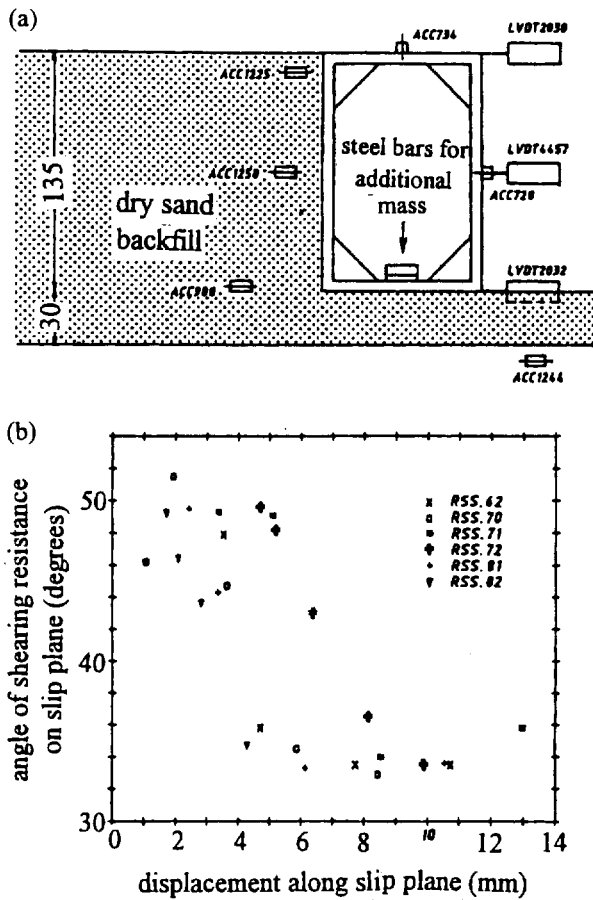

Fig. 4.5 Centrifugal shaking table tests on seismic stability of a box RW model with the backfill of air-dried SLB sand; a) test configuration (dimensions in mm); and b) relationships between the mobilized friction angle along the failure plane and the shear displacement across the shear band (Bolton and Steedman, 1985).

From the measured accelerations and displacements, the shear displacement increment across the shear band (or failure plane)  $\Delta U_s$  by which the stress changed from the peak value to the residual value was obtained to be about  $10 \cdot D_{50}$  (Fig. 4.5b), which is very consistent with the PSC

test results shown in Fig. 4.1. It was then concluded that “10 particle diameters is such a small relative slippage in a typical situation that it might alternatively be accepted that fully softened soil strengths  $\phi_{res}$  be invariably used on slip surfaces in sand irrespective of soil density.” This recommendation has actually been adopted in practice as discussed in INTRODUCTION. The present authors considers that this conclusion cannot be directly applied to the conventional pseudo-static approaches (e.g., the original M-O method and the conventional TW method), whereas this observation is essential for understanding and predicting better the behaviour of RWs at high seismic loads and for modifying properly the pseudo-static approaches, as discussed below.

“The seismic active failure in the backfill” and “the seismic ultimate failure of a RW” are different processes (Fig. 4.3). The seismic active failure could be defined as the mobilization of  $\phi_{peak}$  and associated start of shear banding under seismic loading conditions, while the seismic ultimate failure of a RW occurs when the seismic earth pressure exceeds the ultimate strength of the RW, usually occurring at a wall displacement larger than that at the active failure in the backfill. Therefore, it would be appropriate to assume that  $\phi_{res}$  is predominantly mobilized along the failure plane at the moment of the ultimate failure of RW, but not outside the failure plane (as suggested by Bolton and Steedman, 1985). This would be particularly relevant with ductile RWs, such as GRS-RWs, for which differences between the wall deformation at the seismic active failure in the backfill and that at the seismic ultimate failure of RW would be relatively large.

**Tilting and shaking table model tests:** Munaf et al. (1997) and Koseki et al. (1997) performed a series of small-scale static tilting tests, in which 50 cm-high models of several conventional types of RW and GRS-RWs having a FHR facing were brought to failure (Fig. 4.6a). The backfill was air-pluviated dense Toyoura sand, and each model RW was constructed on a 20 cm-thick sand layer. A model grid made of phosphor-bronze strips was

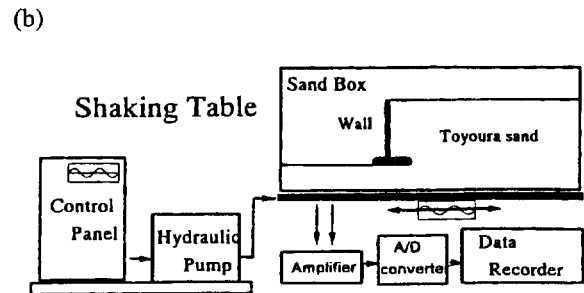

Fig. 4.6 a) Tilting tests and b) shaking table tests of cantilever-type RW model (Munaf et al., 1997).

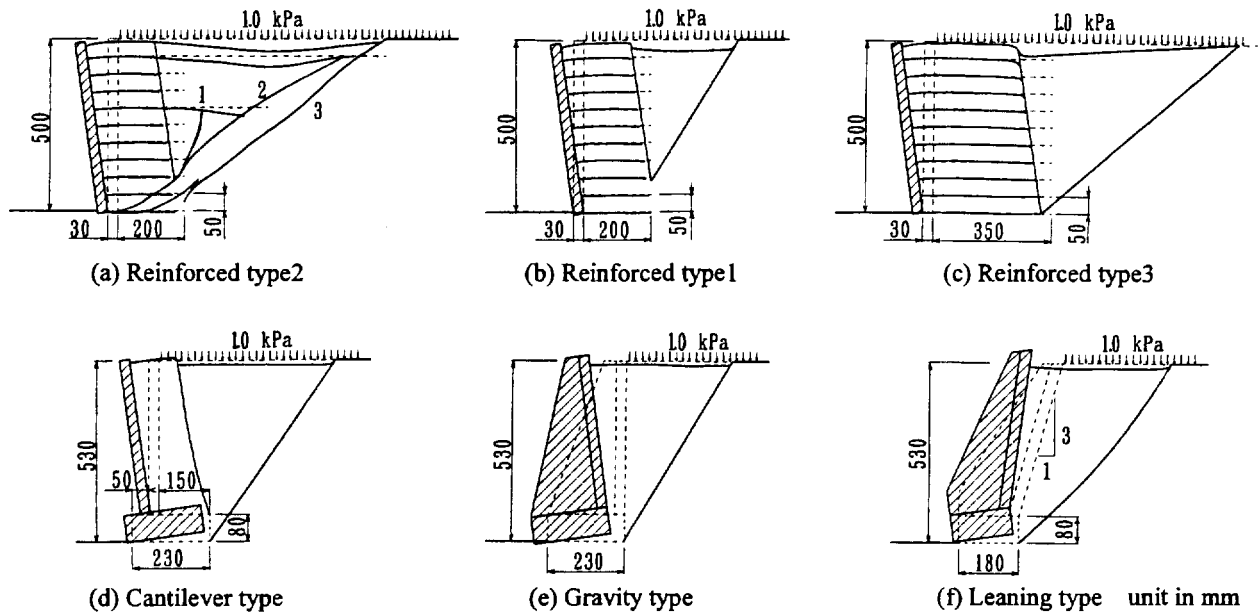

Fig. 4.7 Models of retaining walls showing their initial and displaced locations and observed failure planes; a) GRS-RW having a couple of extended top reinforcement layers, denoted as “Reinforced type 2” in Figs 4.8 and 6.2; b) GRS-RW having short reinforcement layers, denoted as “Reinforced type 1”; c) GRS-RW having moderately long reinforcement layers, denoted as “Reinforced type 3”; d) cantilever-type RW; e) gravity-type RW; and f) leaning-type RW (Koseki et al., 1997).

used to reinforce the backfill. A surcharge of 1.0 kPa, except for one test with 3.1 kPa, was applied on the backfill so as to increase the accuracy in the earth pressure measurements by increasing the pressure level in the backfill. Such static tilting model tests can simulate rather closely the stress conditions assumed in the original M-O method, except that the “vertical” stress (in the original vertical direction) decreases with tilting. In parallel, a series of shaking table tests were performed using the same RW models (Fig. 4.6b), in which the amplitude of sinusoidal waves at a frequency of 5 Hz used as input table acceleration was increased stepwise with an increment of 50 gals until the ultimate failure of RW was observed. The number of cycles at each step was about 50.

Fig. 4.7 shows the deformation of the models observed after failure in the shaking table tests. Commonly in the two series of model tests, only a single straight failure plane developed in the unreinforced backfill in back of the conventional type RWs, while a two-wedge mechanism was observed in the reinforced backfill (except for Reinforced type 2, in which multiple failure planes were observed as shown in Fig. 3.6b and 4.7a). This fact suggests that the pseudo-static approach for reinforced backfill should be different from that for unreinforced backfill such as the original M-O method. The seismic load  $k_h$  (i.e., the tilting angle or the amplitude of shaking

acceleration/g) could be increased further after the active failure plane started developing in the backfill, in particular with the reinforced soil models in the shaking table tests. However, in each test (except for Reinforced type 2), another deeper failure plane (or failure planes), which was (were) deeper than the first one, did not develop. Rather, as the  $k_h$  value increased, shear displacement was concentrated to the first developed failure plane.

Fig. 4.8 shows the relationship between the observed failure plane angle  $\zeta_f$  and the observed values of  $k_h$  at ultimate failure  $(k_h)_{cr}(obs)$ . For the GRS-RWs, the angle  $\zeta_f$  was defined for the failure plane of the back wedge developing in the unreinforced backfill behind the reinforced zone (except for Reinforced type 2). These  $\zeta_f$  values have been corrected for the initial wall configurations before deformations. Each value of  $(k_h)_{cr}(obs)$  was defined as the table horizontal acceleration/g or the tilting angle when a failure plane became clearly visible in the backfill and the wall displacement started increasing in an uncontrollable manner, when horizontal displacement at a wall top was about 5 % of the wall height. Note that single amplitude of the table horizontal acceleration at the active state was used to evaluate  $(k_h)_{cr}(obs)$ . Left-directed arrows next to some symbols mean that the respective failure plane started developing at a  $k_h$  below the  $(k_h)_{cr}(obs)$ . In Fig. 4.8, the theoretical relationships obtained by the original

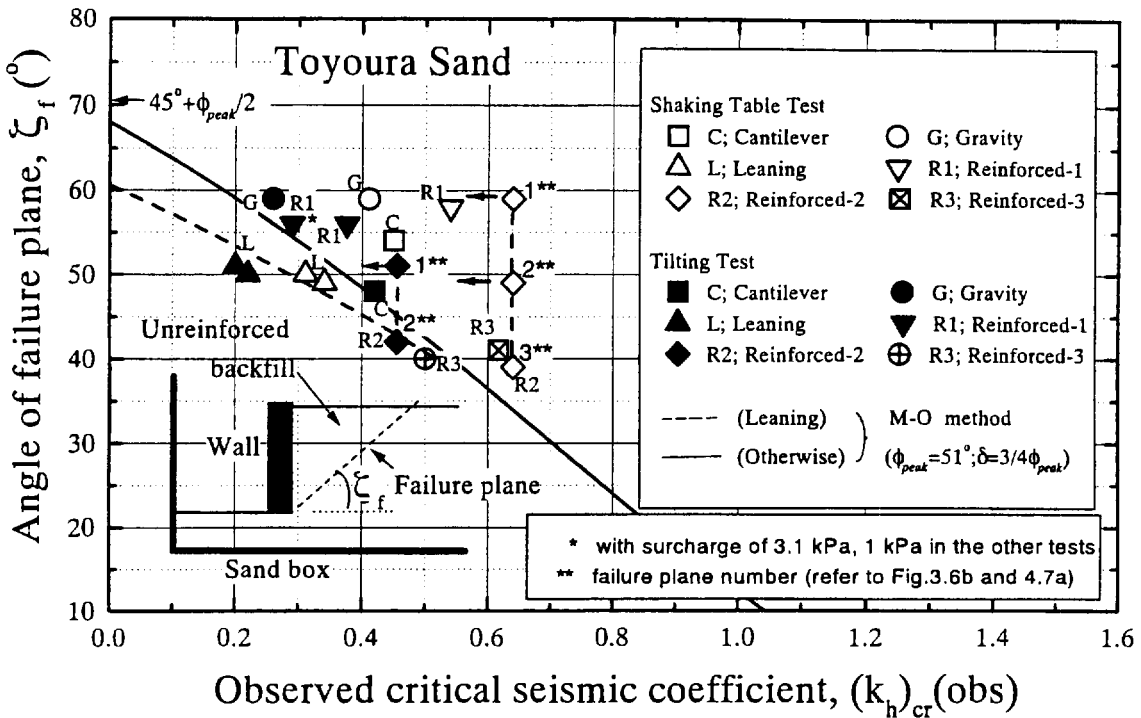

Fig. 4.8 Relationships between angle of failure plane and seismic coefficient at ultimate failure obtained from tilting and shaking table tests of model RWs (Koseki et al., 1997).

M-O method using  $\phi_{peak}$  of the backfill equal to  $51^\circ$  are shown. This  $\phi_{peak}$  value was determined based on results from PSC tests of the air-pluviated Toyoura sand used for the model tests prepared at the same density ( $e = 0.644$  to  $0.654$ ) as the model tests, performed at low confining pressure ( $= 9.8 \text{ kPa}$ ) with the  $\sigma_1$  direction being vertical. The frictional angle  $\delta$  at the interface between the wall back face and the backfill was assumed equal to  $3/4 \phi_{peak}$  ( $= 38^\circ$ ). The ratio of  $3/4$  is equal to the ratio of the angle of friction  $\phi_{SS} = \arctan(\tau/\sigma)_{max}$  on the horizontal failure plane from simple shear tests to the angle of friction  $\phi_{psc} = \arcsin\{(\sigma_1 - \sigma_3)/(\sigma_1 + \sigma_3)\}_{max}$  from PSC tests having the vertical  $\sigma_1$  direction, both obtained for air-pluviated Toyoura sand (Tatsuoka et al., 1991). The broken curve is for the leaning type RW having an inclined back face and the solid curve is for the other conventional type RWs having a vertical back face and the GRS-RWs (except for Reinforced type 2).

The following trends of behaviour can be observed from Fig. 4.8:

- a) In the tilting tests, the observed relationship between  $\zeta_f$  and  $(k_h)_{cr}(obs)$  is generally close to the respective theoretical relationship, irrespective of RW type. It was observed that the increase in  $k_h$  which could be made after the active failure plane started developing until the ultimate failure of RW was generally small,

in particular with the leaning type RW.

- b) For each type of RW, the failure plane angle  $\zeta_f$  is generally similar between the tilting and shaking table tests, while the  $(k_h)_{cr}(obs)$  value is larger in the shaking table test than in the tilting test. The difference depends on RW type, generally larger with the GRS-RWs than the three conventional types of RWs. Furthermore, it was observed that in the shaking table tests, the  $k_h$  value could be increased from the value where the active failure plane started developing without the ultimate failure of RW to a much larger extent than in the respective tilting test, in particular with the GRS-RWs. Therefore, in the shaking table tests on these GRS-RW models, there is no clear correlation between the failure plane angle  $\zeta_f$  and the  $(k_h)_{cr}(obs)$  value. This result indicates that in the shaking table tests, the failure plane angle  $\zeta_f$  is not totally controlled by  $(k_h)_{critical}$  and the difference in the  $\zeta_f$  value between the observation and the original M-O method should be explained by dynamic effects, as discussed later.

#### 4.4 Cyclic changes in earth pressure under dynamic loading conditions

**Dynamic earth pressure with an elastic backfill:** Only the simplest RW configuration illustrated in Fig. 4.9 will herein be discussed. The seismic earth pressure

coefficient  $K_{seismic}$  is defined as "the total earth pressure  $P''/(\gamma \cdot H^2/2)$ ". In general terms, the seismic earth pressure at a given moment is obtained from the equilibrium between the following two quantities;

- a) the earth pressure (in terms of coefficient  $K_{seismic}$ ) acting on the back face of RW, which is a function of wall displacement  $u$ , being affected by seismic loads; the lateral seismic coefficient  $k_h$  is assumed to be uniformly distributed in the backfill and its positive sign is defined for the inertia force acting towards the RW; and
- b) the resistance against the earth pressure (in terms of  $K_{seismic}$ ) of the RW supported by the subsoil, which is a function of  $u$ , being affected by the inertia force of the RW caused by the seismic coefficient  $(k_h)_w$ ;  $(k_h)_w$  may be different from  $k_h$  for the backfill.

Fig. 4.9 Simple RW configuration.

Suppose that the backfill soil is a linear-elastic medium, and a rigid RW is supported linear-elastically with the subsoil (Fig. 4.10a). Suppose further that;

- a) the relationship between " $K_{seismic}$  as the load applied to the RW" and  $u$  is linear with a negative slope  $\alpha$  under static conditions or under a certain seismic condition with a constant  $k_h$ , and at a given  $u$ , the value of  $K_{seismic}$  increases proportionally with  $k_h$ ; and
- b) the relationship between " $K_{seismic}$  as the resistance of the wall" and  $u$  is also linear with a positive slope  $\beta$  under static conditions or under a certain seismic loading condition with a constant  $(k_h)_w$ , and at a given  $u$ , the value of  $K_{seismic}$  decreases proportionally with  $(k_h)_w$ .

Equilibrium state is obtained at the intersect of the two relationships for given values of  $k_h$  and  $(k_h)_w$ , such as point S under the static condition and point A at a seismic condition, Fig. 4.10a. With the values of  $k_h$  and  $(k_h)_w$  cyclically changing proportionally to each other and ignoring any phase difference between them, a linear relationship between  $K_{seismic}$  and  $u$  at equilibrium is then obtained, such as ASB in Fig. 4.10a. Similar relationships under different conditions are obtained as schematically shown in Fig. 4.10b. The slope  $\theta$  of the relationship is controlled by the values of  $\alpha$ ,  $\beta$  and the wall mass  $M_w$  among others. That is, the rate of increase in the seismic earth pressure with the increase in  $k_h$  and

$(k_h)_w$  (i.e., with the increase in  $u$ ) becomes larger, or the positive slope  $\theta$  becomes larger, as;

- a) the backfill becomes softer; i.e., the absolute value of negative  $\alpha$  decreases;
- b) the subsoil becomes stiffer and the RW becomes more rigid; i.e., the slope  $\beta$  increases; and
- c) the wall mass  $M_w$  decreases.

In this case, the active seismic earth pressure is the largest value during each cycle of dynamic loading. On the other hand, the rate of increase in the seismic earth pressure with the increase in  $k_h$  and  $(k_h)_w$  (i.e., with the increase in  $u$ ) becomes smaller, or the positive slope  $\theta$  becomes smaller, as;

- a) the backfill becomes more rigid ; i.e., the absolute of negative value of  $\alpha$  increases;
- b) the subsoil becomes softer and the RW becomes more flexible; i.e., the slope  $\beta$  decreases; and
- c) the wall mass  $M_w$  increases.

Fig. 4.10 Schematic figures showing the relationships between the dynamic earth pressure coefficient  $K_{seismic}$  and the wall displacement  $u$  with the elastic backfill and subsoil as a) the load and resistance; and b) that at the equilibrium.

In extreme cases, with the increase in  $k_h$  and  $(k_h)_w$  (i.e., with the increase in  $u$ ), the seismic earth pressure decreases, or the value of  $\theta$  becomes negative.

**Cyclic plane strain tests:** Actual backfill soil and subsoil are not linear elastic. Typical hysteretic relationships between “earth pressure  $\sigma_a = \sigma_h$ ” and “lateral strain  $\varepsilon_a = \varepsilon_h$ ” obtained from a cyclic plane strain test on isotropically consolidated Toyoura sand are presented in Fig. 4.11 (n.b., this behaviour is close to that of a  $K_0$  consolidated specimen under otherwise the same conditions, and see Fig. 4.2a for the specimen configuration). The results from two monotonic loading PSC and PSE tests are also plotted in Fig. 4.11 for comparison. The relationship after reversing the loading direction from a given stress state can be inferred from this result, which is essential information when interpreting the cyclically changing earth pressure acting in the backfill in shaking table tests.

Fig. 4.11 Relationships between the axial stress  $\sigma_a$  and the axial strain  $\varepsilon_a$  from cyclic active and passive plane strain tests on Toyoura sand (Yamada et al., 1996).

**Dynamic earth pressure in backfill:**

Based on those shown in Fig. 4.10b and referring to the  $\sigma_h$  and  $\varepsilon_h$  relationships shown in Fig. 4.11, the relationship between  $K_{seismic}$  and  $u$  in one loading cycle when the RW reaction is still linear elastic can be inferred as below. When the wall mass  $M_w$  is relatively small and the wall resistance ( $\beta$ ) is relatively large, such a relationship as shown in Fig. 4.12a may result;

- a) With the increase in  $k_h$  from the static equilibrium state (point 1),  $K_{seismic}$  changes to a value at the seismic active earth pressure state (point 2). Under the pre-peak condition (i.e., before the active failure in the backfill), the rate of increase in  $K_{seismic}$  is decelerated by the effects of increasing  $\phi_{mob}$  with  $u$ , and  $K_{seismic}$  exhibits a relatively small change between points 1 and 2. Under the post-peak condition, on the other hand, the rate of increase in  $K_{seismic}$  is accelerated by the effects of decreasing  $\phi_{mob}$  with  $u$ , and  $K_{seismic}$  exhibits a larger increase. At the residual condition, where  $\phi_{mob}$  is independent of  $u$ ,  $K_{seismic}$  increases due solely to the increase in  $k_h$ .

- b) With the decrease in  $k_h$  from point 2,  $K_{seismic}$  changes to a value at the seismic passive earth pressure state (point 3), but the change may be small due to a decrease in the earth pressure caused by the decrease in  $k_h$ .
- c) With the increase in  $k_h$  from point 3,  $K_{seismic}$  first decreases as the earth pressure decreases at a high rate with the increase in  $u$  under the passive earth condition (see Fig. 4.11). Then,  $K_{seismic}$  exhibits a relatively small change due to an increase in the earth pressure caused by the increase in  $k_h$ .

On the other hand, when the wall mass  $M_w$  is relatively large and the wall resistance ( $\beta$ ) is relatively small, another relationship may be obtained (Fig. 4.12b);

- a) With the increase in  $k_h$  from point 1,  $K_{seismic}$  changes to a value at the seismic active earth pressure state (point 2), but the rate of increase is smaller than it is in the case illustrated in Fig. 4.12a.
- b) With the decrease in  $k_h$  from point 2,  $K_{seismic}$  first decreases or does not change largely due to dominant

Fig. 4.12 Schematic diagrams showing the relationships between the dynamic earth pressure coefficient  $K_{seismic}$  and the wall displacement  $u$  at the dynamic equilibrium; a) when the wall mass  $M_w$  is relatively small and the subsoil resistance is relatively large; and b) when the wall mass  $M_w$  is relatively large and the subsoil resistance is relatively small.

effects of decreasing  $k_h$ , but soon increases at an increasing rate of increase to the seismic passive earth pressure value (point 3) as the effects of decreasing  $u$  on the increase in  $K_{seismic}$  under the passive earth condition becomes larger than those of decreasing  $k_h$  on the decrease in  $K_{seismic}$ .

- c) With the increase in  $k_h$  from point 3,  $K_{seismic}$  first decreases at a very large rate under the passive earth condition, accelerated by large outward inertia of the wall, and then increases at a smaller rate under the active earth condition.

The above consideration suggests that the peak active earth pressure is not necessarily the largest earth pressure in each cycle; even two peaks may appear in one cycle.

Matsuo et al. (1997) measured the earth pressures acting near the back face of the facing and the back face of the geogrid-reinforced Toyoura sand backfill in a shaking table test on a 140 cm-high GRS-RW model (EH3 and EH4 in

Fig. 4.13a). As seen from Fig. 4.13b, the earth pressure EH4 has two peaks in each cycle of shaking. The relationship between the earth pressure EH4 and the table acceleration in a representative cycle is shown in Fig. 4.13c; the numbers 1 to 3 attached to the relationship correspond to those shown in Fig. 4.13b. The largest earth pressure is attained at point 3 at the passive state where the facing is moving inwards and the wall never collapses. The second largest peak, much smaller than the largest one, is attained at point 2 at the active state with the facing moving outwards. The ultimate collapse of the wall may be caused by this type of active earth pressure. The pseudo-static stability analysis for RWs deals with this

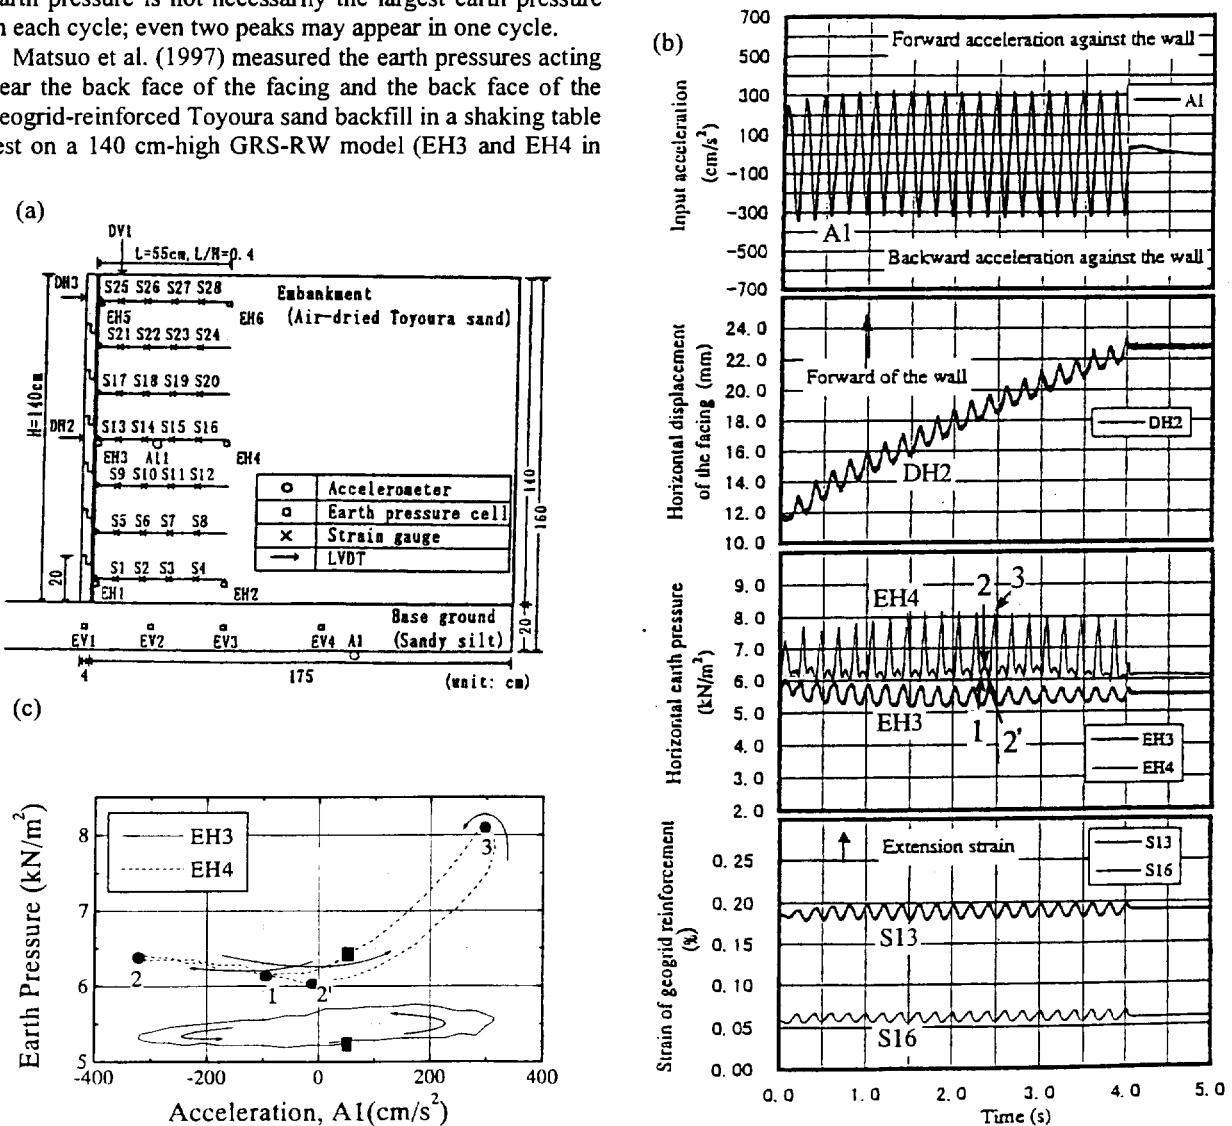

Fig. 4.13 Shaking table tests of GRS-RW model by Matsuo et al. (1997); a) test configuration for case 3; b) time histories at input acceleration of 320 gal; and c) representative hysteretic relationships between the earth pressure and the table acceleration. (A1: input acceleration; EH3 and EH4: earth pressures acting on the facing wall and the back of the reinforced soil; DH2: horizontal displacement; S13 and S16: tensile strain close to the free end and the connected end of the middle-height reinforcement.)

active earth pressure. This result shows that we should be very careful when interpreting earth pressure data from shaking table tests. In some previous cases, it seems that the largest earth pressure in one cycle was incorrectly considered as the dynamic active earth pressure.

The seismic earth pressure acting on the back face of the reinforced zone (EH4) is of the type illustrated in Fig. 4.12b for the case where the wall mass  $M_w$  is relatively large and the wall resistance is relatively low (low  $\beta$ ). These features result from the large mass and flexibility of the massive reinforced backfill zone in the model test.

On the other hand, the earth pressure EH3 shows a very small change in each cycle, having one peak at a moment when the state was changing from passive to active (see Fig. 4.13c). It seems that due to a smaller value of  $\beta$ , despite a smaller value of  $M_w$  of the facing, the behaviour of EH3 became somehow different from the type illustrated in Figs. 4.12a.

There is a noticeable time lag between the moments of peak earth pressure in EH3 and EH4. This phase lag in the reinforced zone helps in increasing the seismic stability of a reinforced soil RW (i.e., part of the dynamic effects). That is, the reinforced and unreinforced zones did not act as a rigid body, and therefore, as seen from Fig. 4.13b, the active earth pressure acting on the facing could be effectively resisted by tensile forces acting in the reinforcement layers. Fukuda et al. (1994) took advantage of this feature in the seismic stability analysis of a GRS-RW (see Fig. 3.8).

## 5. MODIFIED PSEUDO-STATIC APPROACH FOR HIGH SEISMIC LOADS

### 5.1 Seismic active failure process in unreinforced backfill

The progressive process of the seismic active failure in the backfill followed by the ultimate failure of RW discussed in Chapter 4 could be summarized as shown in Fig. 5.1;

1) Stage 1: The initial static equilibrium state I is attained, controlled by many factors such as those indicated in Fig. 4.10a and other construction details such as compaction procedure of backfill. We assume that the state I is attained before reaching the active failure state A in the backfill.

2) Stage 2: With an increase in  $k_h$  from zero to  $(k_h)_A$ , the backfill is subjected to the process of strain hardening, approaching the active failure state A in the backfill with the minimum earth pressure (i.e., the seismic active earth pressure). The angle  $\zeta_f$  of the failure plane that develops by the active failure is equal to " $45^\circ + \phi_{peak}/2 - \Delta\zeta$ ", where the fraction  $\Delta\zeta$  increases with the increase in  $(k_h)_A$ , while it is equal to zero when  $(k_h)_A = 0.0$ .

3) Stage 3: With a further increase in  $k_h$  from  $(k_h)_A$  to  $(k_h)_R$ , the backfill is subjected to strain softening associated with shear banding, approaching the residual earth pressure state R. As discussed before, only a very small wall displacement increment  $\Delta u$  is needed to reach the residual state. The  $\phi_{mob}$  values in the zones outside the shear band also decrease from  $\phi_{peak}$  to some values, but it is by elastic rebound. The possible maximum value of  $\phi_{mob}$  outside the shear band is still  $\phi_{peak}$ . So, unless the seismic active earth pressure arising from the second new failure plane having  $\phi_{peak}$  becomes larger than the earth pressure arising from the first failure plane with  $\phi_{residual}$ , the second failure plane does not develop and the earth pressure is controlled by the first failure plane (see Fig. 5.2).

Fig. 5.1 Progressive process of mobilization of active earth pressure.

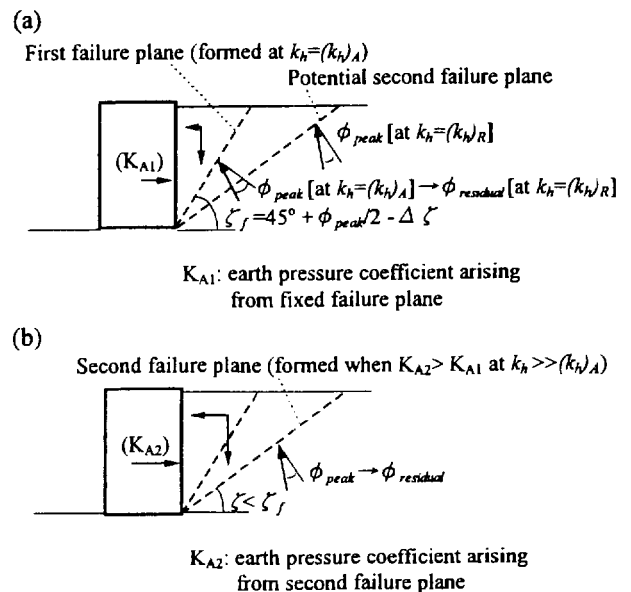

Fig. 5.2 Formation of failure planes considered in the modified method

### 5.2 Modified M-O method for unreinforced backfill (Koseki et al., 1997)

Usually, only a very small wall displacement  $u$  is needed for the active failure to take place in the backfill (about  $0.002 - 0.003 \cdot H$ ). Based on this fact, it is assumed in the modified method that except for the case of a rigid RW structure supported by perfectly rigid subsoil, the seismic active failure occurs in the backfill well before the seismic ultimate failure of the RW. In the conventional pseudo-static approaches including the original M-O method, the direction of failure plane is a function of  $k_h$  for which seismic earth pressure is to be obtained with  $\phi_{peak}$  mobilized along the failure plane. Unlike the above, it is assumed that the failure plane is fixed to the first-developed active failure plane, which is basically independent of  $k_h$ , and both  $\phi_{peak}$  and  $\phi_{residual}$  are used in the analysis. As a result, the fixed failure plane angle  $\zeta_f$  is generally smaller than the one predicted by the original M-O method, the difference decreasing with the increase in  $k_h = (k_h)_A$  at which the active failure plane first develops in the backfill.

Then, the very cumbersome procedure needed in the original M-O method to obtain the maximum earth pressure becomes unnecessary. In the modified method, the value of  $(K_A)_{seismic}$  is obtained by a very simple equation;

$$(K_A)_{seismic} = \left\{ \frac{\tan(\zeta_f - \phi_{residual}) + \tan \theta}{\cos(\zeta_f - \phi_{residual} - \delta)} \right\} \cdot \left\{ \frac{\tan \zeta_f}{\cos(\zeta_f - \phi_{residual} - \delta)} \right\} \quad (5.1)$$

where  $\zeta_f = 45^\circ + \phi_{peak}/2 - \Delta \zeta$ ;  
 $\delta$  = the wall friction angle; and  
 $\tan \theta = k_h$ .

Basically, the value of  $(k_h)_A$  should be determined by considering the deformability of RW system and other relevant factors, but it would not be simple. For practical purposes, the value of  $(k_h)_A$  and the corresponding failure plane angle  $\zeta_f$  may be obtained by the original M-O method using  $\phi_{peak}$ . Then, the value of  $\zeta_f$  decreases as the safety factor  $(F_s)_{static}$  for the static condition increases, since the first active failure occurs at a higher  $(k_h)_A$  as  $(F_s)_{static}$  increases.

Fig. 5.3 compares the relationships between  $(K_A)_{seismic}$  and  $k_h$  for a vertical frictionless RW with level backslope (without  $k_v$ ) obtained by the following three methods;

1. the original M-O method using  $\phi_{peak} = 50^\circ$ ;
2. the original M-O method using  $\phi_{residual} = 30^\circ$ ; and
3. the modified M-O method when  $(k_h)_A$  is equal to zero and 0.2.

In the modified M-O method, as long as using a fixed value of  $\zeta_f$  irrespective of  $k_h$ , the value of  $(K_A)_{seismic}$

Fig. 5.3 Comparison of active earth pressure coefficient between the original and modified M-O methods for  $\phi_{peak} = 50^\circ$ ,  $\phi_{res} = 30^\circ$  and  $\delta = 0^\circ$  (Koseki et al., 1997a).

increases linearly with the increase in  $k_h$ . When the  $k_h$  value becomes a certain value  $k_h^*$ , the value of  $(K_A)_{seismic}$  obtained by the modified M-O method becomes the same with the value obtained the original M-O method using  $\phi_{peak}$ . Then, at the  $k_h^*$  value, the second deeper active failure plane is considered to develop as shown in Fig. 5.2b. The values of  $(K_A)_{seismic}$  at  $k_h$  values higher than  $k_h^*$  should be obtained for the second fixed active failure plane, which becomes larger than the respective value obtained for the first active failure plane. For this reason, each relationship between  $(K_A)_{seismic}$  and  $k_h$  consists of linear segments with discontinuities at the values of  $k_h^*$ . In actuality, the transition from the first active failure plane to the second one (and so on) would be somehow smooth.

The value of  $(K_A)_{seismic}$  at a given  $k_h$  obtained by the modified M-O method is always equal to, or larger than, the value obtained by the original M-O method using  $\phi_{peak}$ , while always smaller than the value obtained by the original M-O method using  $\phi_{res}$ . Therefore, the value of  $(K_A)_{seismic}$  by the modified M-O method does not become very large even at relatively high values of  $k_h$  where the values of  $(K_A)_{seismic}$  by the original M-O method using  $\phi_{res}$  become very large, or even infinite, or not possible to obtain.

Fig. 5.4 shows the relationships between the size of active failure zone, represented by  $L/H = \cot \zeta_f$ , and  $k_h$ , where  $L$  is the size of the failure zone on the crest of

Fig. 5.4 Comparison of the ratio of failure zone length in backfill soil to wall height between the original and modified M-O methods for  $\phi_{peak} = 50^\circ$ ,  $\phi_{res} = 30^\circ$  and  $\delta = 0^\circ$  (Koseki et al., 1997a).

backfill, obtained by the above-mentioned three methods. The size of the active failure zone in the backfill by the modified M-O method is always equal to or smaller than those by the original M-O method using  $\phi_{peak}$  and always considerably smaller than those by the original M-O method using  $\phi_{res}$ . The failure zone size by the original M-O method becomes very deep and long at very high values of  $k_h$ , particularly when using  $\phi_{res}$ , and therefore, the relevant evaluation of the seismic stability of GRS-RWs having short reinforcement becomes very difficult. By the modified M-O method, on the other hand, realistic smaller and shallower failure planes, as observed in the Hyogo-ken-nambu Earthquake (see Fig. 2.6) and in the model tests (Fig. 4.7), are obtained.

As the modified M-O method uses both  $\phi_{peak}$  and  $\phi_{res}$ , it can take into account the effects of initial density of the backfill. On the other hand, in practice, their accurate evaluation would be not simple. In addition, in this method, the seismic active earth pressure is a function of  $(F_s)_{static}$ , which makes this method somewhat more complicated.

### 5.3 Modified two-wedge method for reinforced backfill

A modified two-wedge (TW) method is introduced below, in which the failure mechanism is represented by two wedges as in the conventional TW method to better simulate the seismic active failure in reinforced soil RWs,

particularly those of GRS-RWs having relatively short reinforcement. In the same way as the modified M-O method, the failure plane is basically not  $k_h$ -dependent; the first set of active failure planes with  $\phi_{peak}$  develops at  $(k_h)_A$ , and the seismic earth pressures at  $k_h$  higher than  $(k_h)_A$  are controlled by this first set of active failure plane with  $\phi_{res}$  until the seismic earth pressure controlled by the second set of failure plane with  $\phi_{peak}$  becomes larger.

The seismic active earth pressure coefficient  $(K_A)_{seismic}$  (for the earth pressure acting on the back face of FHR facing) was evaluated by the conventional TW method using either  $\phi_{peak} (= 45^\circ)$  or  $\phi_{res} (= 30^\circ)$  and the modified TW method using both  $\phi_{peak}$  and  $\phi_{res}$  for a typical configuration of GRS-RW (Fig. 5.5a), which was examined by Horii et al. (1994). The values of  $\phi$  used in the three analysis methods are shown in Fig. 5.5b. Fig. 5.5c compares  $(K_A)_{seismic}$  values when the safety factor for either overturning or sliding failure becomes the minimum. In this case, the first set of active failure plane is assumed to develop at  $(k_h)_A = 0.2$ . Note that this  $(k_h)_A$  value was selected rather arbitrarily. Similar to those shown in Fig. 5.3, the modified method yields reasonable earth pressure, which is between those obtained by the conventional TW method using  $\phi_{peak}$  and  $\phi_{res}$ . According to the modified TW method, even the use of short reinforcement layers can increase substantially the seismic stability of GRS-RW at high  $k_h$  values. This feature results from the intersection of many short reinforcement layers with the potential failure planes (Fig. 5.5a).

Fig. 5.5a compares the failure planes evaluated by the different methods when  $k_h = 0.5$ , in which those for unreinforced backfill obtained by the original M-O method using  $\phi_{peak}$  or  $\phi_{res}$  are also shown for comparison. It may be seen that those for the reinforced wall evaluated by the conventional TW method using  $\phi_{peak}$  and  $\phi_{res}$  are similar to the respective one obtained for unreinforced backfill by the original M-O method using  $\phi_{res}$ . On the other hand, the failure zone evaluated by the modified TW method is much smaller, being largely modified by the effects of reinforcement, despite that the reinforcement is generally short. Fig. 5.5d compares the size of the failure zone, where  $L'$  is the total length of the two wedges on the backfill crest. It may be seen that the failure zone evaluated by the modified TW method is considerably smaller, but more realistic, than those obtained by the conventional TW method.

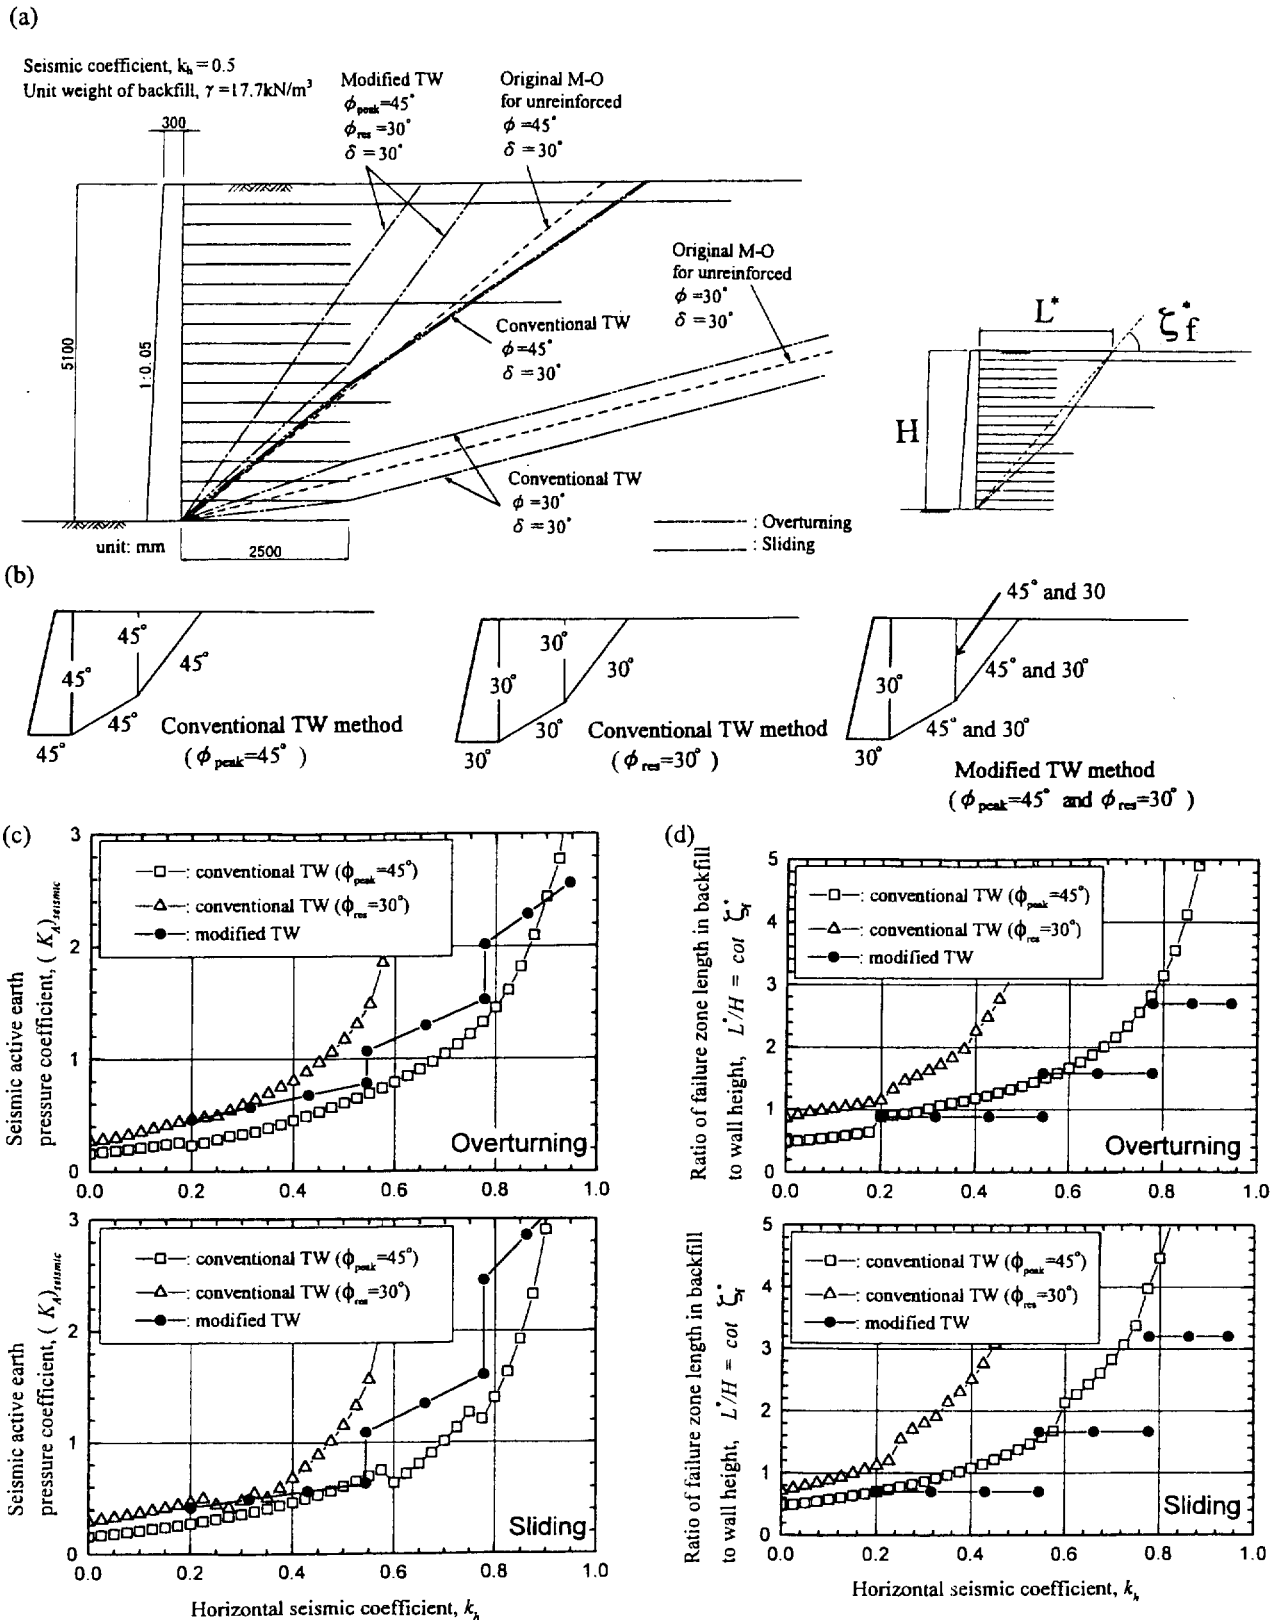

Fig. 5.5 Comparison between the conventional and modified TW methods for  $(k_h)_A = 0.2$ ; a) wall configurations with critical failure planes; b) values of  $\phi$  used in the analysis (the dimensions are not to scale); c) the coefficient  $(K_A)_{\text{seismic}}$  of active earth pressure acting on the facing; and d) ratio of failure zone length in backfill soil to wall height.

Table 5.1 Influencing factors included in different analysis and model testing methods.

		Failure plane for ultimate failure of RW				Dynamic force						
		Location		Shape		Amplification	Non-uniform seismic force	Phase lag in the backfill	Cyclic loading effects	Randomness of cyclic loads	Inclusion of vertical component	
		$k_h$ -dependent with a constant $\phi$	Fixed with $\phi_{res}$	Straight	Compound							
Analysis	M-O for unreinforced backfill	Original	Yes for any $k_h$	No	Yes	No	No	No	No	No	No	Possible
		Modified	Yes for the first failure	Yes	Yes	No	No	No	No	No	No	Possible
	Two-wedge for reinforced backfill	Conventional	Yes for any $k_h$	No	Yes	Yes	No	No	No	No	No	Possible
		Modified	Yes for the first failure	Yes	Yes	Yes	No	No	No	No	No	Possible
Model tests	Tilting tests		Perhaps yes for the first failure	Perhaps yes	Yes	Yes	No	No	No	No	No	No
	Shaking table tests	Uniform waves	Perhaps yes for the first failure	Perhaps yes	Yes	Yes	Yes	Yes	Yes	Yes	No	Possible
		Irregular waves	Perhaps yes for the first failure	Perhaps yes	Yes	Yes	Yes	Yes	Yes	Yes	Yes	Possible
	Actual seismic loads		Perhaps yes for the first failure	Perhaps yes	Yes	Yes	Yes	Yes	Yes	Yes	Yes	Yes

Note: "Yes" does not mean that the behaviour is exactly the same with that in each specific seismic event.

#### 5.4 Discussions on the modified pseudo-static approach

Among a number of the influencing factors for the seismic behaviour of GRS-RWs, Table 5.1 summarized the three major influencing factors; a) failure plane; b) soil strength; and c) dynamic force. It may be noted from Table 5.1 how better or poorly each analysis or model test method can simulate the actual seismic behaviour of GRS-RW. Shaking table tests using random loads could be better than those using uniform cyclic loads, and the latter could be better than pseudo-static analyses and tilting tests. It should be noted, however, that even 'yes' in this table does not necessarily mean that that particular analysis or model test method can simulate satisfactorily that factor involved in the actual behaviour of each specific GRS-RW subjected to specific seismic loads. The use in design of very sophisticated numerical analyses and model tests can be justified when nearly all the influencing factors are properly and sufficiently considered. In other words, simplified pseudo-static approaches could be still a useful engineering tool if they can reflect as better as possible the actual behaviour (such as the failure mode) and they use proper design soil strength values and seismic loads in a balanced way while taking into account the dynamic effects on the RW behaviour.

The modified TW method proposed above to evaluate seismic earth pressure in reinforced soil RWs cannot

simulate many dynamic aspects involved in the actual seismic behaviour of GRS-RWs. In particular, it is the case when it is assumed that  $k_h$  is uniformly distributed in the backfill without amplification and phase difference. Yet, the modified TW method can simulate the failure mode and earth pressure in the reinforced backfill subjected to high  $k_h$  values much better than the conventional TW method, particularly that using conservative soil strength. Similarly, the modified M-O method is more suitable for unreinforced backfill than the original M-O method.

At present, the field cases and the model tests which have been presented in this report have not been analyzed by the modified pseudo-static approach proposed above. This study is now being under way, and the results will be reported by the authors in the near future.

## 6. ULTIMATE FAILURE OF GRS-RWs

### 6.1 Ultimate failure observed in the field and model tests

Before considering a relevant aseismic design method for GRS-RWs to survive high seismic loads, observed ultimate failure of GRS-RWs will be reviewed.

Fig. 6.1 shows the relationships between the observed seismic coefficient  $(k_h)_{cr}(obs)$  and the calculated values

Fig. 6.1 Comparison of observed critical seismic coefficients  $(k_h)_{cr}(obs)$  to calculated values  $(k_h)_{cr}(cal)$  obtained following the conditions listed in Table 3.2 for RWs that experienced extra-ordinary high seismic loads during the 1995 Kobe Earthquake (Koseki et al., 1997).

$(k_h)_{cr}(cal)$  obtained by following the condition B shown in Table 3.2 (see also Table 3.3). Each  $(k_h)_{cr}(obs)$  value was plotted against a common PGA/g value, which was assumed to be equal to 0.7 and the same for these RWs. The upward arrows mean that the RWs were slightly damaged, thus the actual  $(k_h)_{cr}(obs)$  values for ultimate failure should be larger than the PGA/g value. The data points without arrows mean that the RWs were moderately damaged (albeit some deformation and displacement occurred), while the downward arrows mean that the RWs totally collapsed, implying that the actual  $(k_h)_{cr}(obs)$  values should be smaller than the PGA/g value. This result suggests that the ratios  $(k_h)_{cr}(obs)/(k_h)_{cr}(cal)$  is not the same among these RWs, which is likely to be larger in the order of; 1) the GRS-RW having a FHR facing at Tanata; 2) the cantilever RC RWs at Rokko-michi and Ishiyagawa; and 3) the gravity-type RWs at Ishiyagawa and the leaning-type RW at Sumiyoshi (particular the latter) (n.b., the cantilever RC RW at Tanata is not discussed herein, because this is not a usual case; the RW was supported by a temporary cofferdam in front of the wall at the time of the earthquake). This result suggests that the design value  $(k_h)_{design}$  should be different among different types of RW; under otherwise the same conditions, the value of  $(k_h)_{design}$  could be smaller for the GRS-RW.

As the amount of the field data is not sufficient, the data from the tilting and shaking table model tests, described in Figs. 4.6, 4.7 and 4.8, were analyzed. As the failure mode observed in all the tests was overturning, the results were first analyzed for this failure mode. Fig. 6.2a shows relationships between the critical seismic coefficients  $(k_h)_{cr}(cal)$  yielding a safety factor of unity against overturning obtained by the original M-O method and the

conventional TW method (Horie et al., 1994) and the observed seismic coefficients  $(k_h)_{cr}(obs)$ . For the pseudo-static analyses,  $\phi_{peak} = 51^\circ$  was used, obtained from PSC tests at  $\delta = 90^\circ$  at low confining pressures using the backfill of air-dried Toyoura sand. The wall friction angle  $\delta$  at the interface between the rough back face of the wall and the backfill was set  $3/4 \phi (= 38^\circ)$ . For the cantilever type RW, the angle of friction was set equal to  $\phi_{peak}$  along the vertical failure plane starting from the heel of the base part of the RW. For the GRS-RWs, the bearing capacity was evaluated for the facing base having a width of 3 cm, ignoring the surcharge effects of the backfill. The allowable vertical load at the facing base was set to the bearing capacity as obtained above, then the limit equilibrium for overturning was sought. As seen from Fig. 6.2a, for many of the data points, from the tilting tests,  $(k_h)_{cr}(obs)$  is much smaller than  $(k_h)_{cr}(cal)$ . This is likely due to;

- a) the effects of progressive active failure in the backfill were not considered by using  $\phi_{peak} = 51^\circ$ ; and
- b) the overturning failure could have been triggered by bearing capacity failure in the subsoil, which should have taken place before the safety factor for overturning failure obtained not considering the bearing capacity failure became unity. This infer is supported by the measured earth pressure on the base of the model.

Fig. 6.2b shows relationships between whichever the smaller value of  $(k_h)_{cr}(cal)$  yielding a safety factor of unity, against either overturning or bearing capacity failure, obtained by the original M-O method and the conventional TW method using  $\phi_{peak}$  and the observed seismic

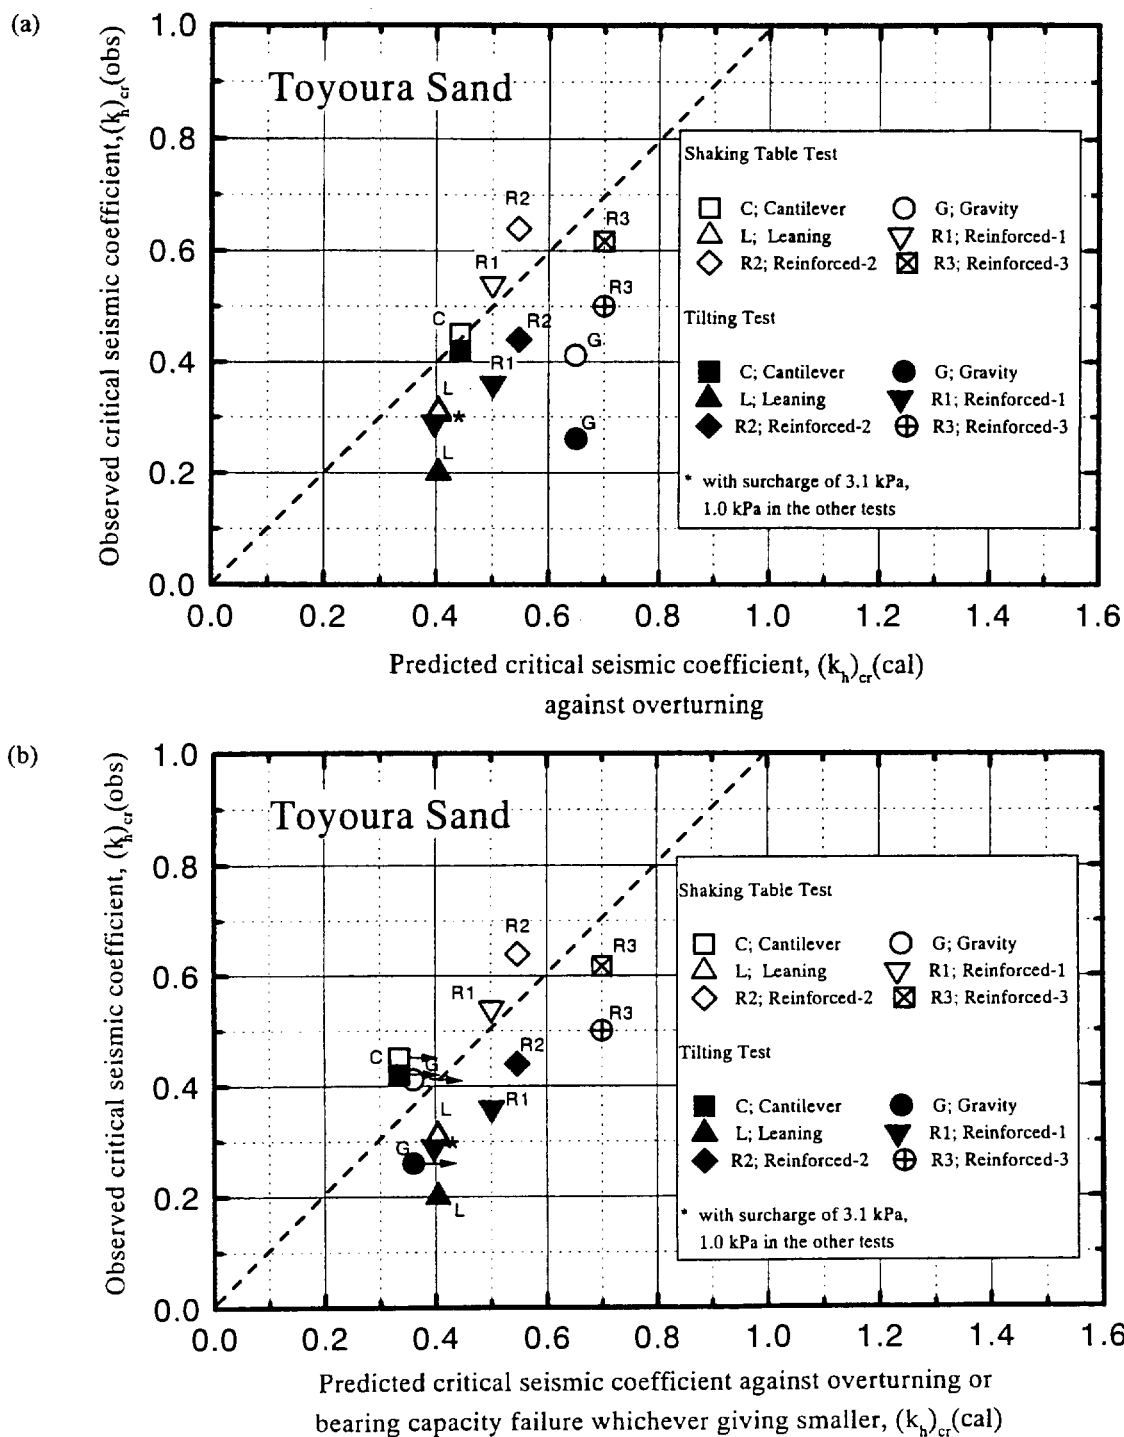

Fig. 6.2 Comparison of observed critical seismic coefficients  $(k_h)_{cr}(\text{obs})$  with predicted values  $(k_h)_{cr}(\text{cal})$  from tilting and shaking table tests of model RWs (Koseki et al., 1997).

coefficients  $(k_h)_{cr}(\text{obs})$ . For the GRS-RWs, the bearing capacity at the facing base has been taken into account for the data shown in Figs.6.2a and 6.2b. In so doing, the ultimate failure of RW due to the bearing capacity failure

has not been considered, since the wall can maintain its stability even when the load acting at the bottom of the facing reaches the bearing capacity of the subsoil, as demonstrated by a large-scale shaking test on a model of

GRS-RW (Murata et al., 1994). Lower  $(k_h)_{cr}(cal)$  values were obtained for bearing capacity failure with the cantilever and gravity-type RWs. The bearing capacity was evaluated assuming the subsoil thickness be sufficient to cause boundary-free subsoil failure despite that the actual thickness of the Toyoura sand layer was only 20 cm. Therefore, the safety factors against bearing capacity failure may have been somehow under-estimated. In Fig. 6.3b, this infer is indicated by arrows directing right shown next the data points for the cantilever and gravity-type RWs. The following trends may be seen from Fig. 6.2b:

1) The base width is the same, equal to 23 cm, among the gravity-type and cantilever RWs and the GRS-RW type 1 (see Fig. 4.7). The base width is 18 cm with the leaning-type RW, whereas the width between the top of the back face and the toe of the base is wider, equal to 33 cm. Despite the above, in the tilting tests, the GRS-RW type 1 and the cantilever RW have larger values of  $(k_h)_{cr}(obs)$  than the leaning-type and gravity-type RWs. In the shaking table tests, the GRS-RW type 1 is noticeably more stable than the others. This results are in a broad sense consistent with the full-scale field behaviour as shown in Fig. 6.1, suggesting a relatively high seismic stability of GRS-RWs having a FHR facing.

2) In the tilting tests, the ratio  $(k_h)_{cr}(obs)/(k_h)_{cr}(cal)$  is generally lower than unity (except for the cantilever RW). This result suggests that the conventional pseudo-static approaches using peak plane strain soil strength obtained when the  $\sigma_1$  direction is normal to the bedding plane direction over-estimate the stability of RW.

3) In the shaking table tests; the ratios  $(k_h)_{cr}(obs)/(k_h)_{cr}(cal)$  are generally larger than unity, except for the leaning type RW, and different among the different RWs. This fact corresponds to; a) the observation in Fig 4.8 that in the shaking table tests, at the same  $(k_h)_{cr}$ , the failure plane angles  $\zeta_f$  observed in the unreinforced backfill are generally larger than those predicted by the original M-O method using  $\phi_{peak}$ ; and b) that in the shaking table tests, the ultimate failure of RW took place at  $k_h$  noticeably larger than the value where the active failure started in the backfill, and the difference depended on the RW type. The difference can be considered to be due to the dynamic effects. It is to be noted that  $(k_h)_{cr}(cal)$  values that are smaller than those shown in Fig. 6.2a are obtained when evaluated by the modified pseudo-static methods proposed in this report, giving larger ratios  $(k_h)_{cr}(obs)/(k_h)_{cr}(cal)$ . In that case, larger dynamic effects are evaluated.

4) In the shaking table test results, the ratios  $(k_h)_{cr}(obs)/(k_h)_{cr}(cal)$  (shown in Fig. 6.2b) for the GRS-RW type 1 is similar to that for the cantilever RW, marginally larger than that for the gravity-type RW, and noticeably larger than that for the leaning-type RW. This trend is similar to that of the difference at a given  $(k_h)_{cr}(obs)$  value

between the measured value of  $\zeta_f$  and that predicted by the original M-O method using  $\phi_{peak}$  (shown in Fig. 4.8). The shaking table test results shown in Fig. 6.2 are, in a broad sense, consistent with the field full-scale behaviour of several representative types of RW which experienced extra-ordinary high seismic loads during the Hyogo-ken-nambu Earthquake (see Fig. 6.1). These results also suggest that the design values  $(k_h)_{design}$  to be used in the pseudo-static analysis should be different, being smaller in the order of i) GRS-RWs having a FHR facing, ii) RC RWs, and iii) leaning and gravity-type RWs.

5) In the shaking table tests, the value of  $(k_h)_{cr}(obs)$  is largest for the GRS-RW type 2 having a couple of long reinforcement layers at high levels in the backfill. As seen from Fig. 4.7a, in this model, multiple failure planes developed; the one numbered 1, which was steepest, developed first from the heel of the backfill zone reinforced with short reinforcement layers and stopped somewhere below the lowest longer reinforcement layers: then, the other two numbered 2 and 3 developed, which were inclined much more horizontally, and developed up to the crest of the backfill. On the other hand, the value of  $(k_h)_{cr}(obs)$  is marginally smaller for the GRS-RW type 3 having the moderately long same-length reinforcement layers than Reinforced type 2, while the total amount of reinforcement was similar. When reconstructing existing slopes to vertical GRS-RWs, the use of relatively short reinforcements is preferred, because the amount of slope excavation can be minimized. Based on the test result described above, using several long reinforcement layers at high levels as the model Reinforced type 2 can be recommended to effectively increase the seismic stability of GRS-RWs having a FHR facing, compared with the GRS-RW type 1.

6) In the shaking table tests, after the first active failure occurred in the backfill, the  $k_h$  value could increase to a higher level until the ultimate failure of RW took place, exhibiting larger positive net dynamic effects, in the order i), ii) and iii) listed in the term 4). It seems that the modified M-O method and the modified TW method are more relevant for aseismic design of RWs exhibiting larger positive net dynamic effects when subjected to high seismic loads.

## 6.2 Dynamic effects

Different ratios of "design  $k_h$ "/(PGA/g) have been proposed for different types of foundation structures and RWs, which include the following:

1) By comparing the seismic behaviour of port and harbor gravity-type caissons placed on underwater mounds with their  $k_h$  values calculated following the design specification, Noda et al. (1975) obtained the following relationship;

$$(k_h)_{critical} = \text{PGA/g} \quad (\text{PGA} \leq 200 \text{ gals}) \quad (6.1a)$$

$$(k_b)_{critical} = (1/3)(PGA/g)^{1/3} \quad (PGA \geq 200 \text{ gals}) \quad (6.1b)$$

When following this relationship,  $(k_b)_{critical} = 0.2, 0.246, 0.281, 0.309$  and  $0.333$  are obtained when  $PGA/g = 0.2, 0.4, 0.6, 0.8$  and  $1.0$ .

- 2) Seed and Whitman (1970) proposed a value of 0.85 for retaining walls and bridge abutments against significant wall displacements.
- 3) The design manual guidelines for Terre Armee RWs of FHWA (FHWA 1990) employs the following relationship to evaluate the maximum wall acceleration coefficient  $\alpha_m$  based on the maximum ground acceleration coefficient  $\alpha_0$ ;

$$\alpha_m = (1.45 - \alpha_0) \alpha_0 \quad (6.2)$$

Note that the horizontal inertia force of the reinforced backfill is reduced by half to consider the effects of phase lag as mentioned in 3. When following this relationship,  $(k_b)_{critical} = 0.25, 0.42, 0.51, 0.52$  and  $0.45$  are obtained when  $PGA/g = 0.2, 0.4, 0.6, 0.8$  and  $1.0$ .

These ratios  $(k_b)_{critical}/(PGA/g)$  are much lower than unity at high  $k_b$  values, which is seemingly due largely to the following three factors;

- a) underestimation of the soil strength used in evaluating the seismic stability of structure in terms of  $k_b$  to be compared with  $PGA/g$  (as in ordinary design procedures);
- b) simplifications in the design procedure leading to a safe side result such as that the passive pressure on the front face of the underground part of RW is ignored (but this could actually largely contribute to the seismic stability of actual RWs); and
- c) factors related to the so-called dynamic effects.

As seen from Figs. 4.8 and 6.2b, for the relatively

ductile RWs (i.e., the GRS-RWs), the value of  $(k_b)_{cr}(obs)$  is larger than the corresponding value in the tilting test. This feature is likely due to that the net dynamic effects were positive. The following factors are important for the so-called dynamic effects on the seismic behaviour of RWs;

- 1) dynamic ductility of RW, which is the capability of the RW to survive “accelerations/g” exceeding the pseudo-static ultimate strength  $(k_b)_{critical}$  by deforming without exhibiting seismic ultimate failure; this factor makes the structure more stable;
- 2) flexibility (or rigidity) of RW, resulting into the following three sub-factors;
  - a) phase difference in the lateral direction in the backfill, which usually increases with the RW flexibility, making also the RW more stable;
  - b) the coefficient  $\beta$  in Fig. Fig. 4.10a; for example, cantilever RC RWs, particularly those supported pile foundations, are rigid having a high value of  $\beta$ , resulting into higher seismic active pressure, while GRS-RWs are flexible having a low value of  $\beta$ , resulting into lower seismic active pressure; and
  - c) dynamic response of the structure, usually giving larger accelerations in the backfill than at the ground surface; this factor makes the RW less stable.

Related to the above factors 2a, 2b and 2c, in any shaking table test, the response acceleration, or dynamic amplification, is not uniform in both vertical and lateral directions, as typically seen from Fig. 6.3.

The difference in the  $(k_b)_{critical}$  value between shaking table and tilting tests using the same model should become

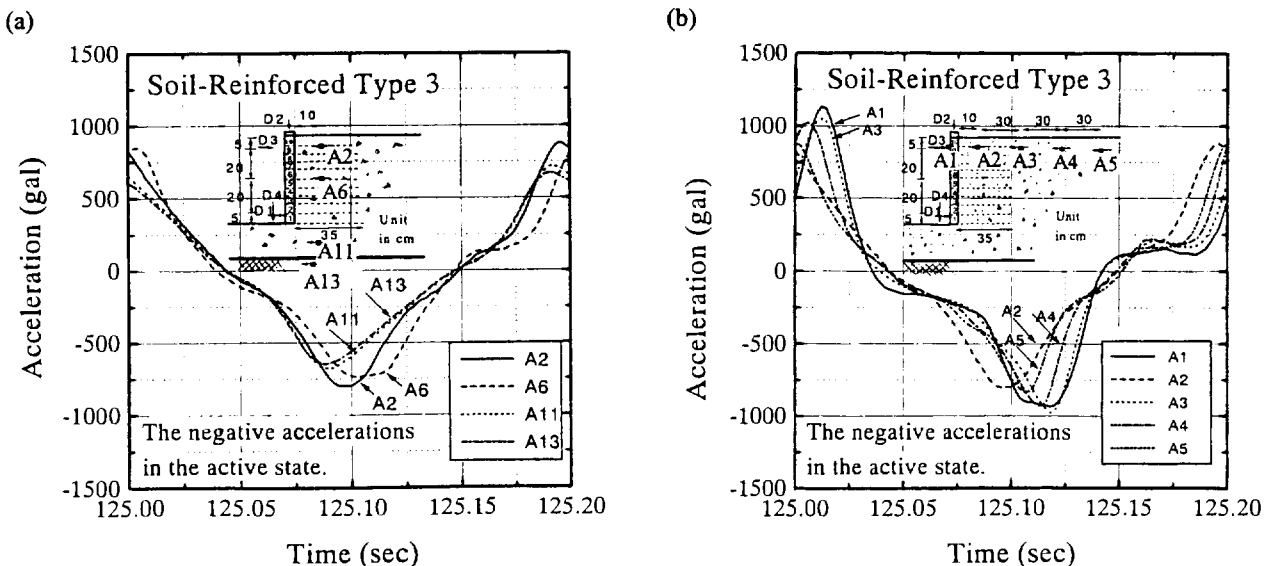

Fig. 6.3 Typical shaking table test of GRS-RW model (“Reinforced type 3”) performed by the authors; a) comparison of response horizontal accelerations in the vertical (A2, A6, A11 and A13); and b) lateral (A1 to A5) directions, at input acceleration of about 600 gal.

larger when the shaking table test uses random cyclic loads with the value of  $(k_h)_{critical}$  being defined as "the maximum table horizontal acceleration"/g at ultimate failure. For example, in the shaking table tests on the same type GRS-RW model having a discrete panel facing reported by Matsuo et al. (1997), the model wall failed by excessive outward deformation at a peak acceleration equal to 464 gals when the N-S component recorded at the Kobe Maritime Observatory during the 1995 Hyogo-ken-nambu Earthquake was used as the input random loads and at a single amplitude acceleration equal to 370 gals when twenty uniform sinusoidal waves were used as the input cyclic loads.

By using the cumulative damage theory, Murata et al. (1990) estimated the deformation of the GRS-RW having a FHR facing when subjected to a random cyclic loading based on the behaviour of the wall when subjected to uniform cyclic loadings at different acceleration levels. The procedure is similar to the one used for estimating the liquefaction strength of saturated sand when subjected to random seismic cyclic stresses based on the results obtained when subjected to uniform cyclic stresses (e.g., Tatsuoka et al., 1986). It was suggested by Murata et al. (1990) that for a given maximum input acceleration, the deformation of the model wall becomes much smaller when subjected to an irregular input motion than when subjected to a uniform motion, and the difference becomes larger as the number of cycles in the uniform motion increases, as the irregular motion becomes of more shock-type and as the RW becomes more dynamically ductile (i.e., factor 1 above).

### 6.3 Design $k_h$ values

The design value of  $k_h$ ,  $(k_h)_{design}$ , to be used in any pseudo-static analysis should reflect the fact that effects of the influencing factors, as listed in Table 6.1, are not perfectly, or are only poorly, reflected in the analysis. Therefore, the proper ratio of  $(k_h)_{design}$  to the PGA/g of the design seismic load should depend on, at least, the following six factors;

- 1) the analysis method (e.g., the original M-O method and the conventional TW method using either peak or residual soil strength, or the modified M-O method and modified TW method using both peak and residual soil strengths);
- 2) the ratio of the design soil strength to the true operating soil strength;
- 3) positive effects of simplification used in the design (e.g., no consideration of passive pressure on the front face of the underground part of facing);
- 4) the seismic ductility of RW, which depends on structure type (e.g., masonry, gravity, leaning, cantilever, or reinforced soil);- this factor is linked to the objective of aseismic design, which is different for Levels 1 and 2 seismic loads, as discussed before;

- 5) the seismic flexibility or rigidity of RW, which also depends on structure type and affects the dynamic response of RW; and
- 6) the global safety factor used in the aseismic design, which is usually 1.5 for RWs in Japan.

In the following, only design methods for Level 2 design seismic loads will be considered. Fig. 3.9 shows the values of  $(k_h)_{cr}(cal)$  giving the safety factor equal to unity for several RWs which experienced extra-high seismic loads during the 1995 Hyogo-ken-nambu Earthquake. These  $(k_h)_{cr}(cal)$  values were obtained by the conventional pseudo-static analyses (i.e., the original M-O method for the conventional type RWs and the conventional TW method for the GRS-RW) under the following two different conditions (see Table 3.3);

- A) the conventional design conditions using conservative soil strength (condition A; Table 3.1); and
- B) the conditions as close as the respective actual condition, while using peak soil strength (condition B; Table 3.2).

For all the data points, the estimated value of PGA/g is assumed to be 0.6 - 0.8 with an average of 0.7. As discussed before, to attain reasonable seismic stability, with a global safety factor equal to unity, the design value  $(k_h)_{design}$  should be larger than the value of  $(k_h)_{cr}(cal)$  for the collapsed types of RW, could be similar to the values of  $(k_h)_{cr}(cal)$  for the moderately damaged but uncollapsed types of RW, and could be smaller than the values of  $(k_h)_{cr}(cal)$  for the slightly damaged types of RW (note; for the cantilever RC RW at Tanata, this notion is valid only under the condition of the presence of the coffer dam in front of the wall, but it is not usual case and will not be discussed herein).

The following remarks are important:

- a) When based on the conventional pseudo-static analyses (i.e., the original M-O method for the conventional types of RW and the conventional TW method for GRS-RWs, both using conservative soil strength), the value of  $(k_h)_{cr}(cal)$  was 0.10 for bearing capacity failure leading to overturning failure with the gravity type unreinforced concrete RW at Ishiyagawa and 0.09 for overturning failure with the leaning type unreinforced concrete RW at Sumiyoshi, both of which totally collapsed. These results suggest that for masonry RWs and leaning and gravity types unreinforced concrete RWs, even when based on the conventional pseudo-static analyses using conservative soil strength, the use of  $k_h$  equal to 0.1 - 0.2 is unconservative for Level 2 design seismic load. Obviously, the design value  $(k_h)_{design}$  should be increased to a level much higher than 0.1 - 0.2, whereas it would be lower than, but a large fraction of, PGA/g of Level 2 seismic load (about 0.7- 0.8).
- b) When based on the conventional pseudo-static analyses using peak soil strength, the value of  $(k_h)_{cr}(cal)$  was 0.34

with the gravity type RW at Ishiyagawa and 0.48 for overturning failure with the leaning type RW at Sumiyoshi. Therefore, the use of  $(k_h)_{design} = 0.1 - 0.2$  in the conventional pseudo-static analyses using peak soil strength is more unconservative than the current design method using conservative soil strength and therefore never be acceptable.

c) It is to be noted again that these values of  $(k_h)_{cr}(cal)$  were back-calculated with an operating safety factor equal to unity. On the other hand, the allowable safety factor employed in the current aseismic design in Japan is typically 1.5. Part of the fraction 1.5 is considered to be assigned to uncertainties of load, and a lower allowance for uncertainties in the load is acceptable considering that the Level 2 seismic load is nearly the possible upper-bound design seismic load. Then, the suitable design value  $(k_h)_{design}$  can be set to be, say, 0.9 times the value of  $(k_h)_{cr}(cal)$  by which a given type of RW is moderately damaged but does not collapse with an operating safety factor equal to unity.

d) For the cantilever RC RWs, which were moderately damaged, when based on the conventional pseudo-static analyses using conservative soil strength, the values of  $(k_h)_{cr}(cal)$  was 0.36 and 0.40 for bearing capacity failure with the two cantilever RC RWs at Ishiyagawa and 0.45 for bearing capacity failure with the cantilever RC RW at Rokko-michi. This result suggests that the use of  $(k_h)_{design} = 0.1 - 0.2$  in the conventional pseudo-static analyses using conservative soil strength is also unconservative. However, the appropriate design value  $(k_h)_{design}$  should be smaller than that for masonry RWs and leaning type and gravity type unreinforced concrete RWs. A value between  $0.35 \times 0.9 \cong 0.3$  and  $0.45 \times 0.9 \cong 0.4$  would be appropriate. Perhaps, this value is appropriate also for modern RC RWs supported by a pile foundation.

e) For the cantilever RC RWs, when based on the  $(k_h)_{cr}(ob)$  values = 0.45 - 0.60 that were obtained by using peak soil strength, a value of  $(k_h)_{design}$  is around  $(0.45 - 0.60) \times 0.9 \cong 0.5$  would be appropriate.

f) For the Tanata GRS-RWs having a FHR facing, which was damaged only slightly, when based on the conventional pseudo-static analyses using conservative soil strength, the values of  $(k_h)_{cr}(cal)$  was 0.36 for base sliding. It seems that the use of  $(k_h)_{design}$  equal to 0.1 - 0.2 is unconservative, and a design value around  $0.35 \times 0.9 = 0.3$  or less would be appropriate. When based on peak soil strength, a value of  $(k_h)_{design}$  which is around  $0.5 \times 0.9 = 0.45$  would be appropriate.

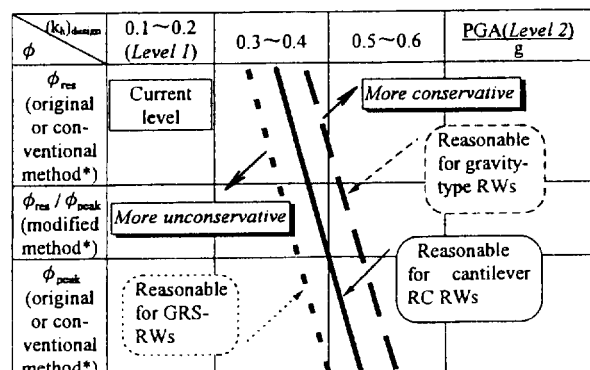

g) Summarizing the above, when based on the conventional pseudo-static analyses using conservative soil strength,  $(k_h)_{design}$  equal to 0.4, 0.35 and 0.3 would be appropriate for, respectively, a) masonry RWs and leaning

type and gravity type RWs, b) properly designed and constructed RC cantilever RWs and c) GRS-RWs having a FHR facing. This proposed classification is supported by the shaking table model test results shown in Figs. 4.8 and 6.2b.

h) If the conventional pseudo-static analyses using peak soil strength is employed, the design value  $(k_h)_{design}$  should be larger than those shown above;  $(k_h)_{design} = 0.55, 0.50$  and 0.45 would be appropriate for, respectively, a) masonry, leaning type and gravity type RWs, b) properly designed and constructed RC cantilever RW and c) GRS-RWs having a FHR facing.

i) When based on the modified pseudo-static approach proposed in this report, the  $(k_h)_{design}$  value would become higher than those used with the conventional pseudo-static analyses using conservative soil strength, becoming closer to the Level 2 PGA/g value (about 0.7). Considering that the failure mechanism can be better simulated, the use of the modified pseudo-static approach can be suggested for the aseismic design of GRS-RWs, particularly those having a FHR facing with relatively short reinforcement.

Based on the above and others, Fig. 6.4 was prepared. The design values  $(k_h)_{design}$  which are tentatively proposed for Level 2 seismic loads, are indicated by the three inclined lines, which are respectively for a) GRS-RWs having a FHR facing; b) cantilever RC RWs; and c) masonry, gravity and leaning types of RWs. Along each line, the value of  $(k_h)_{design}$  becomes smaller in the order of; a) the original M-O method and the conventional TW method using conservative soil strength; b) the modified M-O method and TW method using both peak and conservative soil strengths; and c) the original M-O method and the conventional TW method using peak soil strength.

\* The M-O method or the two-wedge method, depending on the soil structure type.

Fig. 6.4 Interrelations between seismic load (in terms of  $k_h$  or PGA/g), analysis method, structure type and seismic behaviour for Level 2 design load (tentative proposal).

6.4 Other important issues

**Effects of reinforcement length:** As discussed before, in the shaking table model tests described in Figs. 4.8 and 6.2, the GRS-RW having relatively long reinforcement (Reinforced type 3) was more stable than the GRS-RW having relatively short reinforcement (Reinforced type 1). In addition, the failure acceleration of the GRS-RW increased from 530 gals to 650 gals for over-turning failure by extending only a couple of top reinforcement layers (i.e., Reinforced type 2). Also in the shaking table tests on 100 cm-high grid-reinforced sand RW models performed by Murata, et al. (1990, 1992)(Fig. 6.5), under otherwise the same conditions, the GRS-RW model having longer reinforcement (case 2) was more stable than that having shorter reinforcement (case 1). This increase in the stability was attained by preventing the active failure plane starting from the heel of the reinforced zone to develop up to the backfill crest.

These results suggest that a shear band or failure plane is difficult to develop crossing reinforcement. Therefore, it is not relevant to always assume a single wedge to develop in reinforced backfill as in the unreinforced backfill. In particular, when based on the original M-O method using conservative soil strength assuming a single wedge, a very deep and largely inclined failure plane is predicted at a high  $k_b$  (see Fig. 5.5a); in that case, only one or two layers of short reinforcement can intersect with this failure plane, which may result into a design using long reinforcement layers from the bottom level. The modified TW method can properly evaluate the relatively high seismic stability

of the GRS-RW having short reinforcement at lower levels in the backfill.

On the other hand, in the shaking table model tests on 100 cm-high models of vertical GRS-RWs having a discrete panel facing with reinforcement layers truncated to the same length performed by Matsuo et al. (1997) (see Fig. 4.13), the failure acceleration increased from 370 gals to 575 gals by increasing the length of reinforcement from  $L/H= 0.4$  to  $0.7$  under otherwise the same testing conditions. This test result is consistent with the shaking test results described above.

**Effects of facing rigidity:** The following trends of behaviour have been observed in the shaking table model tests of GRS-RWs with sand backfill (described so far in this report):

a) When the reinforcement was relatively short, such as  $L/H= 0.4$ , with a FHR facing, the predominant failure mode is overturning (Matsuo et al., 1997; Koseki et al., 1997).

b) In the tests on a 100 cm-high grid-reinforced sand model wall performed by Matsuo et al. (1997), under otherwise the same model configurations, when the facing was of discrete panels, the predominant failure mode was sliding with a failure plane passing inside the reinforced zone, resulting into a bulging deformation of the wall face.

c) In the tests by Matsuo et al. (1997), the effect of facing rigidity on the failure acceleration was small; the failure acceleration was 370 gals for a GRS-RW model having a discrete panel facing and 397 gals for a GRS-RW model having a FHR facing. It seems that this small difference

Case	Facing	NRL*	LR**	Slope of wall face	Note
1	One unit	10	40	Vertical	Standard
2	One unit	10	60	Vertical	Longer reinforcement
3	One unit	10	40	1:0.1(V:H)	Inclined facing
4	One unit	5	40	Vertical	Smaller NRL
5	Discrete	10	40	Vertical	Less rigid facing

\* NRL: Number of reinforcement layers.  
 \*\* LR: Length of reinforcement (in mm).

Fig. 6.5 Shaking table tests of GRS-RW models by Murata et al. (1992); a) test configuration; and b) relationships between table horizontal acceleration and outward displacement of wall.

resulted from that the stability of the GRS-RW having a FHR facing was relatively low. This was due likely to; a) relatively small pull-out resistance of the grid reinforcements resulting from; b) relatively short reinforcement length,  $L = 0.4H$ , with a relatively large vertical spacing  $S_v$  of reinforcement layers, 20 cm or  $S_v/H = 0.2$ ; and c) a low density of the backfill ( $D_r = 60\%$ ). On the other hand, in the shaking table tests presented in Fig.6.5, under otherwise the same conditions, the GRS-RW model having a FHR facing (case 1) was much more stable than that having a discrete panel facing (case 5), despite that the ratio of the reinforcement length to the wall height was  $L/H = 0.4$  as the tests by Matsuo et al. (1997). In these tests, the pull-out strength of grid was sufficiently large resulting from a small vertical grid spacing of 10 cm and a high density of the backfill ( $D_r = 94\%$ ). Similar positive effects of using a FHR facing has been observed in the model tests reported by Bathurst and Alfaro (1996), in which the pull-out resistance of geogrid was large enough. It is likely, therefore, that the effects of facing rigidity become more important as the pull-out strength of reinforcement becomes larger; a) by preventing the occurrence of sliding failure having a failure plane passing inside the reinforced zone and appearing at an intermediate height at the wall face; and b) by confining better the backfill adjacent to the facing.

**Effects of vertical acceleration (or  $k_v$ ):** Fig. 6.6 shows the plot of the combination of peak horizontal and vertical components of acceleration obtained from the time histories of acceleration recorded on the ground surface at Kobe Marine Meteorological Observation Station during the 1995 Hyogo-ken-nambu Earthquake. Table 6.2 shows the results of stability analysis of a typical GRS-RW having a FHR facing (see Fig. 2.2a) obtained by the conventional TW method using  $\phi = 41^\circ$  for the backfill. It may be seen that the safety factor for the worst combination with the largest ratio of the outward horizontal acceleration to the upward vertical acceleration along the envelop of the data points is lower by only 1 % than that obtained using only the peak horizontal acceleration. It can be concluded, therefore, that

differences in results between the pseudo-static analyses of reinforced soil structure having a cohesionless soil backfill with and without considering the effects of vertical seismic load components are usually very small. A similar conclusion has been obtained by Bathurst and Alfaro (1996). Therefore, when considering a high degree of uncertainty in other factors, it is not unreasonable not to use vertical component of seismic load in routine aseismic design of reinforced soil structures including GRS-RWs having a FHR facing.

**Evaluation of seismic ductility of RW:** This could be made in a very approximated way by the method introduced in Tatsuoka et al. (1996). In this method, the ductility is evaluated by the area between the curve showing the relationship between the safety factor  $F_t$  and the tilting angle of RW and the horizontal axis implying  $F_t = 0.0$ . However, the ductility could be better evaluated by estimating the deformation and displacement of RW by the method proposed by Newmark (1965) or its modifications, or the equivalent energy method described below, or the cumulative damage method.

Fig. 6.6 Plot of the combination of horizontal and vertical components of acceleration obtained from the time histories of acceleration recorded on the ground surface at Kobe Marine Meteorological Observation Station during the 1995 Hyogo-ken-nambu Earthquake.

Table 6.2 Comparison of calculated critical seismic coefficients ( $k_h$ )<sub>cr</sub>(cal) following the conditions listed in Table 3.2 for GRS-RW at Tanata with or without considering the effects of vertical acceleration.

Calculated critical seismic coefficients ( $k_h$ ) <sub>cr</sub> (cal)	Neglecting effects of vertical acceleration	Considering north component as outward horizontal acceleration and corresponding vertical acceleration	Considering south component as outward horizontal acceleration and corresponding vertical acceleration
Overturning	0.597	0.591	0.626
Sliding	0.502	0.498	0.501

In the Newmark method, the displacement of a monolith during a seismic event is obtained as follows (Fig. 6.7):

1. The critical acceleration beyond which the monolith starts to slide is evaluated by a proper method such as pseudo-static analyses.
2. When the ground acceleration is in excess of the critical acceleration, the monolith is assumed to respond at a constant acceleration equal to the critical acceleration.
3. The residual displacement of the monolith relative to the ground is obtained by simply double-integrating difference between the accelerations of the monolith and the ground until the relative velocity of the monolith becomes zero upon the reversal of the ground acceleration direction.

Cai and Bathurst (1996a, b) and Ling et al. (1997) used this method to evaluate seismic residual lateral outward displacements of GRS-RW. On the other hand, only limited literature can be found on the method to evaluate the seismic overturning of retaining wall. Steedman and Zeng (1996) proposed a method to evaluate seismic rotation by rocking motion of large gravity walls placed on rigid foundations. Siddharthan et al. (1992) proposed a simple rigid plastic model for seismic tilting of rigid walls. Both methods consider both translation and tilting of the wall, and contact pressure on the bottom of the RW is evaluated by the method similar to the one used by the Japanese Railway Company (Haya et al., 1995 and RTRI, 1997). If the center of rotation of RW is assumed to be located near the toe of the wall, only a sliding mode of deformation is likely to occur, while when the center of rotation is located back the toe of the RW, a coupled (sliding and tilting) mode of displacement may result. It was also shown that the effects of the wall-soil friction angle  $\delta_1$  on the wall base be very large on the sliding displacement, while the effects of the wall-soil friction angle  $\delta_2$  on the wall back face be significant on the rotational displacement of the wall; a higher  $\delta_2$  results in a smaller rotational displacement.

The equivalent energy method (Fig. 6.8) has been proposed also by Newmark (1965) to estimate the seismic plastic deformation of a structure. Here,  $\tau_y$  and  $u_y$  are the yielding stress and displacement, and  $\tau_e$  and  $u_e$  are the elastic stress and displacement obtained without considering the effects of yielding. The total displacement  $u_m$ , which includes both the elastic and plastic components, is computed so that the elasto-plastic energy denoted by the total of the areas 1, 2 and 4 becomes equal to the elastic energy denoted by the total of the areas 1, 2 and 3. This method is popular in Seismic Structural Engineering to accommodate very high design seismic loads, such as Level 2, by allowing some plastic deformation of RC and steel structures. It is not certain whether this method is relevant also for soil structures, since they do not have an obvious yielding point. More

detailed discussion is beyond the scope of this short report.

**FEM analyses:** Even the failure of densely compacted unreinforced soil subjected to static loads is very difficult to be simulated by FEM, due mainly to the fact that proper simulation of strain localization into a shear band (or shear bands) and associated strain softening is an extremely complicated task (e.g., Tatsuoka et al., 1991). Complicated interaction between shear band deformation and reinforcement makes the failure analysis of reinforced soil more difficult (Kotake et al., 1997). Therefore, FEM analysis of the seismic failure of reinforced soil structure is still not a practical tool, and will not be discussed more.

**Rupture strength of reinforcement for seismic loads;** Recent laboratory deformation and strength tests on

Fig. 6.7 Concept of Newmark's sliding block method (Cai and Bathurst, 1996a)

Fig. 6.8 Concept of equivalent energy method (Newmark, 1965)

geosynthetics showed that under the same strain rate, the strength after long-term creep is not smaller than that before creep (Bernardi and Paulson, 1997). This point is also discussed by Greenwood (1997). Therefore, no reduction factor is needed for the tensile strength of geosynthetic reinforcement to be used in seismic design compared with short-term design strength for static loads.

## 7. SUMMARY AND CONCLUSIONS

From the observations in the field, the model test results and the theoretical considerations summarized in this report, the following conclusions can be derived:

1. There exists a big gap between the design horizontal coefficients  $(k_h)_{design}$  used in the current pseudo-static aseismic design approaches for retaining walls (RWs) and the peak ground accelerations (PGA) divided by the gravitational acceleration ( $g$ ) experienced by a number of RWs during the 1995 Hyogo-ken-nambu Earthquake. This gap is due partly to; a) the use of conservative design soil strength; b) positive net dynamic effects that are not considered in the pseudo-static analyses; and c) the use of global safety factor larger than unity. At the same time, serious damage to a number of RWs during the earthquake shows that the current  $(k_h)_{design}$  values should be increased appropriately to avoid such damage.
2. In both the field behaviour and the laboratory model tests, for the same safety factor evaluated by the pseudo-static approach, the seismic stability of GRS-RW having a FHR facing was marginally higher than that of cantilever RC RWs not supported by a pile foundation, and noticeably higher than that of leaning and gravity-type RWs not supported by a pile foundation.
3. The observations in both the field and the laboratory revealed that large apparent inconsistencies exist in the size of failure zone between the conventional pseudo-static analyses and the actual observations.
4. In the laboratory static tilting model tests, irrespective of RW type, a failure plane or a set of failure planes developed in the backfill associated with the active failure in the backfill, followed by the ultimate failure or collapse of RW only at a slightly larger tilting angle. On the other hand, in the laboratory shaking table model tests, the ultimate failure or collapse of RW occurred at a later stage associated with relative large deformations and displacements of RW occurring after the first active failure plane developed in the backfill. The difference was due to positive net dynamic effects, which were different among the different types of RW. Yet, it is likely that the first developed active failure mechanism controlled the ultimate failure of the RW (except for the GRS-RW having several top or all long reinforcement layers). Therefore, similarly to the pseudo-static approaches, the static tilting tests are not appropriate to evaluate such seismic stability of RW as observed in the field and the shaking table tests.
5. The soil strength along the failure plane can drop very rapidly with very small shear deformation from the peak value to the residual value. It is very likely, therefore, that the peak strength along the failure plane has dropped to the residual value at the moment of the ultimate failure or collapse of RW.
6. Based on the above observations 1~5, a modified pseudo-static approach can be proposed to evaluate the dynamic active earth pressure acting on; a) the back face of RW with unreinforced backfill; and b) the back face of the full-height rigid facing of GRS-RW. The modified approach predicts smaller dynamic earth pressure and smaller failure zones in the backfill than those predicted by the conventional pseudo-static approaches using conservative soil strength, which is usually similar to the residual strength. According to the modified pseudo-static approach, the use of short reinforcement layers can increase largely the seismic stability of GRS-RW, particularly at high seismic loads. This estimation is consistent with the field and laboratory observations.
7. The design horizontal seismic coefficient  $(k_h)_{design}$  depends not only the PGA value of design seismic load, but also many other factors, among which; a) stability analysis method; b) design soil strength; c) simplification of wall configurations employed in the design; d) dynamic effects, among which the ductility and rigidity of RW and the frequency properties and randomness of seismic loads are important; and d) the global safety factor.
8. It is suggested that under otherwise the same conditions, the design value  $(k_h)_{design}$  for well-designed and constructed GRS-RW having a FHR facing could be marginally smaller than that for cantilever RWs and noticeably smaller than that for masonry RWs and leaning and gravity types RWs. When RWs are designed against Level 2 seismic loads by the conventional pseudo-static analysis using conservative soil strength, while using an allowable global safety factor equal to 1.5;
  - a) for masonry RWs and leaning and gravity types RWs; the use of  $(k_h)_{design} = 0.1 - 0.2$  is unconservative, and  $(k_h)_{design} = 0.40$  could be tentatively suggested;
  - b) for cantilever RC RWs; the use of  $(k_h)_{design} = 0.1 - 0.2$  is unconservative, and  $(k_h)_{design} = 0.35$  could be tentatively suggested; and
  - c) for GRS-RWs having a FHR facing; the use of  $(k_h)_{design} = 0.1 - 0.2$  may be unconservative, and  $(k_h)_{design} = 0.30$  could be tentatively suggested.
9. The use of several long reinforcement layers at high levels is effective to increase seismic stability of GRS-RWs.

## 8. ACKNOWLEDGMENTS

Funding for this study was provided by the Ministry of Education, Science, Sports and Culture, Japan. The authors wish to thank Messrs. S. Nishihara at Chuo Kaihatsu Co., K. Kojima at Railway Technical Research Institute, T. Tsutsumi at Public Works Research Institute, K. Hayano, T. Uchimura and T. Sato at University of Tokyo for their help in preparing the manuscript.

**ABSTRACT:** The governing principles of Limit Equilibrium Methods and the Limit State Approach for the design of reinforced soil structures are presented. The components, construction and behaviour of geosynthetic reinforced soil structures are described, including a discussion of their internal force equilibrium and strain compatibility. The Limit State Approach to design is strictly applied to geosynthetic reinforced walls, steep slopes and embankments with suggestions given for the selection of properties of materials, actions, geometrical data and behavioural mechanisms. The Partial Factors to be applied to these are indicated. Lastly, the development of a computer-aided Limit State Approach design method for geosynthetic reinforced soil structures is described and outcome designs are given.

**KEYWORDS:** Design, Partial Factors, Geosynthetic Reinforcement, Retaining Walls, Steep Slopes, Embankments.

## 1 INTRODUCTION

Geosynthetic reinforced soil structures were progressively introduced into modern civil engineering practice during the 1970's. The earliest applications were in road pavements, and embankment slopes, although there were some notable steep slopes and walls constructed, McGown and Ozelton (1973), Holtz and Massarsch (1976), Bell and Steward (1977) and Jarrett et al (1977). In most cases, a Limit Equilibrium Method was used to design these structures. In these designs, the soils were uniquely represented by their peak strengths and the geosynthetics by their short term strength, (the latter determined from constant rate of deformation tensile test data).

Little or no account was taken of the deformation characteristics of the soil, the geosynthetics or their interaction behaviours. Large global *Factors of Safety* were applied which were intended to ensure *explicitly* that collapse did not occur and to ensure *implicitly* that deformations under working conditions were not excessive. As implemented, many of these design methods were semi-empirical and they proved to be generally acceptable and economic compared to other technical solutions available at that date. As a result they allowed the rapid acceptance of geosynthetics.

At the same time as geosynthetics were being introduced, a fundamental change in the design of civil engineering structures was underway. This involved the introduction of deformations and strains as design criteria to be assessed and controlled in an *explicit* manner. These were incorporated into what is now known as the *Limit State Approach*, in which both collapse conditions, *Ultimate Limit States*, and operational conditions, *Serviceability Limit States*, are analysed. Another feature of this approach is the introduction of risk factors, *Partial Factors*, to replace the use of global Factors of Safety.

The Limit State Approach was rapidly adopted in structural engineering in the 1980's and it has been gaining acceptance in geotechnical engineering in the 1990's. A number of the latest codes of practice relating to geosynthetic reinforced structures in various countries now take account of Limit State principles (e.g. BS 8006, 1995), however in most cases, these include partial factors that ensure that the outcome designs are close to those based on the preceding semi-empirical Limit Equilibrium Methods.

This paper comprises four main parts together with an overall discussion. Part A describes the governing principles of the Limit Equilibrium Methods and the Limit State Approach. Part B describes the components and construction methods used to form reinforced soil

structures and identifies the factors influencing their internal force equilibrium and strains. In Part C the Limit State Approach to design is strictly applied to geosynthetic reinforced walls, steep slopes and embankments. The soil and material parameters, loads and Partial Factors to be used in Ultimate and Serviceability Limit State analyses are set out and discussed. Part D describes the development of a computer-aided Limit State Approach design for geosynthetic reinforced soil structures and examples of outcome designs are given.

## PART A - THE GOVERNING PRINCIPLES OF LIMIT EQUILIBRIUM METHODS AND THE LIMIT STATE APPROACH

### 2 LIMIT EQUILIBRIUM METHODS

Historically the main objective of employing Limit Equilibrium Methods to analyse soil structures, was to establish the load combinations that soil masses could support against ultimate failure/collapse with a suitable Factor of Safety. Such loadings were termed *Design Loads*. It was generally assumed that the soil structures would meet their serviceability requirements under *Working Loads*, which were equal to or less than the Design Loads. In some cases, quite separate volume change/settlement analyses were undertaken using Working Loads.

The Limit Equilibrium Methods dealt with the various conditions of ultimate failure of a soil mass, including problems such as earth pressures, bearing capacity, and slope stability. Solutions were often obtained by simple statics, assuming failure surfaces of various shapes, such as planar, circular, or log-spiral, and by using simple failure criteria. In addition, all the soil elements along the failure surface were assumed to have reached their peak strength.

One of the earliest contributions to the use of Limit Equilibrium Methods in soil mechanics was that of Coulomb in 1773. He proposed a simple failure criterion for soils and established the important geotechnical design concept of treating the soil mass as a continuum which he applied to the determination of the action of fills on retaining walls, Chen and Liu (1990) and Clayton et al (1993). Later, in 1857, Rankine similarly represented an infinite body of a granular fill as a continuum and developed his Limit Equilibrium Method for earth pressures. Only much later was it suggested that real soils do not behave as rigid plastic materials, that is they do not act in the simple continuum manner proposed by Coulomb and Rankine, Terzaghi (1936), Fig. 1(a). Terzaghi indicated that the peak strength of the soil was mobilised only after significant displacement of the soil mass and pointed out that most soils exhibit increase in strength with

strain, which is known as *Strain Hardening*. In dense sands, this is followed by plastic failure, which is associated with a drop in shear strength and is known as *Strain Softening*, Fig 1(b). Thus given that real soils are compressible and may be subject to Strain Softening, it may be suggested that there are situations where the peak strength of a soil cannot be mobilised over the entire shear surface at any one time. Roscoe (1970) confirmed this and showed from the results of triaxial tests that soils can reach the same shear strength by lateral expansion (*Active Case*) and by lateral compression (*Passive Case*), but at very different strain levels.

Fig. 1. Idealised and observed stress/strain behaviour of soil: (a) idealised and (b) observed (after Clayton, 1993)

As stated earlier, in some cases volume change/ settlement analyses were carried out to deal with the deformation of the soil at stress levels developed by the working loads, when no failure of the soil is usually involved. Solutions to this problem are obtained either by using the theory of elasticity or by a theory of consolidation, such as Terzaghi (1923) or Biot (1941). The elasticity approach is rational for problems involving short-term loads, however, it is obviously wrong to analyse all soil deformations using as a basis Hooke's law which is time-independent. In many cases the design must consider the influence of time on the deformations. Such behaviour may be modelled by

adopting the theory of viscoelasticity. However, in soil mechanics the complex multi-phase nature of the soils often requires a more complex approach.

### 3 THE LIMIT STATE APPROACH

#### 3.1 General Principles

The introduction to soil mechanics of design methods based on the Limit State Approach allows the following factors to be taken into consideration:

- (i) The nature and size of the soil structure, including any special requirements for the structure or its surroundings.
- (ii) The nature of the existing ground and groundwater conditions.
- (iii) The nature of the operational environment, including any seismicity.

To set the design requirements various *Geotechnical Categories* are introduced. In Eurocode 7 (1995), three categories are identified:

*Geotechnical Category 1* - Small or relatively simple soil structures, which may be designed using experience and qualitative geotechnical data and analysis.

*Geotechnical Category 2* - Conventional types of soil structures with no abnormal risks nor any exceptional ground or loading conditions, which may be designed using routine quantitative geotechnical data and analysis.

*Geotechnical Category 3* - Soil structures or parts of structures involving abnormal risks or difficult ground or loading conditions, which require to be designed using specialised non-routine quantitative geotechnical data and analysis.

For each geotechnical design problem, performance criteria during the period of construction and over the design life are set. Whenever a structure or a part of a structure operates at a level equal to any of the performance criteria, it is said to have reached a *Limit State*. Limit States are divided into two categories; *Ultimate Limit States (ULS)* and *Serviceability Limit State (SLS)*:

Ultimate Limit States are concerned with the safety, loss of static equilibrium or rupture of either a critical component or the entire structure. In brief, they set performance criteria such that no catastrophic damage can occur to a structure.

Serviceability Limit States are conditions, or performance criteria, beyond which the functional or aesthetic utility of a component or the entire structure are lost. The loss of serviceability may be due to deformation in the ground or deformation in the structure itself. For example, if a retaining wall supporting a bridge abutment deforms excessively, the serviceability of the bridge might be lost. Alternatively, due to a wall deformation there may be noticeable subsidence of a road subgrade which may cause discomfort to the users of that road or put the road out of service until proper maintenance is undertaken.

Two aspects of the Limit State Approach are of particular significance to geosynthetic reinforced soil structures. These are the considerations given to the *Strain Compatibility* of materials involved at the various Limit State conditions, and the assessment of the significance of internal and external environmental conditions on the durability of the materials used.

Designs based on the Limit State Approach require the identification of suitable *Calculation Models, Properties of Materials, Actions, Geometrical Data* and *Limiting Values of Deformations* etc.

The Calculation Models should consist of appropriate methods of analysis, based on valid *Behavioural Mechanisms*.

Design values of the Properties of Materials should be assessed directly for particular site conditions or derived from *Characteristic Values* based on field and laboratory test data.

Actions should include all loads, forces and displacements identified to be contributing to any specific Limit State condition. However, not all loads, forces or displacements will be treated as Actions in all Limit State analyses. Further the *Duration of Actions* needs to be considered, including changes in Actions resulting from changes in the Properties of Materials with time.

Geometrical Data should include all level, slope and other dimensional data important to the design and allowances made for variations in these.

Limiting Values should be chosen for each of the Limit States conditions.

The Limit State Approach does not use global Factors of Safety, instead Partial Factors are applied in the calculations where the uncertainties lie. The use of Partial Factors aims to distribute margins of safety to the places in the calculation where there are uncertainties. Also Partial Factors have the advantage that "margins of safety" can be

shared appropriately among the main parameters employed in the design. For example, a structure may be subjected to two actions, one adverse and the other beneficial, so that the nominal value of each cancels the other. Hence the resistance required for the structure will be very small or zero, on the basis of the nominal action. However, if in reality one of the actions is different from the expected value, the required resistance may be very high. This possible situation can be anticipated using Partial Factors, but could be missed in the global Factor of Safety approach.

Partial Factors relevant to soil structures have been suggested in Eurocode 7 (1995). Significantly, this suggests that different Partial Factors should be applied in the cases of favourable and unfavourable actions, Table 1. In the calculation of Serviceability Limit States, Eurocode 7 (1995) suggests the use of Partial Factors of unity.

### 3.2 Design Criteria

Design criteria are based on equating the effects of the destabilising actions and the stabilising actions. These are given in general terms by Eurocode 1 (1996) for both Ultimate and Serviceability Limit States as follows:

#### 3.2.1 Ultimate Limit States

For Ultimate Limit State analysis, static equilibrium and strength have to be verified so that the possible Ultimate Limit States are not exceeded.

##### (i) External Stability

When considering external Ultimate Limit States, the equilibrium or gross displacement of a structure are considered assuming the structure to be a rigid body. It must be verified that:

$$E_{d,dst} \leq E_{d,stab}$$

where,  $E_{d,dst}$  = Design value for the effect of the destabilising actions (direct, overturning or sliding), and

$E_{d,stab}$  = Design value for the effect of the stabilising actions (resisting).

##### (ii) Internal Stability

When considering internal Ultimate Limit States, rupture or excessive deformation of sections, members and connections, it must be verified that:

$$E_d \leq R_d$$

where,  $E_d$  = Design value of the effect of actions (internal forces, moments or vectors of several internal forces or moments), and

$R_d$  = Design value of the corresponding resistance (obtained from the design values of properties).

Table 1 Partial Safety Factors  
- Ultimate Limit States (Eurocode 7, 1995)

Case	Actions	Situations	
		Persistent -transient	Accidental
Permanent actions caused by structural and non-structural components, ground and groundwater			
- Loss of equilibrium: strength of structural materials or ground	unfavourable	1.10	1.00
	favourable	0.90	1.00
- Failure of structures or structural elements governed by the strength of materials	unfavourable	1.35	1.00
	favourable	1.00	1.00
- Failure of structures or structural elements governed by the strength of the ground	unfavourable	1.00 <sup>(1)</sup>	1.00 <sup>(1)</sup>
	favourable	1.00 <sup>(1)</sup>	1.00 <sup>(1)</sup>
Variable actions	unfavourable	1.50 <sup>(2)</sup>	1.00
Accidental actions	-	-	1.00

<sup>(1)</sup> In design calculations of lateral earth pressures, partial factors are used for the ground properties and for surface loads. Design earth pressures are not derived by multiplying characteristic earth pressures by partial factors.

<sup>(2)</sup> Unfavourable Variable Actions related to the failure of a structure or structural element governed by the strength of the ground should use a Partial Factor of 1.5/1.35 equal to 1.11.

### 3.2.2 Serviceability Limit States

It must be verified that no Serviceability Limit State is exceeded, using the following equation:

$$E_d \leq C_d$$

where,  $E_d$  = Design value of the effect of actions, (displacements, accelerations), and

$C_d$  = A nominal value or a function of certain design properties of materials related to the design effects of actions considered.

### 3.3 Material Properties for Ultimate Limit States

In geosynthetic reinforced soil structures the following four groups of material properties require to be identified for Ultimate Limit State analysis.

#### 3.3.1 Soils

In structural analysis, the ultimate tensile strength of low-carbon steels is usually ignored, and designs are based on the lower yield stress, Fig. 2(a). Thus it may be stated that structural engineers have decided not to utilise the strain-hardening which develops beyond the yield stress and in so doing they have decided to avoid the problems associated with progressive failure.

Fig. 2. Choice of steel and soil parameters for Ultimate Limit States (after Bolton, 1993)

In conventional geotechnical engineering practice the problems of progressive failure are avoided by geotechnical engineers neglecting the ultimate shear strength of soils in favour of the use of the peak shear strength of soils. However, peak shear strength is a transient value which is greatly dependent on the state of compaction of the soil and much less reliable than the ultimate shear strength. Additionally, the possibility of progressive failure is avoided, by the widespread use of large global Factors of Safety within analyses involving the peak shear strength of soils.

Ultimate Limit State analysis is concerned with collapse conditions, thus the ultimate large strain constant volume strength, Fig 2(b), (the large strain *Constant Volume Angle of Friction*,  $\phi'_{cv}$ ) should always be employed. Further given that at large strain, the constant volume shear strength is the lowest value achievable, at least in granular soils, then no Partial Factor is required for this parameter when it is used in designs.

Unfortunately, at the time of design the source of the soil to be used in the construction works may not be known and the quality of the compaction control may not be guaranteed. In such cases an appropriate design value for the angle of friction must be assumed based on the presumed nature of the soil and the compaction methodology most likely to be used. This assumed design value should be that for the large strain constant volume angle of friction of the soil presumed to be used. A small Partial Factor is appropriate in such cases.

#### 3.3.2 Geosynthetics

The choice of the design parameters for geosynthetic soil reinforcements to be used in Ultimate Limit State analysis has not yet been widely agreed. Some codes/design guides presently recommend the use of factored short term constant rate of deformation tensile test data, whilst others recommend the use of factored sustained load, (creep), test data. This matter will therefore be given detailed consideration in a later section.

#### 3.3.3 Soil Reinforcement Interaction

The choice of the design parameters for soil reinforcement interaction in Ultimate Limit State analysis has not yet been widely agreed. Some codes/design guides presently recommend the use of shear box test data and others pull-out test data. This matter will therefore be given detailed consideration in a later section.

### 3.3.4 Other Materials

For the Ultimate Limit State design of facings, in concrete, metal or other materials, connections and other components, relevant Limit State codes of practice may be followed, e.g. Eurocode 1 (1996).

### 3.4 Material Properties for Serviceability Limit States

As with Ultimate Limit State analysis, the following four groups of material properties require to be identified for Serviceability Limit State analysis.

#### 3.4.1 Soils

At working conditions, i.e., with actual working loads, the mobilised strains in and around soil structures can be relatively small. In such cases, the strains in the soil are likely to mobilise a friction angle between the at rest condition and peak strength, (i.e. between the *At Rest Angle of Friction*,  $(\phi'_o)$  and the *Peak Angle of Friction*,  $(\phi'_p)$ ). Hence, for Serviceability Limit States, no fixed value for the angle of friction can be suggested rather various values must be used, depending on the Serviceability Limit State being analysed.

#### 3.4.2 Geosynthetics

As for Ultimate Limit State analyses, there is no general agreement to date on the choice of the design parameters for Serviceability Limit State analyses. This matter will be dealt with in a later section.

#### 3.4.3 Soil Reinforcement Interaction

As for Ultimate Limit State analyses, there is no general agreement to date on the choice of the design parameters for Soil Reinforcement Interaction for Serviceability Limit State analyses. Thus this matter will be dealt with in a later section.

#### 3.4.4 Other Materials

For the Serviceability Limit State design of facings, in concrete, metal or other materials, connections and other components, relevant Limit State codes of practice may be followed, e.g. Eurocode 1 (1996).

### 3.5 Actions to be used in Designs

For any calculation the values of all the Actions must be known. Two categories of Actions have been defined in Eurocode 1 (1996):

*Direct Actions* - which are loads or forces applied to the soil structure, and

*Indirect Actions* - which are imposed or constrained deformations.

Within these two categories there are many *Types of Actions*, including *Permanent Actions*, (likely to act throughout a given design situation); *Variable Actions*, (likely to vary but with a mean value of significance); *Accidental Actions*, (likely to be of short duration and unexpected but of sufficient magnitude to cause severe consequences); *Fixed Actions*, (likely to be of known magnitude and direction with a fixed distribution over the structure); *Free Actions*, (likely to be of known magnitude and direction but a variable distribution over the structure); *Static Actions*, (likely to be stable and not cause significant acceleration of the structure or any of its components); *Dynamic Actions* (likely to cause acceleration of the structure or of its components), and *Quasi-static Actions*, (likely to be essentially static but have some dynamic effects).

Within design calculations it is necessary to identify *Representative Values* of the Actions known as *Characteristic Values*, in order to verify the Limit State conditions. These values should be established on a statistical basis to correspond to a prescribed probability of not being exceeded on the unfavourable side during the period taken into account in the design. Combinations of these are chosen to take account of the probability of simultaneous occurrence of the most unfavourable values of the independent Actions. This requires the identification of *Frequent* and *Quasi-permanent* values of Actions.

Frequent values are determined so that, (a) the total time during which the value of an Action is exceeded is only a small part of the chosen period of design life, or (b) the frequency of the exceedance of the values of Actions is limited.

Quasi-permanent Values are determined so that the total time during which the values of Actions are applied is a considerable part of the design life. Generally this means the Actions are applied for more than half of the design life.

Eurocode 1 (1996) generally requires that for Limit States with severe consequences, (generally Ultimate Limit States), design values shall represent the most unfavourable values which may occur in extreme circumstances and for Limit States with less severe consequences, (generally Serviceability Limit States), design value shall be the most unfavourable values which may occur in normal circumstances.

### 3.6 Partial Factors

Partial Factors need to be applied to the properties of materials, actions, geometrical data and behavioural models.

#### 3.6.1 Soils

The classical geotechnical Limit Equilibrium Methods were developed in the first half of this century following the pioneering work of Terzaghi (1925), but it was Krey (1926) who introduced the concept of global Factors of Safety with different values for slopes, retaining walls and foundations. Similar global Factors of Safety became customary for geotechnical design in Europe, North America and elsewhere during the first half of this century. The ranges for these global Factors of Safety are given in Table 2, Terzaghi and Peck, (1948). Taylor (1948) introduced separate Factors of Safety for the cohesive and frictional components of soil strength, ( $c$  and  $\tan \phi$ ) in the analysis of the stability of slopes. This approach was generalised by Brinch Hansen (1953 and 1956) when he proposed "Partial Factors" on different types of loads and the shear strength parameters of the soils used in the design of earth retaining structures and foundations. The principal numerical values of these "Partial Factors" related to soil structures are summarised in Table 3. The "Partial Factors" were chosen to give about the same estimates as conventional global Factors of Safety and have been used in the Danish Code since 1965, (Meyerhof, 1993).

The magnitudes of Partial Factors applied to the soil parameters in the modern Limit State Approach are governed by the reliability of the geotechnical information. The values of Partial Factors related to soils suggested in Eurocode 7 (1995) are given in Table 4.

#### 3.6.2 Geosynthetics

There is no general agreement to date on the choice of the Partial Factors for either Ultimate or Serviceability Limit State analyses involving geosynthetics. Thus this matter will be dealt with in a later section.

#### 3.6.3 Soil Reinforcement Interaction

There is no general agreement to date on the choice of the Partial Factors for either Ultimate or Serviceability Limit State analyses involving soil reinforcement interaction. Thus this matter will be dealt with in a later section.

Table 2. Values of Global Factors of Safety

Failure type	Item	Safety factor
Shear strength	Earthworks	1.3 to 1.5
	Earth retaining structures and excavations	1.5 to 2
Seepage	Uplift, heave	1.5 to 2
	Exit gradient, piping	2 to 3

Table 3. Values of Partial Factors in Various Codes

Item	Brinch Hansen		Denmark DS 415
	(1953)	(1956)	(1965)
Loads			
Dead loads, soil weight	1.0	1.0	1.0
Live loads	1.5	1.5	1.5
Environmental loads	1.5	1.5	1.5
Water pressure	1.0	1.0	1.0
Accidental loads	-	1.0	1.0
Shear strength

### 3.6.4 Other Materials

For the Partial Factors to be used in Ultimate or Serviceability Limit State designs of facings, in concrete, metal or other materials, connections and other components, relevant Limit State codes of practice may be followed, e.g. Eurocode 7 (1995).

### 3.6.5 Other Partial Factors

For any calculations the design values of the effects of Actions ( $E_d$ ) are determined from the design values of the Actions and Geometrical Data as well as the Properties of Materials. In some cases, the effects of the uncertainties in the Behavioural Model used in the calculations need to be considered explicitly and this may lead to the application of a *Coefficient of Behavioural Model Uncertainty* applied either to the Actions or to the internal forces and moments, whichever is the more conservative. For situations where deviations in the Geometrical Data will have a significant effect on the reliability of the structure, nominal geometrical design values may be modified to take account of the possibility of unfavourable deviations.

## PART B - REINFORCED SOIL STRUCTURES: THEIR COMPONENTS CONSTRUCTION AND BEHAVIOUR

### 4 TYPES OF REINFORCED SOIL STRUCTURES

The principal types of reinforced soil structures have been classified by Bonaparte et al (1985). They subdivided these structures into two broad categories, *Earth Structures* and *Load Supporting Structures*:

Earth Structures include walls, slopes, embankments, low permeability soil layers used in dams and waste containment facilities etc. Earth structures are not stable under their own weight and may or may not require to support significant external loads. The primary design criterion is the stability of the structure under its own weight and possibly external loads.

Load Supporting Structures include flexible pavements, unpaved roads, railroad track structures, and load supporting pads such as drilling pads, fabrication yards, and construction staging areas. These structures are usually stable under their own weight, and the primary design consideration is the ability of the structure to support the applied loads with limited deformations.

This paper is concerned only with the first category, the so-called Earth Structures, which may be sub-divided as follows:

### 4.1 Reinforced Soil Walls and Steep Slopes

Reinforced slopes and walls are typically constructed with alternating horizontal layers of compacted soil and reinforcement. With walls and very steep slopes, a facing is necessary to prevent localised surface erosion along the exposed side of the reinforced soil mass, which may lead to a progressive overall failure.

In these applications, the reinforcements strengthen the structure by adding tensile strength to the soil mass and by increasing soil strength as a result of increased soil confinement, Jewell (1980). This strengthening permits the construction of stable soil structures at angles steeper than the mobilised angle of friction of the soil. Examples of such soil structures include:

- (i) Vertical or near vertical soil walls with various types of facings such as full height panels, sectional panels and segmental concrete facings, "wrap around" facings and other facings such as timber, brick, or gabions, Fig. 3.
- (ii) Reinforced slopes used for embankment construction, natural slope stabilisation and excavations, Fig. 4.

The performance criteria for reinforced soil walls and steep slopes may be grouped into two categories. The first grouping is related to adequate stability against various internal and external collapse modes, McGown et al (1993a), Fig. 5. The second grouping is related to limits on deformations. These deformation limits are selected on the basis of architectural considerations regarding facing units, visual impact or on serviceability criteria imposed by supported structures, such as pavements and bridges.

Fig. 3. Some examples of reinforced soil walls: (a) concrete faced retaining walls (b) "wrap-around" faced retaining wall (c) bridge abutment and (d) dam (after Bonaparte et al, 1985)

Fig. 4. Reinforced slopes: (a) embankment and (b) landslide repair (Bonaparte et al, 1985)

#### 4.2 Reinforced Embankments

Reinforced embankments on weak foundations are usually constructed by placing a layer of reinforcement, or a small number of soil and reinforcement layers, on the natural soil to produce a thin working pad on which the embankment is constructed in the conventional manner, Fig. 6.

There are at least two categories of weak foundations. If construction is to take place on a site underlain by a uniformly weak soil deposit such as soft clay, peat, or muskeg layers, the roles of the reinforcement are to increase the "margin of safety" against a slip-surface failure of the embankment and foundation soil, and to reduce lateral spreading and cracking of the embankment. If the foundation soil is locally weak, e.g. due to the presence of lenses of soft soil or sinkholes, the role of the reinforcement is to bridge the weak areas, (by the so called tension membrane effect), in order to reduce the risk of localised failure and to reduce differential settlements.

The two performance criteria usually considered for embankments are adequate external and occasionally internal stability, together with acceptable total and differential settlements, Fig. 5. Reinforcement placed at the embankment/foundation interface enhances stability and reduces embankment spreading. It should be noted that such reinforcements have little influence on the total time-dependent settlement of the embankment or the foundation soil, however, for non-uniform conditions, reinforcements at the embankment/foundation interface may reduce differential settlements, Bonaparte et al (1985).

## 5 COMPONENTS OF REINFORCED SOIL STRUCTURES

Reinforced soil structures consist of a number of components, including reinforced fill; retained fill; sub-soil; in-situ soil behind the reinforced fill; reinforcements; facing units and connections. The nature and important properties of these components are discussed in the following sections.

### 5.1 Reinforced Fill

The type of reinforced fill used in reinforced soil structures is dependent on the technical requirements of the structure and the basic economics associated with it. The main load transfer mechanism in reinforced soil structures is dependent on the shear forces developed at the soil-reinforcement interface. This major requirement of frictional forces has led to the use of cohesionless or slightly cohesive soil backfills with high friction angles, Yogarajah (1993). Most codes of practice and most design methods are based on the use of a suitable frictional backfill. For example, BS8006, (1995) requires a cohesionless fill with an effective angle of friction greater than  $25^\circ$  and with no more than 15% of the material less than  $63\mu\text{m}$  to be present. Generally, it has been suggested that granular materials should not contain more than 15% finer than 0.08mm, Lee (1978). Further, the reinforced fill is usually required to conform to certain electro-chemical and other conditions to reduce the corrosion/degradation of reinforcements.

From the point of view of operational performance the most important property of granular material is the relationship between the mobilised angle of friction and the tensile strains in the soil under plane strain conditions, Fig. 7. The plane strain apparatus should be used to determine this relationship but this is rarely the case. More usually the triaxial or shear box apparatuses are used to determine the peak angle of friction, ( $\phi'_p$ ), and constant volume angle of friction, ( $\phi'_{cv}$ ). However, various researchers have carried out experiments to find out the relationship between the mobilised angle of friction, ( $\phi'_m$ ), and the lateral tensile strain in the soil, ( $\epsilon_t$ ), Cornforth (1964), Barden et al (1969), Al-Hasani (1978) and Bolton (1986). According to their findings, the peak angle of friction, ( $\phi'_p$ ), of granular soils occurs at lateral tensile strains in the range 3 to 6% and the constant volume angle of friction, ( $\phi'_{cv}$ ), occurs at tensile strains in the range 6 to 12%, McGown et al (1993a), Fig. 7.

8. Overturning	-		
9. Overall stability	-		

Fig. 5 Suggested Limit States for Walls, Steep Slopes and Embankments (McGown et al, 1993)

Fig. 6. Embankments on weak foundations: (a) embankment on uniform soft soil and (b) embankment on locally weak foundations (Bonaparte et al, 1985)

Fig. 7. Relationship between the mobilised angle of friction and tensile strain in cohesionless soil (after McGown et al, 1993)

In practice the maximum strain measured in reinforcing elements in walls is usually much less than 2%, Yogarajah (1993). At working conditions in walls, a mobilised angle of friction numerically equal to the value of the constant volume angle of friction, ( $\phi'_{cv}$ ), would appear to be the most appropriate value, Fig. 7.

A number of experiments and full-scale trials have been carried out to assess the use of cohesive backfills in reinforced soil structures, Murray and Boden (1979), Ingold (1981), Bonaparte et al (1989), Fourie and Fabian (1989) and Wu (1991). These show that cohesive soils may require a large amount of reinforcement with good adhesion and possibly good drainage qualities. Cohesive reinforced soil structures are presently being constructed in some countries on an increasing scale especially in Japan, Kasahara et al (1992), but these soils are not dealt with in this paper.

Fig. 8. Different sections of reinforced soil structures: (a) with retained fill (b) and (c) without reinforced fill (Pradhan, 1996)

## 5.2 Retained Fill

Fill behind the reinforced soil section may or may not be present depending on the site conditions, Fig. 8. Structures built to reinstate existing slopes or to widen an Existing road will not contain the retain fill, Fig. 8(b) and (c), instead they will have the in-situ soil behind the reinforced fill. Otherwise retained fills will be the same soil as that of the reinforced fill. The properties of the retained fill can govern the external stability of the reinforced soil structures. Hence, good quality retained fill should be used and its constant volume angle of friction ( $\phi'_{cv}$ ) needs to be appropriately determined.

## 5.3 Sub-Soil and In-Situ Soil Behind Reinforced Fill

The shear strength, (possibly, consolidated undrained, and drained parameters), and compressibility properties of the subsoil and the in-situ soils behind reinforced fills are important design parameters in reinforced soil structures.

Most of the design methods assume a competent foundation in the design of reinforced soil walls and steep slopes. In the case of embankments over a soft soil foundation, the properties of embankment materials themselves may not be critical rather the properties and changes in properties of the sub-soils with time may be the dominant influences. In-situ soil behind reinforced soil walls and steep slopes may have a significant effect on the length of the reinforcing elements required in the fill, hence the properties of these soils should be carefully determined, Pradhan (1996).

## 5.4 Reinforcing Elements

The type of materials used at the present time as reinforcing elements include steel, fibreglass and polymer synthetics in the forms of sheets, strips or grids. Some of the forms of polymer synthetic products, (so called *Geosynthetics*), are shown in Fig. 9. The choice of material and the form in which it is used (i.e., sheet, strip or grid) generally dictates the load transfer mechanism from the soil to the reinforcement. In the case of strips, sheets and grids with melded junctions, the load transfer mechanism at the soil/reinforcement interface is principally surface friction, while for grid with integral junctions, stress transfer is a combination of surface friction and bearing stresses developed at the junctions or protrusions, Fig. 10.

Two types of reinforcements have been identified by McGown et al (1978), *Relatively Inextensible* and *Relatively Extensible* reinforcements.

Relatively Inextensible reinforcements are defined as those which have rupture strains less than the maximum tensile strain in the soil without reinforcement, under the same operational conditions. The properties of this type of reinforcement are often independent of time and

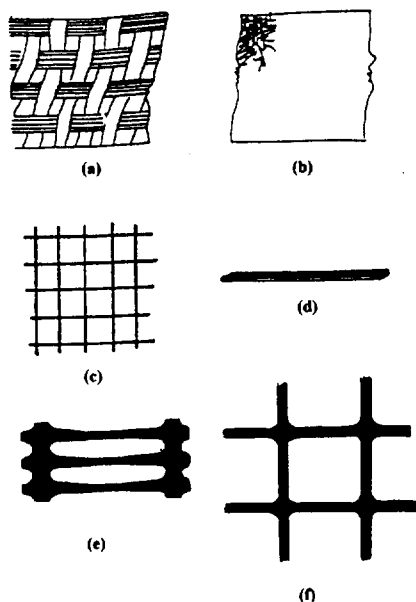

Fig. 9. Forms of geotextiles and related products: (a) wovens (b) non-wovens (c) nets and grids with melded junctions (d) straps (e) uniaxial grids with integral junctions and (f) biaxial grids with integral junctions

Fig. 10. Load transfer between soil and grid reinforcements (a) surface friction (b) bearing stress

temperature, in which case their stress-strain behaviour can be determined from short term, constant rate of deformation tensile tests.

Relatively Extensible reinforcements, which includes almost all geosynthetic strips, sheets or grids, are defined as those which have rupture strains larger than the maximum tensile strain in the soil without reinforcement, under the same operational stress conditions. The properties of this type of reinforcement are usually time and temperature dependent. For this reason, it has been suggested that long term, sustained load, (creep), tests at the appropriate temperature are required to determine their load-strain-time-temperature behaviour, Kabir (1984), McGown et al (1984a), Murray and McGown (1987), Andrawes et al (1986) and many others. Where the materials are highly compressible or change shape during straining, it has been further suggested that "in-soil" testing at appropriate confining stresses in the confining soil is required to determine representative load-strain-time-temperature behaviour, McGown et al (1982).

Embedding Relatively Inextensible reinforcements in soil, in the direction of the principal tensile strain, results in a net increase in the load carrying capacity of the soil and a reduction of soil boundary movements when compared to the soil alone under the same operational conditions. However, when rupture of the reinforcement occurs, the composite behaviour reverts back to the behaviour of the soil alone.

Embedding Relatively Extensible reinforcements in soil again results in a net increase in the load carrying capacity of the soil and a reduction of soil boundary movements when compared to the soil alone under the same operational conditions. The difference is that the extensibility of the reinforcements allows larger strains to occur without the reinforcements rupturing than for

Fig. 11. Stress-strain behaviour of relatively extensible and inextensible reinforcements

Relatively Inextensible reinforcements. In these circumstances, the benefit of the mobilised tensile strength of the reinforcement exists even after the peak strength of the soil has been reached, Fig. 11, McGown et al (1978).

Relatively inextensible metallic reinforcement strips were the first type of reinforcing elements widely used in reinforced walls and steep slopes, Vidal (1969). These reinforcements have stiffnesses which do not allow the development of large enough soil boundary movements to mobilise Active earth pressures, McGown et al (1988 and 1992), Jones (1991), and Yogarajah et al (1993). Relatively Extensible reinforcements, such as geosynthetics, have stiffnesses which can allow the development of sufficiently large soil boundary movements to fully mobilise Active earth pressures. They are therefore potentially much more efficient than Relatively Inextensible reinforcements, in so far as they utilise the strength of the soil more effectively. However, they have to be carefully designed into structures in order to take account of possible long term creep (or stress relaxation) and degradation by UV exposure, thermal cycling and physical, chemical or biological attack. Nevertheless, because of the economic advantages they provide, they have become more and more widely accepted.

### 5.5 Facing Units

As stated earlier, reinforced soil walls and very steep reinforced slopes may require a facing to prevent localised surface erosion. Many types of facings can be used. Two of the most common are concrete panels, (incremental, full height and segmental) and "wrap around" facings. (the facing is provided by wrapping the reinforcement around the outside of the compacted soil layer), Fig. 3. Facings can be designed to be relatively rigid or flexible and lightweight, the latter when they are required to resist low pressures only, Jones (1993), Tatsuoka (1993). They generally represent a relatively

low cost per unit area of exposed surface, Jones et al (1987).

Unfaced slopes and embankments represent the condition of no restraint on the lateral soil boundary. Steep slopes and walls with facings represent various levels of lateral restraint conditions. The actual lateral soil boundary conditions depend upon four factors imposed by the nature of the facing employed, McGown et al (1993), Fig. 12:

- i) Axial compressibility
- ii) Lateral compressibility
- iii) Flexural rigidity, and
- iv) Frictional characteristics of the rear surface of the facing.

The effect of facing type on reinforced soil structures has been studied by various researchers, Fahim (1983), Ahmad (1989), Andrawes et al (1990), Loke (1991) and Saad (1993). Where a compressible boundary layer is present, the lateral earth pressure has been shown to greatly reduce during construction, Andrawes et al (1990), Yeo et al (1992) and Saad (1993).

### 5.6 Connections

Connections are important in walls and steep slopes which are faced. The connections between the reinforcement and the facings must be capable of transmitting the stress from the ends of reinforcement to the facing. The tensile load-deformation behaviour and flexural properties of the connections are important. Various forms of connections are possible such as, vertically sliding connections, loose fitting connections, rigid connections and connections tightened up during or after placement of the fill, McGown et al (1993).

Results from large scale model tests carried out on 2m high reinforced soil walls with different connection types have been reported by Andrawes and Yogarajah (1994). They showed that when the reinforcing elements were *Locked-on* to facing units, (with no horizontal or vertical movement allowed), the maximum tensile strain occurred close to the facing and thereafter was essentially linear away from the facing. In contrast, for loose fitting connections, the maximum tensile strain occurred away from the facing. For the latter case, larger shear resistance was mobilised in the soil and this resulted in reduced lateral earth pressures on the facing units.

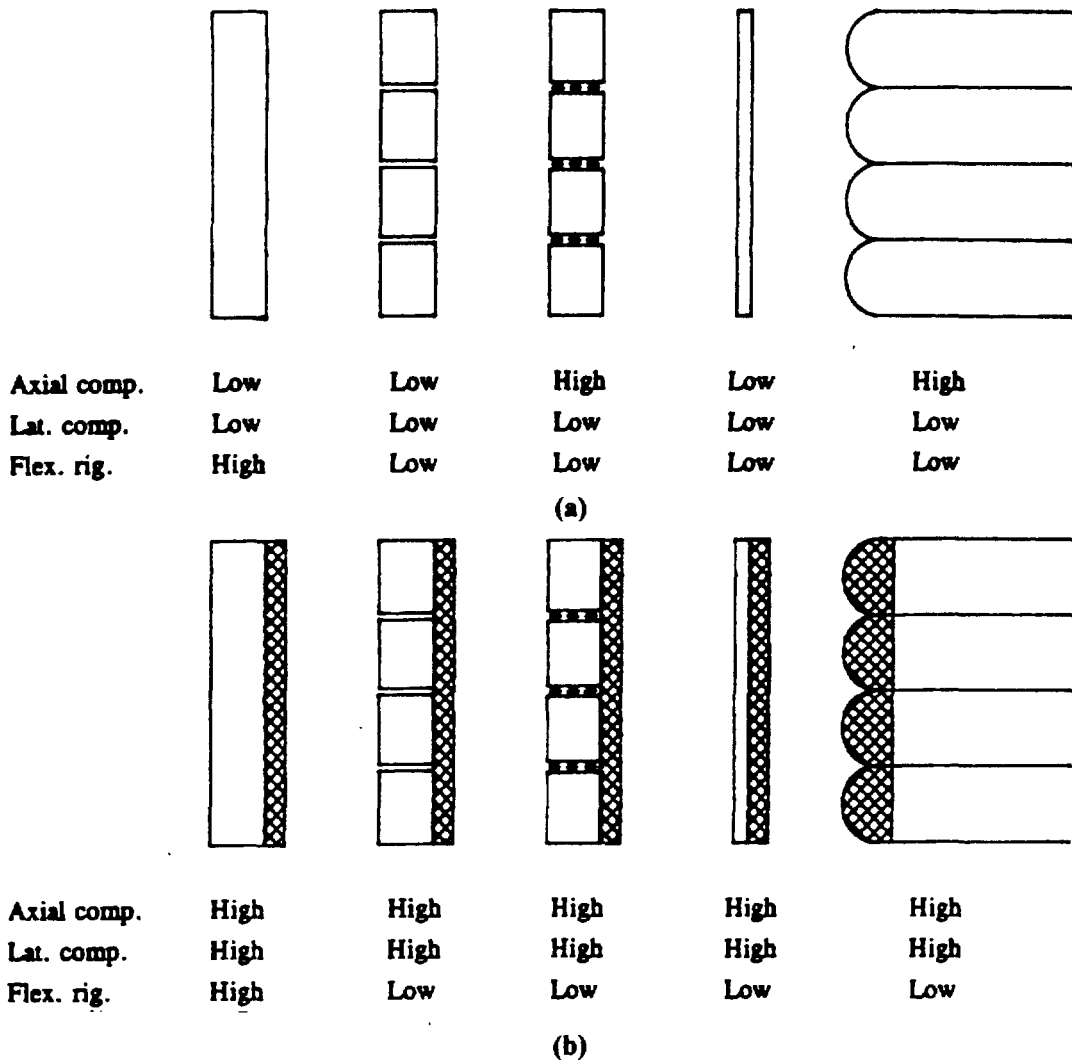

Fig 12. Factors relevant to the nature of the facings: (a) without and (b) with a compressible layer (McGown et al, 1993)

## 6 INTERNAL FORCE EQUILIBRIUM AND STRAIN COMPATIBILITY OF GEOSYNTHETIC REINFORCED SOIL STRUCTURES

The external force equilibrium and deformations of geosynthetic reinforced soil structures are treated in the same manner as for conventional soil structures. The main analytical difference for geosynthetic reinforced soil structures lies with the need to analyse the internal force equilibrium and strain conditions.

### 6.1 The Internal Role of Reinforcements

Soil deforms when it is loaded or allowed to deform under self-weight. In addition to any elastic distortion of

the soil particles themselves, shear deformation occurs as soil particle contacts realign. In so doing the soil mobilises shearing resistance. Deformations result in the development of a strain field in the soil, with both compressive and tensile strains developing as the soil shears, Fahim (1983).

When reinforcements which can develop bond, (either through frictional contact between the soil particles and planar surface areas or from soil bearing stresses on transverse surfaces), are placed in soil, any deformations in the soil will develop forces in the reinforcements. Whether or not tensile or compressive forces develop in the reinforcements, depends on whether they lie in the direction of tensile or compressive strains in the soil.

The mobilised reinforcement forces, ultimately limited by the available bond, act to alter the force equilibrium in the soil and so modify the strain field developed in the soil.

Studies have shown that reinforcements are most effective when aligned in the directions of principal strains in the soil, McGown et al (1978). If reinforcements are placed in or close to the direction of principal tensile strain in the soil, a tensile force develops which directly supports some of the applied loading and increases the normal stresses on potential rupture surfaces. This increased normal stress in turn develops greater frictional shearing resistance. This may be examined for the simple case of a singly reinforced wall, shown in Fig. 13. The self-weight loading of the soil causes a disturbing shear force, ( $P_s$ ), to act on the section of the shear surface shown in Fig. 13(a). The force polygon for an unreinforced wall is shown in Fig. 13 (b). This indicates that the earth pressure, ( $P_a$ ), on the wall would decrease with the increase of shearing resistance in the soil, ( $F$ ), (i.e. increase in the mobilised angle of friction,  $\phi_m$ ).

Fig. 13. Role of reinforcement: (a) forces on conventional retaining wall (b) force polygon and (c) components of reinforcement

Deformations in the soil will cause a tensile force to be mobilised in the reinforcement, ( $T_g$ ), and provide two additional components of resistance in the slope, Fig. 13 (c). The tangential component of the reinforcement force, ( $T_g \sin \theta$ ), directly resists the disturbing shear force in the soil, while the normal component of the force, ( $T_g \cos \theta$ ),

mobilises additional shearing resistance, ( $T_g \cos \theta \tan \phi'_m$ ). The net increase in shear resistance due to the reinforcement is then,  $\Delta P_r = T_g (\sin \theta + \cos \theta \tan \phi'_m)$ .

In practice, multiple layers of reinforcement are used and with a high *Concentration of Reinforcements*, theoretically no lateral earth pressure will be transferred to the wall. In fact, a high Concentration of Reinforcements in a granular soil would give the whole soil mass a “pseudo-cohesion” which would enable the granular soil mass to wholly or partly stand against its self weight and any imposed loads.

## 6.2 Internal Force Equilibrium

Equilibrium is considered in terms of *Required Forces* and *Available Forces*. The geometry of the structure (wall height etc.), loadings (external, self-weight, porewater pressures) and mobilised soil shearing resistance (friction) determine the Required Forces. The aim is to calculate both the magnitude and the distribution of the reinforcement forces needed to maintain equilibrium everywhere in the soil.

Possible reinforcement layouts (reinforcement type, spacing length) are then considered. A satisfactory reinforcement layout is one in which the Available Forces from the reinforcements exceed or equal the Required Forces everywhere in the soil. The calculation of the Available Forces involves consideration of the reinforcement material properties (strength and stiffness) and the available bond between the reinforcement and the soil. Clearly the Available Force in the reinforcement cannot exceed the strength of the material, and the magnitude of force selected governs the corresponding tensile strain in the reinforcement, Jewell (1988).

## 6.3 Internal Strain Compatibility

The link which determines whether a pair of Required and Available Force distributions are indeed balanced is the mobilised strains in the soil and the reinforcements. A common assumption made for geosynthetic reinforcements, due to their high level of bond, is that the tensile strains in the soil and the reinforcements are equal in the direction of the reinforcement. This concept is known as *Strain Compatibility*.

The Strain Compatibility of a reinforced soil structure is most conveniently represented in terms of the overall Required and Available Forces in the soil and the reinforcements respectively, plotted against the tensile strain in the soil and the tensile strain in the reinforcement, Jewell (1985).

The resulting *Strain Compatibility Curve* is most simply drawn for a propped wall construction. Initially both the

soil and the reinforcement have zero tensile strain, with the soil in the At Rest condition, i.e., the Required Forces for equilibrium taken by props are due to At Rest earth pressures, shown as point A in Fig. 14(c). Releasing the props disturbs the initial equilibrium, consequently tensile strains develop in the soil and in the reinforcement. This strain allows another equilibrium condition to be established, shown as the intersection of the Required and Available Forces, point B, in Fig. 14(c).

Fig. 14. The compatibility curve for determining the equilibrium of reinforced soil: (a) mobilised angle of friction - lateral tensile strain (b) tensile force in reinforcement - tensile strain and (c) strain compatibility curve (after Jewell, 1985)

An important feature of the Strain Compatibility Curve not always recognised, is that if creep strain occurs with time in the reinforcement, a decreasing load will require

to be carried by the reinforcement up to the strain required to mobilise the peak angle of friction of the soil. This suggests that if creep occurs in the reinforcement under working conditions, then a constant load is not applied to the reinforcements. Only if the change of load carried by the reinforcements under working conditions is not very significant, can this be overlooked.

It should be noted that Relatively Extensible reinforcements may have to strain quite considerably in order to mobilise significant forces and to contribute to the equilibrium of the structure. By definition, equilibrium calculations only examine stresses and forces and pay no attention to the strains in the soil mass as failure is approached. The generation of reinforcement forces depends on the reinforcement straining with the adjacent soil, thus when performing such calculations it is necessary to determine if the reinforcement forces can occur without exceeding tolerable deformations at the lateral soil boundary. An outcome of this is that a geosynthetic reinforced soil structure may have a reinforcement layout safe against Ultimate Limit States but it may excessively deform under self-weight and imposed loads.

Deformations developing in a reinforced soil structure depend on the *Concentration of Reinforcements*. This may be represented in terms of the stiffness of the structure. Thus if one reinforcement layout is found to deform unacceptably, the Concentration of Reinforcements, and so the stiffness of the system, can be increased in order to reduce the deformation of the lateral soil boundary. These additional reinforcements are not required from a force equilibrium point of view rather for deformation limitation. This concept is no different to that used by structural engineers to control excessive deflections in reinforced concrete beams.

All these concepts are included in the Limit State Approach, in which reinforcement layouts are determined both by Ultimate Limit State analysis, and by Serviceability Limit State Analysis.

## 7 CONSTRUCTION EFFECTS ON INTERNAL STRESSES AND STRAINS IN GEOSYNTHETIC REINFORCED SOIL STRUCTURES

### 7.1 Compaction and the Development of Interlock

Broms (1971), Aggour and Brown (1974) and Ingold (1979, 1980, 1981) investigated the effects of compaction on soil backfill behind rigid retaining walls. Based on empirical formulations, Broms (1971) and Ingold (1979, 1980, 1981) suggest that due to compaction stresses the assumption of At Rest lateral earth pressures at the back of rigid retaining walls, may be an underestimation of the horizontal stresses within the soil mass.

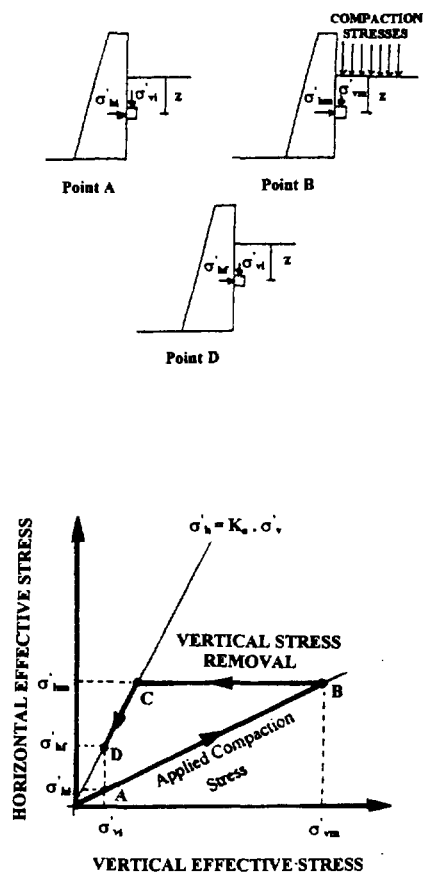

Fig. 15. Broms simplified compaction pressure theory (after Broms, 1971). where  $\sigma'_{hi}$  and  $\sigma'_{vi}$  are initial horizontal and vertical pressures before the application of compaction stress at  $K_0$  condition,  $\sigma'_{hm}$  and  $\sigma'_{vm}$  are increased horizontal and vertical pressure due to compaction stress at  $K_0$  condition and  $\sigma'_{hf}$  is "locked-in" horizontal pressure after removal of compaction stress.

These larger stresses were attributed to *Locked-in Stresses* within the soil mass. Broms (1971) suggested a simplified model of the development of these Locked in Stresses, Fig. 15. Ingold (1979), developed an analytical model, Fig. 16, to calculate the stresses generated due to compaction. He suggested that the horizontal earth pressures, ( $\sigma_{hcomp}$ ), caused by compaction can be calculated by:

$$\sigma_{hcomp} = \sqrt{(2p\gamma/\pi)}$$

where  $p$  is the weight per unit width of the compaction machine and  $\gamma$  is the unit weight of the soil backfill.

Fig. 16. Horizontal earth pressure due to compaction (Ingold, 1979) where  $z_c$  = critical depth below which there will be no reduction in the horizontal pressure.  $h_c$  = critical depth below which the active earth pressure exceeds the compaction induced pressure,  $p$  = weight per unit width of the compaction machine,  $\gamma$  = unit weight of soil,  $K_a$  = Rankine's coefficient of active earth

Broms (1971) and Ingold (1979) also compared roller and vibrator compaction machines of similar weights and suggested that the weight of a vibrator machine should be doubled to account for vibratory effects as these lead to increased locked-in stresses. Using this analogy and applying the above equation, the ratio of horizontal earth pressures from a vibrator and roller compaction machine of similar weights would be 1.4:1.

The effects of compaction on geosynthetic reinforced soil masses was carried out by Yogarajah (1993). McGown et al (1990 and 1994) suggested that when geogrids with integral junctions were used as reinforcements a mechanism developed which was additional to the interlock concept initially introduced by Mercer (1986). He identified the presence of *Static Interlock* mechanism based on the soil particles being locked into grids due to static loads. McGown et al (1990 and 1994) showed that an additional mechanism called *Dynamic Interlock*, was available and could be developed by repeated loading in soil masses containing geogrid reinforcements with integral junctions.

This Dynamic Interlock mechanism may be explained as follows:

- (i) During compaction of a soil backfill containing a geogrid with integral junctions, the compaction loads force soil particles into the apertures of the grids.
- (ii) When the compaction load is released, the grid attempts to return to its initial condition, but it is resisted from doing so by the particles within the apertures. This results in the development of *Locked-in Strains* within the geogrid, Fig. 17.
- (iii) The Locked-in Strains have a similar effect to a confining stress on the soil, therefore they increase the strength of the soil. This reduces the lateral earth pressures from the level that would be expected from the model given by Broms (1971) under At Rest conditions.

Fig. 17. Build-up of the dynamic interlock mechanism (Yogarajah, 1993)

The effectiveness of the Dynamic Interlock mechanism is dependent on the resilient nature of the polymeric material in the strands of the grid and the integrity of the junctions between the strands in the grid.

## 7.2 Horizontal Earth Pressures from Compaction against Rigid and Yielding Walls

Two limiting cases must be considered. Firstly, if the lateral boundary is not allowed to yield, the resulting pressures will be equal to or greater than those obtained under At Rest conditions. This case produces the upper

limit of the lateral pressure acting on the wall. Secondly, if the lateral boundary is allowed to yield sufficiently to mobilise large tensile resistance in the reinforcements and if the Required Forces and the Available Forces balance, theoretically there will be no horizontal pressure acting on the wall. This provides the lower limit case. However, even for this lower limit case the soil masses between the reinforcing layers may have a tendency to produce localised stresses near the facing. This develops because each soil layer between the reinforcement tends to act separately, causing the wall to be subjected to Active horizontal pressures over the depth of that layer.

Yogarajah (1993) carried out full scale tests on three full height panel walls. Walls 1 and 2 were compacted using a vibratory method, the props were released from bottom to top and top to bottom respectively. For Wall 3 a roller method of compaction was used for compaction and props were released from bottom to top in the same way as Wall 1. Figures 18, 19 and 20 show the horizontal earth pressure distributions on the facing of Walls 1, 2 and 3 respectively for two conditions; (i) full height fill before the reinforcements were attached and before prop removal, and (ii) full height fill after the reinforcements were attached then all the props removed.

Before prop removal, the horizontal earth pressures recorded at the rear of the facing panels, following vibratory compaction (Walls 1 and 2), were higher than the pressures recorded due to the roller compaction (Wall 3). The ratio of the pressures were approximately 1.8:1. Employing the Ingold (1979) mathematical model, a ratio of 1.96:1 is obtained for the two compaction machines used. The total force on the facing panels was carried by the props at this stage of construction. The horizontal earth pressures acting on the lower half of the full-height propped panel walls were less than the theoretical earth pressure At-Rest. This was caused by the Locked-in Strains developed within the geogrid reinforcement during compaction.

After attachment of the reinforcements to the facing panels and removal of the props, the walls started yielding outwards and tensile strains were developed in both the reinforcements and in the adjacent soils. According to the mechanism previously described the prop load was carried partly by the increasing stress in the reinforcements and partly by the adjacent soils. However, small pressures were recorded on the facings because of the tendency of the soil masses near the facing between the reinforcing layers to deform. These small pressures on the facings are evident in Fig. 18, 19 and 20, shown as horizontal pressures 7 days after prop removal.

Saad (1993) carried out tests on reinforced soil walls with compressible boundary. Figure 21 shows the distribution of horizontal earth pressure on the facing panels before prop removal and after 1 day and 6 months from prop removal. The results show that the horizontal pressure on the facing was much less than the Active earth pressure during construction. The reason may be attributed to the deformation of the compressible layer, and thereby that of the soil boundary. The induced deformation of the soil boundary due to the deformation of the compressible layer strains both the reinforcements and the adjacent soils and reduces the horizontal pressure on the facing panel. This is the same mechanism that operates for a rigid boundary after prop removal. The introduction of the compressible boundary thus allows the design of less

Fig. 18. Horizontal earth pressure distribution on 1.8m high Wall 1: (a) backfill height 1.8m and (b) 7 days after prop removal (after Yogarajah, 1993), where  $K_c$  = Coulomb's coefficient of active earth pressure,  $K_a$  = Rankine's coefficient of active earth pressure and  $K_o$  = Jaky's coefficient of earth pressure at rest.

robust props than for a wall with a rigid boundary. It may also be noted that most of the deformations occurred during construction hence the horizontal earth pressure on the facing remained almost unchanged after prop removal. This is highly significant, in that it shows that the compressible boundary helps not only in reducing the loads on the props during construction, but that it helps to reduce the post construction displacement of the wall.

Fig. 19. Horizontal earth pressure distribution on 1.8m high Wall 2: (a) backfill height 1.8m and (b) 7 days after prop removal (after Yogarajah, 1993), where  $K_c$  = Coulomb's coefficient of active earth pressure,  $K_a$  = Rankine's coefficient of active earth pressure,  $K_o$  = Jaky's coefficient of earth pressure at rest.

Fig. 20. Horizontal earth pressure distribution on 1.8m high Wall 3: (a) backfill height 1.8m and (b) 7 days after prop removal (after Yogarajah, 1993), where  $K_c$  = Coulomb's coefficient of active earth pressure and  $K_a$  = Rankine's coefficient of active earth pressure and

### 7.3 Strain Distributions Along Geosynthetic Reinforcements due to Compaction and Connecting Reinforcements to Facings

During construction of the three walls tested by Yogarajah (1993), the geosynthetic reinforcements were not attached to the facing panel. At the end of construction, strains in the range of 0.05 to 0.1% were recorded along the reinforcements layers in the three walls, Fig. 22. The strains can be attributed to the Dynamic Interlock due to placing and compaction of the reinforced backfill on the geogrids

Fig. 21. Distribution of horizontal earth pressure: (a) wall movement, (b) deformation of geomattress, and (c) lateral earth pressure distribution after the end of construction on 2.0m high wall W6 (after Saad, 1993)

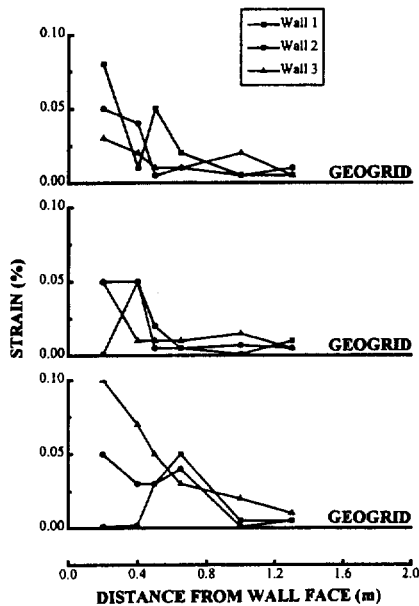

Fig. 22. Comparison of strain distribution along reinforcements at the end of construction on 1.8m high Walls (after Yogarajah 1993)

It was anticipated that the strains recorded along the reinforcement for the roller compaction method (Wall 3) would be higher than the vibrator compaction (Wall 1 and 2). In the roller compaction method, the rolling motion on the reinforced soil mass would have stretched the reinforcement. This additional stretching allowed larger amounts of soil particles to be embedded within the aperture of the geogrid used. Larger resistance to the contraction of the reinforcement would therefore have developed causing larger interlock forces and reduced horizontal earth pressures on the wall. The difference in behaviour, however, was not found to be significant.

After the 'hand tightening' of the reinforcements to the facing and removal of the props in Walls 1, 2 and 3, Yogarajah (1993) found that strains with similar distributions were recorded at all the reinforcement levels, Fig. 23. The strain distribution was not uniform, with small strains occurring at the front end of the reinforcements and increasing to a peak value along the reinforcement, before reducing to zero strains at the rear of the reinforcement. The positions of peak strains when joined together followed a straight line approximately  $0.18H$  away from the face of the wall. Obviously, if no slippage occurs between the reinforcement and the soil, the total displacement of the wall at the level of a particular reinforcement should be equal to the area of the strain diagram at the level of that reinforcement. This was confirmed by Yogarajah (1993).

A similar strain distribution was found by Saad (1993) for the geogrid reinforced walls with compressible boundary. Figure 24 shows the strain distribution along the reinforcements before prop removal with the

reinforcements unattached to the facing, with zero strain at the front end of the reinforcement and the locus of the peak tensions following a log-spiral line having its peak at a distance of  $0.3H$  from the facing at the top of the wall. The strain then drops back to zero at the rear end of the reinforcement.

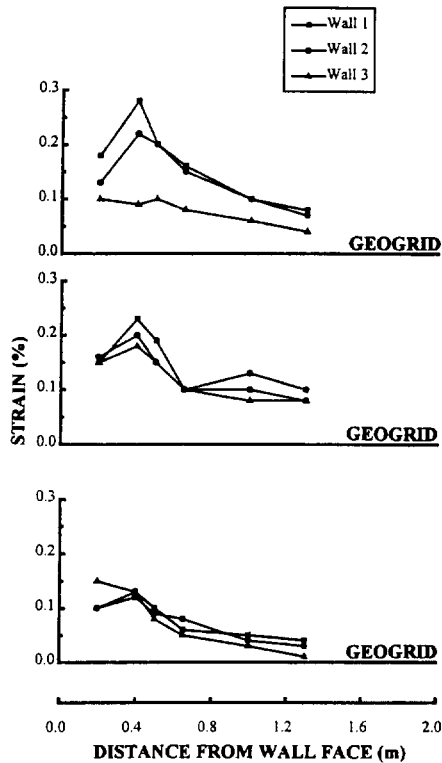

Fig. 23. Comparison of strain distribution along reinforcements 7 days after prop removal in 1.8m high Walls 1, 2 and 3 (after Yogarajah, 1993).

After the attachment of the reinforcements to the facings and removal of the props, the peak strain did not change significantly because almost all the movements of the compressible boundary had already occurred during construction. An appreciable change of strain, however, may be noted at the front end of the reinforcements, Fig. 25. This change of strain may be attributed to the 'hand tightening' of the reinforcements to the facings.

#### 7.4 Significance of Construction Effects on Design

The above sections are highly significant in terms of the approach to be taken to the design of geosynthetic reinforced soil structures. They emphasise the importance of the construction procedures in determining the internal stress-strain behaviour of geosynthetic

reinforced soil structures. Particularly important are the compaction procedures, imposed restrictions to lateral soil boundary movements and the nature and formation of connections between reinforcements and facings. Clearly construction procedures must be taken into account in design approaches and in particular in the Limit State Approach which involves assessment of the stress-strain behaviour of structures.

Fig. 24. Load/strain distributions along the geogrid reinforcements at the end of construction in 2.0m high wall W6 (after Saad, 1993)

Fig. 25. Strain distributions along the geogrid reinforcements after the end of construction wall W6 (after Saad, 1993)

## PART C - THE LIMIT STATE APPROACH APPLIED TO GEOSYNTHETIC REINFORCED SOIL STRUCTURES

### 8 LIMIT STATE MECHANISMS APPLICABLE TO GEOSYNTHETIC REINFORCED SOIL STRUCTURES

The mechanisms related to the external stability and operational performance of geosynthetic reinforced soil structures is taken to be the same as for conventional soil structures. The main differences between conventional reinforced soil structures and geosynthetic reinforced soil structures are the mechanisms related to internal stability and operational performance.

#### 8.1 A Model for the Internal Ultimate Limit State Mechanism

The behaviour of geosynthetics is time, temperature and load dependent. The load-strain behaviour of geosynthetics may be determined either from constant rate of deformation tensile tests or long term sustained load (creep) tests, but the relationship between constant rate of deformation tensile test data and the long term load carrying capacity of geosynthetics has been shown to be highly product specific and test condition specific, Yeo (1985). In addition constant rate of deformation tensile test data do not provide the necessary stress-strain-time-temperature relationships needed for Limit State analyses. Thus constant rate of deformation tensile test data are not appropriate for use in the Limit State Approach. Long term, sustained load, (creep), test data should be used.

To simulate the long term, sustained load (creep) test conditions and to facilitate the direct application of the test data to the design of a prototype structure, a constant *Out of Balance Force* (OBF) must be applied to the reinforcements from the *End of Construction* (EOC) to the *End of Design Life* (EDL). Such a situation can be achieved only if the tensile strain in the soil is large enough to mobilise the large strain constant volume angle of friction, ( $\phi'_{cv}$ ), at the End of Construction. Thereafter, until the End of Design Life, the soil may strain further but the mobilised shear strength of the soil will remain constant, i.e. the constant volume angle of friction, ( $\phi'_{cv}$ ), will continue to be mobilised.

For the above condition, a *Model Limit State Mechanism* for geosynthetic reinforced soil structures can be identified. In this model it is assumed such that a constant load is applied to the reinforcements from the time of *Switch-on of Gravity* ( $t_{SOG}$ ) to the End of Design Life, ( $t_{EDL}$ ), Fig.26.

Now in practice all the loads are not applied instantaneously, although it is generally assumed that they are applied simultaneously at some point during the *Construction Period*, ( $t_{CP}$ ). An important point to realise is that the Construction Period may be much longer than the *Reinforcement Loading Period*, ( $t_{RL}$ ), depending on the construction procedures adopted. For example a wall may be fully propped until the fill is placed to full height, during which time the reinforcements will not be loaded. Only on removal of the props will the reinforcements be loaded. Thus great care must be taken when selecting the Reinforcement Loading Period, ( $t_{RL}$ ).

When the loads are "switched-on", at say two thirds the Reinforcement Loading Period, ( $2/3 t_{RL}$ ), they will develop a strain in the soil, ( $\epsilon_{SOG}$ ) sufficient to mobilise the large strain constant volume angle of friction of the soil, ( $\phi'_{cv}$ ). If such a situation is achieved, there will be no change in the Out of Balance Force from the time of Switch-on of Gravity to the End of the Design Life and the geosynthetic reinforcements will always carry the same load. Long term, sustained load, (creep), test data thus directly apply and the Model Limit State Mechanism applies.

#### 8.2 A Model for the Internal Serviceability Limit State Mechanism

As stated above, in practice all loads are not applied instantaneously. As for the Ultimate Limit State condition, it can be assumed that all the Serviceability Limit loads are applied at say two-thirds of Reinforcement Loading Period ( $2/3 t_{RL}$ ), although this depends on the construction procedures.

Normally, these loads mobilise an angle of friction in the soil, ( $\phi'_{mRL}$ ) less than the peak angle of friction ( $\phi'_p$ ), Fig. 27. With time, the soil and the reinforcement strain and at the End of Design Life, the mobilised angle of friction ( $\phi'_{mEDL}$ ) is likely to remain less than the peak angle of friction but higher than the mobilised angle of friction at the End of Construction Loading. As the mobilised shear strength of the soil increases with time, the force required to be carried by the reinforcements will gradually become less, which means that the applied force on the reinforcements will change with time. If the change is significant, then an iterative approach to the determination of the deformations in the soil and the reinforcements must be undertaken.

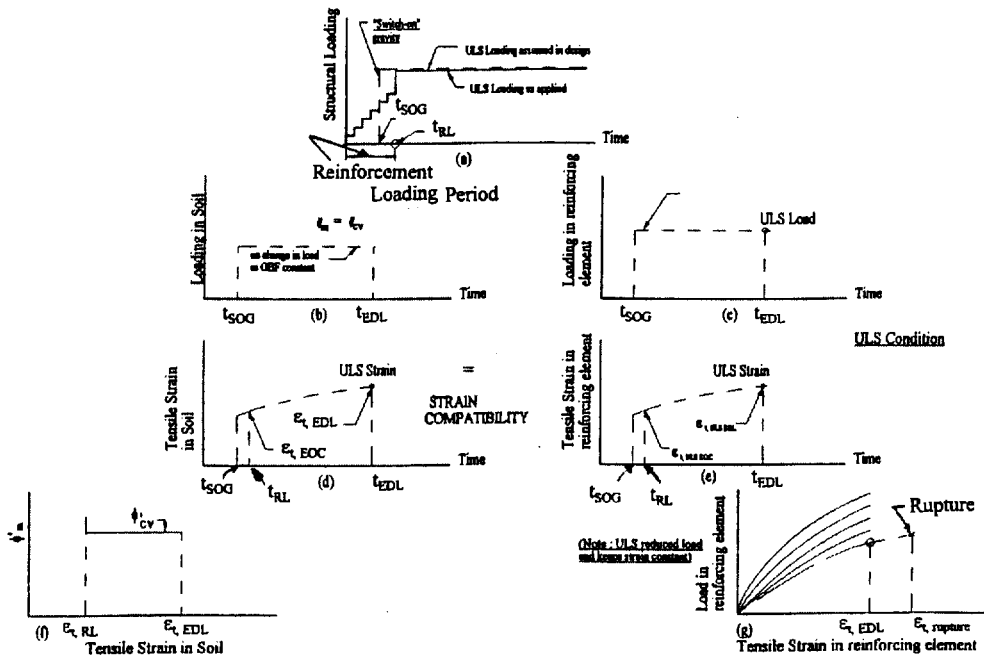

Fig. 26. Model ultimate limit state mechanism

Fig. 27. Model serviceability limit state mechanism

## 9. MATERIAL PARAMETERS TO BE USED IN LIMIT STATE APPROACH DESIGNS OF GEOSYNTHETIC REINFORCED SOIL STRUCTURES

Geosynthetic reinforced soil structures act externally in the same manner as conventional soil structures, hence the choice of material design parameters is the same as for the Limit State analyses of conventional soil structures, which are covered by existing Limit State codes. The difference, once again, is related to internal behaviour.

### 9.1 Soil Properties

As stated previously, the collapse of geosynthetic reinforced soil structures will occur at relatively large deformations, hence the soil will have strained sufficiently to develop the large strain constant volume angle of friction, ( $\phi'_{cv}$ ). Therefore this value should be taken in all Ultimate Limit State analyses of geosynthetic reinforced soil structures.

To account for Serviceability Limit States, limiting strains have to be imposed. Depending on these limiting strains, an appropriate mobilised angle of friction requires to be selected. In general, it is likely that this value will be in the numerical range of at rest angle of friction ( $\phi'_o$ ) to peak angle of friction ( $\phi'_p$ ). Thus for Serviceability Limit State analyses values must be chosen from the relationship between mobilised angle of friction and strain ( $\phi'_m - \epsilon_t$ ) for the soil used, the choice of value will depend on the mobilised strain levels.

Bolton (1986), found that for many granular soils the constant volume angle of friction was in the numerical range of 32 to 37°. Further he suggested that the peak angle of friction is related to the constant volume angle of friction by the equation:

$$\phi'_p = \phi'_{cv} + 0.8 \psi$$

where  $\psi$  is the Angle of Dilatation.

Thus a reasonably close approximation of the shape of the ( $\phi'_m - \epsilon_t$ ) relationship for a dense granular soil may be postulated, as previously indicated in Fig.7 and a mathematical model may be used to represent this relationship, Pradhan (1996).

### 9.2 Geosynthetic Reinforcement Properties

Because of their tendency to creep or suffer stress relaxation, the properties of geosynthetic reinforcements should be determined from long term sustained load (creep) test data. As they are temperature dependent, the sustained load, at which a synthetic polymeric reinforcement element ruptures, must be determined for the operational temperature. The long term load to cause rupture at the End of the Design Life may be designated  $T_{g \text{ rupture EDL}}$ . The tensile strain at which this occurs is

termed the End of Design Life rupture tensile strain and is designated  $\epsilon_{t \text{ rupture EDL}}$ .

The Ultimate Limit State design strength of the reinforcing element at the end of design life, ( $T_{g \text{ ULS EDL}}$ ), may be derived in one of three ways, Fig. 28. Figure 28 (a) shows that the rupture load may be factored and the rupture strain kept constant, whereas Fig.28 (b) shows that the rupture load can be kept constant and the rupture strain factored. However, both the rupture load the rupture strain may be factored, as shown in Fig.28 (c). To date it would appear that the last case is being adopted and this is certainly the most conservative approach.

Fig. 28. Three ways of factoring the rupture strength/rupture strain of geosynthetics

For Serviceability Limit State analysis, the mobilised tensile strength of the reinforcement ( $T_{g \text{ MOB}}$ ) should be

derived from *Isochronous Stiffness* data using the mobilised tensile strain data. The isochronous stiffness data should be appropriate to the operational temperature and other factors which will influence the stiffness of the geosynthetic over the strain range appropriate to the Serviceability Limit State. Thus great care must be taken when choosing appropriate Isochronous Stiffness data.

### 9.3 Soil Reinforcement Interaction Properties

There are two limiting modes of soil reinforcement interaction, *Direct Sliding*; in which a block of soil slides over a layer of reinforcement, and *Pull-out*; in which a layer of reinforcement pulls out from the soil after it has mobilised the maximum available bond stresses.

Fig. 29. Determination of friction coefficient between soil and reinforcement: (a) direct shear test; (b) pull-out test

Fig. 30. Mechanisms of interaction in reinforced soil structures

The two tests commonly used to measure soil and reinforcement interaction are the *Direct Shear Test* and the *Pull-out Test*, Fig. 29. In typical reinforced soil structures, the mechanism represented by Direct Sliding is likely to occur in region A and Pull-out in region B in Fig. 30. Each of these tests has limitations in the modelling of the real problem, including differences in boundary conditions and in scaling.

The shortcomings of Direct Shear test are the small area of contact between the soil and reinforcement, the development of friction between the sides of the upper part of the box and the soil together with the development of friction at the edges of the top box due to the soil particles being wedged into the clearance space. However, the errors produced from the development of these frictions at the boundary and the interface usually have a negligible effect on the results as they would be of opposite sign, Butterfield and Andrawes (1972).

A considerable amount of research has been carried out on the Pull-out behaviour of soil reinforcements, including Schlosser and Vidal (1969), Bacot et al. (1978), Chang et al (1977), Schlosser and Elias (1978) and Schlosser and Guillox (1979). Such tests were originally considered to be a useful means of obtaining data for reinforced earth structures. However, their value for design purposes later became somewhat discredited when the measured interface friction coefficient was often found to be several times larger than that of the soil friction, Murray (1983). The interpretation of the Pull-out test results was realised to be complex when pronounced boundary condition effects were identified, Alimi et al (1977) and Schwab et al (1977). Later, Bacot et al. (1978) identified the influence of the length of reinforcement on the apparent coefficient of friction. More recently investigations have shown that test data are highly sensitive to boundary conditions, wall roughness, length of the reinforcement and the scale of the test, Palmeira and Milligan (1989). Because of the complex nature of the test, careful interpretation is required before it is used in the design of reinforced soil structures.

The Direct Shear test can be applied to the determination of the soil reinforcement interaction coefficient for sheet and strip reinforcements, the interaction mechanisms of these types of reinforcement being very similar, Jewell (1996). For geogrid reinforcements, however, the mode of interaction during Pull-out is quite different. Dyer (1985) and Milligan et al. (1990) showed that it is partly developed through the concentration of bearing stresses against the transverse members of the grid and partly developed by Direct Sliding. Thus the *Bond Coefficient* of grids can only be measured by Pull-out testing, Jewell (1996).

McGown et al (1984b) suggested the possibility of applying a Partial Factor to soil-reinforcement interaction coefficients. At present no Limit State code or design method specifies any such Partial Factor. However, it may be suggested that although only a small Partial Factor, equal to or slightly greater than unity, is required for cases where the Direct Shear test results would be applicable, where interaction coefficients are obtained using Pull-out test results a higher Partial factor will be required. Further, since the *Coefficient of Direct Sliding* and the *Coefficient of Bond* are both functions of soil angle of friction, care should be taken when applying such Partial Factors. If in the calculation of the coefficients, a factored soil angle of friction has been used, application of a further Partial Factor on the soil reinforcements interaction coefficients would give an extremely conservative value for use in design.

## 9.4 Other Material Properties

For other materials (concrete, steel connections etc.), a relevant Limit State code may be followed. Normally this exists for use in the design of reinforced concrete and steel structures and material properties can be appropriately selected.

## 10 ACTIONS TO BE USED IN LIMIT STATE APPROACH DESIGNS OF GEOSYNTHETIC REINFORCED SOIL STRUCTURES

To date no benefits related to the short duration of some Actions are taken. All self weight and externally applied Actions are considered to be long term, sustained Actions for the purposes of design. Some of the externally applied loads are not sustained over long periods, for example traffic loads. It has been considered that this assumption represents a conservative basis for estimating the long term rupture and operational strength of geosynthetics and is therefore an acceptable practice. However, it has yet to be determined just how conservative is this assumption. Further investigation of the behaviour of geosynthetics subject to combined sustained and transient loading will require to be undertaken before this can be determined.

## 11 PARTIAL FACTORS TO BE USED IN LIMIT STATE APPROACH DESIGNS OF GEOSYNTHETIC REINFORCED SOIL STRUCTURES

Partial Factors require to be applied to the Properties of Materials, Actions Geometrical Data and Behavioural Models. Existing Limit State codes deal with all these, but are not always in agreement, particularly relating to the Partial Factors to be applied to determine the design strength of geosynthetics and their interaction with soil either for Ultimate or Serviceability Limit State analyses. The Partial Factor for soil-reinforcement interaction has been discussed in Section 9.3, thus in the following section, the Partial Factor related to geosynthetics will be discussed.

### 11.1 Partial Factors for Geosynthetics

Four Partial Factors of major concern have been identified, Voskamp and Risseuw (1987), Jewell and Greenwood (1988), Greenwood and Jewell (1989) and Troost and Ploeg (1990). These are:

- Damage Factor*; to allow for the mechanical damage during construction.
- Environmental Factor*; to allow for the chemical environment and microbiological exposure in the ground.
- Material Factor*; to allow for the uncertainty inherent in the extrapolation of test data, and
- Overall Factor*; to allow for the properties of materials not meeting the manufacturers specification.

Partial Factors are applied to some value of the strength of the geosynthetic reinforcement. Thus the first stage must be to agree the *Reference Strength* to which Partial Factors need to be applied.

Bush (1988), Billing et al (1990), Watts and Brady (1990) and Koerner and Koerner (1990) have carried out tests to identify damage effects on geosynthetics on the basis of constant rate of deformation tensile tests. They defined the maximum load at rupture of the control materials under constant rate of deformation tensile testing as the Reference Strength. However, as stated previously, constant rate of deformation tensile test data depend on many factors such as rate of strain, temperature, etc., and in any case are not suitable for defining geosynthetic properties in Limit State Analysis.

Troost and Ploeg (1990), Viezee et al (1990) and Voskamp (1989) carried out long term sustained load (creep) tests to identify the damage effects on a range of geosynthetics. They defined the Reference Strength as the load to cause rupture of a control specimen at the End of Design Life, Fig. 31. Jewell (1996) has supported this definition but it should be noted that many geosynthetics show a wide range of scatter of their rupture strains at different load levels, Fig. 32. Hence the Reference Strength, defined on the basis of load at rupture for a specific design life time can be very difficult to identify, i.e. it can be difficult to select specific values of loads and strains at rupture for geosynthetics.

Fig. 31. Reference strength of geosynthetics (after Voskamp, 1990)

A number of manufacturers, for example Netlon (1997), define the Reference Strength as the load, obtained from the load-isochronous creep curves, corresponding to a Performance Limit Strain. Figure 33 shows a typical Sherby-Dorn plot for a geogrid and identifies the *Instability Strain Limit*. A lesser value is then adopted as the Performance Limit Strain for use in Limit Equilibrium Method designs, McGown et al (1984a). This is a very

Fig. 32. Typical Sherby Dorn Plot

conservative approach. It is suggested that it would be more appropriate to suggest that the load to develop the Instability Strain, or a lesser defined Limiting Strain at the End of Design Life, should be used to define the Reference Strength for Limit State analyses. Partial Factors for use in Ultimate Limit State analyses should then be obtained by comparing the load carrying capacity of the geosynthetics corresponding to Instability Strain Limit, or to a lesser defined Limiting Strain at the End of Design Life, before and after damage and environmental attacks or due to manufacturing problems. For Serviceability Limit State analysis, the required Partial Factors can be suggested by comparing the load-isochronous curves (before and after damage) at strain levels appropriate to the Serviceability Limit conditions being analysed.

It should be noted that Partial Factors to be used with geosynthetics may be time dependant. Esteves (1996) carried out tests to identify damage effects on geosynthetics using long term sustained load (creep) tests. Figures 34 and 35 show the variation of the Partial Factor for a geogrid with time at large strain (10%) and at a relatively small strain (2%). It can be seen from these data that Partial Factors will vary with time and are therefore dependent on the Design Life of the reinforced soil structure.

Fig. 33. Sherby Dorn plots for a geogrid at 20°C

Fig. 34. Variation of damage Partial Factor for a geogrid with time at 10% strain (after Esteves, 1996)

Fig. 35. Variation of damage Partial Factor with time for a geogrid at 2% strain (after Esteves, 1996).

## PART D - THE DEVELOPMENT OF AN INTEGRATED COMPUTER-AIDED LIMIT STATE APPROACH DESIGN METHOD FOR CATEGORY 2 GEOSYNTHETIC REINFORCED SOIL STRUCTURES

### 12 THE BASIS OF THE LIMIT STATE DESIGN PROGRAM

Recently a computer program has been developed for the design of Category 2 geosynthetic reinforced soil structures using the Model Limit State Mechanism outlined previously and assuming the principles of internal force equilibrium and strain compatibility, Pradhan (1996). The integrated program is capable of designing reinforced soil walls, steep slopes and embankments on soft soils, for both Ultimate Limit States and the Serviceability Limit States. Within the program two approaches are adopted:

- i) Design based on Ultimate Limit States with a check of Serviceability Limit States (ULS-SLS Approach).
- ii) Design based on Serviceability Limit States with a check of Ultimate Limit States (SLS-ULS Approach).

In the ULS-SLS Approach, the structure is first designed to satisfy the Ultimate Limit State external and internal criteria and then the Serviceability Limit States are checked for the given reinforcement layout. In the SLS-ULS approach, the structure is first designed to the Serviceability Limit State Criteria and then the external and internal Ultimate Limit States are checked.

For ULS analyses, the large strain constant volume angle of friction, ( $\phi'_{cv}$ ), of the soil is used and for the SLS analyses, the relationship between the mobilised angle of friction, ( $\phi'_m$ ), and lateral strain in the soil, ( $\epsilon_t$ ), is used. In all cases, a Partial Factor of unity is applied.

The design strength of the reinforcements for ULS analysis has been adopted using the method described in Fig. 28(c). As a basis, the load to develop the Instability Strain Limit at the End of Design Life has been chosen and Partial Factors adopted in the program, covering the damage, environmental, material and overall effects, as prescribed by the manufacturer of the products. For SLS analysis, appropriate Isochronous Stiffness data and mobilised strains have been used to obtain the mobilised tensile strength of the reinforcement.

A Partial Factor of unity has been adopted for the soil-reinforcement interaction for both ULS and SLS analysis.

All loads have been taken to be long term, sustained loads. The combinations of loads for ULS and SLS analysis have been chosen according to BS8006 (1995). Partial Factors applied to the Actions for ULS analysis have been chosen from Eurocode 1 (1996). For SLS analysis, a Partial Factor of unity has been applied to the Actions.

### 13 INPUTS FOR THE ULS - SLS DESIGN APPROACH

The Input parameters are chosen from a pre-selected range, e.g., loads, soils, reinforcements, temperature, facings and construction methods. Some of the properties are interrelated and values are assigned as default values, e.g., once the soil type is chosen, the default values and a suggested range of properties are displayed. The default value can be changed within the suggested range but if a value out of this range is chosen then a warning is given, suggesting that the value is "out of range". Some of the Inputs are restricted to default parameters which are dependent on other Inputs, e.g., for a sloped facing, a structure cannot have full height panels. Similarly segmental wall facings can only have either a vertical face or a specific inclination to the horizontal, which is dependent on the facing unit type.

#### 13.1 Inputs for Walls

##### 13.1.1 Load Types

The walls can be designed for one of the following loadings situations:

- i) No external loading
- ii) Surcharge load only
- iii) Bankseat load only
- iv) Surcharge and Bankseat load
- v) Sloped retained fill above the wall

Fig. 36. Basic inputs for geometry of structure

##### 13.1.2 Basic Input

The basic inputs required for the analysis are:

- i) Design life of the structure (yrs)
- ii) Construction time (hrs)
- iii) Height of the structure above ground level, H (m)
- iv) Slope angle of the face of the structure,  $\beta_f$  ( $^\circ$ )
- v) Height of sloped retained fill,  $h_s$  (m)
- vi) Depth of embedment below ground level,  $D_m$  (m)

The parameters for defining the geometry of the structure are shown in Fig. 36.

### 13.1.3 Length of the Reinforcements

The option is given to define the minimum length of the reinforcements. The default value is 0.6 times the height of the structure. He user may define any other minimum length of the reinforcement.

### 13.1.4 Reinforced Fill, Retained Fill and Sloped Retained Fill Types

The following soil types are built into the program for the Reinforced, Retained and Sloped Retained fills:

- i) Well graded crushed rock.
- ii) Well graded sand and gravel.
- iii) Well graded sand.
- iv) Uniformly graded fine/medium sand.

### 13.1.5 Foundation Soil Types

The following soil types built in for the Foundation Soil are:

- i) Well graded crushed rock.
- ii) Well graded sand and gravel.
- iii) Well graded sand.
- iv) Uniformly graded fine/medium sand.
- v) Stiff clay.
- vi) Medium soft clay.
- vii) Soft clay.
- viii) Very soft clay.
- ix) Peat.
- x) Pulverised fuel ash.

### 13.1.6 Reinforcement Types

To date, the program is product specific.

### 13.1.7 Operational Temperature

The in-soil operational temperature in the structure has to be specified. The range of values included are between 5°C and 40°C, in increments of 5°C.

### 13.1.8 Facing Types

A range of Facing Types are available in the program and include:

- i) Full height panels.
- ii) Incremental panels.
- iii) External shutter wraparound.
- iv) Segmental facings.

In the program, if an out of range angle for the wall facing is chosen, information is given on alternative types of facings which are valid for the chosen facing angle .

### 13.1.9 Reinforcement Spacings

The maximum allowable spacing between the reinforcements may be restricted by the facing type and the minimum allowable spacing by the compaction layer thickness in the specification. In the program, the default values of maximum and minimum spacing are automatically chosen depending upon the type of facing.

### 13.1.10 Water Table

The water table can be entered as depth of water above or below the original ground level and it can be different within and outside the structure. A positive value represents the water table above the original ground level and a negative value represents the water table below the original ground level. A zero value represents the condition of no water table. The input data required for the depth of water are:

- i) Depth within the structure,  $h_{wt1}$  (m).
- ii) Depth outside the structure,  $h_{wt2}$  (m).

### 13.1.11 Construction Methods

The construction method is important in the case of the Serviceability Limit State as it dictates the mode of boundary deformation at the Serviceability Limit State condition.

The incremental construction method is applicable to all forms of facing except the full height panel wall construction. The full height panel has a series of separate construction methods, so that the range of methods is as follows:

- i) Incremental.
- ii) Full height panel: props released from Top to Toe.
- iii) Full height panel: props released from Toe to Top.
- iv) Full height panel: restrained at Toe during and after construction and props released at Top after construction.
- v) Full height panel: restrained at Top during and after construction and props released at Toe after construction.

To date compaction effects have not been included but this is now being introduced as it is known to be a very significant factor..

### 13.1.12 Mode of Boundary Deformation

The following ranges of modes of boundary deformation are given for the Serviceability Limit State condition:

- i) Rotation about Top.
- ii) Rotation about Toe.
- iii) Rotation about Top and Translation.
- iv) Rotation about Toe and Translation.
- v) Translation.
- vi) Others

The modes of boundary deformation are shown in Fig. 37.

### 13.1.13 Amount of Boundary Deformation

In the case of the modes of deformation (i) to (v), the slope of the boundary deformation at the Serviceability Limit State condition is defined in the form of deformations (mm) at the Top and the Toe of the facing. For the mode of deformation (vi), the shape of the deformations is entered by defining deformations (mm) at different depths. It may be noted that in the ULS-SLS approach the deformations given for the Top and Toe are only used to define the slope of the boundary, the output deformations of the boundary, (which can be different from these initial inputs), are calculated by an iteration process.

Fig. 37. Different modes of boundary deformation for retaining walls: (a) rotation about top, (b) rotation about toe, (c) translation, (d) rotation about top with translation, (e) rotation about toe with translation, (f), (g) and (h) others.

### 13.2 Inputs for Steep Slopes

The input parameters for Steep Slopes are no different from those of Walls except that the slope of the face of the structure has to be defined and full height panel facings cannot be chosen. The most common types of mode of deformation for Steep Slopes is Rotation about Top and Translation.

### 13.3 Inputs for Embankments

In the program, the embankments are assumed to have a slope angle less than or equal to the large strain constant volume angle of friction of the backfill material and they are resting on a weak Foundation Soil. Hence, a slope angle less than or equal to the large strain constant volume angle of friction of the backfill material has to be entered. The appropriate Foundation Soil type can be selected as one from (vi) to (x) mentioned previously in Section.

The program checks the external stabilities but does not need to check for internal stabilities. In the design, *Slope Change* or *No Slope Change* conditions can be chosen. If the *Slope Change* condition is chosen the slope of the embankment is changed until the most critical external stability is greater or equal to unity. If the *No Slope*

*Change* condition is chosen, the program does not change the slope of the embankment to be safe against all the external stabilities, however, it gives a warning that the Foundation Soil is not strong enough.

The program performs the Overall Stability Analysis for embankments using either a Total Stress Approach or an Effective Stress Approach. For the Total Stress Approach, the undrained shear strength, ( $C_u$ ), of the Foundation Soil at the surface has to be entered. The value of this undrained shear strength is programmed to change with time. It is also possible to vary the undrained shear strength linearly with depth, using the slope of the change in undrained strength versus depth relationship ( $m_c$ ).

For Effective Stress Analysis, Skempton's pore water pressure parameter 'A' at different times has to be entered.

No input for Serviceability Limit State Analysis is required to be entered for embankments having slope angle less than or equal to the large strain Constant Volume Angle of Friction of the embankment soil.

## 14 INPUTS FOR THE SLS-ULS DESIGN APPROACH

The input parameters in this approach are essentially the same as those for the ULS-SLS approach. The exceptions are that this approach is not appropriate for embankments and that the inputted lateral boundary deformations at the Top and Toe should represent the Serviceability Limit State values. These will determine the distribution of the reinforcements, which will then be checked for the Ultimate Limit State conditions.

## 15 OUTPUTS FROM THE ULS - SLS DESIGN APPROACH

The program checks the external and internal stabilities using the appropriate material properties and loadings and determines the deformations at force equilibrium at the End of Construction and at the End of Design Life.

### 15.1 Outputs for Walls and Steep Slopes

External Stability:

- Sliding Ratio
- Overturning Ratio
- Bearing Pressure
- Bearing Resistance

Internal Stability:

- Reinforcement Rupture Ratio
- Pull-out Ratio
- Sliding Ratio through reinforcements
- Sliding Ratio through reinforced fill layers.

Reinforcement Layout:

- Theoretical Layout
- Practical Layout

**Boundary Deformations:**

- At the End of Construction
- At the End of Design Life

**Force at Equilibrium:**

- Out of Balance Forces
- Available Forces

**15.2 Outputs for Embankments**

**External Stability:**

- Sliding Ratio
- Overturning Ratio
- Bearing Pressure
- Bearing Resistance
- Foundation Instability Ratio

**Reinforcement Layout for Slope Stability**

- Practical Layout

**Forces:**

- Required Forces and Available Forces
  - at the End of Construction (EOC)
  - after 1 year from EOC
  - after 5 years from EOC
  - after 10 years from EOC
  - after 120 years from EOC

**16 OUTPUTS FROM THE SLS-ULS DESIGN APPROACH**

The outputs from the SLS-ULS approach are similar to the outputs of the ULS-SLS approach with the difference that the calculated boundary deformations at the End of Construction and End of Design Life will be less than or equal to the Serviceability Limit State limiting values.

**17 SOME DESIGN EXAMPLES AND RESULTS**

**17.1 Walls**

A 5.0m high wall with flat top surface resting on a competent foundation has been designed . Well graded sand and gravel ( $\phi'_p = 40^\circ$  and  $\phi'_{cv} = 32^\circ$ ) was chosen as the Reinforced, Retained and Foundation Soils. Geogrids working at  $10^\circ\text{C}$  operational temperature were chosen. The mode of boundary deformation, the slope of boundary deformation and types of facings were varied to identify their effects on the amount of boundary deformation at the End of Design Life. Additionally, the design life of the structure was varied and its effect on the number of reinforcements and amount of boundary deformations at the End of Construction. The results of these analyses are shown in Figs. 38 to 42 and confirm the influence of the factors varied.

Fig. 38. Effect of mode of boundary deformation on the amount of boundary deformation at the end of design life.

Fig. 39. Effect of the slope of the boundary deformation on the amount of boundary deformation at the end of design life.

Fig. 40. Effect of facing type on the amount of boundary deformation at the end of design life.

## 17.2 Steep Slopes

A 5.0m high Steep Slope with a flat top surface resting on a competent foundation has been designed. Well graded sand and gravel ( $\phi'_p = 40^\circ$  and  $\phi'_{cv} = 32^\circ$ ) was chosen as the Reinforced, Retained and Foundation Soils. Geogrids working at  $10^\circ\text{C}$  operational temperature were chosen. The angle of the slope was varied to identify its effect on number of reinforcements and deformation at the End of Design Life. The results are shown in Fig. 43 and 44 and confirm the influence of the factors varied.

## 17.3 Embankments

A 5.0m high embankment with a flat top surface and a slope angle of  $30^\circ$  has been designed resting on a weak Foundation Soil. Medium soft clay was chosen as the Foundation Soil. Well graded sand and gravel ( $\phi'_p = 40^\circ$  and  $\phi'_{cv} = 32^\circ$ ) was chosen as the Reinforced and Retained Soils. Geogrids working at  $10^\circ\text{C}$  operational temperature was chosen and both the Slope Change and the No Slope Change conditions were adopted. The Total Stress Approach was used and the undrained shear strength at the surface and the rate of change of undrained shear strength with depth were varied to identify their effects on number of reinforcements for both the Slope Change and the No Slope Change conditions. The results are presented in Figs. 45, 46 and 47 and confirm the influence of the factors varied.

Fig. 41. Effect of design life on the number of reinforcements.

Fig. 42. Effect of design life on the amount of boundary deformation at the end of construction.

Fig. 43. Effect of angle of steep slope on the number of reinforcements.

Fig. 44. Effect of slope of the structure on the amount of boundary deformation at the end of design life.

## 18 DISCUSSION AND CONCLUSIONS

The aim of this paper has been to demonstrate the methodology required in order to strictly apply the Limit State Approach to the design of geosynthetic reinforced soil structures. In the process of demonstrating the application of the Limit State Approach, the general principles of the Limit Equilibrium Methods, to date the most widely used design methods, were set out and the explicit and implicit assumptions involved have been highlighted.

From the detailed consideration of the Limit State Approach, it may be concluded that:

(i) The Limit State Approach allows consideration of the nature and size of soil structures, the nature of existing ground and groundwater conditions and the nature of the operational environment. It also allows the introduction of the concept of Geotechnical Categories to take account of the degree of complexity and/or importance of soil structures.

(ii) Two aspects of the Limit State Approach are of particular significance to geosynthetic reinforced soil structures, viz., the consideration given to the Strain Compatibility of the various materials within the soil structure and the assessment of the significance of internal and external environmental conditions on the durability of materials.

(iii) Designs based on the Limit State Approach required the identification of appropriate Calculation Models, Properties of Materials, Actions, Geometrical Data and Limiting Values. Design Values of the Properties of Materials are based on Characteristic Values determined on a statistical basis. The values to be used for collapse/failure and for serviceability conditions may well be very different.

(iv) Design criteria are based on equating the effects of the de-stabilising Actions and the stabilising Actions.

(v) Global Factors of Safety are not used in analyses, rather Partial Factors require to be applied to the Properties of Material, Actions, Geotechnical Data and Behavioural Models.

(vi) Particular attention requires to be given to the internal force equilibrium and strain behaviour of geosynthetic reinforced soil structures and to the effects of construction methods on these.

(vii) Detailed consideration requires to be given to the identification of model mechanisms applicable to the Ultimate and Serviceability Limit States.

The development of an integrated computer-aided Limit State Approach design for Category 2 geosynthetic reinforced walls, steep slopes and embankments has been

Fig. 45. Variation of number of reinforcements with undrained shear strength and with the rate of change of shear strength with depth for "no slope change" condition

Fig. 46. Variation of number of reinforcements in an embankment slope with different undrained shear strengths for "slope change" condition.

Fig. 47. Effect of undrained shear strength on the final slope angle for "slope change" condition.

presented. Details of the inputs required for the Ultimate and Servicability Limit State analyses have been given and the form of the outputs from the analyses set out. Some design examples have been included which indicate the significance of the various conditions and inputs included in the design program.

Overall, it has been shown that the Limit State Approach is ideally suited to the design of geosynthetic reinforced structures, taking into account many factors not included, nor possible to include, in Limit Equilibrium Methods of design. The computer-aided design package described showed that it is practically possible to apply the Limit State Approach to geosynthetic reinforced soil structures and to account for a wide range of the factors that influence their behaviour.

**ABSTRACT:** Geosynthetic leachate collection layers used in landfills (e.g. geonet drainage layers overlain by geotextile filters) are often covered with a sand protective layer. If the sand contains fine particles and if the leachate infiltrating through the sand causes some of the fine particles to migrate, then the migrating fine particles may clog the geotextile filter or, if they pass through the filter, may clog the geosynthetic leachate collection layer. This paper presents an evaluation of the effect of migrating fine particles on the performance of the filter and the leachate collection layer. It is shown that a relatively small amount of migrating particles may clog geotextile filters and geonet leachate collection layers. It is unlikely that leachate flow will cause the migration of all of the fines contained in the sand protective layer; however, this paper indicates the importance of assessing the potential for fines migration and the consequences of this phenomenon.

**KEY WORDS:** Geosynthetic, Leachate collection layer, Geotextile, Filter, Clogging.

## 1 INTRODUCTION

### 1.1 Geosynthetics and the Need for Protection

Geosynthetic leachate collection layers used in landfills typically consist of a geonet. Geosynthetic leachate collection layers and the associated geosynthetics (i.e. the overlying geotextile filter and the underlying geomembrane liner) need to be protected from mechanical damage that may result from waste placement operations, and the geotextile filter needs to be protected from deterioration caused by sunlight. The required protection for these geosynthetics is typically provided by a soil protective layer (Figure 1). The degree of protection against

mechanical damage provided to the geosynthetics is a function of, among other factors, the thickness of the soil protective layer. The thickness of soil protective layers typically ranges from 0.3 to 1 m.

### 1.2 Sand Protective Layers Containing Fines

At many landfill sites, the material available for the soil protective layer is a sand containing fines. Fines are generally defined as particles smaller than a certain size (e.g. 75  $\mu\text{m}$  in the United States). Sometimes, a maximum fines content is specified, e.g. 5%. The maximum fines content specification is often treated by design engineers as a secondary consideration to which not much attention is paid, perhaps because no analytical approach has been available to rationally select the specified value. Furthermore, during construction, the specification may not be met, and/or conformance tests to check that the specification is met may not be performed. Based on the authors' experience, the specification regarding the fines content of a sand protective layer is not often well thought out, properly implemented, or seriously enforced.

As shown in this paper, the specification regarding the fines content of a sand protective layer is an important design consideration that must be carefully addressed because clogging of the leachate collection layer and/or its filter may result from the presence of fines in sand protective layers.

Figure 1. Soil protective layer overlying geosynthetics in a landfill liner system.

### 1.3 Potential Effects of Fines

If fines are “washed” by leachate flow (i.e. if fines migrate as leachate infiltrates through the sand protective layer), then the fines may accumulate on, or in, the geotextile filter, which impedes the flow of leachate toward the leachate collection layer; this problem is addressed in Section 4.2. If some of the migrating fines pass through the geotextile filter, they may accumulate in the leachate collection layer, thereby reducing its hydraulic conductivity and, consequently, its hydraulic transmissivity; this problem is addressed in Section 4.3.

Prior to evaluating the detrimental consequences of the migrating fines (Section 4), it is necessary to quantify the amount of fines contained in the soil protective layer (Section 2) and analyze the conditions that govern the mobility of these fines (Section 3).

## 2 DESCRIPTION OF SAND CONTAINING FINES

### 2.1 Particle Size Distribution of Sand Containing Fines

A typical particle size distribution curve of a sand containing fines is presented in Figure 2a. This curve can be broken down into three segments: AB, representing the fine fraction; BC, representing the coarse fraction; and CD, representing the very coarse fraction. Points B and C are the points of maximal curvature (i.e. minimal radius of curvature) of the particle size distribution curve. As indicated by Giroud (1996), the very coarse fraction, when it is a small portion of the total mass of soil particles (as is the case in Figure 2a where the very coarse fraction is less than 15% of the total mass), does not affect the mobility of the fine particles. Therefore, for the purpose of analyzing the effects of migrating soil particles, the particle size distribution curve can be truncated to eliminate the very coarse fraction (Figure 2b); this type of particle size distribution curve is used in the remainder of this paper.

The soil represented by the particle size distribution curve shown in Figure 2b comprises two distinct fractions: a fine fraction, characterized by the relatively flat curve AB, and a coarse fraction, characterized by the steep curve BC. The limit between the fine fraction and the coarse fraction, Point B in Figure 2, was selected, as indicated above, as the location of maximal curvature of the particle size distribution curve. In Figure 2, the abscissa of Point B is 0.12 mm (120 μm), and, in Figure 2b, the fine fraction proportion,  $f_M$ , is 6%. In this paper, the term “fine particles” is used to designate the particles of the fine fraction, i.e. the particles smaller than the abscissa of Point B, whereas the traditional term “fines” is used to designate particles smaller than 75 μm.

The particle size distribution curve shown in Figure 2 is that of a gap-graded soil if the AB portion of the curve

Figure 2. Typical particle size distribution curve of a sand containing fines: (a) fine fraction (AB), coarse fraction (BC) and very coarse fraction (CD), where B and C are points of maximal curvature; (b) particle size distribution curve after removal of the very coarse fraction.

includes, on the left of Point B, a plateau, which indicates a gap between the fine fraction and the coarse fraction. Filtration problems associated with gap-graded soils have been known for a long time (Giroud 1982). Herein, it is not assumed that the particle size distribution curve includes a plateau, but the problems discussed are similar to those of gap-graded soils.

As discussed in Section 3, the extent to which the fine fraction “fills” the pore space of the coarse fraction is an important factor governing the mobility of the fine particles. This is addressed in Section 2.2.

### 2.2 Critical Value of the Fine Fraction Proportion

The critical value of the fine fraction proportion,  $f_{M \text{ crit}}$ , is defined as the value of the fine fraction proportion,  $f_M$ , for which the fine fraction exactly fills the pore space of the coarse fraction. The value of  $f_{M \text{ crit}}$  (for which the derivation is not shown here) is:

$$f_{M \text{ crit}} = \frac{n_c (1 - n_r)}{1 - n_r n_c} \quad (1)$$

where:  $n_f$  = porosity of the fine fraction of the soil when the fine particles fill the pore space of the coarse fraction; and  $n_c$  = porosity of the coarse fraction, which can be expressed as follows:

$$n_c = n + f_M (1 - n) \quad (2)$$

where  $n$  is the porosity of the entire soil comprising the fine and the coarse fraction;  $n$  is obtained experimentally from simple volume measurements. Equation 2 makes it possible to eliminate the unknown parameter  $n_c$  from Equation 1. Combining Equations 1 and 2 gives:

$$f_{M\text{crit}} = \frac{(1 - n_f)[n + f_M (1 - n)]}{1 - n_f [n + f_M (1 - n)]} \quad (3)$$

The only unknown parameter in Equation 3 is the porosity of the fine fraction,  $n_f$ . Values of the order of 0.3 to 0.5 are typically assumed. Table 1 (which was established using Equation 1) shows that  $f_{M\text{crit}}$  does not depend much of the assumption made on  $n_f$  and is typically of the order of 20 to 40%. As a result, the fine fraction proportions of 5% or less used in typical specifications for sand protective layers are much smaller than  $f_{M\text{crit}}$ . In this paper, only cases where  $f_M$  is much smaller than  $f_{M\text{crit}}$  are considered, i.e., approximately:

$$f_M / f_{M\text{crit}} < 1/3 \quad (4)$$

where  $f_M / f_{M\text{crit}}$  is the degree of filling.

Table 1. Values of  $f_{M\text{crit}}$  (%).

Porosity of the fine fraction, $n_f$	Porosity of the coarse fraction $n_c$		
	0.3	0.4	0.5
0.3	23	32	41
0.4	20	29	38
0.5	18	25	33

### 2.3 Methodology for Evaluating the Degree of Filling

Based on the discussions presented in Sections 2.1 and 2.2, the methodology for evaluating the degree of filling of the pore space of the coarse fraction by the fine fraction of a soil composed of a coarse and a fine fraction can be summarized as follows:

- The proportion by mass of the fine fraction,  $f_M$ , is obtained from the truncated particle size distribution

curve of the soil;  $f_M$  is the ordinate of the point of maximal curvature that separates the portion of the curve representing the coarse fraction from the portion of the curve representing the fine fraction (Figure 2b).

- The porosity of the soil,  $n$ , is obtained experimentally.
- The porosity of the coarse fraction,  $n_c$ , is then calculated using Equation 2.
- An assumption is then made regarding the value of the porosity of the fine fraction,  $n_f$ . Typical values are assumed to range between 0.3 and 0.5.
- The value of  $f_{M\text{crit}}$  is then calculated using Equation 1 or 3, and  $f_M$  is compared to  $f_{M\text{crit}}$  to evaluate the degree of filling of the pore space of the coarse fraction by the fine fraction and to check if the condition expressed by Equation 4 is satisfied.

## 3 MOBILITY OF THE FINE PARTICLES

### 3.1 Mechanisms Governing the Mobility of Fine Particles

In a soil comprising two fractions (i.e. a coarse fraction and a fine fraction), the fine particles are located within the matrix formed by the coarse particles. All of the particles (coarse and fine) are subjected to drag forces from the downward flow of leachate. However, it is assumed herein that the matrix formed by the coarse particles is stable, implying that the drag forces do not dislodge the coarse particles. Therefore, only the mobility of the fine particles is considered. (Mobility is defined herein as the tendency of particles to migrate.) The drag forces tend to cause the fine particles to migrate through the matrix formed by the coarse particles. In other words, the drag forces tend to "wash" the fine particles through the matrix formed by the coarse particles. The mobility of the fine particles increases as the drag forces increase and the fine particles' resistance to the drag forces decreases.

The drag forces applied to the fine particles increase if the flow velocity increases. If the degree of filling of the pore space of the coarse fraction is small, i.e. if the condition expressed by Equation 4 is satisfied, the hydraulic conductivity of the soil is anticipated to be high and, consequently, the flow velocity is anticipated to be high. Therefore, in this case, the drag forces applied to the fine particles should be large, and the fine particles are likely to be mobile, thus the consideration in this paper of small degrees of filling.

A fine particle resists drag forces as a result of: (i) cohesive forces that attract the considered particle to other fine or coarse particles; (ii) physical interlocking of the fine particle within other fine particles; and (iii) entrapment of the fine particles within the matrix formed by the coarse particles. The first two mechanisms are discussed below, and the third one is discussed in Section 3.2.

Cohesive forces are difficult to quantify. Cohesive forces are conservatively neglected in the analyses

presented herein. As a result, the mobility of the fine particles predicted by the analysis presented herein is greater than the mobility that would be calculated if cohesion was taken into account.

Interlocking of the fine particles with other fine particles requires that fine particles be in contact with each other. Therefore, the portion, resulting from interlocking, of the resistance to drag forces increases as the amount of fine particles in the pore space of the coarse fraction increases. Only cases where the amount of fine particles is small are considered in this paper (see Equation 4 in Section 2.2). As a result, in the cases considered in this paper, the fine particles are not strongly interlocked.

If cohesion is negligible and interlocking is weak, as assumed in this paper, a significant number of fine particles are likely to migrate individually. In this case, the main factor that governs the ability of the fine particles to migrate is their size.

### 3.2 Influence of Particle Size on Particle Mobility

As indicated in Section 3.1, the mobility of the fine particles of a soil comprising a fine and a coarse fraction depends on their ability to pass between the coarse particles. In other words, the coarse fraction is acting as a filter with respect to the fine particles. Therefore, for the purpose of this analysis, the coarse fraction must be characterized by its filtration opening size. As shown by Kenney et al. (1985) and discussed by Giroud (1996), the filtration opening size of a granular material, such as the coarse fraction considered herein, is given approximately by the following equation:

$$O_F = D_{15}/5 \quad (5)$$

where:  $O_F$  = filtration opening size of the coarse fraction; and  $D_{15}$  = particle size of the coarse fraction such that 15% by weight of the particles of the coarse fraction are smaller than  $D_{15}$ . (Herein,  $D$  is used for the particles of the coarse fraction and  $d$  for the particles of the fine fraction.)

When fine particles migrate individually, they pass through the filter formed by the coarse fraction if they are smaller than the filtration opening size of the coarse fraction, i.e. if:

$$d \leq O_F \quad (6)$$

Combining Equations 5 and 6 gives the following condition for fine particles to migrate individually through the coarse fraction:

$$d \leq D_{15}/5 \quad (7)$$

However, if several particles smaller than  $O_F$  migrate at the same time toward the same area of the coarse fraction pore space, these particles may locally interlock and bridge the filter openings. If this mechanism takes place at many locations, it may gradually prevent many fine particles from migrating. For example, experience from grouting indicates that grout flows freely through a soil if the  $d_{85}$  of the grout particles meets the following requirement with respect to the  $D_{15}$  of the soil (Mitchell 1970):

$$d_{85} \leq D_{15}/25 \quad (8)$$

Grouting is an extreme case where many particles are likely to migrate at the same time into a given volume, whereas, in the case discussed in this paper (i.e. the case where the fine fraction proportion is small), only a small number of fine particles are likely to migrate at the same time. Nonetheless, Equation 8 provides a useful boundary for the case discussed in this paper, as shown below.

In conclusion all the particles that meet the condition expressed by Equation 8 should migrate through the coarse fraction: (i) if the amount of fine particles is small enough that particles are not interlocked (Equation 4); (ii) if leachate flow is able to overcome the cohesion between fine and coarse particles; and (iii) if the cohesion between fine particles is small enough that it will not prevent fine particles from migrating individually. (It is realized that restrictions of particle migration due to cohesion may be significant. For example, even gravel considered clean after thorough washing with water contains some fines.) Additionally, the particles that do not meet the condition expressed by Equation 7 cannot migrate through the coarse fraction, because they are entrapped due to their size. Therefore, the proportion by mass of the particles likely to migrate,  $f_{Mm}$ , is between a lower boundary,  $f_{Mm \min}$ , and an upper boundary,  $f_{Mm \max}$ :

$$f_{Mm \min} < f_{Mm} < f_{Mm \max} \quad (9)$$

Figure 3 shows how to obtain  $f_{Mm \max}$  from the value of  $d$  defined by Equation 7 and  $f_{Mm \min}$  from the value of  $d$  defined by Equation 8 (with  $d$  used instead of  $d_{85}$ ). Figure 3 shows that there is not a large difference between  $f_{Mm \min}$  and  $f_{Mm \max}$  if the particle size distribution curve of the fine fraction is relatively flat in the relevant region.

Often, the particle size distribution curve is known only for particles greater than, or equal to, 75  $\mu\text{m}$ . If the point of maximum curvature of the particle size distribution curve is close to 0.1 mm (100  $\mu\text{m}$ ), then only a small portion of the particle size distribution curve of the fine fraction is known and the method presented in Figure 3 can only be used if the particle size distribution curve is extrapolated. Alternatively, based on Figure 3, it may be assumed that  $f_{Mm}$  is approximately between  $f_M$  and  $f_M/2$  or  $f_M/3$ .

Figure 3. Determination of the amount of fine particles likely to migrate.

#### 4 EFFECTS OF MIGRATING FINE PARTICLES

##### 4.1 Overview

As indicated in Section 3.2, in a soil comprising two fractions, some fine particles can migrate through the coarse fraction. Depending on the opening size of the geotextile filter and other factors, these fine particles may pass through and/or accumulate in, or on, the geotextile filter. The effect of fine particles that accumulate on the geotextile filter is addressed in Section 4.2 and the effect of the fine particles that pass through the geotextile filter and may accumulate in the leachate collection layer is discussed in Section 4.3. A numerical example is presented in Section 4.4.

##### 4.2 Effect of Fine Particles on Filter

The fine particles that accumulate on, or in, the geotextile filter create a low-permeability layer that reduces the rate of leachate flow toward the leachate collection layer. The case where the particles accumulate on the filter is considered herein. Calculations (not presented here, but to be published elsewhere) show that the thickness of the low-permeability layer formed by fine particles accumulated on the geotextile filter is given by the following equation:

$$t_f'' = \frac{t}{n_c} \left( \frac{1-n_c}{1-n_f''} \right) \left( \frac{f_{MF}}{1-f_{MF}} \right) \quad (10)$$

where:  $t$  = thickness of the soil protective layer;  $n_f''$  = porosity of the fine fraction formed in the low-permeability layer by fine particles accumulated on the geotextile filter; and  $f_{MF}$  = proportion by mass of particles accumulated on the geotextile filter. Note that  $f_{MF} \leq f_M$ , the proportion by mass of the particles likely to migrate.

Table 2. Thickness of the low-permeability layer formed by fine particles accumulated on the geotextile filter in the case of a 0.6 m thick soil protective layer.

Proportion by mass of particles accumulated on the filter, $f_{MF}$ (%)	0.5	1	2	5
Thickness, $t_f''$ (mm)	14	28	57	147

Values of  $t_f''$  calculated using Equation 10 for  $t = 0.6$  m,  $n_c = 0.3$  and  $n_f'' = 0.5$  are presented in Table 2. It appears from Table 2 that the calculated thickness of the low-permeability layer formed by the fine particles accumulated on the filter may be significant, even when the proportion by mass of accumulated particles is relatively small (e.g.  $f_{MF} \leq 2\%$ ).

The effect of the low-permeability layer formed by fine particles accumulated on the geotextile filter on the flow of leachate toward the leachate collection layer can be evaluated by comparing the permittivity of this layer to that of the soil protective layer. According to Table 2, the thickness of the low-permeability layer formed by fine particles accumulated on the geotextile filter is of the order of 10 mm if the proportion by mass of the accumulated particles is of the order of 0.5%. If the hydraulic conductivity of this layer is  $1 \times 10^{-7}$  m/s, then the permittivity of this layer is  $1 \times 10^{-5}$  s<sup>-1</sup>. This value is approximately 20 times less than the permittivity of a 0.5 m thick sand protective layer with a hydraulic conductivity of  $1 \times 10^{-4}$  m/s (a hydraulic conductivity that corresponds to a sand containing approximately 1% fines). Clearly, a significant reduction of the leachate flow toward the leachate collection layer may be caused by the accumulation on the filter of as few as 0.5% of the particles (i.e. one tenth of the fines if the fines content is 5%).

##### 4.3 Effect of Fine Particles on Leachate Collection Layer

The fine particles that pass through the geotextile filter migrate into the leachate collection layer, where a significant fraction of the fine particles may tend to accumulate in areas where the leachate collection layer slope is gentle (e.g. 2%), as shown by sedimentation calculations. It is, therefore, important to evaluate if the leachate collection layer can accommodate these fine particles without becoming clogged. Calculations (not presented here, but to be published elsewhere) show that the thickness of leachate collection layer occupied by the accumulated fine particles is given by the following equation:

$$t_{fLCL} = \frac{t}{n_{LCL}} \left( \frac{1-n_c}{1-n_{fLCL}} \right) \left( \frac{f_{MLCL}}{1-f_{MLCL}} \right) \quad (11)$$

where  $n_{LCL}$  = porosity of the leachate collection layer;  $n_{fLCL}$  = porosity of the soil formed by the fine particles accumulated in the leachate collection layer; and  $f_{MLCL}$  = proportion by mass of particles accumulated in the leachate collection layer. Note that  $f_{MLCL} \leq f_M$ , the proportion by mass of the particles likely to migrate.

Values of  $t_{LCL}$  calculated using Equation 11 for  $t = 0.6$  m,  $n_c = 0.3$ ,  $n_{fLCL} = 0.5$ ,  $n_{LCL} = 0.3$  (granular leachate collection layer) and  $n_{LCL} = 0.8$  (geosynthetic leachate collection layer) are presented in Table 3. Table 3 shows that a typical 5 to 10 mm thick geosynthetic leachate collection layer is filled with fine particles, even if the amount of particles accumulated in the leachate collection layer is as low as 0.5 to 1% of the soil protective layer mass. In contrast, a 300 mm thick granular leachate collection layer is filled by fine particles only if the amount of particles accumulated in the leachate collection layer is approximately 10% of the soil protective layer mass.

Table 3. Thickness of leachate collection layer occupied by fine particles,  $t_{fLCL}$  (mm), in the case of a 0.6 m thick soil protective layer.

	Porosity of the leachate collection layer without fine particles, $n_{LCL}$	Proportion by mass of particles accumulated in the leachate collection layer, $f_{MLCL}$ (%)			
		0.5	1	2	10
Granular layer:	0.3	14	28	57	311
Geosynthetic layer:	0.8	6	11	21	117

#### 4.4 Numerical Example

Based on data presented in this paper, the following may be said about a 0.6 m thick sand protective layer containing 5% fines (a fines content generally considered acceptable): (i) the 5% fines content is small compared to the critical fine fraction proportion (which is of the order of 20 to 40%, according to Table 1) and, therefore, the condition expressed by Equation 4 is satisfied; consequently, the fines fill only a small portion of the pore space of the coarse fraction; as a result, the leachate flow velocity may be high and there is likely no interlocking between fine particles; thus, the fines are likely to be mobile unless they are retained on the coarse (i.e. sand) particles due to cohesion; (ii) more than one third or one half of these fines (i.e. approximately 2% by mass of the total soil) may pass through the coarse fraction (according to the comment at the end of Section 3.2), on the basis of their particle size with respect to the particle size of the coarse fraction; (iii) the 2% fines which are most mobile are the finest of the fines and many of them may be retained on the coarse

particles due to cohesion; however, if only one quarter of these fines, i.e. 0.5%, do migrate, the consequences may be significant; (iv) if the migrating fines accumulate on the geotextile filter, they can be expected to form a low-permeability layer at least 10 mm thick (according to Table 2), which may significantly reduce the rate of leachate flow toward the leachate collection layer; and (v) if, instead, the migrating fines pass through the filter, a portion of them may accumulate in the leachate collection layer, which would decrease the geonet hydraulic transmissivity (whereas the hydraulic performance of a typical 0.3 m thick granular leachate collection layer would not be significantly affected, according to Table 3).

## 5 CONCLUSION

The theoretical analysis presented in this paper shows that a small amount of fine particles, migrating under the action of leachate flow from a soil protective layer used in a landfill liner system, may clog the underlying geosynthetic leachate collection layer or its geotextile filter. The analysis presented herein does not take into account the cohesion that may retain fine particles on the coarse (i.e. sand) particles and, therefore, overestimates the amount of fine particles that may migrate. It is, therefore, recommended that, in specific cases where the above analysis indicates a risk of clogging, tests be conducted to determine the amount of fine particles that actually migrate in order to prepare adequate specifications.

**ABSTRACT:** Laboratory test results conducted on a leachate collection pipe under simulated service conditions are presented for the particular case of a 320 mm outside diameter, 32 mm thick, HDPE drainage pipe surrounded by 50 mm crushed stone backfill. The testing facility and laboratory procedure are discussed. Pipe deformations were found to vary widely along the pipe axis. These measured variations are attributed to the discontinuous backfill support provided to the pipe by the coarse stone. Comparisons of deflections calculated from current design procedures indicates that the Modified Iowa equation over estimates pipe deflections. Equations based on the theory of elasticity applied to thick tubes provide good agreement with the measured deflections.

**KEY WORDS:** landfill, leachate collection system, laboratory tests, plastic pipe.

## 1 INTRODUCTION

Leachate collection systems are intended to control the hydraulic head acting on the barrier and therefore are an important component of modern waste disposal facilities. It is known that both geosynthetic and geologic materials of granular leachate collection systems (eg. geotextiles, pipes and stone, Figure 1) can experience clogging because of particulate, chemical and biological effects (see Rowe et al. 1995). Clogging reduces the effectiveness of leachate collection and may lead to an increase in hydraulic head acting on the landfill liner system.

Design measures intended to minimize the potential of clogging of the leachate collection system can lead to adverse service conditions for the pipe that are not experienced in typical buried pipe applications. For example, large particle size drainage stone is now commonly specified to minimize clogging (50 mm stone is desirable). The relatively large open void space and small surface area per unit volume provided by coarse stone help to minimize biologically induced clogging. However, there is a paucity of data that can be used to assess whether coarse stone has a detrimental effect on pipe performance. Because the stone particles are relatively large, coarse stone loads the pipe at discrete points around the outside surface rather than providing the more continuous support of other, traditional backfill materials (eg. sand, well graded gravel). The magnitude of the stress concentrations from coarse stone backfill, and their effect on the performance of the drainage pipes is presently unknown. Thicker polyethylene pipes are typically specified for use in landfill applications as a result of this uncertainty.

Previous testing conducted by various researchers has shown that plastic pipes can sustain large applied pressures. For example, Watkins (1987), Sargand (1993) and Zanzinger and Gartung (1995) have tested thick, small diameter plastic pipe for use in landfills. These tests did not involve the coarse drainage stone that is desirable to minimize clogging (gravel passing the 19 mm sieve, 25 mm crushed stone, and 8 to 16 mm stone, respectively, were tested). Also, the loading conditions imposed by Watkins differ from those expected to prevail under field conditions. Further, Brachman et al. (1996a) demonstrated that the boundary conditions of the test reported by Sargand were complex and had a significant effect on the pipe response.

Laboratory tests reported by Brachman (1997) conducted under axisymmetric loading conditions showed that coarse stone had an effect on the structural performance of 320 mm outside diameter (32 mm thick) polyethylene pipes, manifested by non-

Figure 1. Section through a typical primary leachate collection system.

uniform pipe deformations and large variations in surface strain when backfilled with 50 mm (nominal size) crushed stone.

Laboratory testing of thick, high density polyethylene pipes is needed to assess the effect of coarse stone backfill on the structural performance of these pipes when buried below significant amounts of waste. The ability of design methods to calculate pipe deformations when used with coarse stone backfill must also be considered.

Test results for a 320 mm outside diameter, 32 mm thick, high density polyethylene pipe under simulated field conditions are presented. The nature of the loading applied to the pipe and the testing facility are briefly discussed. Pipe deflections measured at the crown, invert and springline, as well as vertical and horizontal diameter changes are presented to examine the response of the pipe to the applied load. Measured deflections are then compared to those obtained using current design procedures.

## 2 DESCRIPTION OF LABORATORY TESTS

Deep burial leads to large vertical and horizontal stresses in the drainage blanket containing the pipe. These conditions are closely simulated in the laboratory using the test facility described by Brachman et al. (1996b). A transverse section of the test cell is shown in Figure 2. The pipe specimen is centrally placed within a prism of soil that is 2 m wide  $\times$  2 m long  $\times$  1.6 m high. The soil is contained within a stiff steel structure. Lid and base units are connected with tie rods

capable of resisting large vertical pressures (1 MPa). The sidewalls consist of thick steel plates that are stiffened by four support frames. Vertical load is applied by a pressurized air bladder, providing a uniform vertical pressure across the top surface. Horizontal stresses develop in the soil by limiting the deflection of the sidewalls.

The sidewalls of the test cell were treated to reduce the boundary effects from friction. The interface consisted of a thick nonwoven geotextile (430 g/m<sup>2</sup>) and thin (0.1 mm) polyethylene sheet. This arrangement yielded a friction angle of 24°, determined from direct shear tests conducted over appropriate stress levels (25 to 150 kPa) and strain rate (0.41 mm/min). It is estimated that this level of friction reduces the vertical stresses reaching the pipe by roughly 15% and has only a small effect on the pipe diameter change (Brachman et. al 1996b).

Tests were conducted with 50 mm (nominal size) crushed dolomitic limestone as the backfill material. This material is a poorly-graded coarse gravel (GP) and consists of large angular particles with 70% finer than 50.8 mm sieve size and only 8% finer than 38.1 mm. The crushed stone was uncompacted and placed at an average density of 1520 kg/m<sup>3</sup>.

The tests were conducted on specimens of high density polyethylene (PE 3408) pipe with an average outside diameter of 320 mm and an average wall thickness of 32 mm (300 mm OD, DR11 nominal pipe size, where DR is the ratio of outside diameter OD to the minimum wall thickness). The 2 m long specimen contained three butt-fusion joints, located at the centre and 400 mm from each end.

Measurements of deformation were made at various locations

Figure 2. Transverse section through laboratory testing facility.

along the pipe using a laser analog sensor capable of translating and rotating to any position within the pipe. The tolerance associated to the deflection readings is estimated to be  $\pm 0.1$  mm.

Pressure in the bladder was rapidly increased by 50 kPa every 50 minutes and held constant until the next increment was applied. The maximum applied pressure was 250 kPa. Further testing has since been conducted using 1000 kPa pressure. Note that an overburden pressure of 250 kPa in the field corresponds to roughly 19 to 25 metres of waste, assuming that the unit weight of waste is between 13 to 10 kN/m<sup>3</sup>.

### 3 LABORATORY RESULTS

The pipe deformations measured in the laboratory are now presented. First, the measured deflections at the pipe crown, invert and springline are used to show the mode of pipe deformation. Second, the variation of diameter change along the pipe is considered to illustrate the effect of coarse stone backfill on the pipe response.

#### 3.1 Measured Pipe Deflections

Measured values of vertical deflections at the crown and invert ( $\delta_{cr}$  and  $\delta_m$ ) and horizontal deflections at the east and west springline ( $\delta_{sp E}$  and  $\delta_{sp W}$ ) of the pipe are plotted versus the applied bladder pressure in Figure 3. These values were measured near the centre of the pipe ( $z=880$  mm) and are typical of the results recorded for other locations along the pipe.

Downward vertical movements are shown as negative values while outward movements of the springline are taken to be positive.

The magnitude of the deflections increase linearly with an increase in bladder pressure apart from early data. The measured crown deflection was -9.3 mm at a pressure of 250 kPa, Figure 3. At this load level the mean of 17 crown deflection readings recorded at different locations along the pipe axis was -9.1 mm, with a standard deviation of 0.45 mm. The pipe did not remain level once load was applied, as the crown at one end of the pipe deflected 1.3 mm more than the other end. All intermediate measurements of crown deflection were between the values measured at the ends. No noticeable boundary effects from the sidewalls were observed. Also, the presence of the butt fusion joints caused no discernable effect on crown deflections.

The magnitude of the invert deflection measured at  $z=880$  mm was -5.7 mm at 250 kPa (Figure 3). At other locations along the pipe, the mean invert deflection was -6.2 mm with a standard deviation of 0.5 mm. Unlike the crown deflections, the maximum and minimum values were not measured at the ends of the pipe, but rather varied along the pipe with no apparent trend. This implies that the variation arises from the 50 mm coarse stone bedding upon which the pipe rests.

Lateral movements at the springline are also plotted in Figure 3. These values increase with pressure to 1.1 mm and 2.1 mm at the east and west springline, respectively. These values are small relative to the crown and invert deflections. The observation that west springline deflections are larger than those

Figure 3. Measured pipe deflections at the crown, invert and springline.

Figure 4. Variation of vertical ( $\Delta D_v$ ) and horizontal ( $\Delta D_h$ ) diameter change along the pipe axis at a bladder pressure of 250 kPa.

at the east springline was consistent along the length of the pipe. This suggests a lateral shift in the pipe. Lateral springline movements varied more than vertical movements of either the crown or invert. The mean deflection at the east springline was 0.7 mm (std. dev. 0.34), and 1.6 mm (std. dev. 0.46) at the west springline. The relatively large variations in springline deflection are probably a direct result of the discontinuous backfill support provided to the pipe by the coarse stone.

### 3.2 Measured Diameter Changes

The vertical ( $\Delta D_v$ ) and horizontal ( $\Delta D_h$ ) diameter changes are plotted in Figure 4 for various axial positions along the pipe at a bladder pressure of 250 kPa. Figure 4 shows a decrease in vertical diameter ( $\Delta D_v = \delta_{cr} - \delta_{in}$ ) and an increase in horizontal diameter ( $\Delta D_h = \delta_{p,e} + \delta_{p,w}$ ). There is a 70% difference in vertical diameter change varying from -2.2 mm near the end at  $z=1900$  mm, to -3.7 mm closer to the centre at 1156 mm. The mean vertical diameter change at this load level was -2.9 mm (std. dev. 0.71 mm). The magnitude of these values represent deflections of roughly 1% of the average pipe diameter at 250 kPa.

The small  $\Delta D_v$  value at  $z=1900$  mm results from a relatively small measured crown deflection and a relatively large invert deflection. This may have resulted from a boundary effect. However, similar vertical diameter changes were recorded at another location ( $z=398$  mm) implying that the variations in vertical diameter change are largely from the nature of the coarse stone backfill rather than a boundary effect.

The horizontal diameter change of the pipe also varies along the pipe axis. The mean  $\Delta D_h$  value is 2.2 mm (std. dev. 1.1 mm) with maximum value of 3.1 mm at  $z=880$  mm, and minimum value of 0.9 mm recorded at  $z=1900$  mm. Both east and west lateral springline deflections were small at  $z=1900$  mm, leading to the low value of  $\Delta D_h$ . This may possibly be a result of some boundary effect associated with the pipe in contact with the steel sidewall.

Overall, there is consistency between variations in vertical and horizontal diameter change with the maximum of the measured values occurring near the middle, and the minimum near the ends of the pipe.

This test shows that the coarse stone backfill does influence the deformation behaviour of the pipe. This is not surprising given the large particle size of the stone relative to the pipe. These measured variations do not, however, preclude the use of coarse 50 mm stone in direct contact with leachate collection pipes. Further study is required to ascertain the effect of the non-uniform deformations on the stresses within the pipe.

## 4 COMPARISON WITH DESIGN PROCEDURES

Limiting deflection is one structural performance criteria often considered when specifying leachate collection pipes. Various methods are available to estimate the pipe deflection for a proposed design. Calculations of deflections are now presented for the present pipe (320 mm OD, DR 11) backfilled with uncompacted, crushed stone, subject to an overburden pressure

of 250 kPa. These calculations are intended to provide a comparison of diameter changes between design values and those measured in the laboratory tests. Deflections are calculated using semi-empirical and theoretical based equations. For all cases, key parameters related to the stiffness of the soil are obtained from recommended values published in the literature. Calculations were performed with the AASHTO (1996) values for polyethylene pipe modulus of 758 MPa (short term) and 152 MPa (long term). The results are summarized in Table 1.

#### 4.1 Modified Iowa Equation

One commonly used method to estimate pipe deflections is the Modified Iowa equation (eg. see Howard 1977). This semi-empirical equation was originally developed to predict the horizontal diameter change of flexible metal pipes. Estimates of pipe deflection are a function of: soil support (characterised by the modulus of soil reaction,  $E'$ ), pipe stiffness, and empirical deflection lag ( $D$ ) and bedding constant ( $k$ ) parameters. Calculated deflections are largely dependent on the empirical parameter  $E'$ , which is a function of soil modulus, pipe size, type of material, and ratio of horizontal to vertical stresses (Gumbel 1983).

Diameter changes calculated using the Modified Iowa equation are presented in Table 1 for a range of  $E'$  values that Howard (1977) recommends for use with crushed rock material (7 MPa for uncompacted, to 20 MPa for compacted conditions). The diameter change calculated with the lower  $E'$  value (to represent material dumped in place) and the short term pipe modulus, is larger than the measured vertical diameter change by a factor of two. The Iowa equation assumes that the full prism load acts on the pipe. This neglects the redistribution of stresses (ie. arching) which may occur because of the difference in stiffness between the pipe and the backfill material.

Also, the Iowa equation is generally used under the assumption that vertical and horizontal diameter changes are of equal magnitude and opposite sign. For polyethylene pipes this is not necessarily the case, as the pipe experiences some circumferential shortening. As a result, the estimate of  $\Delta D_h$  using the Iowa equation ( $E_p=758$  MPa,  $E'=7$  MPa) is nearly three times the measured value.

Increasing  $E'$  from 7 MPa to 20 MPa (with  $E_p=758$  MPa) decreases the pipe deflection by 42%. Using the long term polyethylene modulus yields larger deflections, particularly for the case with the lower value of  $E'$ . Conceivably, a better estimate of  $E'$  for use in the Iowa equation could be made based on the measured deflections, or even from empirical relationships with the elastic soil modulus (Selig, 1990). However, care is required because of the empirical nature of the Iowa equation.

#### 4.2 Elastic Continuum Approach - Thin Tube Theory

Calculations of pipe deflection based on the theoretical solution of Höeg (1968) are also included in Table 1. This solution

considers the plane strain response of a thin, elastic, circular tube buried within an elastic, isotropic, homogeneous medium subject to biaxial stresses applied distant from the pipe. This approach explicitly considers the stiffness of the soil (Young's modulus  $E_s$  and Poisson's ratio  $\nu_s$ ) and the pipe ( $E_p$  and  $\nu_p$ ) as well as the loading conditions similar to those under deep burial in a landfill.

Estimates of elastic soil modulus can be made from the data of Selig (1990). For appropriate levels of confining stress,  $E_s$  varies between 20 to 40 MPa, for 85% and 95% of maximum dry density compaction levels (ASTM D698 test).

Calculations using the short term pipe modulus and  $E_s=20$  MPa are larger than the measured results by a factor of 1.55. The calculated vertical diameter changes are larger than the horizontal diameter changes by a factor ranging from 1.3 to 1.5 (for  $E_p=758$  MPa), depending on the soil modulus. This is consistent with the measured laboratory results, where  $\Delta D_v$  is 1.3 times larger than  $\Delta D_h$ . The elastic continuum approach estimates the mode of deformation similar to that measured in the laboratory tests.

The sensitivity of calculated values to changes in soil and pipe modulus are also shown in Table 1. Decreasing the modulus of the polyethylene to the AASHTO long term value of 152 MPa results in larger values of vertical diameter change, where as the horizontal diameter calculated may be smaller depending on the soil stiffness relative to that of the pipe.

Table 1. Comparison of measured and calculated diameter change at a vertical pressure of 250 kPa.

Method	Pipe Deformation (mm)			
	$E_p=758$ MPa <sup>1</sup>		$E_p=152$ MPa <sup>2</sup>	
	$\Delta D_v$	$\Delta D_h$	$\Delta D_v$	$\Delta D_h$
Measured				
Mean	-2.9	2.2		
Standard Deviation	0.7	1.1

### 4.3 Elastic Continuum Approach - Thick Tube Theory

Thin ring theory, as assumed by Høeg, is typically satisfactory for pipes with  $DR > 50$ . However leachate collection pipes typically are much thicker than this limit. Thin tube theory assumes there is no radial variation of hoop stresses through the pipe wall and negligible radial stresses compared to the hoop stresses. The assumption of thin pipe response for use with thick leachate collection pipes is now assessed by presenting calculated deformations for thick elastic tubes using the method of Moore (1990).

The results from the thick tube analysis are also presented in Table 1, using the same values considered for the thin tube case. For soil modulus of 20 MPa and the short term AASHTO pipe modulus, the thin solution overestimates the pipe deflections by 40% when compared to values from thick theory. There is good agreement between calculations using thick theory and the measured values in the laboratory.

Increasing the soil modulus reduces pipe deflections. Decreasing the pipe modulus increases the vertical diameter change, while the horizontal diameter change decreases. These calculations show the importance of circumferential shortening when examining pipe deflection.

Although the calculation may be more tedious, the use of the thick elastic solution is recommended to estimate the deformation of leachate collection pipes. This method of analysis also allows calculation of stresses within the pipe. Additional study on the stiffness of coarse stone materials would be useful in characterising the response of these pipes.

## 5 SUMMARY

Measured deflections of a 320 mm outside diameter, 32 mm thick, high density polyethylene leachate collection pipe backfilled in 50 mm crushed stone have been presented. The average vertical and horizontal diameter changes were approximately -1% and 0.8%, respectively, of the mean diameter at an applied pressure of 250 kPa. Circumferential shortening of the pipe was observed as the decrease in vertical diameter was larger than the increase in horizontal diameter of the pipe. Variations in diameter change associated with discontinuities in support from the coarse stone backfill were noted.

Published values of modulus of soil reaction ( $E'$ ) for use in the Modified Iowa equation yielded large values of pipe diameter change. Analysis based on thick elastic tubes provided reasonable values of pipe deflection when compared with measured laboratory results.

Further testing and analysis is required to confirm these observations and to examine the effect of coarse stone on the stress distributions within the pipe.

## ACKNOWLEDGEMENTS

This research is part of a collaborative project investigating the clogging of leachate collection systems funded by the Natural Sciences and Engineering Research Council of Canada.

E. Gartung

LGA, Geotechnical Institute, Nuremberg, Germany

**ABSTRACT:** Perforated geopipes are part of the leachate collection system at the base of solid waste landfills. Their structural performance depends on the embedment which is formed by a compacted clay layer, a geomembrane and a sand-bentonite cushion below and coarse gravel above the pipe. Two large scale model tests were carried out. A big geopipe-basal liner model was submitted to uniformly spread static loads up to 1200 kPa. The deformations of the 300 mm diameter pipes were measured by a mobile laser device and by strain gauges applied at the surfaces of the pipes. Earth pressure cells and extensometers recorded the deformation pattern and the load distribution within the soil layers surrounding the pipes. The evaluation of the data reveals a clear picture of the soil-structure interaction of the HDPE-geopipes at the base of high landfills. The test results facilitate the calibration of analytical and numerical methods of structural analysis.

**KEYWORDS:** Leachate Collection System, Landfills, Model Tests, Geopipes

## 1 INTRODUCTION

Leachate collection pipes at the base of solid waste landfills are submitted to high loads under as much as 50 to 70 m of waste material, or more. The pipes, typically 250 to 300 mm in diameter, consist of HDPE. They are embedded in coarse grained drainage gravel or crushed rock material and rest on the compacted clay liner (CCL) or on a special bedding of sand-bentonite above a geomembrane (GM). The structural performance of HDPE-geopipes (GPI) for leachate collection at the base of landfills is not well understood.

Zanzinger et al. (1992) reviewed the currently applied design methods and the influence of the range of typical soil parameters involved. The study comes to the conclusion that analytical models which are applied as a routine to the design of embedded flexible pipes under shallow soil cover do not describe the soil-structure interaction of heavily loaded flexible GPIs at the base of landfills with sufficient accuracy. Example calculations showed that numerical procedures based on the finite element technique facilitate the variation of material parameters and the mechanical behavior of ground conditions in a wide range. However, to properly apply them to design calculations, they ought to be calibrated by measured data obtained under field conditions. Since field measurements in the leachate collection system at the base of an operating landfill would require many years to obtain data under high cover of waste, and since the adverse conditions would strongly impede accurate measurements, large scale model tests were undertaken at the LGA Geotechnical Institute to determine the performance of drainage GPIs under heavy load.

## 2 TEST SETUP AND INSTRUMENTATION

The large scale of the model required very careful preparations. Designing the overall concept, selecting and acquiring the measuring instruments, developing the software for data recording and processing took much time.

A GPI of 315 mm nominal external diameter, with a wall thickness 28.7 mm, was selected for the large scale tests. The upper 2/3 of the GPI circumference were provided with slits, 7 mm wide and 132 mm long for the entry of leachate. The test setup accurately modeled field conditions at 1:1 scale with a CCL at the bottom, drainage gravel surrounding the GPI, and a layer of compressible material to simulate the mechanical properties of waste. The required dimensions of the physical model, width of the entire setup, thickness of the CCL and thickness of the waste-substitute were determined on the basis of finite element analyses to make sure that the measurements of the significant data would not be influenced by the boundaries. The dimensions are given in the cross section (Figure 1). The length of the model was 5.4 m. The model was confined by reinforced concrete elements which were braced against the walls of the test bin in one direction and tied together by steel rods in the other two orthogonal directions.

The load was applied by means of hydraulic flat jacks below the upper concrete beam. It was not easy to find a manufacturer for suitable rubber flat jacks which can reliably be pressurized to more than 1000 kPa. The first set of flat jacks failed during the suitability tests and the research project was delayed by one year. The lesson learned was, that sufficient time has to be allocated to manufacturing, testing and repair of the loading equipment.

The applied vertical load was measured and controlled by pressure gauges in the hydraulic system. In addition, the forces of the tie rods were monitored by force transducers.

In total 59 earth pressure cells were installed in the clay layer, in the drainage gravel and in the waste-substitute material for the determination of the magnitude and the

Figure 1. Cross section of the large scale model

distribution of vertical and horizontal stress components in the soil materials surrounding the GPI. The vertical deformation of the soil body was measured by 22 glass fiber rod extensometers, 16 extensometers were installed for the measurement of the horizontal deformation.

The GPI was equipped with 48 electrical resistance strain gauges at the external and 10 at the internal surface. The shape of the GPI was monitored by a mobile laser device, specially developed for this purpose. The laser traveled to 6 sections inside the GPI and took readings there of the distance between the center of the GPI and the wall by revolving around a horizontal axis. The interval of measurements was  $0.25^\circ$ , the precision of deformation measurements by laser technique was 0.1 mm. In order to evaluate the temperature influence on the measurements, thermocouples were installed near the upper and lower surfaces within the clay layer and attached to the GPI.

All measured data were recorded by computer. A special software was developed for data recording and processing. It was very important to have a certain redundancy in data acquisition. Since the great number of measuring instruments proved to be necessary, it was found useful to have different measuring systems for plausibility checks e.g. strain gauges and laser measurements of the GPI.

### 3 EXECUTION OF TESTS

The precast members of the concrete containment had to be placed by crane. The weight of single concrete members was up to 10 t, the entire weight of the confining concrete structure amounted to 235 t. The placement of approximately  $16 \text{ m}^3$  of clay and compaction by small vibratory roller in the laboratory was a challenge. 19.3 t of drainage gravel and about  $30 \text{ m}^3$  of waste substitute material consisting of a mixture of sand and saw dust, had to be handled. All soil materials used for the model test had undergone extensive standard soil mechanics suitability testing before selection.

The relevant soil properties were controlled throughout the installation process and during dismantling of the model. An important observation was that the CCL did not experience substantial changes in water content over the long duration of the model tests.

Plastic sheets and lubricants were placed at the interface between the concrete side walls and the model to reduce wall friction. The installation of all loading and measuring devices, transmission cables and water pressure hoses was carried out with great care. Their proper functioning was verified before the start of the loading test.

Two slightly differing test setups were examined. Figure 1 shows the cross section of the leachate collection GPI above a standard composite liner, consisting of a CCL and a 2.5 mm thick HDPE GM with smooth surfaces. This section was to be tested second. The first test was carried out on a model with the CCL only, so in test no. 1, the cross section looked like Figure 1, but without the GM and the sand-bentonite bedding between GM and GPI.

For test no. 1, the load was applied in 9 steps from 50 to 1200 kPa pressure in the flat jacks, for test no. 2 in 13 steps from 50 to 1300 kPa. The duration of the loading processes was governed by the response of the model to some extent, and by time required for maintenance and repair of some devices such as the mobile laser. The loading process of test no. 1 took 120 days, in case of test no. 2 it took 270 days in total.

Figure 2. Vertical stress distribution, example for 700 kPa loading

### 4 RESULTS

#### 4.1 Behavior of the Soils

The stress measurements in the soil indicate that an interaction between the soil and the GPI takes place. The load applied at the surface of the model is carried by the soil

and the GPI. Stresses in the soil are redistributed in such a way, that a load carrying arch is formed in the gravel around the GPI. Figure 2 shows an example of the stress distribution in the soil measured in three horizontal planes. In the horizontal plane immediately above the GPI inside the gravel drainage layer, the vertical stresses besides the GPI are increasing and reach maximum values, above the crown they are decreasing and show a minimum. The vertical stresses in the CCL below the GPI qualitatively exhibit the same shape of the stress distribution curve, but less pronounced. The vertical stresses in the waste-substitute material appear to be unaffected by the stress concentration. Measurements of all loading steps reveal that the shape of the arch and the location of maximum stress concentrations in the drainage gravel are independent of the magnitude of the load. The vertical stresses are increasing linearly with increasing load.

The horizontal earth pressures in the midplane of the GPI are variable. They reach a maximum next to the GPI. Their minimum is located about three times the GPI diameter from the center of the GPI. The lateral deformations of the soil are almost zero at about 0.5 m from the center of the GPI. They occur near the maximum of vertical stresses.

Figure 3. Strain in the GPI, example for 700 kPa loading

#### 4.2 Structural Behavior of the Geopipe

Precise measurements indicate that the GPIs are not exactly circular before they are loaded, but show a considerable deviation from the theoretical geometry of the cross section. Once the GPI is undergoing deformations under load, the mode of the deformation is kept, the magnitude of the deformations increases linearly with the applied load.

The strain and accordingly also the stress at the surface of the GPI is distributed in a sinusoidal pattern as shown for an example measurement on Figure 3. This applies to

the normal forces and to the bending moments as well. The normal forces and the bending moments can be deduced from the measured strains.

Maximum stresses occur at 0°, 90°, 180° (crown); 270°. In between there are locations of zero strains at 50°, 130°, 230° and 310°. These locations of zero strains are independent of the magnitude of loading. Once established, they remain geometrically stable during the entire loading sequence for all load steps.

In addition to the bending strains, the GPI experiences compressive strain due to the normal forces which reached the magnitude of 1% at elevated loads during the tests. This means that the deformed shape of the GPI is not exactly an ellipse. The lateral displacement  $\delta_v$  of the side walls is smaller than the vertical displacement (deflection)  $\delta_v$  of the crown. The relationship between these two displacements can be described by the simple formula  $\delta_v = -(1.2 \div 1.3)\delta_H$ . This result is interesting with respect to deformation measurements in the field. Since the GPIs at the base of an operating landfill will carry leachate and often also be covered by incrustations at the bottom, it is almost impossible to get correct measurements of the deformed shape of the leachate collection GPIs as expressed by a reduction of the vertical distance between crown and invert. It is much easier to measure the increase of the lateral distance between the side walls and deduce the vertical deformation from there.

Figure 4. Example for the deformed shape of the GPI

The GPIs showed considerable deformations in the tests, an example is presented on Figure 4. The measured maximum values of clearance decrease amounted to 19% deflection under maximum vertical loads representative of about 65 m of waste material. There were no indications of an approach to structural failure under the applied loads.

At the interface between clay and gravel where the stiffness of the embedment conditions of the GPI change, finite element analyses indicate discontinuities in the distribution of stresses due to bending moments. The actual measurements taken at the large scale model however, do not reveal any irregularities in the shape of the stress distribution curve.

Under the test conditions, that is temperatures between 20° and 25 C and vertical loads up to about 800 kPa acting upon the drainage gravel surrounding the GPI for a maximum duration of the test of 270 days, no substantial creep was observed. Since essentially a linear structural response of the embedded GPI was observed, and no relevant creep effects occurred, it seems to be justified to use linearly elastic constitutive models for design analyses.

#### 4.3 Influence of the Geomembrane

The results of test no. 2, where the GPI was installed on a sand-bentonite bedding above the GM do not differ substantially from those of test no. 1, where the GPI rested directly on the CCL. A direct comparison of the stresses in the soils surrounding the GPI under equivalent vertical loads shows slightly smaller stress concentrations in the test with the GM and a comparison of the GPI deformations yields slightly larger deformations of the GPI under equivalent loads in the setup with the GM. These differences are marginal and do not call for special design rules for the GPIs above GMs although they indicate that the smooth surface of the GM has some affect on the structural performance of the GPI-soil system.

## 5 CONCLUSIONS

The large scale model tests show that at the base of landfills the structural performance of the GPIs is governed by the interaction with the surrounding soil. As the flexible GPI deforms, an arching effect develops inside the drainage gravel initiating vertical and horizontal stress redistributions. So the placement of the drainage blanket is important for the structural safety of the GPI. The shape and thickness (twice the pipe diameter above the GPI) of the drainage gravel according to German design practice is satisfactory. The waste material above the GPI embedment zone does not experience any stress redistribution due to the deformation of the GPI. So even if the waste has a certain strength and stiffness, it should not be taken into account in the design of the GPI.

There is no substantial difference in the performance between GPIs placed on CCL directly and GPIs placed on a sand-bentonite bedding above a smooth GM.

Under heavy loads GPIs experience considerable deformations and the deformation rather than the stability appears to be the controlling criterion. It is necessary to adjust analytical methods for the determination of GPI deformations according to the experience gained by the large

scale model tests, reported in this paper. Current design analyses may underestimate the magnitude of the expected deformations. When methods are applied which predict the deformations reliably, greater maximum deformations may be able to be tolerated than according to currently practiced specifications.

For the evaluation of the performance of GPI it is useful to determine the deformed shape of the GPI by the measurement of the lateral deformation. With the experience gained in the large scale model tests, it is possible to deduce the state of stress within the GPI from deformation measurements.

Not all problems concerning the behavior of embedded GPIs have been solved. To mention some open questions, the behavior of very thin walled GPIs or profiled GPIs cannot be judged on the basis of the present study on thick walled GPIs. Research on thin walled GPIs seems to be of primary interest with respect to economy. Another question that should be addressed is the influence of higher temperatures, and the performance of GPI junctions.

## ACKNOWLEDGMENTS

The research on the structural behavior of HDPE GPIs at the base of solid waste landfills was financially supported by the authorities of the State of Bavaria.

**ABSTRACT:** Geomembranes have been used as a landfill liner to remove the leachate, which is generated from ash waste to prevent it infiltrating into the surrounding ground and groundwater. At the bottom of the landfill, the geomembrane is covered with protective soil but in many cases, the geomembrane on the slope is laid without protective soil or geotextile. Consequently, the geomembrane must be exposed for a long time. In this situation, there exists anchoring problems such as pull out of the anchorage when the temperature of a geomembrane decreases. This behavior is caused by thermal stress induced within a geomembrane. In this paper, tensile stress tests for four different geomembranes were conducted at temperatures ranging from  $-20$  to  $80^{\circ}\text{C}$ . Thermal stress tests were also conducted by decreasing the temperatures from  $80$  to  $-25^{\circ}\text{C}$ . The test results show that the relation between temperature and tensile strength are linear, and that the relation between temperature and Young's modulus is exponential. They also show that the results of co-energy evaluation which is the factor of safety of geomembrane for differential settlement.

**KEYWORDS:** Geomembrane, Thermal Stress, Young's Modulus ,Tensile Behavior

## 1. PROPERTIES OF THE GEOMEMBRANES TESTED

Four kinds of geomembrane with smooth surfaces and 1.5mm thickness were selected among geomembranes popularly used for a liner of a landfill in Japan. These are High Density Polypropylene (HDPE), Ethylene Propylene Diene Methylene Rubber (EPDM), Thermo Plastic Olefin (TPO) and Poly Vinyl Chloride(PVC).

## 2. TESTING METHOD

Two shapes of the specimen were tested. One was the #3 dumbbell shape with 100mm length and 5mm width at the neck indicated by the Japanese Industrial Standard. The other was an original square shape with 200mm length and 60mm width. The specimens were set in the jaws in the oven and tested after heating or cooling at a constant temperature for thirty minutes as shown in Figure 1. Elongation was estimated by measuring the distance between the two jaws.

The jaw separation speed was 50mm/min for dumbbell shaped specimens and 1mm/min for square shaped specimens. The slow(1mm/min) speed was selected ,because forces such as a downdrag force or a thermal stress increases slowly. In the case of the thermal stress test, the force was adjusted to zero at  $80^{\circ}\text{C}$  degree by moving the jaw separation slowly. Then, the temperature of the oven was decreased to  $-25^{\circ}\text{C}$  by decrements of  $10^{\circ}\text{C}$  in 30 minutes.

Figure 1. Setting of Specimens

## 3. TEST RESULTS AND DISCUSSIONS

### 3.1 Temperature effect on tensile strength

The tensile test were conducted by using dumbbell shaped specimens at a temperature of  $-25, 0, 20, 40, 60^{\circ}\text{C}$ . The test results was shown in Figure 2. Among the four kind of geomembrane, the values for HDPE indicated the yielding strength, while the others indicated peaking strength.

Figure 2. Temperature Effect on Tensile Strength

Figure 3. Temperature Effect on Young's Modulus

HDPE	$\sigma_t = -0.265t + 41.16$	MN/m <sup>2</sup>	(1)
EPDM	$\sigma_t = -0.167t + 14.70$	MN/m <sup>2</sup>	(2)
TPO	$\sigma_t = -0.255t + 21.36$	MN/m <sup>2</sup>	(3)
PVC	$\sigma_t = -0.421t + 32.14$	MN/m <sup>2</sup>	(4)

HDPE	$E = 794 \cdot 10^{-0.0102t}$	MN/m <sup>2</sup>	(5)
EPDM	$E = 17.6 \cdot 10^{-0.0102t}$	MN/m <sup>2</sup>	(6)
TPO	$E = 274 \cdot 10^{-0.0128t}$	MN/m <sup>2</sup>	(7)
PVC	$E = 43.1 \cdot 10^{-0.0340t}$	MN/m <sup>2</sup>	(8)

For all geomembranes tested, the tensile strength increases as the temperature decreases. The relationship between the temperature and the tensile strength is linear. The slope of the line, which indicates the ratio of tensile strength to temperature, is similar for all the lines, though PVC shows that the temperature affects tensile strength more severely than the other geomembrane types tested.

### 3.2 Temperature effect on Young's modulus

Young's modulus of geomembranes was investigated using square shaped specimens. The tests were conducted in the oven in which temperature was set at -25°C, 0°C, 20°C, 40°C, 60°C and the jaw was moving at the rate of 1mm/min. The secant modulus at 1% strain was calculated as the slope of the line connecting the origin to a point corresponding to 1% strain on the stress strain curves. The secant modulus at 1% for the geomembranes are shown in Figure 3.

There is large a difference in 1% secant modulus between the types of geomembrane. The modulus of HDPE at 20°C is the largest and is about fifty times that of PVC. The secant modulus of all geomembranes tested increases significantly with a decrease in temperature.

According to Figure 3, the relationship between the secant modulus and temperature is exponential, resulting in equations (5) to (8). Among the four geomembranes, the modulus of PVC is most sensitive to temperature. The other geomembrane types have similar slopes on a semilog plot, but the value of secant modulus are very different from each other.

### 3.3 Thermal Stress

Thermal stress was measured by square shaped specimens in the oven in which the temperature decreased slowly from 80°C to -25°C. The results are shown in Figure 4 and Figure 5.

The figures show that thermal stress occurred in all the membranes

Figure 5. Thermal Stress

Figure 6. Co-Energy VS. Temperature

Table 1. Comparison of Thermal Stress (MN/m²) at 0°C

	Results	Calculated
HDPE	7.002	5.442
HPDM	0.119	0.099
TPO	1.628	1.347
PVC	0.109	0.102

$$\sigma_{ab} = \int \Delta \sigma dt = - \int_{tb}^{ta} \beta \cdot E_0 \cdot 10^{-\alpha t} dt \quad (9)$$

$$= -\beta \cdot E_0 \int_{0^{\infty}}^{tb} e^{-2.3025851\alpha t} dt = \frac{\beta \cdot E_0}{2.3025851\alpha} [e^{-2.3025851\alpha t}]_{0^{\infty}}^{tb} \quad (10)$$

The thermal stress of HDPE was the largest. From Figure 5, the relation between the thermal stress and temperature is exponential

The authors presented the evaluation method by leading equation as (9) and (10).

The coefficient of thermal expansion  $\beta$  used for calculation is 0.00019 for HDPE, 0.00016 for EPDM, 0.00016 for TPO, and 0.00018 for PVC. The calculated thermal stress and test results at 0°C is shown in Table 1. The calculated thermal stress of EPDM and PVC from theoretical equation (10) was almost same as the test results, but that of HDPE and TPO, which indicated large values of thermal stress, were smaller than test results. The differences are assumed to depend on experimental errors at the setting specimens in jaws.

The tension of a membrane with 1.5mm thickness can be calculated from the thermal stress results. If the membrane is installed in the field during the day time when the surface temperature is 80°C, the tension that will occur at night time when the surface temperature is 0°C is 10.5kN/m for HDPE, 0.175kN/m for EPDM, 2.44 kN/m for TPO, and 0.164kN/m for PVC. The thermal stress of EPDM and PVC should be negligible, but that of HDPE and TPO would be significant.

### 3.4 Evaluation of Co-Energy

The concept of Co-Energy and the equation (11) was presented by Giroud .

$$s \cdot p \cdot \tan \phi = \int_0^T \epsilon \cdot dT \quad (11)$$

S; The total elongation of the geomembrane (equal to the settlement), P; Pressure, T; Tension,  $\epsilon$ ; Strain,  $\phi$ ; Friction angle. The integral of the equation (11) is equal to the area between the geomembrane tension-strain curve and tension axis up to the maximum tension value, which is shown co-energy area in the figure above. If P and  $\phi$  is the same, the maximum differential settlement S can be

evaluated by co-energy. So, the amount of the co-energy area from the test results can estimate the ability to withstand differential settlement. The results are shown in Figure 6.

The co-energy is different between the kinds of geomembrane. As the amount of HDPE was measured at yield point and that of the others were measured at break point, they should not be compared directly. The co-energy of EPDM, TPO and PVC is greater than HDPE. They present their peak at temperature of 0°C and decrease at lower and higher temperature than 0°C.

#### 4. CONCLUSION

- (1) Temperature effect on tensile strength: The tensile strength at break of EPDM, TPO, and tensile strength at yield of HDPE, increases linearly with decreasing temperature. PVC appears to be the most sensitive of the material tested.
- (2) Temperature effect on Young modulus: Young's modulus is different between the types of geomembrane tested and Young's modulus of HDPE is fifty times as large as PVC at 20°C. The modulus of all samples tested indicate an exponential increase with decreasing temperature.
- (3) Thermal stress: Thermal stress was measured in all cases. The thermal stress of HDPE and TPO is much larger than EPDM and PVC. The calculated thermal stress by theoretical equations was close to the test results for EPDM and PVC was significantly less than the test results for HDPE and TPO.
- (4) Temperature effect on co-energy: The value of co-energy shows changing according to the temperature of the testing and differences between the kinds of geomembranes. In case of HDPE, the value of the co-energy is the lowest and indicates a very small decreasing with increasing temperature. In case of EPDM, the value of the co-energy is the highest at the temperature from -25°C to 60°C and indicate the peak at 20°C. In case of TPO, the value is a little smaller than EPDM and indicates the almost same shape of the curves. In case of PVC, the incline of the curve indicate increasing the co-energy with temperature.

The thermal stress of EPDM and PVC would generally be negligible in the case of an exposed landfill liner. The thermal stress of HDPE and TPO may be significant. Since, thermal stress occurs only when the temperature changes, the temperature of the membrane under the thick protective soil may not be great concern because the temperature would be relatively stable. However, an exposed geomembrane on a steep side slope may result in large temperature changes. Thermal stress may be important for designing and installing exposed geomembranes on the steep side slope and the designer may need to account for these when designing anchorage for the geomembrane.

# Measuring the In-situ Moisture Content of Geosynthetic Clay Liners (GCLs) Using Time Domain Reflectometry (TDR).

Matthew A. Eberle

*Geofabrics Australasia Pty Ltd, Australia.*

Kent P. von Maubeuge

*Naue Fasertechnik GmbH & Co. KG, Germany.*

**ABSTRACT:** A method that enables accurate in-situ measurement of moisture content in thin clay layers would advance performance monitoring of geosynthetic clay liners (GCLs) in many applications. The ability of a GCL to act as a gas or vapour barrier, or the friction/shear resistance of a GCL can be significantly affected by the degree of hydration of the bentonite within the geocomposite. Time domain reflectometry (TDR) emerged as a new technique to monitor soil-water content during the early 1980s. Advances in theoretical understanding and TDR equipment allows the technology to be used to continuously monitor in-situ moisture contents in a GCL at multiple locations, and remotely, if so desired. This paper will focus on the practical aspects of applying TDR technology to GCL testing and monitoring. These aspects include; obtaining relationships between gravimetric moisture content ( $w$ ) and apparent dielectric constant ( $K_a$ ), factors influencing the accuracy of measurements, and the effect of probe geometry and orientation on the GCL/soil influence zone. The results of some preliminary tests on a GCL under simulated prolonged evapotranspiration conditions are presented which indicate the potential of the technique.

**KEYWORDS:** Time domain reflectometry (TDR), Geosynthetic clay liners (GCL), Moisture content measurement, In-situ monitoring, Desiccation.

## 1. INTRODUCTION.

The moisture content or degree of hydration within a GCL will have an effect on many physical and chemical properties. Some of these properties include; the ability to act as a barrier to gases, vapours, and contaminants in landfill liners and secondary containment facilities, and the internal (mid-plane) shear strength and interface friction values (particularly in non-reinforced GCLs).

Removing GCL samples for oven drying is a direct and reliable method of measuring moisture content, however the technique is destructive, time consuming and highly impractical. There are a number of non-destructive options that can be employed to measure in-situ moisture content in a GCL that have evolved primarily out of the agriculture and forestry sectors.

## 2. ELECTRICAL RESISTANCE BLOCKS.

Electrical resistance blocks made from porous gypsum or fibreglass can be used as an indirect method of determining soil-water content. The technique relies on the equilibrium of soil-water potential in the block with that of the surrounding soil (White and Zegelin, 1995). Gypsum from the block dissolves in the pore water to provide electrolyte. Changes in electrical resistance in the embedded electrodes

within the block can be monitored with an AC or pulsed DC bridge. Fibreglass blocks rely on the electrolytes in the soil-water solution itself to provide conduction.

The electrical resistance in the blocks is sensitive to changes in electrolyte concentrations and electrical conductivity. Resistance blocks also tend to respond to soil matrix potential, not soil moisture, which leads to a hysteresis response between wetting and drying cycles (which subsequently require separate calibrations). The change in resistance of a block over the typical moisture content range in most granular soils is small, which limits the precision of the technique (Gardner, 1986). However, the fluctuation in gravimetric moisture content ( $w$ ) in a GCL can be very large in some cases, (up to 400%).

Gypsum blocks are not particularly suited to long-term monitoring of moisture content in soils as their pores become clogged with deposited material, and they gradually dissolve over time. This causes continual change in the relationship between electrical resistance and moisture content, leading to errors when using the original calibration (White and Zegelin, 1995).

In addition to the above mentioned disadvantages of resistance blocks, there are some practical difficulties embedding them within a GCL due to dimensional constraints. The advantages are that they are cheap and

many blocks can be multiplexed from a single hand-held meter (bridge) with relative ease. However, in order to use this technique with any precision, electrical conductivity and moisture content must be determined independently, and at regular intervals throughout the monitoring period.

### 3. TIME DOMAIN REFLECTOMETRY (TDR).

Time domain reflectometry (TDR) measurements relate measurements of apparent dielectric constant to volumetric water content. The application of TDR in soil water measurements was reported by Topp *et al* (1980). There are many potential advantages in using TDR in the measurement of gravimetric moisture content in GCLs over the electrical resistance (conductance) technique. These include:

- flexibility in probe (waveguide) geometry,
- insertion of probe into the GCL results in minimal damage to the GCL (non-destructive),
- a high level of accuracy,
- fewer calibration requirements,
- able to provide continuous soil water measurements through automation and multiplexing.

Some of the limitations of the TDR method include:

- relatively high equipment costs,
- possible limited applicability under highly saline conditions due to signal attenuation,
- soil-specific calibrations are required for soils having large amounts of bound water (eg. clays).

Signal attenuation can be a problem under saline conditions and in dense clays, but can be minimised by a combination of careful probe geometry selection and techniques involving coating the waveguides with some form of insulation. The inconvenience of having to perform soil-specific calibrations when dealing with some clays is minimised when applying the technology to GCLs as they contain relatively homogeneous bentonite clay.

#### 3.1 Theory.

The TDR technique involves sending a microwave pulse generated from the TDR cable tester/processor down a parallel transmission line of known length  $L$  embedded in the soil. The pulse propagates down the line and is reflected back from the end of the transmission line. It is possible to isolate the portion of the pulse representing the transit time,  $t(s)$ , in the buried waveguide/probe. The propagation velocity ( $v=2L/t$ ) is a function of the soil bulk dielectric constant,  $K_a$ , of the surrounding medium, which can be estimated from Eq.[1] (Topp *et al*, 1980),

$$K_a = (c/v^2) = (ct/2L)^2 \quad [1]$$

where  $c$  is the velocity of light in a vacuum ( $3 \times 10^8$  m/s). The bulk dielectric constant of the soil is governed by the dielectric of liquid water,  $K_{water} \rightarrow 80.36$  ( $20^\circ\text{C}$ ), as the dielectric of other constituents are much smaller, ( $K_{soil} \rightarrow 3$  to 5, and  $K_{air} \rightarrow 1$ ). Due to the large difference in dielectric constants, the electromagnetic pulse propagation time is very dependent on the water content of the soil (Figure 1) and relatively insensitive to soil composition and texture.

Figure 1: Sample traces measured in bentonite with various moisture contents (3-pronged waveguide)

#### 3.1.1 Establishing a $\theta_v(K_a)$ Relationship.

Several relationships between  $K_a$  and volumetric moisture content,  $\theta_v$ , have been established. The first approach developed by Topp *et al* (1980) utilises an empirically derived third order polynomial, fitted to observed relationships between  $K_a$  and  $\theta_v$ , for multiple soils.

$$\theta_v = -5.3 \times 10^{-2} + 2.92 \times 10^{-2} K_a - 5.5 \times 10^{-4} K_a^2 + 4.3 \times 10^{-6} K_a^3 \quad [2]$$

A second approach adopted by Dobson *et al* (1985) and Roth *et al* (1990) attempts to predict the bulk  $\theta_v(K_a)$  relationship based on the individual dielectric constants of the three soil components (soil particles, air and water). In this approach  $K_a$  is given by the mixing model,

$$K_a = [\theta_v K_{water}^\alpha + (1-\phi) K_{soil}^\alpha + (\phi-\theta_v) K_{air}^\alpha]^{1/\alpha} \quad [3]$$

with  $\phi$  the soil porosity, and  $\alpha$  a geometric factor relating to the spatial arrangement of the three phase mixture. Roth *et al* (1990) found a best fit  $\alpha=0.46$  for various soils (Zegelin *et al*, 1992).

The suitability of both of these approaches is limited when applied to GCLs due to a number of factors:

- the Topp calibration Eq.[2] was based upon test results on soils concentrated in the  $\theta_v < 0.5$  range, and subsequently fails to adequately describe the relationship for water contents exceeding 0.5 and fine textured, dense, heavy clay soils.
- predictions based on Eq.[3] require the bentonite porosity and dielectric constant (dry) to be known or estimated, which can potentially lead to additional errors in the methodology.

To avoid the problems associated with these two approaches, along with need to convert volumetric moisture contents to gravimetric moisture content ( $w$ ), it is a relatively simple task to construct a  $w(K_a)$  calibration for the particular TDR equipment and GCL being used. Because most TDR equipment can be integrated with software capable of reporting and logging  $K_a$  values for data reduction at a later stage, individual calibrations can be developed to replace default  $\theta_v(K_a)$  calibrations such as Eq.[2], which are not suitable for clays with high moisture contents.

### 3.1.2 Probe Geometry and Influence Zone.

Probably the most critical factor affecting the accuracy of the TDR technique when applied to measurements in GCLs lies in the selection of probe type and geometry. Zegelin *et al* (1992) describe a number of different coaxial insertion probes that have been used in soil water measurements. The electric field distribution of a 3-rod probe is shown in cross-section (qualitatively) in Figure 2. The sensitivity is highest within the soil in the immediate vicinity of the probe rods and falls off rapidly with distance from the conductors. Knight (1991) has shown that there is a strong weighting by the TDR measurement of water content close to the central rod of a three (or more) rod probe. A 3-rod probe is relatively easy to insert into a GCL and disturbance/damage to the insertion region can be minimised.

Figure 2: Approximate electric field distribution of 3-rod probe when inserted into a GCL.

There are limitations on the minimum length of TDR probes, and the ratio of probe rod-to-rod spacing to rod diameter. Clearly these limits are critical for measurements

in a thin layer of bentonite (only 6 to 10 mm thick). The lower limit on probe length is due to the accuracy of time-of-travel measurements of pulse propagation within the probe, which becomes questionable for probes less than 50 mm length (Zegelin *et al*, 1992).

### 3.1.3 Influence of Temperature ( $T$ ) on $K_a$ .

The dielectric constant of free water  $K_{water}$ , on which  $\theta_v(K_a)$  calibrations are based, is temperature dependent. In the field, ground surface temperatures can often exceed 50°C. In these situations, a temperature correction needs to be implemented (Eq.[4] → Handbook of Chemistry and Physics, 1974),

$$K_{water} = 78.54[1 - 4.579 \times 10^{-3}(T-25) + 1.19 \times 10^{-5}(T-25)^2 - 2.8 \times 10^{-8}(T-25)^3] \quad [4]$$

therefore, accurate measurement of moisture content will require simultaneous temperature monitoring when temperature fluctuations are expected.

## 4. TEST RESULTS FROM PRELIMINARY LABORATORY STUDY.

Prior to embarking on a large scale field trial using the TDR techniques discussed, the suitability for long-term in-situ monitoring of GCL moisture content was assessed in a laboratory trial, the results of which warrant further discussion.

### 4.1 Laboratory Test Method.

The laboratory study involved placing a GCL on a bedding layer of well graded sand (90% passing 4.75 mm sieve) in a large open box, with a 300 mm cover layer of the same sand over the GCL. A cross-section of the set-up is shown in Figure 3.

The sand had an initial gravimetric moisture content of around 8 to 10%, and the GCL was installed in a 'dry' state ( $w_{GCL} \approx 9\%$ ). A 1000 Watt halogen lamp was placed 250 mm above the sand in order to simulate a relatively hot and dry environment. A timer automatically cycled the lamp 'on' during non-working hours in the lab (15 hours per day) to limit exposure of the laboratory staff to glare resulting from the lamp during this cycle. A temperature sensor was placed centrally in the box at the surface level to monitor temperature during both cycles. The average temperature during the heating cycle was 43°C. The ambient temperature and humidity in the laboratory averages 23°C and 20% respectively.

Figure 3: Schematic of test set-up and apparatus showing the position of the 2 mini-buriable waveguides (L=60 mm) within the GCL, and the 6 buriable waveguides (L=200 mm) in the surrounding soil.

#### 4.1.1 Probe Selection and Placement.

Probes (3-rod) were inserted in the GCL and surrounding material to monitor soil moisture. Two probes were inserted within the GCL, both had a rod length of 60 mm, a rod diameter of 1 mm, and the spacing between the two outside rods was 15 mm. TDR probes (3-rod) with a larger measurement volume were used in the sand material surrounding the GCL. These probes had a length of 200 mm, a rod diameter of 3 mm, and a spacing between outside rods of 40 mm. The probe locations are shown in Figure 3.

#### 4.2 Test Results.

The two moisture contents readings at each level in the soil profile were averaged and plotted against testing duration (Figure 4). The plot shows the moisture content within the GCL reached 100% in under 24 hours, and continued to gradually increase over the duration of testing to a maximum of 140% at around 1500 hrs. There is no evidence of significant drying within the GCL since this time. Probes at levels one and two indicate considerable drying in the cover soil as a result of the heating cycles. The water content in the bedding layer increased from 8% to 10.5%, possibly as a result of pore water movement towards the GCL due to condensation or suction.

#### 4.2.1 Discussion of Results.

The maximum moisture content that a GCL will reach is a function of confining stress. Previous experimental work by *Petrov et al* illustrates the relationship between confining stress and moisture content for a needle-punched GCL and a 'fibre-free' GCL (essentially the same needle-punched GCL with the needle-punched fibres cut). The presence of needle-punched fibres limits the swelling of the bentonite in the lower confining stress range, leading to lower fully-hydrated moisture contents, and subsequently lower hydraulic conductivity in comparison to a fibre-free sample (in the low confining stress range).

The relationship between confining stress and maximum hydrated moisture content was developed for the GCL used in testing (Figure 5). The peak moisture content reached in the GCL during the trial, as a result of wetting from the surrounding soil, is within approximately 20% of the expected maximum under confinement from the 300 mm cover soil.

The moisture content at which desiccation in the bentonite is expected to commence is typically between 70 and 90% (and is confining stress dependent). Although desiccation has not occurred to date in the trials, samples were deliberately dried in an oven to the point of significant cracking and TDR readings taken.

Figure 4: Moisture content within the GCL and throughout the soil profile versus duration of testing (approximately 2000 hrs to date).

The presence of air voids in the composite (due to cracking) was evident from the shape of the resulting TDR trace. Thus, careful monitoring of the waveform shape can potentially be used to indicate the onset of desiccation.

Additional tests were carried out in which 21°C air at 40 to 80% relative humidity was blown directly over the GCL. The GCL was confined with 9 kPa pressure over a drainage net, which allowed the air to pass directly over the GCL. The onset of desiccation occurred at 3000 hours, after which the moisture content within the GCL fell from 110% to 45% within two hours. The tests are ongoing and will be presented at a later date.

The ability of the GCL used in the trial to resist drying can, in part, be attributed to the hydrophilic nature of bentonite and to the moisture trapped beneath the GCL in the bedding layer, which appears to be continually hydrating/re-hydrating the GCL.

#### 4.2.2 Load Effects on the $w(K_d)$ Calibration.

In developing the  $w(K_d)$  calibration for the mini-buriable probes placed within the GCL, it became apparent that load effects were significant. To overcome the potential for error, the calibration was performed under the same

level of confinement as the GCL in the trial. The influence of confining stress or GCL bulk density on the calibration requires further investigation, but was beyond the scope of these preliminary trials.

Figure 5: Fully hydrated moisture contents in the GCL under various confining stresses.

## 5. SUMMARY.

The trials performed illustrate the potential of TDR methods to monitor hydration levels within a GCL. In the

opinion of the authors, the level of accuracy is well within acceptable limits when appropriate calibrations and corrections for temperature are applied, and the probe type and geometry are carefully selected. Developments in telecommunications and data logging equipment make continuous remote monitoring of field sites feasible.

As for the test results, it has been shown that GCLs have the ability to hydrate from moisture in surrounding soils and remain hydrated for considerable periods without additional water being introduced.

In conclusion, a GCL may be a more appropriate mineral layer choice (as opposed to a compacted clay) in barrier applications where vapours and gases need to be contained, and the potential for desiccation in a compacted clay liner exists. A GCL will offer superior resistance to desiccation in the first instance, and if desiccation occurs, the bentonite has the ability to swell and heal cracks due to desiccation.

## 6. ACKNOWLEDGEMENTS.

The authors would like to thank Steve Zegelin of the CSIRO (Centre for Environmental Mechanics) in Canberra, Australia, and Steven Laird of Irricrop Technologies Pty Ltd, in Narrabri, Australia for their assistance in supplying and setting up equipment. The lab staff at the Geosynthetic Testing Service (GTS) in Albury, Australia, and at Naue Fasertechnik GmbH & Co. KG, Germany, need to be thanked as well.

**ABSTRACT:** Landfill closure represents a significant cost to owners and operators when the combined costs of cover system construction, maintenance of the cover system, and maintenance of the storm-water management system are considered. Owners and operators may reduce costs by constructing a cover system that consists of an exposed geomembrane (i.e., a cover system that does not include the typical drainage, vegetative support, and topsoil layers of the cover system), thereby eliminating the construction and maintenance costs associated with the portions of the cover system overlying the geomembrane. The advantages and disadvantages of the exposed geomembrane cover system, selection criteria for the exposed geomembrane, and key design considerations for the exposed geomembrane cover system are discussed in this paper. Two of the key design considerations, for which design approaches have only recently been developed, are then discussed in detail: (i) damage of the geomembrane by hail stones; and (ii) resistance of the exposed geomembrane to uplift forces caused by wind. Lastly, a case history for design is presented. By providing the necessary tools for selecting a geomembrane that is resistant to environmental factors, this paper can be used by landfill owners and designers as a basis to consider the exposed geomembrane closure approach for potentially appropriate sites.

**KEYWORDS:** Exposed geomembrane, Cover system, Landfills, Wind uplift, Hail impact.

## 1 INTRODUCTION

Solid and hazardous waste landfills are typically required to be closed with a cover system. The purposes of the cover system are to prevent direct contact of people and the environment with the waste, to prevent erosion of the waste materials, and to minimize infiltration of storm water (which causes leachate) into the landfill. From top to bottom, the components of a typical final cover system for a municipal solid waste landfill consist of: (i) a topsoil layer; (ii) a vegetative support soil layer; (iii) a drainage layer; (iv) a low-permeability layer (i.e., compacted clay or geomembrane); and (v) a soil final grading layer over the existing daily/intermediate cover layer and waste (Figure 1). Once constructed, such final cover systems require inspection and maintenance, such as mowing of vegetation and repair of eroded areas. In addition, construction of the typical final cover system represents a significant cost to owners and operators; this approach to closure may not be cost-effective, particularly in the cases where the design life of the cover system is relatively short (i.e., approximately 5 to 10 years), when future removal of the cover system may be required (e.g., for landfill reclamation), or when the landfill may be overfilled in the future. In these cases, it may be more cost-effective to construct an exposed geomembrane cover system. An example of the exposed geomembrane cover system is presented in Figure 2. As described in this paper, exposed geomembrane cover systems

represent a new direction in landfill cover system design that, depending on site-specific requirements, may represent a more cost-effective method of landfill closure.

Figure 1. Typical Final Cover System

Figure 2. Exposed Geomembrane Cover System

In this paper, the applicability and design methods for an exposed geomembrane cover system are discussed; this discussion is focused on the design of an exposed geomembrane cover system for a 17-hectare landfill (Cell 1&2) at the Delaware Solid Waste Authority's (DSWA's)

disposal facility in Sussex County, Delaware. Based on experience from numerous designs of typical final cover systems and the design of this exposed geomembrane cover system, the advantages and disadvantages of exposed geomembrane cover systems are presented in Section 2. The design considerations required for selection of the exposed geomembrane component of the cover system are presented in Section 3. A summary of the design methods (e.g., geomembrane selection) and design features (e.g., geomembrane anchors) necessary to satisfy these considerations are then described in Section 4. The application of these design methods are described in the case history presented in Section 5. Finally, in the conclusion of the paper (Section 6), recommendations are provided regarding the applicability of exposed geomembrane cover systems to other sites.

## 2 ADVANTAGES AND DISADVANTAGES

### 2.1 Introduction

As indicated in Figure 2, the exposed geomembrane cover system represents a simpler design than the typical cover system (Figure 1), which results in several advantages. However, the functions performed by the materials overlying the geomembrane in the typical final cover system are not performed in the case of the exposed geomembrane cover system, which results in disadvantages. The advantages and disadvantages for the exposed geomembrane cover system are presented in the subsections 2.2 and 2.3 and should be reviewed prior to proceeding with any design.

### 2.2 Advantages

The typical advantages of an exposed geomembrane cover system are: (i) reduced construction cost; (ii) reduced soil maintenance requirements, (iii) increased landfill volume; (iv) easier access to landfilled materials for reclamation; (v) reduced post-construction waste settlement; (vi) reduced hydraulic head on the cover system barrier layer, and (vii) enhanced visual inspection. These advantages are described below.

*Reduced Construction Cost.* Elimination of the topsoil layer, vegetative support soil layer, and drainage layer components of the typical final cover system may reduce construction costs by as much as \$80,000 to \$120,000 per hectare, depending on site-specific conditions and the availability of construction materials at the site.

*Reduced Soil Maintenance Requirements.* The level of soil maintenance required for the exposed geomembrane cover system is expected to be much less than that required for a typical final cover system. Because the amount of soil on an exposed geomembrane cover system is limited, repairs to eroded areas would be minimized

and mowing of vegetation would be eliminated.

*Increased Landfill Volume.* Using an exposed geomembrane adds volume to the landfill if the final elevation of the geomembrane is set equal to the permitted final grades of the typical final cover system. For potential lateral landfill expansions, eliminating the soils overlying the geomembrane also results in added volume when the lateral landfill expansion is developed. In addition, because there is no potentially unstable material on top of the exposed geomembrane, it can be constructed on a slope that is steeper than a typical final cover system, thereby increasing landfill volume.

*Easier Access to Landfilled Materials for Reclamation.* Elimination of the cover soils allows the owner easier access to the waste in the event of future landfill reclamation without having to remove the existing cover soils.

*Reduced Post-Construction Waste Settlement.* Because an exposed geomembrane cover system is lighter than an a typical final cover system, post-construction settlement of the waste and settlement around landfill structures (i.e., landfill gas wells, drainage terraces, etc.) is reduced.

*Reduced Hydraulic Head on Cover System Barrier Layer.* Drainage off an exposed geomembrane cover system is not restricted by the hydraulic conductivity of cover drainage materials. Accordingly, the hydraulic head on the cover system barrier layer is reduced compared to a typical final cover system.

*Enhanced Visual Inspection.* Because the geomembrane is exposed, it may be easily inspected for damage; any identified damage may be inexpensively repaired.

### 2.3 Disadvantages

Several potential disadvantages of an exposed geomembrane cover system must be considered prior to initiating the design, including: (i) increased vulnerability to environmental damage; (ii) increased volume and velocity of storm-water runoff; (iii) susceptibility to uplift damage by landfill gas; (iv) limited vehicular access; (v) limited design life; (vi) limited regulatory approval; and (vii) aesthetic concerns. These potential disadvantages are described below.

*Increased Vulnerability to Environmental Damage.* Because the geomembrane is not protected by overlying cover soils, it is susceptible to damage from vandalism, animals, exposure to sunlight, low temperatures, and extreme weather (i.e., puncture from hail and damage from wind uplift). Potential damage to the exposed geomembrane from hail and wind is discussed in greater detail in Section 4 of this paper.

*Increased Volume and Velocity of Storm-Water Runoff.* Because there are no soils or vegetation over the exposed geomembrane, storm-water runoff is conveyed quickly

off of the cover system, resulting in increased peak flow quantities and increased runoff velocities. The increased peak flow quantity requires that storm-water drainage features (i.e., ditches and culverts) be designed for a greater flow capacity and that the on-site storm-water management ponds be designed for a significantly greater storage capacity than for a typical final cover system.

*Susceptibility to Uplift Damage by Landfill Gas.* Because there is no overlying cover soil to limit uplift of the geomembrane by landfill gas, a landfill gas collection and removal system must be designed to effectively collect landfill gas that is generated within the landfill.

*Limited Vehicular Access.* Vehicular access on the landfill is usually required to perform maintenance and associated repairs to damaged features on landfill cover systems. On a typical final cover system, light vehicles can usually drive on any soil-covered portion of the landfill cover system; for the exposed geomembrane cover system, vehicular access must be restricted to only the landfill cover access road.

*Limited Design Life.* Because the exposed geomembrane is not protected from environmental damage, it has an expected design life that is shorter than that of a geomembrane in a typical final cover system.

*Limited Regulatory Approval.* Because an exposed geomembrane cover system is not common, there may be concerns among regulators regarding its technical feasibility. Also because this cover system represents a departure from typical final cover systems, regulatory approval may be difficult, or may have strict limitations.

*Aesthetic Concerns.* A large landfill that is covered by an exposed geomembrane cover system may be perceived as less visually appealing than a landfill with a fully-vegetated typical final cover system.

### 3 DESIGN CRITERIA

To prevent impacts to the environment or excessive operation and maintenance costs, each of the disadvantages listed in Section 2.3 must be addressed and resolved during the cover system design. This paper is only focused on selection and design of the geomembrane component of the exposed geomembrane cover system. Design criteria that are directly related to selection of the geomembrane are presented in this section. The exposed geomembrane component of the cover system should be designed to meet the following criteria: (i) resist damage caused by exposure to sunlight; (ii) resist damage caused by low temperatures; (iii) resist damage caused by tensile strain due to downslope creep; (iv) resist puncture damage from hail stones; and (v) resist damage from wind. These criteria are discussed below.

*Resistance to Sunlight.* The geomembrane must not be adversely affected by long-term exposure to sunlight, which generates heat and contains ultra-violet radiation.

Therefore, geomembranes having plasticizers that could volatilize or geomembranes having components that could degrade during long-term exposure to ultra-violet radiation should not be used.

*Resistance to Low Temperatures.* The geomembrane polymer must not become brittle when subjected to low temperatures. The effect of low temperatures on the field performance of geomembranes is discussed in Giroud (1994) and Koerner and Koerner (1995).

*Resistance to Downslope Creep.* The combined action of gravity and thermal expansion/contraction of the geomembrane over long periods of time could lead to downslope creep of the geomembrane, thus creating additional stresses at the anchors. Desirable geomembrane properties are: (i) light color; (ii) low coefficient of thermal expansion; (iii) high interface friction with the underlying material; (iv) low bending modulus to minimize the formation of large wrinkles (Giroud and Morel, 1992); and (v) high tensile modulus and high activation stress to minimize creep. Only geomembranes that consist of a flexible polymer and are reinforced internally with a scrim can meet both the low bending modulus and high tensile modulus requirements.

*Resistance to Puncture from Hail Stones.* The exposed geomembrane would be susceptible to damage caused by extreme weather, including puncture from large-diameter hail stones. Geomembranes with a low resistance to puncture should not be used. Resistance to damage caused by hail stones is addressed in Section 4.2.

*Resistance to Wind Damage.* The geomembrane must have sufficient tensile strength and must be sufficiently anchored to the landfill slope to resist the tensile stresses caused by wind uplift. Use of unreinforced geomembranes, which have a relatively low tensile strength, would require closely spaced anchor trenches (i.e., 3-m to 5-m vertical intervals) or closely spaced surface anchors (such as sandbags, tires, or other ballast placed every 1 to 3 square meters on the landfill slope) to prevent wind damage. The surface anchors would be effective for short-term conditions; however, over a period of several years, they would likely move under the combined effects of wind, storm-water runoff, and thermal expansion/contraction of the geomembrane. In addition, the surface anchors would require regular maintenance, which could possibly offset the initial construction cost savings. A cost-effective design for providing protection against wind uplift damage involves selecting a geomembrane having a high tensile strength and constructing geomembrane anchors at widely spaced vertical intervals (i.e., 10 to 12 m). Resistance to damage caused by wind uplift is addressed in Section 4.3.

*Other Criteria.* There are other site-specific considerations that should be addressed, such as the potential for damage caused by vandalism or by animals (e.g., chewing or hooved animals). The owner or

operator should assess the risk and potential for this type of damage. A solution may be to construct a security fence to prevent unauthorized landfill access.

## 4 DESIGN METHODS

### 4.1 Introduction

In this section, design methods that can be used to address hail damage and wind uplift are presented. When using these methods, site-specific conditions must be considered, as described hereafter.

### 4.2 Hail Damage

To calculate the potential for damage to the exposed geomembrane by hail, a comparison must be made between the impact energy of a hail stone and the impact resistance of the exposed geomembrane. The impact energy of a hail stone is equivalent to its kinetic energy given by:

$$I_e = 0.5 M v_t^2 \quad (1)$$

where:  $I_e$  = impact energy of the hail stone (N-m);  $M$  = mass of the hail stone (kg); and  $v_t$  = terminal velocity of the hail stone (m/s). Therefore, the mass and terminal velocity of the hail stone must be calculated. The mass of the hail stone is a function of the hail stone density,  $\rho_h$  (kg/m<sup>3</sup>), and volume,  $V$  (m<sup>3</sup>):

$$M = \rho_h V \quad (2)$$

The volume is a function of the diameter,  $d$  (m):

$$V = \pi d^3/6 \quad (3)$$

hence,

$$M = \pi \rho_h d^3/6 \quad (4)$$

Now, the velocity of the hail stone is calculated. The driving force,  $F_g$  (N), on the hail stone is due to gravity:

$$F_g = M g \quad (5)$$

hence,

$$F_g = \pi \rho_h g d^3/6 \quad (6)$$

This force being constant, the hail stone tends to accelerate. However, this force is resisted by the drag force exerted by air,  $F_d$  (N), which is proportional to the square of velocity:

$$F_d = (1/2) \rho_a v^2 A c_d \quad (7)$$

where:  $\rho_a$  = density of air (1.225 kg/m<sup>3</sup>);  $c_d$  = dimensionless drag coefficient (range is typically 0.45 to 0.60);  $v$  = velocity of hail stone (m/s); and  $A$  = cross section of hail stone perpendicular to velocity (m<sup>2</sup>):

$$A = \pi d^2 / 4 \quad (8)$$

hence,

$$F_d = \pi \rho_a v^2 d^2 c_d / 8 \quad (9)$$

As the hail stone accelerates,  $F_d$  increases until it becomes equal to  $F_g$ :

$$F_d = F_g \quad (10)$$

At this point, the resulting force applied to the hail stone is zero and the velocity of the hail stone becomes constant (i.e.,  $v = v_t$ ). This constant velocity is calculated by combining equations 1, 2, and 3 (Straka, 1995):

$$v_t = [(4/3)(\rho_h / \rho_a)(gd / c_d)]^{0.5} \quad (11)$$

Finally, the impact energy of the hail stone is calculated by combining the derived Equations 1, 4 and 11;

$$I_e = (\pi \rho_h^2 g d^4) / (9 \rho_a c_d) \quad (12)$$

Equation 12 gives the impact energy for the case where hail falls in a direction perpendicular to the geomembrane. This is conservative because the impact energy is less if hail does not fall in a direction perpendicular to the geomembrane. One may be even more conservative by calculating the impact energy using Equation 1 with a value of  $v_t$  that is greater than that given by Equation 11 to account for an increase in the terminal velocity of the hail stone due to wind.

The factor of safety against puncture of the geomembrane by a hail stone must be greater than a specified value, e.g., 1.0. This factor of safety is calculated using the following equation:

$$\text{Factor of Safety} = I_r / I_e \quad (13)$$

where  $I_r$  is the impact resistance of the geomembrane measured in a test.

Because the hail stone impacts the geomembrane in the cross-plane direction, standard impact resistance tests that simulate in-plane impact are not appropriate. Rollin (1991, 1993) and Kilius (1993) present cross-plane geomembrane impact resistance data obtained from tests that used a large-scale dynamic testing apparatus. The apparatus is described as a "modified drop-weight

apparatus" in which the specimen is held taut while a mass is dropped from a fixed height. Using a different test method, Koerner et al. (1986) evaluated the cross-plane impact resistance of geomembranes with a floor-mounted pendulum device. For either of these test methods, the shape of the impact apparatus should be spherical in order to simulate the assumed shape of a hail stone. Impact resistance of the geomembrane is a function of the geomembrane material properties and the thickness of the geomembrane, and is reported in terms of energy.

### 4.3 Wind Damage

The resistance to wind uplift of the exposed geomembrane is a function of the tensile characteristics of the geomembrane, the landfill geometry, and the design wind velocity. The analyses for geomembrane wind uplift presented in this paper are based on the procedures developed by Giroud et al. (1995), extended by Zornberg and Giroud (1997). For a detailed design, these references should be reviewed. The analyses are organized into two criteria: (i) resistance of the exposed geomembrane to tensile failure caused by wind uplift; and (ii) resistance of the geomembrane anchor to the tensile forces caused by wind uplift on the geomembrane. The forces acting on the geomembrane that cause geomembrane uplift, geomembrane tension, and tensile forces at the geomembrane anchors are a function of the wind velocity and the exposed length of the geomembrane. The wind velocity may be selected based on the local building codes or other appropriate guidelines.

For the selected wind velocity, the wind uplift pressure (i.e., suction) on the geomembrane at or near sea level is given by the following equation (Giroud et al., 1995):

$$S = (0.05) \lambda v_w^2 \quad (14)$$

where:  $S$  = suction (Pa);  $\lambda$  = suction factor (dimensionless); and  $v_w$  = design wind speed (km/hr).

The recommended values for suction factor,  $\lambda$ , vary according to the location along the landfill slope, as indicated in Figure 3. The suction decreases slightly with increasing elevation above sea level (Giroud et al., 1995); this effect is conservatively ignored herein. Also, the suction given by Equation 14 can be slightly decreased to account for the weight of the geomembrane (Zornberg and Giroud, 1997); however, this effect is generally not significant and is also conservatively ignored herein. As a result, the effective suction,  $S_e$  (defined by Giroud et al., (1995) as the suction corrected for the site elevation and the geomembrane weight) is considered in this paper as equal to the suction expressed by Equation 14.

The effect of wind suction on the exposed

geomembrane is characterized by the term  $S_e L$ , where  $L$  is the length of exposed geomembrane.  $L$  is calculated using Equation 15 as follows:

$$L = h/\sin\beta \quad (15)$$

where:  $\beta$  = slope angle (degree); and  $h$  = vertical distance between geomembrane anchors (m).

Figure 3. Recommended Values of the suction factor,  $\lambda$  (Giroud et al., 1995).

To evaluate the potential for tensile failure caused by wind uplift, the suction force acting over the length of geomembrane (i.e.,  $S_e L$ ) is compared to the ability of the geomembrane to resist this force. The properties of the geomembrane required for this analysis can be obtained from the stress-strain curve of the geomembrane, which may be established by performing American Society for Testing and Materials (ASTM) test method D 4885 (i.e., "Standard Test Method for Determining Performance Strength of Geomembranes by the Wide Strip Tensile Method"). The properties to be obtained from the stress-strain relationship are: (i) the allowable tensile strain,  $\epsilon_a$  (tensile strain at break for the reinforcing component of a reinforced geomembrane, or tensile strain at yield for unreinforced geomembranes); and (ii) the tensile stiffness,  $J$ , of the geomembrane.

The first part of the analysis involves calculation of the factor of safety for the geomembrane to resist rupture when subjected to the design wind event. Using the values obtained for  $S_e L$  and  $J$ , the normalized tensile stiffness for the geomembrane,  $J/S_e L$ , is calculated. Referring to Table 4 in the paper by Giroud et al. (1995) and using the calculated value of  $J/S_e L$ , the geomembrane strain,  $\epsilon_c$ , can be calculated. The factor of safety against geomembrane rupture (recommended to be a minimum of 1.5) is calculated by dividing the allowable geomembrane strain,  $\epsilon_a$ , by the strain calculated for the design wind speed,  $\epsilon_c$ :

$$FS_r = \epsilon_a / \epsilon_c \quad (16)$$

The second part of the analysis involves calculating the uplift force exerted on the geomembrane anchors. The required weight (hence the cross-sectional area) of the geomembrane anchor to resist the calculated uplift force can then be calculated. The geomembrane tension,  $T$ , is

calculated using Equation 17:

$$T = J \epsilon_c \quad (17)$$

where:  $T$  = tension in the exposed geomembrane (kN/m);  $J$  = geomembrane tensile stiffness (kN/m); and  $\epsilon_c$  = calculated strain (%). Using the strain calculated as indicated, the values for uplift distance,  $u$ , uplift angle,  $\theta$ , and normalized tension,  $T/S_e L$ , can be found from Table 2 of Giroud et al., (1995). These parameters are identified in Figure 4. The value of  $T$  calculated using Equation 17 may be confirmed by multiplying  $T/S_e L$  (obtained in Table 2 of Giroud et al., 1995) by  $S_e L$  to give  $T$ .

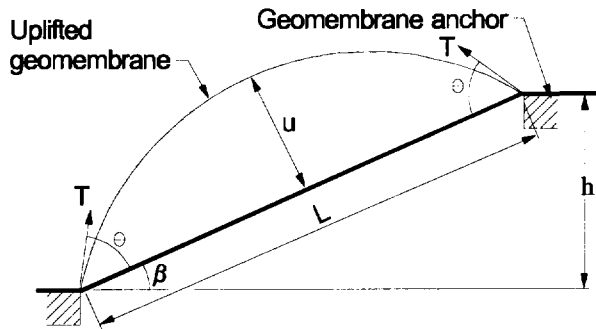

Figure 4. Exposed Geomembrane Uplift

A geomembrane anchor located on a slope between two portions of exposed geomembrane is subjected to the forces shown in Figure 5. The vertical component of these forces is a function of the uplift angle,  $\theta$  (identified in Table 2 of Giroud et al., (1995) and Figure 4 of this paper), the slope angle,  $\beta$ , and the tension,  $T$ , calculated in Equation 17. The weight of the geomembrane anchor required to resist the vertical components of the tensile forces acting on the geomembrane can be calculated using Equation 18.

$$W = T_d \sin(\theta_d - \beta) + T_u \sin(\theta_u + \beta) \quad (18)$$

where:  $W$  = weight per unit length of anchor trench (kN/m);  $T_d$ ,  $T_u$  = tension on geomembrane at the downslope and upslope side of the geomembrane anchor, respectively (kN/m);  $\theta_d$ ,  $\theta_u$  = uplift angle on the downslope and upslope side of the geomembrane anchor, respectively (degree); and  $\beta$  = slope angle (degree).

Figure 5. Tensions Acting on a Geomembrane Anchor

Assuming a continuous geomembrane anchor, the calculated anchor weight can be translated into a volume and a corresponding required area per unit width. For a geomembrane anchor consisting of soil, the required area per unit width is a function of the calculated vertical force,  $W$ , and the unit weight of the anchor soil,  $\gamma$ , and is calculated using Equation 19:

$$A_{\text{required}} = W / \gamma \quad (19)$$

The value for  $A_{\text{required}}$  is calculated assuming that the geomembrane is continuous through the cover system anchor. The calculation applies to uplift of the geomembrane anchor and does not apply to pullout of the geomembrane from the anchor. If the geomembrane is not continuous through the anchor or if the seam strength of the geomembrane is less than the geomembrane strength, then a geomembrane pullout calculation would be required. For this calculation, the soil/geomembrane interaction and/or the geomembrane seam strength would be required. These calculations are not provided in this paper.

## 5 CASE STUDY

### 5.1 Introduction

Use of the design equations and analyses presented in the previous sections is illustrated in the following case study, in which the impact of hail and wind uplift on an exposed geomembrane cover system is evaluated. The conditions presented in the case study are based on the design of an exposed geomembrane cover system for the DSWA's Cell 1&2 landfill. The geomembrane used for the design is a 0.9-mm thick green polypropylene geomembrane with a polyester scrim reinforcement. The following data are used for the analyses: (i) based on discussions with DSWA, a maximum hail stone diameter of 0.05 m was selected; and (ii) based on the local building code for structures in the area, the design wind velocity was 130 km/hr. The landfill has 4H:1V slopes (i.e., slope angle,  $\beta = 14^\circ$ ) and will have cover benches with corresponding drainage swales and geomembrane anchors spaced at 12 m vertical intervals (i.e.,  $h = 12$  m) (Figure 6).

Figure 6. Case Study Landfill Slope Geometry

Using these data, the following analyses were performed: (i) calculation of the impact energy of the hail stone on the exposed geomembrane; and (ii) calculation of the total strain and tension in the geomembrane, and the minimum geomembrane anchor cross section required to resist the calculated uplift force. The analyses are described in the following two subsections.

## 5.2 Hail Impact

The impact energy,  $I_e$ , for a 0.05 m diameter hail stone assuming,  $g = 9.81 \text{ m/s}^2$ ,  $d = 0.05 \text{ m}$ ,  $\rho_h = 900 \text{ kg/m}^3$ ,  $\rho_a = 1.225 \text{ kg/m}^3$ , and  $c_d = 0.45$  is calculated using Equation 12 as follows:

$$I_e = [(\pi (900)^2 (9.81)(0.05)^4) / [(9)(1.225)(0.45)]] = 31.4 \text{ N}\cdot\text{m}$$

Therefore, to resist puncture by hail stones, the impact resistance,  $I_p$ , of the geomembrane must be greater than 31.4 N·m. The impact resistance is a function of the geomembrane polymer and thickness. The properties of the material underlying the geomembrane also affect the impact resistance (Koerner et al., 1986). The test results reported by Rollin (1991, 1993), Kilius (1993), and Koerner et al. (1986) were reviewed during the selection process of the geomembrane. As indicated from the published test results, the selected geomembrane has an impact resistance greater than the calculated impact energy, such that the factor of safety calculated from Equation 13 is greater than 1.0.

## 5.3 Wind Uplift

### 5.3.1 Introduction

Several geomembranes were considered for the design of the exposed geomembrane cover system. Calculations for the selected geomembrane are presented in this section. A reinforced geomembrane with a linear stress-strain curve characterized by a tensile stiffness,  $J=165 \text{ kN/m}$ , and a strain at break (i.e., of the reinforcement),  $\epsilon_b=27 \%$ , was selected for the design.

### 5.3.2 Analysis for Geomembrane Rupture

First, the factor of safety against tensile failure for the design wind speed is calculated. From Figure 3, the suction factor near the top of the slope is,  $\lambda=0.85$ . Ignoring the elevation factor and the mass of the geomembrane, the effective suction force,  $S_e$ , for a wind velocity,  $v_w$ , of 130 km/hr is calculated using Equation 14, as follows:

$$S_e = (0.05)(0.85)(130)^2 = 720 \text{ Pa}$$

Using Equation 15, the length of exposed geomembrane between the geomembrane anchors is:

$$L = 12 / \sin(14^\circ) = 50 \text{ m}$$

The suction force acting on this length is:

$$S_e L = (720)(50) = 36,000 \text{ N/m} = 36 \text{ kN/m}$$

And the normalized tensile stiffness is:

$$J/S_e L = (165 \text{ kN/m}) / (36 \text{ kN/m}) = 4.6$$

For  $J/S_e L = 4.6$ , Table 4 by Giroud et al. (1995) gives the calculated strain,  $\epsilon_c = 14.1\%$ . Using Equation 16, the factor of safety against geomembrane tensile failure is calculated, which is greater than the recommended minimum value of 1.5:

$$FS_r = (27\%) / (14.1\%) = 1.9$$

### 5.3.3 Geomembrane Anchor Analysis

Next, using the parameters obtained in the previous subsection, the tension caused by uplift and the required anchor area per unit width for the geomembrane is calculated. First, the uplift of the geomembrane is calculated. For the calculated strain,  $\epsilon_c = 14.1\%$  (obtained in subsection 5.3.2), Table 2 by Giroud et al. (1995) gives  $\theta = 50.3^\circ$  and  $u/L = 0.235$ . For an exposed geomembrane length,  $L = 50 \text{ m}$ , the total uplift,  $u$ , of the geomembrane is 11.75 m (Figure 4).

The wind generated tension,  $T$ , on the geomembrane is calculated from the normalized tension,  $T/S_e L$ . From Table 2 by Giroud et al., (1995),  $T/S_e L = 0.648$ ; multiplying this value by  $S_e L = 36 \text{ kN/m}$  gives  $T = 23.3 \text{ kN/m}$ . To confirm this value,  $T$  is also calculated using Equation 17:

$$T = J \epsilon_c = (165)(14.1\%) = 23.3 \text{ kN/m}$$

On either side of the geomembrane anchor it is assumed that the length of exposed geomembrane,  $L$ , and the suction factor,  $\lambda$ , for the slope are equivalent. Therefore,  $T_u = T_d$ , and  $\theta_u = \theta_d$  (Figure 5). For  $\theta_u = \theta_d = 50.3^\circ$ ,  $T_u = T_d = 23.3 \text{ kN/m}$ , and  $\beta = 14^\circ$ , the vertical force,  $W$ , required to resist uplift of the geomembrane anchor is calculated using Equation 18, as follows:

$$W = (23.3)\sin(50.3^\circ-14^\circ)+(23.3)\sin(50.3^\circ+14^\circ)=35 \text{ kN/m}$$

Assuming that the anchor consists of soil with a unit weight of  $18 \text{ kN/m}^3$ , the required cross-sectional area of the geomembrane anchor is calculated using Equation 19, as follows:

Figure 7. Exposed Geomembrane Anchor at Cover Benches

$$A_{\text{required}} = (35 \text{ kN/m}) / (18 \text{ kN/m}^3) = 1.95 \text{ m}^2$$

At the case study site, the geomembrane anchors on the cover system were designed to include a swale that conveys storm-water runoff from the landfill in a non-erosive manner. As indicated in Figure 7, the soils in the anchor trench and the soils that form the drainage swale are covered by a protective geomembrane that is welded to the exposed geomembrane in order to eliminate the potential for soil erosion at these locations.

## 6 CONCLUSION

An exposed geomembrane cover system may be appropriate at landfill sites when the design life of the cover system is relatively short or when overfilling or landfill reclamation are future possibilities. Sites that are considered for this application should also have adequate landfill gas collection systems and storm-water management controls. To design an exposed geomembrane cover system, a number of issues must be addressed. These issues are reviewed in this paper, and guidance is provided. Furthermore, design methods for two key issues, hail damage and wind uplift, are described and are illustrated using a case history. Considering the available design tools and the example provided by the case history, it is possible to safely design an exposed geomembrane cover system that can be constructed at a lower cost than a typical final cover system.

## ACKNOWLEDGMENTS

The authors acknowledge Messrs. N.C. Vasuki and R. Watson, and Ms. A. Germain for the opportunity to apply the design methods described in this paper to DSWA's Cell 1&2 landfill. The authors are grateful to Mr. J. O'Connor for his assistance in the preparation of the figures for this paper.

# Current Issues in Seismic Design of Geosynthetic Cover Systems

Edward Kavazanjian, Jr.

Principal, GeoSyntec Consultants, 2100 Main Street, Suite 150, Huntington Beach, California, USA

**ABSTRACT:** Current issues in the seismic design of geosynthetic cover systems for landfills include establishment of a rational seismic performance standard, determination of the allowable displacement, and evaluation of the seismic coefficient for use in pseudo-static analyses. Prevention of harmful discharge is a cost effective and environmentally protective alternative to current performance standards which require landfill covers to withstand the design earthquake without damage. Calculated seismic displacement is the most commonly used index of seismic performance. The allowable calculated displacement for a geosynthetic cover system depends upon the ability of the cover to sustain displacement without damage or discharge, the accuracy with which displacements can be calculated, and the feasibility of repair of damage to the cover. Rational selection of the seismic coefficient for a pseudo-static design analysis implicitly depends upon the allowable displacement. Evaluation of the seismic coefficient also depends on the potential for amplification and attenuation of ground motions.

**KEYWORDS:** Landfill, Cover, Geosynthetic, Seismic, Earthquake.

## 1 INTRODUCTION

Geosynthetic interfaces of low or reduced strength compared to soil or solid waste materials combined with the potential for amplification of free-field ground motions by the waste mass make seismic performance an important consideration in the design of geosynthetic cover systems. Even in areas of moderate seismicity, amplification of free-field ground motions and low interface strengths can combine to limit final cover side slope inclination and, hence, landfill capacity. Current issues in the seismic design of geosynthetic cover systems for landfills include the establishment of a rational seismic performance standard, determination of the allowable calculated permanent seismic displacement of cover system components, and determination of the appropriate seismic coefficient for pseudo-static design analyses.

In parts of the United States (e.g., California), current regulations require landfill cover systems to withstand the design earthquake "without damage." Experience with the seismic design of geosynthetic cover systems for landfills has shown that requiring the cover to unconditionally withstand the design earthquake without damage can be prohibitive. A rational, environmentally sound, and cost-effective alternative to this burdensome seismic performance standard is to require that the landfill cover system withstand the design earthquake without a discharge of contaminants that is harmful to human health or the environment.

The most commonly used index of the seismic performance of landfill cover systems is the calculated permanent seismic

displacement. However, little guidance exists as to what constitutes an allowable value of calculated permanent seismic displacement. Factors influencing the magnitude of allowable calculated permanent seismic displacement may include the seismic performance standard (e.g., without damage or without harmful discharge), the ability to detect and repair damage, design details of the cover system (e.g., the presence of penetrations through the geomembrane barrier layer), and the degree of confidence in the calculated displacement.

The seismic coefficient method is the most common analytical approach used in engineering practice for the seismic design of geosynthetic cover systems. In the seismic coefficient method, pseudo-static limit equilibrium analysis is used to design the cover system to achieve the required minimum factor of safety for a specified seismic coefficient. The seismic coefficient employed in pseudo-static limit equilibrium analysis is generally specified as a function of the free-field peak horizontal ground acceleration (PHGA) at the project site. Rational selection of the seismic coefficient depends upon allowable displacement considerations.

Due to the need to account for potential amplification of the free-field PHGA by the waste mass, seismic coefficient values established solely on the basis of the free-field PHGA generally incorporate significant conservatism. Reduction of the conservatism in seismic coefficient values associated with the potential for amplification requires relatively sophisticated project-specific seismic site response analysis. Project-specific response analyses may yield amplification factors lower than those based upon design charts. Project-specific response

analyses also facilitate averaging of spatially and temporally incoherent ground motions over the potential failure mass, another mitigating factor with respect to the relationship between peak ground acceleration and the seismic coefficient.

## 2 SEISMIC PERFORMANCE STANDARDS

In the United States (U.S.), federal regulations for design of municipal solid waste landfills require design of containment systems, including liners, covers, and facilities that control leachate and surface water, to “resist” the design earthquake. Interpretation of the term “resist” is left to the discretion of state regulatory agencies. Many state regulators strictly interpret “resist” to mean that the landfill containment system should unconditionally survive the design earthquake without damage. California explicitly requires solid waste landfill containment systems “withstand without damage” the design earthquake.

Experience with the seismic design of landfill cover systems shows that requiring a geosynthetic cover system to unconditionally withstand the design earthquake without damage is an extremely burdensome standard. Particularly when coupled with a relatively extreme design event (e.g., the prescriptive U.S. federal standard of a PHGA with a 90 percent probability of not being exceeded in 250 years), the “withstand without damage” seismic performance standard can severely limit cover slope inclinations and, hence, landfill capacity. Even in areas of relatively low seismicity (i.e., areas where the design PHGA equals 0.10 g to 0.20 g, where g is the acceleration of gravity), design of a geosynthetic cover system to unconditionally withstand the design earthquake without damage can be prohibitive due to the potential for amplification of ground motions and the low seismic resistance of many geosynthetic interfaces.

### 2.1 Damage threshold

Permanent seismic displacement is generally assumed to accumulate whenever the earthquake-induced horizontal acceleration averaged over the potential failure mass (termed the average acceleration) exceeds the seismic coefficient resulting in a factor of safety of 1.0 in a pseudo-static limit equilibrium analysis (termed the yield acceleration). Figure 1 presents yield acceleration values from infinite slope stability analyses (Matasovic, 1991) as a function of slope inclination and friction angle for a veneer failure surface with no cohesion. As many regulators consider permanent seismic displacement synonymous with damage, the yield acceleration values plotted in Figure 1 indicate that, even at slope inclinations as gentle as 4H:1V (4 horizontal to 1 vertical), many typical geosynthetic interfaces may possess insufficient strength to unconditionally resist even modest seismic loads (e.g., average accelerations greater than 0.1 g) without damage (i.e., with zero permanent seismic displacement).

Figure 1 Yield Acceleration versus Friction Angle for an Infinite Slope with Zero Cohesion

#### 2.1.1 Mitigation measures for geosynthetic covers

The data in Figure 1 suggests that, for side slopes steeper than 4H:1V, use of a geomembrane with texturing on both sides may be required to satisfy the withstand without damage seismic performance standard for many geosynthetic cover systems. If a geosynthetic drainage element is employed on top of the geomembrane, it may be necessary to use a geocomposite with non-woven filter geotextiles heat-bonded on both sides of a drainage net in order to achieve unconditional stability. If a cohesion component of shear strength (i.e., interface adhesion) is relied upon to provide a yield acceleration sufficient to withstand the design earthquake without damage, it may be necessary to limit protective soil cover thickness, as the contribution of cohesion to the yield acceleration decreases with increasing cover soil thickness. In areas of moderate to high seismicity (i.e., areas where the design free-field PHGA is greater than 0.2 g), even these measures may not be sufficient for design of a cover that can unconditionally resist the design earthquake without damage.

### 2.2 Seismic performance of landfill cover systems

Observations of the performance of landfills in earthquakes indicate that solid waste landfill cover systems can sustain considerable damage without a discharge of contaminants harmful to human health or the environment. While there is no record of the performance of geosynthetic cover systems subject to strong shaking in earthquakes, observations of the performance of landfills with soil cover systems indicates that cracking and displacement of soil cover is the most common

mode of damage at landfills subjected to strong shaking in earthquakes (Anderson and Kavazanjian, 1995; Matasovic and Kavazanjian, 1996). In fact, cracking and displacement of cover soil has been noted in every post-earthquake damage survey of landfill facilities reported in the literature (Johnson, et al, 1991; Orr and Finch, 1990; Buranek and Prasad, 1991; Matasovic, et al, 1995). In some cases, cover soil displacement in excess of 0.5 m has been reported. Despite this prevalence of cover soil cracking and displacement and the occurrence of other modes of damage (e.g., disruption of the gas collection system), not one incident of a discharge of contaminants harmful to human health or the environment at a solid waste landfill facility has been attributed to earthquake ground motions. This satisfactory record of observed performance demonstrates clearly that design of landfill cover systems to unconditionally withstand the design earthquake without damage is not necessary, at least for short term protection of human health and the environment.

### 2.3 Alternative seismic performance standard

Design of landfill cover systems to withstand the design earthquake without a discharge of contaminants harmful to human health or the environment (i.e., design to “withstand without discharge”) provides a rational, cost-effective, and protective alternative to the “withstand without damage” seismic performance standard. Design to withstand without discharge requires consideration of seismically-induced discharge under both short-term and long-term conditions. Short-term discharge considerations may include mass movement of soil or waste and discharge of gas or leachate. For typical solid waste landfills, earthquake-induced damage to the cover will not result in harmful discharge in the short-term. However, earthquake-induced damage may result in harmful discharge in the long term if the integrity of the cover is not restored after the earthquake. Long-term discharge from a landfill due to seismically-induced damage to the cover system may result from both direct damage (e.g., an earthquake-induced tear in the geomembrane) and indirect damage (e.g., ultra-violet radiation-induced damage to the geomembrane resulting from loss of soil cover).

#### 2.3.1 Mitigation of potential for harmful discharge

To mitigate the potential for harmful discharge from the landfill, a post-earthquake response and recovery plan is an essential element of designing to withstand without discharge. The response and recovery plan should include guidelines for a comprehensive post-earthquake inspection to assess the earthquake-induced damage. The criteria for determining when a post-earthquake inspection is necessary is often based upon combinations of earthquake magnitude and site-to-source distance which induce the threshold value of free-field PHGA

with the potential for causing damage, considering amplification due to both foundation soils and the waste itself.

Identification of anticipated actions required for short-term repair and long-term restoration of the cover should also be included in a post-earthquake response and recovery plan. For many landfills, provisions in the post-closure Operation, Maintenance, and Monitoring Plan for cover damage that occurs under “normal” operating conditions may implicitly provide for response to and restoration of earthquake-induced cover system damage. However, explicit consideration should be given to response and recovery after a seismic event due to the potential for earthquake-induced damage to larger areas of the facility (compare to damage which occurs under “normal” operating conditions) and due to the potential impact of the earthquake on the availability of the required resources (e.g., materials, equipment, and/or skilled labor) for repair and restoration. Consideration should also be given to stockpiling special-order materials required for cover repair and to maintaining lists of approved suppliers and contractors (e.g., geomembrane installers) to facilitate cover repair.

## 3 ALLOWABLE DISPLACEMENTS

Calculated permanent seismic displacement is the most common measure used in practice for quantifying the seismic performance of a geosynthetic cover system. Due to the difficulty of designing a geosynthetic cover system that is unconditionally stable, seismic design criteria generally specify a value for the maximum, or “allowable,” calculated permanent seismic displacement for the cover system. However, little guidance exists as to the magnitude of the allowable calculated permanent seismic displacement for geosynthetic cover systems. There are some values for the allowable seismic displacement for geomembranes cited in the literature. These values tend to be based upon a 1992 survey of values used in engineering practice in the U.S. for seismic design of geosynthetic liner systems by Seed and Bonaparte (1992). However, the values cited by Seed and Bonaparte (1992) are often incorrectly referred to as “recommendations,” despite these authors specific caveat that they are merely reporting results of a survey of current practice.

The allowable value for the calculated permanent seismic displacement of a geosynthetic cover system logically depends upon the seismic performance standard (e.g., withstand without damage or withstand without harmful discharge), the level of confidence in the calculated displacement, and details of the cover system. If the seismic performance standard is to withstand without damage, the allowable calculated displacement will be small. For a cover system designed to the withstand without discharge standard, the allowable calculated displacement will be larger than for the withstand without damage standard. The accuracy of the displacement analysis is an essential consideration in establishing the allowable calculated displacement value.

### 3.1 Calculation of permanent seismic displacement

Permanent seismic displacement is generally calculated using Newmark's (1965) "sliding block on a plane" method of analysis. In a Newmark analysis, excursions of the time-history of the average acceleration of the potential failure mass above the yield acceleration of the mass are integrated to calculate the accumulated "permanent" seismic displacement. Theoretically, this calculated permanent displacement is a rigid body displacement that accumulates everywhere along the potential failure surface.

Conventional Newmark analyses generally employ a series of simplifying assumptions. The yield acceleration in a conventional analysis is usually calculated using residual shear strengths. Typically, only the horizontal component of the earthquake ground motion is considered in the analysis. Computation of the acceleration time-history of the failure mass is generally based upon a response analysis which ignores relative displacement along the failure surface (i.e., the seismic response analysis is "de-coupled" from the computation of permanent displacement.). These simplifying assumptions generally result in a conservative assessment of permanent seismic displacement. In fact, Anderson and Kavazanjian (1995) state that the permanent seismic displacement calculated in this conventional manner may be more appropriately considered an index of seismic performance rather than an engineering estimate of the anticipated displacement. These authors suggest that, in a conventional Newmark analysis, calculated displacement of 300 mm or less should be considered indicative of small displacement while calculated displacement of 1 m or more should be considered indicative of large displacement.

Seismic displacement analyses that are more advanced than the conventional Newmark analysis are available for seismic design of geosynthetic cover systems. These more advanced analyses include Newmark analyses which consider the degradation of shear strength from peak to residual conditions over the course of the earthquake and/or the coupling of earthquake ground motions and relative displacement. Finite element seismic deformation analyses with interface elements in which permanent seismic displacement is directly calculated are also available. However, these advanced analyses are not widely used in practice.

### 3.2 Current standards for cover system design

In current U.S. practice, the 150 to 300 mm of displacement cited by Seed and Bonaparte (1992) as the commonly employed allowable value for the calculated permanent seismic displacement of geosynthetic liner systems is sometimes also used as the allowable calculated seismic displacement for a geosynthetic cover system. However, an allowance is often made for the presumption that cover systems can reasonably be designed to sustain larger

displacements than liner systems because damage to cover systems is observable and repairable (Richardson, et al., 1994). Thus, the 150 to 300 mm allowable calculated displacement cited by Seed and Bonaparte (1992) for geosynthetic liner systems is often increased to values in the range of 500 mm to 1 m for the allowable calculated permanent seismic displacement of a geosynthetic cover system. Strictly speaking, because of the presumption that the cover can sustain some damage in the design event, these larger values may be applicable only if the withstand without discharge performance standard is employed. Allowable permanent seismic displacement values of 1 m are consistent with current practice for seismic design of slopes and embankments (Seed, 1979; ASCE 1983).

### 3.3 Recommended allowable displacement values

Based upon current standards of practice for the seismic stability of slopes and embankments, allowable values of calculated seismic displacement of 1 m, or more, should be acceptable for geosynthetic cover systems designed to withstand the design earthquake without discharge. When designing a cover system to withstand without discharge, provisions are needed to mitigate potential hazards associated with discharge of leachate and/or gas from disrupted conveyance systems (e.g., use of automatic shut-off valves, secondary containment, and/or articulated seismic joints) and facilitate post-earthquake repair of damage.

Multiple penetrations through geomembrane cover elements for gas and leachate collection or other purposes may limit allowable displacement to less than 1 m on an economic basis due to the cost of repair. However, if the anticipated displacement is above the geomembrane, there are no penetrations through the geomembrane on slopes, and benches provide sufficient capacity to retain cover soil that sloughs from the above, the allowable seismic displacement of a geosynthetic landfill cover system may be unlimited, provided the owner is prepared to repair and/or replace the protective soil cover and drainage layer (if any) on top of the geomembrane after a severe earthquake.

Based upon current standards of practice for seismic design of geosynthetic liner systems, 150 to 300 mm appears to be a reasonable range of values for the allowable calculated permanent seismic displacement of a geosynthetic cover system designed to withstand the design earthquake without damage. The upper end of the range (i.e., 300 mm) is more appropriate for simplified analyses which use upper bound displacement curves from generic Newmark displacement charts (e.g., Hynes and Franklin, 1984), residual shear strength, and/or simplified seismic response analyses. The lower end of the range (i.e., 150 mm) is more appropriate for more sophisticated analyses which strive to accurately calculate the permanent seismic displacement by using project-specific seismic response and formal Newmark displacement analyses.

Due to its simplicity, the seismic coefficient method remains the most common method of analysis used in practice for seismic design of geosynthetic cover systems. In the seismic coefficient method, the factor of safety for the cover system calculated in a pseudo-static limit equilibrium analysis using a specified seismic coefficient is compared to the minimum acceptable factor of safety to determine the adequacy of the design. The seismic coefficient equals the fraction of the weight of the potential failure mass that is applied as a horizontal force to the centroid of the mass in a pseudo-static limit equilibrium stability analysis. The seismic coefficient is typically specified as a fraction of the free-field PHGA of the design earthquake divided by the acceleration of gravity. Unless the criteria for seismic design is unconditional stability (zero seismic displacement), rational specification of the appropriate combination of seismic coefficient and pseudo-static factor of safety implicitly requires consideration of the allowable seismic displacement.

#### 4.1 Displacement basis for seismic coefficient values

Figure 2 presents a chart developed by Hynes and Franklin (1984) from the results of Newmark displacement analysis of 354 accelerograms from earthquakes of magnitude 5 to 8+. This figure presents mean, mean plus one standard deviation, and upper bound values for the calculated permanent seismic displacement from these records as a function of the ratio of yield acceleration to the peak acceleration of the time history used in the displacement analysis.

Figure 2 Calculated Permanent Seismic Displacement (after Hynes and Franklin, 1984)

Evaluation of the Hynes and Franklin data and experience with formal Newmark displacement analysis indicate that the mean curve in Figure 2 may be considered representative of the displacement potential of small magnitude earthquakes (magnitude less than or equal to 5.5) and of intermediate magnitude earthquakes (magnitude less than or equal to 6.5) at relatively short site-to-source distances (less than 10 km). On the same basis, the mean plus one standard deviation curve in Figure 2 may be considered representative of the displacement potential of intermediate magnitude events at site-to-source distances in excess of 10 km and larger magnitude events.

Evaluation of the data presented by Hynes and Franklin indicates that data points between the mean plus one standard deviation and upper bound lines in Figure 2 correspond either to very low intensity accelerograms from distant events or to synthetic accelerograms for very large magnitude (magnitude 8+) events and thus may not be representative of field conditions. Other important caveats on the applicability the Hynes and Franklin curves are that experience with seismic response and displacement analysis indicates that they may not be applicable to landfills on soft clay foundations, where amplification of long period motions by the foundation soils may significantly increase seismic displacement potential, and that the number of large magnitude events (magnitude greater than 7.4) in the data base is limited.

The Hynes and Franklin data indicates that when the ratio of yield acceleration to peak acceleration is greater than 0.4, calculated permanent seismic displacement will be small (less than 100 mm) for most situations encountered in practice. The data from Hynes and Franklin further indicates that calculated permanent seismic displacement will be less than 300 mm when the ratio of yield acceleration to peak acceleration is greater than 0.08 for small magnitude events and nearby intermediate magnitude events (i.e., for the mean curve in Figure 2) and 0.17 for more distant intermediate magnitude events and large magnitude events (i.e., for the mean plus one standard deviation curve). For a calculated permanent seismic displacement of less than 1 m, the Hynes and Franklin data indicates that the ratio of yield acceleration to the peak average acceleration should be greater than 0.03 for small magnitude events and nearby intermediate magnitude events and 0.06 for more distant intermediate magnitude events and large magnitude events.

Table 2 summarizes values of the ratio of yield acceleration to peak acceleration for various calculated permanent seismic displacement levels from Figure 2. Values from both the mean curve (i.e., for small magnitude events and nearby intermediate magnitude events) and the mean plus one standard deviation curve (i.e., for more distant intermediate magnitude events and large magnitude events) of Figure 2 are summarized in Table 2.

Table 2 Ratio of Yield Acceleration to Peak Acceleration as a Function of Calculated Permanent Seismic Displacement (based upon Hynes and Franklin, 1984)

Calculated Displacement	Mean	Mean + 1 Std. Dev.
100 mm	0.23	0.35
150 mm	0.17	0.27
300 mm	0.08	0.17
500 mm	0.05	0.11
1 m	0.03	0.06

#### 4.2 Amplification of free-field ground motions

The peak acceleration in Figure 2 and Table 2 represents the peak average acceleration of the potential failure mass, and not the free-field PHGA. Observations and analyses of the seismic response of solid waste landfills indicate that the free-field ground motions can be significantly amplified at the top of a landfill by the waste mass. This amplification can result in a landfill cover peak acceleration significantly larger than the free-field peak acceleration. Figure 3 presents amplification curves relating the free field PHGA to the peak acceleration at the top of an embankment or soft soil deposit developed by Singh and Sun (1995) for a 30-m-high landfill, by Idriss (1990) for soft soil sites, and by Harder (1991) for earth dams.

Figure 3 Amplification of Free-Field Ground Motions

Also plotted on Figure 3 are data points derived from the recorded motions at the OII landfill. Each OII data point is plotted twice, once using the peak acceleration recorded on

compacted fill at the base of the landfill as the “free-field” motion (Hushmand Associates, 1996) and once using the free-field PHGA evaluated by deconvolution in back analyses performed by GeoSyntec (1996). The results of the back analysis presented in Figure 3 indicate that amplification at the OII landfill was greater than reported by Kavazanjian and Matasovic (1995) based on the assumption that the motions recorded at the base of the landfill were free-field motions

The data plotted in Figure 3 indicate that the earthquake motions to which a landfill cover is subjected may be significantly greater than the free-field ground motions and that the Harder “upper bound” amplification curve for dams may also be appropriate as an upper bound for amplification by solid waste landfills. In order to account for the potential for amplification of the earthquake motions by the waste mass, the peak average acceleration of a potential cover system failure mass may be estimated from Figure 3 using the free-field PHGA and the Harder earth dam curve.

#### 4.3 Derivation of a displacement-based seismic coefficient

Table 2 and Figure 3 can be used to derive displacement-based seismic coefficient values for design of geosynthetic cover systems. The yield acceleration used to develop Table 2 represents the seismic coefficient for a factor of safety of 1.0. The peak acceleration used to develop Table 2 represents the peak average acceleration of the potential failure mass. Therefore, seismic coefficient values for specified levels of calculated permanent seismic displacement can be derived by multiplying the ratios presented in Table 2 by the peak average acceleration of the potential failure mass derived from the free-field PHGA using the Harder curve in Figure 3. For earthquakes of magnitude less than or equal to 6.5 within 10 km of the site and for any earthquake of magnitude less than or equal to 5.5, the ratios in the “Mean” column of Table 2 should be used. For earthquakes of magnitude greater than 6.5 and for earthquakes between magnitude 5.5 and 6.5 that are greater than 10 km from the site, the ratios in the “Mean + 1 Std. Dev.” column of Table 2 should be used.

Seismic coefficients derived from Table 2 should be used with a factor of safety of 1.0. Use of higher factors of safety (e.g., 1.1 or 1.15, as used with some methodologies) with a seismic coefficient derived from the Hynes and Franklin chart is not recommended, as their use would constitute unnecessary compounding of factors of safety. Furthermore, the ratios in Table 2 apply to the peak average horizontal acceleration of the failure mass and not to the free-field PHGA. The difference between these two peak acceleration values may be substantial. The relationship of the peak average horizontal acceleration of a potential failure mass to the free-field PHGA is influenced by two primary factors: amplification of the free-field ground motions by the waste mass (discussed in the previous section) and averaging of the earthquake ground motions over the potential failure mass.

#### 4.4 Attenuation by averaging of accelerations

A mitigating factor with respect to the seismic displacement potential of a geosynthetic cover system is the reduction in the peak average acceleration of a potential failure mass when compared to the peak acceleration of the mass. This reduction is due to the incoherence of the earthquake induced motions (i.e., to the spatial and temporal variability of the ground motions) of the potential failure mass. The phase difference (temporal incoherence) between motions at different points of the failure mass is particularly important in this respect. The ground motions at two points within the failure mass that are completely identical in all respects except for phase will cancel each other out entirely if they are 180 degrees out of phase. The larger the potential failure mass, the greater the reduction in the peak average acceleration compared to the peak acceleration, as incoherence increases with the size of the potential failure mass. Figure 4 illustrates the relationship between peak average acceleration and the size of the potential failure mass for a hypothetical landfill cover system.

Figure 4 Yield Acceleration and Peak Average Acceleration Versus Size of Failure Mass

The seismic displacement potential of a geosynthetic cover systems is further mitigated by the inter-relationship between the size (length) of the potential failure mass and the yield acceleration. For veneer stability, shorter potential failure masses, which tend to have larger peak average accelerations than longer failure masses due to relatively small amounts of incoherence, serendipitously tend to have larger yield accelerations than the longer potential failure masses. The

yield acceleration tends to increase with decreasing size of veneer failure mass because as the potential failure mass decreases in size the contribution to the yield acceleration from the passive “buttressing” of the soil wedge at the bottom of the failure mass progressively increases the yield acceleration from the minimum value associated with infinite slope stability. The impact of the length of a potential veneer failure mass on yield acceleration is also illustrated in Figure 4.

The inter-relationship among yield acceleration, peak average acceleration, and the size of the potential failure mass illustrated in Figure 4 indicates that conventional seismic design analyses for geosynthetic cover systems which employ a seismic coefficient based upon the peak acceleration at the crest of a landfill (Point A in Figure 4) and a yield acceleration from an infinite slope veneer stability analysis (Point B in Figure 4) may be extremely conservative. Despite the conservatism associated with it, this conventional approach is commonly used in current practice due to its simplicity. Relatively sophisticated seismic response and limit equilibrium analyses are generally required to reduce the level of conservatism associated with such conventional analysis.

## 5 CONCLUSIONS

The low shear strength often associated with geosynthetic interfaces and the potential for amplification of earthquake ground motions by the waste mass combine to make seismic design an important consideration for geosynthetic cover systems for landfills, even in areas of low to moderate seismicity. Due to these factors, design of geosynthetic cover systems to be unconditionally stable when subjected to the design earthquake (i.e., so that the yield acceleration exceeds the peak average acceleration for all potential failure masses) is frequently burdensome and may be prohibitive.

Design of geosynthetic cover systems to withstand the design earthquake without a discharge of contaminants harmful to human health or the environment is a logical, cost effective, and environmentally protective alternative seismic performance standard to design for unconditional stability. A post-earthquake response and recovery plan is an essential element of designing a cover system to sustain damage in the design earthquake without a harmful discharge.

Due to the conservatism inherent to conventional Newmark seismic displacement analyses, wherein the calculated permanent seismic displacement is based upon seismic motions calculated in a de-coupled analyses and a yield acceleration calculated using residual shear strengths, geosynthetic cover systems may be assumed to be able to withstand the following calculated seismic displacements:

- at least 1 m for covers designed to withstand the design earthquake without a harmful discharge; and
- 150 to 300 mm for covers designed to withstand the design earthquake without damage.

With proper attention to detail, the ability of a geosynthetic cover system to sustain seismically-induced displacement of the overlying cover soil may be unlimited.

Generic Newmark seismic displacement analyses indicate that the seismic coefficient for use in pseudo-static limit equilibrium design analyses of geosynthetic cover systems may be a small fraction of the peak average acceleration of the potential failure mass. However, the potential for amplification of the free-field ground motions must be considered when evaluating the peak average acceleration of a potential failure mass. Observations and analyses of the seismic response of landfills indicate that the potential for amplification of earthquake motions at the top of solid waste landfills may be similar to that of earth dams.

The amplification potential of a landfill is mitigated by the reduction in the peak average acceleration of a potential failure mass due to the incoherence of earthquake ground motions and the increase in the yield acceleration of a failure mass of limited size compared to the yield acceleration calculated in an infinite slope veneer stability analysis. Detailed seismic response and limit equilibrium analyses are required to accurately account for these factors in landfill cover design.

# Seismic Response of Landfills with Geosynthetic Liners

M.K. Yegian

Professor and Chairman, Department of Civil and Environmental Engineering, Northeastern University, Boston, MA.

H.U. Kadakal

Research Assistant, Department of Civil and Environmental Engineering, Northeastern University, Boston, MA

**ABSTRACT:** Geosynthetic liners can have important effects on the seismic response of a landfill. Slip deformations occurring along a geosynthetic interface can limit the earthquake energy transmitted to the overlying waste or soil. A dynamic response analysis procedure is described in which a geosynthetic liner is replaced by an equivalent soil layer. The dynamic material properties of the equivalent soil layer were developed such that the response of the layer to earthquake excitation is similar to that of the geosynthetic liner it replaces. An example landfill cross section is analyzed using equivalent soil layers representing geosynthetic liners and the earthquake-induced accelerations within the landfill are calculated. The results obtained from the dynamic response analysis, that included the geosynthetic liners are compared with those that ignored the liners. It is demonstrated that smooth HDPE geomembrane/geotextile liners significantly reduce the landfill acceleration, beyond an input base acceleration of 0.2 g. Hence, a dynamic response analysis that assumes a complete shear transfer through the geosynthetic liners (not allowing slip) can significantly overestimate landfill accelerations. Such overestimation of landfill accelerations can lead to unrealistic values of landfill side slope displacements.

**KEYWORDS:** Friction layer, Geomembranes, Geotextiles, Landfills, Seismic design

## 1 INTRODUCTION

Earthquake ground motions when propagating through a landfill can induce permanent deformations of the waste fill, and slip displacements along geosynthetic liners used as impervious barriers. Such potential deformations, if excessive, can compromise the integrity of a landfill. To safeguard against this environmental hazard, in the U.S., federal regulations have been formulated that address the seismic vulnerability of new landfills.

The calculation of earthquake-induced permanent deformations of a landfill requires the investigation of the dynamic response of the landfill. In engineering practice, wave propagation analysis is performed to estimate the accelerations and shear stresses within the landfill that is experiencing a design level earthquake motion. In such an analysis, the presence of geosynthetic liners within the landfill cross section poses a significant challenge. Kavazanjian et al. (1991, 1995), Yegian et al. (1992), and Zimmi et al. (1994) have demonstrated that under dynamic excitations geosynthetic interfaces can transmit limited shear stresses. Stresses larger than this limiting level will induce slip displacements along the geosynthetic interface. In current engineering practice, to simplify the dynamic analysis of a landfill, the presence of geosynthetic liners is generally ignored. This practice effectively assumes that there is no slip induced along the liners during a seismic event. As will be illustrated in this paper, this assumption can lead to significant overestimation of the earthquake-induced shear stresses in a landfill, leading to unrealistic estimates of permanent deformations of the landfill.

This paper presents a brief description of a model that can be used to represent the dynamic response of

geosynthetic liners in wave propagation analysis of landfill cross sections. The paper includes an example analysis of a landfill. A discussion of the results is included to demonstrate the effect of the geosynthetic liners on the seismic response of the landfill.

Figure 1. a) Waste fill with cover and bottom liners, b) Equivalent soil layers that replace the liners in dynamic response analysis.

## 2 MODELLING OF GEOSYNTHETIC LINERS

In engineering practice, the dynamic response of a landfill cross section is investigated, typically by considering a one-dimensional column of layered soil/waste fill profile. The earthquake-induced accelerations and shear stresses in each layer are computed using the equations that govern wave propagation through elastic media. The computer program SHAKE is commonly used for this purpose. In this SHAKE

Figure 2. A simple landfill cross section analyzed to demonstrate the effect of geosynthetic liners on seismic response

analysis, the shear modulus and damping of each soil or waste fill layer are used together with the layer thickness and material unit weight. An earthquake motion is then specified, typically at the base of the landfill or at a nearby

outcropping of rock, and the accelerations and the shear stresses within the landfill profile are calculated.

To allow the performance of dynamic analysis of landfill cross sections that include geosynthetic liners, a model has been developed by (Yegian et al. 1996) that can represent the dynamic response of the liners in the analysis. Figure 1a shows a schematic diagram of a simple landfill profile consisting of a layer of waste fill, and cover and bottom geosynthetic liners. In Figure 1b, the same profile is shown except that the liners are replaced by equivalent soil layers that have identical dynamic response characteristics as the liner interfaces as measured in shaking table tests. The use of equivalent soil layers permits the dynamic response analysis of a landfill to be performed easily with the computer program SHAKE.

To illustrate the application of the procedure and to demonstrate the potential effects of geosynthetic liners on the dynamic response of landfills, the following example landfill is investigated using the equivalent soil layer model.

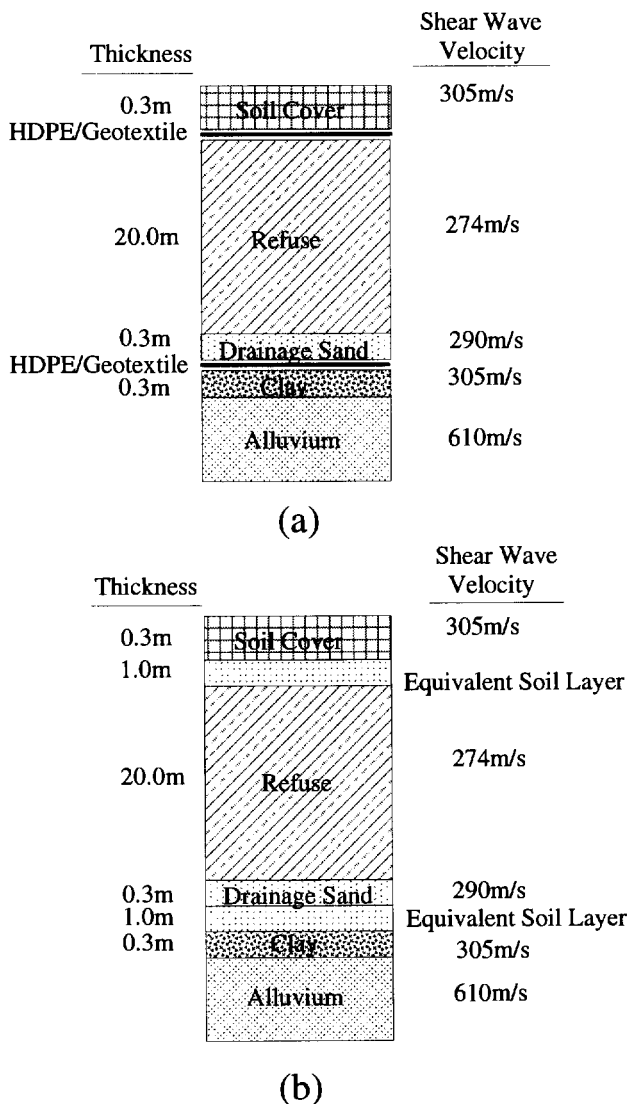

Figure 3. a) Soil/waste column analyzed, b) equivalent soil layers representing geosynthetic liners.

Figure 5. Peak accelerations with depth of landfill calculated with and without geosynthetic liners, and base acceleration of 0.1g.

### 3 EXAMPLE ANALYSIS OF A LANDFILL

Figure 2 shows a simple cross section of a landfill with cover and bottom geosynthetic liners. The dynamic response of this landfill profile was investigated by selecting a one-dimensional column as shown in Figure 2. The layer thickness and material properties of the landfill column are shown in Figure 3. In this landfill column, the geosynthetic liners (smooth HDPE geomembrane/geotextile) are replaced by equivalent soil layers. Figure 4 shows the equivalent shear modulus versus shear strain curve (of the selected interface) normalized by the shear modulus at an equivalent shear strain of 0.5%. The basis for selecting  $\gamma_e=0.5\%$  for normalizing is that this value corresponds to a slip amplitude of 0.5 cm below which an HDPE/geotextile interface observed to exhibit almost rigid behavior and its dynamic response is very difficult to record accurately based on shaking table tests. Thus, at displacement amplitudes smaller than 0.5 cm, for practical purposes an HDPE/geotextile interface can be assumed infinitely stiff. A hysteretic damping ratio of 0.43 was used for the equivalent soil layer. This damping, measured from the shaking table tests did not vary significantly for different slip amplitudes. In this example analysis the equivalent shear modulus at a shear strain of 0.5% were  $8622 \text{ kN/m}^2$  and  $210 \text{ kN/m}^2$  for the bottom and cover liners, respectively.

Using the equivalent shear moduli of the two liners and a damping ratio of 0.43, as determined from shaking table tests, the dynamic response of the landfill column was performed using the SHAKE program. The earthquake motion from the 1988 Spitak earthquake was normalized to 0.1 g and 0.4 g and used as input at the base of the landfill. Figure 5 shows the computed peak accelerations (with and

Figure 6. Peak accelerations with depth of landfill calculated with and without geosynthetic liners, and base acceleration of 0.4g.

without considering the geosynthetic liners) as a function of depth when the input earthquake motion had a peak acceleration of 0.1 g. The results show that the presence of the geosynthetic bottom and cover liners has no discernible effect on the acceleration within the landfill. This is not surprising because shaking table tests by Yegian and Harb (1995) show that slip deformations along smooth HDPE geomembrane/geotextile interfaces occur only at accelerations larger than about 0.2 g. Hence, if landfill accelerations are less than 0.2 g, ignoring the presence of smooth HDPE geomembrane/geotextile liners in the dynamic analysis of a landfill is reasonable.

Figure 6 shows peak accelerations, with and without geosynthetic liners, computed using an input motion scaled to 0.4 g. In this case, the bottom and cover geosynthetic liners have played an important role in modifying the earthquake motion propagating through the landfill. For example, the acceleration at the base of the waste fill is 0.47 g, if the geosynthetic liners are ignored in the analysis. Including the liner responses by using equivalent soil layers reduces the acceleration at the base of the waste fill by a factor of 2, to about 0.21 g. Similarly, if the liners are ignored the acceleration on top of the landfill is 0.58 g, and if the liners are included 0.28 g. Clearly, when the base acceleration is larger than 0.2 g, slip occurs along the geosynthetic liners thus limiting the accelerations transmitted through the liner interfaces. Ignoring this can unreasonably overestimate the landfill response.

Figure 7 summarizes the results of the dynamic analysis with and without considering the geosynthetic liners. The average acceleration of the waste fill is a parameter of importance in the calculation of the permanent deformations of the waste fill, and in the estimation of slip displacements along the side slope. In the example where

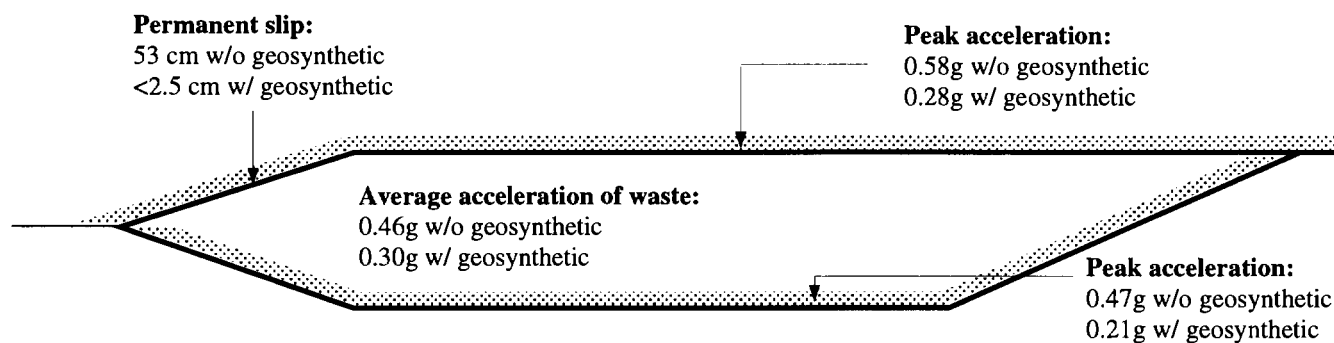

Figure 7. Results from seismic analysis of the example landfill showing the effect of geosynthetic liner on the landfill accelerations and side slope slip deformations.

the base acceleration was 0.4 g, the average acceleration of the waste fill is about 0.46 g, if the liners are ignored, and about 0.3 g if the liners are modeled in the dynamic response analysis of the landfill. These values of the average accelerations of the waste fill were used to calculate slip displacements along the side slope of the example landfill. The procedure of Yegian and Harb (1995) was used for the calculation of the side slope slip, assuming that the liner is a textured HDPE geomembrane/geotextile. The results again indicate that ignoring the dynamic response of the geosynthetic liners can lead to unrealistically large slip displacements (53 cm). Whereas, including the liner response the slip displacement on the slope is estimated to be less than one inch (< 2.5 cm).

#### 4 CONCLUSIONS

To perform realistic analysis of the seismic response of a landfill it is very important that geosynthetic liners are properly modeled. Beyond an acceleration of 0.2 g, slip displacements may occur along geosynthetic liner interfaces. This paper presents a model that can be used to represent the dynamic response of smooth HDPE geomembrane/geotextile liners in the seismic analysis of landfills.

Example analysis of a simple landfill profile is presented. The results demonstrate that smooth HDPE geomembrane/geotextile liners significantly reduce the accelerations and shear stresses transmitted through the landfill profile, especially when the base acceleration exceeds 0.2 g. Ignoring these effects can result in unrealistic estimates of seismic accelerations, shear stresses and permanent deformations in a landfill.

#### ACKNOWLEDGEMENTS

This research has been funded by a grant from the Earthquake Hazard Mitigation program of the National

Science Foundation. The authors express their appreciation to NSF and the program director Dr. Clifford Astill.

**ABSTRACT:** A 1.5 mm thick HDPE geomembrane was exhumed from a landfill leachate lagoon after 14 years of service. The differences in geomembrane properties that arise from five different exposure conditions are examined. The paper demonstrates the importance of antioxidant and stress crack resistance towards the longevity of the geomembrane. Severe cracking was observed in the geomembrane. Although most cracks were above the leachate level, the few below the level were sufficient to allow leachate to get between the geomembrane and clay liners. The diffusion profile through the clay implies that leachate has been in contact with the clay for most (if not all) of the 14 years of operation.

**KEYWORDS:** Liquid containment, Geomembrane, Clay liner, Aging, Diffusion

## 1 INTRODUCTION

Composite liners (geomembranes over clay) are now being widely used as the liner system for landfills and waste water lagoons. The understanding of factors associated with the design, selection of materials, construction quality, and long term protection of the composite liner has improved considerably over the past two decades. The importance of some of these factors can best be illustrated with reference to case records. The objective of this paper is to provide one such case record based on the exhumation of a 14 year old geomembrane from a leachate lagoon. This investigation examines: (a) the difference in geomembrane properties that can arise from different exposure conditions; (b) the influence of small cracks on the effectiveness of the geomembrane liner in the lagoon; and (c) the important role that the compacted clay can play as both an advection and diffusion barrier in the event of holes developing in the geomembrane.

## 2 FIELD INVESTIGATION AND GENERAL OBSERVATIONS

Due to expansion of the East Quarry Municipal Solid

Waste Landfill in the City of Niagara Falls, Ontario, Canada, one of two leachate lagoons was decommissioned in September 1996, after 14 years of service, to be replaced by another lagoon system at a different position in the landfill.

The lagoons were lined with a 1.5 mm (60 mil) thick HDPE geomembrane underlain by a more than 2 m thick compacted clay liner. There was no protection layer above the geomembrane which was directly exposed to the leachate and, above the leachate level, to the sun and atmosphere.

According to the operators of the landfill, the geomembrane component of the lagoon liners had a history of problems. During the lifespan of the lagoons, the two lagoons alternately had to be drained in order to clear out sludge from the lagoon and to patch defects that developed in the geomembrane liner.

When the lagoon was drained, the geomembrane at the bottom of the lagoon was like a "waterbed" with a significant amount of liquid trapped between the geomembrane and the clay. Even though the majority (93%) of cracks and holes were above the leachate level (see Figure 1), the remaining cracks/holes in the geomembrane along the side slopes appear to have been sufficient to allow leachate to get between the geomembrane and clay under conditions of zero effective

Figure 1. Photo of crack in geomembrane.

Figure 2. Photo of clay desiccation under geomembrane (above leachate level).

stress. There were no cracks or holes found in the geomembrane at the bottom of the lagoon at the time of decommissioning although 6 of the 54 patches were observed here. Many scratches were observed on the geomembrane from the bottom.

In total, 82 cracks, holes and patches were observed in the geomembrane over an area of 1352 m<sup>2</sup> (about 600 defects per hectare over the 14 year period of operation). Of these, 70% were above the leachate level and 30% were below the leachate level.

Samples were obtained from the anchor trench (NSNL: no sunlight exposure, no leachate exposure), above the leachate levels in the lagoon (SNL: sunlight but no leachate exposure), leachate level interface (MSL: sunlight and leachate exposure), and below the leachate level (NSL: no sunlight but leachate exposure). Selected samples were also taken from the bottom of the lagoon (NSLB: no sunlight, leachate/sludge exposure).

When the geomembrane was removed to expose the underlying clay liner, it was observed that clay liner sections above the leachate level were desiccated (see Figure 2). This phenomenon has been observed by others (Corser et al., 1992; Basnett & Brungard, 1992). The clay on the slopes below the leachate level and at the bottom was saturated and had an approximate 25-225 mm layer of black sludge present on the surface (the larger thicknesses generally occurred on the bottom of the liner).

### 3 GEOMEMBRANE TEST RESULTS

To assess the properties of the HDPE geomembrane, samples collected from locations in the five different exposure conditions were tested for their mechanical and physical and chemical properties. Unfortunately, due to the age of the lagoon, it was not possible to obtain the properties of the original geomembrane. Table 1 gives the values obtained on the 14 year old geomembrane removed from the lagoon. The carbon black content was within the typical range of 2-3% and will not be discussed further. Other properties are discussed in the following subsections.

#### 3.1 Density

HDPE geomembrane is a semi-crystalline polymer and its density is related to the degree of crystallinity. Any change in the density is regarded as a modification in the crystallinity. For example, any decrease in density implies a decrease of the crystalline content of the material. The density of the geomembrane under investigation was measured according to ASTM D792. Five specimens cut from samples from each exposure category were tested and the average values are presented in Table 1. The results are very similar for all locations and vary slightly between 0.965 and 0.967 g/cm<sup>3</sup>.

Table 1. Summary of average results for sheet samples

Location	$\rho_g$ (g/cm <sup>3</sup> )	CBC (%)	MI (g/10 min)	Std-OIT (min.)	SCR (hr.)	ITR (N)	Tensile Strength			
							Yield		Break	
							T (kN/m)	$\epsilon$ (%)	T (kN/m)	$\epsilon$ (%)
NSNL	0.965	2.58	0.36	3.5	3.5	284	37	11	33	646
SNL	0.967	2.64	0.5	1.8	2.6	271	37	11	25	379
MSL	0.967	2.67	-	3.3	-	284	37	10	26	479
NSL	0.966	2.73	0.41	6.3	3.1	284	37	11	32	703
NSLB	0.965	2.20	0.31	5.0	3.0	294	39	10	27	456

$\rho_g$  Geomembrane Density  
 CBC Carbon Black Content  
 MI Melt Index

ITR Initial Tear Resistance  
 $\epsilon$  strain  
 SCR Stress Cracking Resistance

These measured densities are for the geomembrane sheet and include the mass of the carbon black (which increases the overall density of the geomembrane). The density of the polymer can be back-calculated using the following equation given in ASTM D3350:

$$D_r = D_p - 0.0044C$$

where  $D_r$  is the density of resin,  $D_p$  is the density of the product and  $C$  is the weight percent of carbon black (obtained via ASTM D1603). Based on this, the calculated polymer density values were all very similar and the value of 0.954-0.955 g/cc falls within the high density range. The high density implies a high degree of crystallinity and a geomembrane that would be more susceptible to stress cracking than a less crystalline geomembrane. These days, HDPE geomembranes are made from medium density polyethylene with density less than 0.940 g/cc. Thus, properties of this geomembrane would not be the same as those of the current HDPE geomembrane.

### 3.2 Oxidative Induction Time Tests

The overall lifetime of a HDPE geomembrane is greatly dependent on the antioxidant package added to its formulation (Hsuan & Koerner, 1997). The initial step in the oxidation of HDPE geomembrane is the depletion of antioxidants. One laboratory accelerated aging study indicated that the antioxidants in the formulation must be essentially consumed before the mechanical property begins to degrade (Hsuan & Guan, 1997). Thus, by knowing the amount of antioxidant remaining in the geomembrane, the extent of the oxidation can be estimated. However, it should be emphasized that direct

comparison between different OIT values (expressed in minutes) is only applicable when the same type of antioxidant package is used, as in this case.

The amount of antioxidants in the 14 year old HDPE geomembrane was evaluated using two different oxidative induction time (OIT) tests: Standard (Std) OIT test and High Pressure (HP) OIT test. The Std-OIT test was performed according to ASTM D3895 at an isothermal temperature of 200°C and 35 kPa pressure, whereas the procedure for the HP-OIT test followed was ASTM D5885 at an isothermal temperature of 150°C and 3500 kPa. Tests were carried out on ten samples taken from the various locations. All ten samples were evaluated by the Std-OIT. Only six of the ten samples were evaluated by the HP-OIT test since the purpose of the HP-OIT test was merely to confirm the data of the Std-OIT tests. The consistency between HP-OIT and Std-OIT data suggests that the high isothermal temperature used in Std-OIT tests did not bias the result by destroying some of the antioxidants. Thus, the following discussion on the oxidation behaviour of this geomembrane will be based on the results of the Std-OIT tests. Modern geomembranes would be expected to have a Std-OIT value in excess of 100 minutes at the time of installation. However, the initial OIT values for this 14 year old membrane are unknown.

Table 1 shows the average results of the Std-OIT tests. The resulting values at ten different locations are all very short, signifying that there is only a limited amount of antioxidant remaining in this 14 year old geomembrane. As expected, geomembranes exposed to sunlight have the shortest OIT time of all. This is because the exposed geomembranes were subjected to both photo-oxidation and thermo-oxidation. In addition, the surface temperature of the exposed geomembrane was much

higher than the covered geomembrane; this further accelerated the thermo-oxidation. However, the OIT values from the north, south, east and west were similar. Thus the effect of the orientation with respect to the sun seems to be minor (the south and west slopes having slightly higher OIT values than the north and east slopes). Three of the six exposed samples had OIT values in the 1 minute range, suggesting that their antioxidant levels have almost reached zero. (A non-stabilized HDPE geomembrane has 0.5 minute of Std-OIT). Thus, oxidation degradation might already have started in the geomembrane at these locations, particularly on the surface.

For covered geomembranes, temperature is the crucial factor. Geomembranes which were fully covered by the leachate would experience the most consistent and lowest maximum temperature in the entire liner system since the leachate temperature would remain relatively constant through the year unlike the surface temperature which would be high in the summer. Thus, the relatively long OIT times measured for the leachate covered samples are reasonable. Approximately 5-6 minutes of Std-OIT were measured indicating that some antioxidant remained in these geomembranes. For the geomembrane that was located at the interface between the leachate and the sunlight, the OIT value of approximately 3 minutes falls between those of the fully exposed and the fully leachate covered geomembranes. Also, its value is very similar to the geomembrane that was located in the anchor trench. Due to the shallow depth of the anchor trench (approximately 0.75 m), the temperature of the geomembrane at this location would have reached the ambient temperature which could be 28°C in the summer season. Consequently, the oxidation of the anchor trench geomembrane proceeded faster than that covered by the leachate.

### 3.4 Melt Index Test (MI)

If oxidation degradation takes place in the polymer, the molecular weight of the polymer will be altered due to either a cross-linking or a chain scission reaction. The melt index (MI) test, ASTM D1238, is a qualitative method to assess molecular weight. A high MI value indicates a low molecular weight, and vice versa. Geomembrane samples were taken from the west slope at four different locations: anchor trench (NSNL), sunlight exposed region (SNL), below the leachate level (NSL) and at the bottom of the lagoon (NSLB). Tests were performed under the condition of 190°C and 2.16 Kg. Two replicates were tested for each sample. The MI results are shown in Table 1.

The MI value varies with the location of the geomembrane. The geomembrane that was completely covered by leachate has the lowest MI value, whereas

the fully exposed geomembrane shows the highest. The geomembrane at the anchor trench has a slightly lower value than that located at the leachate interface. Additionally, there is an inverse relationship between MI and OIT values; geomembrane with a high MI value has a low OIT value. The increase of the MI value suggests that the oxidation induced a chain scission in the polymer. This behaviour is different from that observed in some of the laboratory aging results obtained at oven aging temperatures in the range of 110-115°C at which a cross linking was observed (Thomas & Ancelet, 1993; Yim & Godin, 1993).

### 3.5 Tensile Properties

Tensile properties may be used to evaluate the macroscopic changes in a geomembrane. These properties were obtained in accordance with ASTM D638-90 (Type IV) with a strain constant rate of 50 mm/min. Tests were performed on 10 dumb-bell specimens cut from samples taken at different locations as previously described. The results presented in Table 1 show no significant difference in either the strength and strain values at yield. The yield strength varied from 37 to 39 kN/m and is higher than typical values (30 kN/m) while the yield strains were between 10 and 11% and were lower than typical values for new geomembrane (15%) today (all based on 25 mm gauge length).

Both the breaking strength and strain values are lower than expected for new material (50 kN/m). The highest values are observed for the anchor trench samples and samples from the slopes exposed to leachate. The lowest values are observed for samples exposed to sun and samples from leachate-sun interface (26 kN/m). However, a surprisingly low value of about 27 kN/m is observed for the bottom sample. This may be due to the highly scratched nature of the geomembrane on the bottom.

These results seem to agree with those reported by Rollin et al. (1994) who observed that, for a 7 year old HDPE, there was an increase of strength at yield and a decrease of both strength and strain at rupture. This behaviour of HDPE geomembrane suggests that the material has become brittle and hence is indicative of aging of the geomembrane.

### 3.6 Stress Cracking Resistance (SCR)

Stress cracking has been defined by ASTM D883 as an external or internal rupture in a plastic caused by tensile stress less than its short term mechanical strength. In this study, the SCR was assessed by the single point notched constant tensile load (SP-NCTL) test according to ASTM D5397-appendix instead of the bent strap

D1693 test. The notch was introduced from the exposed side of the geomembrane to minimize the surface effects such as scratches or surface degradation. Geomembrane samples were taken from the west side slope at four different locations and the results are given in Table 1. The overall failure time of this geomembrane is remarkably short; all specimens failed in less than 4 hours. The results suggest that the geomembrane is highly susceptible to stress cracking as reflected by the cracking behaviour observed in the field. Since there is no SP-NCTL test data on the original material, one can not conclude whether or not the short failure time was caused by the aging effect. Nevertheless, geomembranes at locations where they were covered or partially covered by soil or leachate show a very similar failure time. The geomembrane exposed to the sunlight shows a slightly lower failure time, suggesting that some degradation may have taken place in this portion of the geomembrane.

#### 4 DIFFUSION OF CONTAMINANTS INTO THE CLAY LINER

The geomembrane was underlain by a compacted clay liner in excess of 2 m thick. The liner was composed of 88-93% clay sized particles, a plastic limit of 23% and plasticity index of 18%. This low activity clay liner had a porosity of that typically ranged between 0.3 and 0.39 with an average value of about 0.33. The hydraulic conductivity below the leachate level was about  $2 \times 10^{-10}$  m/s (based on one laboratory test).

Figure 3 shows the observed chloride profiles with depth in the clay liner obtained by performing pore water squeezes and chemical analyses on samples from a borehole in the clay liner. The profile shows a generally consistent trend of chloride migration over a 14 year period. The depth of penetration of almost 2 m is consistent with expectations based on previous field cases (see Rowe et al., 1995) over a time period of the order of 14 years. The lower concentration at the surface (relative to 0.2 m depth) suggests that the average chloride concentration in the leachate over the year prior to exhumation was lower than the long term average concentration for the previous 13 years which gives rise to some back diffusion. This is consistent with the leachate chemistry data. The profile implies that the compacted clay liner performed well and the liner system protected the environment from contaminant escape over the 14 year operating life of the lagoon.

Figure 3. Variation in chloride concentration with depth in clay liner below the geomembrane after 14 years.

#### 5 SUMMARY AND CONCLUSIONS

Geomembrane samples were taken from five different locations of a 14 year old leachate lagoon. Their physical, chemical and mechanical properties were evaluated in order to assess the possibility of the degradation in the material during this service period. The overall amount of antioxidant present in the geomembrane was measured using the Std-OIT test. The OIT values at all five locations were relatively short, less than 7 minutes. Although the percent reduction in the 14 years service could not be estimated due to the unavailability of the original OIT value, the consumption rate at various locations of the lagoon was evaluated. As expected, the lowest OIT value was detected in the geomembrane that was constantly exposed to sunlight. A value as low as 1 minute was detected in some of the exposed geomembranes, implying only a small amount of antioxidant remaining in the geomembrane. Thus, some degrees of oxidation probably has already occurred in this part of the geomembrane, particularly on the exposed surface. The extent of the photo-oxidation has caused a reduction in tensile break properties and stress crack resistance of the geomembrane. The results of the Melt Index test suggest that the degradation was induced by a chain scission reaction in the polymers.

For geomembranes that were either covered by soil or leachate, their properties were largely the same. Their depletion of antioxidant was slower than the exposed and partially exposed geomembranes. The amount of antioxidant present in these geomembranes seems to be sufficient to protect the geomembrane from oxidation degradation as indicated by their relatively high tensile

break properties. Although tensile break properties of the bottom geomembrane showed a decrease, they might be due to surface scratches which appeared everywhere on this part of the geomembrane. The correlation between the OIT and tensile break properties of this 14 year old geomembrane illustrates the significant role of antioxidant in protecting the mechanical properties of the geomembrane.

The severe cracking observed on the geomembrane indicated that the material was highly susceptible to stress cracking, and this was confirmed by the results of SP-NCTL tests. The average failure time of unexposed geomembranes was 3 hours at 30% yield stress which is well below the current recommended value of 200 hours.

The results of this investigation substantiate the importance of the antioxidant and stress crack resistance towards the longevity of the geomembrane. Therefore, these two properties should be evaluated and incorporated in the specification of a HDPE geomembrane to assure their quality.

The presence of only a few small holes/cracks below the leachate level was, apparently, sufficient to allow leachate to get below the geomembrane and diffuse almost 2 m into the clay liner. However, notwithstanding the holes in the geomembrane, the liner system provided an excellent advective-diffusive barrier and provided the environmental protection required over the required service life of the lagoon liner system (14 years).

## ACKNOWLEDGEMENT

The authors very gratefully acknowledge the assistance of Niagara Waste Systems Limited in conducting the field sampling described in this paper. The testing and research was funded by the Natural Sciences and Engineering Research Council of Canada under a Grant to the senior author and by the Geosynthetic Research Institute at Drexel University. The authors also appreciate the assistance of Ms. C. Orsini in the preparation of Figure 3.

# Solubilities, Diffusion and Partition Coefficients of Organic Pollutants in HDPE Geomembranes: Experimental Results and Calculations

W. Mueller, I. Jakob, R. Tatzky-Gerth and H. August  
Federal Institute for Materials Research and Testing, BAM, Berlin, Germany

**ABSTRACT:** Solubilities and diffusion coefficients of organic pollutants in HDPE geomembranes and the partition coefficients for acetone, acetic acid and trichloroethylene in the water-geomembrane system were measured in immersion tests. Solubilities and partition coefficients are the most relevant parameters in determining the permeation rate in geomembranes and in composite lining systems which include geomembranes. Theoretically these parameters can be obtained from calculations using group-contribution methods. Two methods (the UNIFAC procedure and the Retention-Index procedure) are described. The calculated results are compared with experimental values. It is shown that for various types of organic pollutant the calculated solubility and partition coefficient values agree with acceptable accuracy with the experimental results.

**KEYWORDS:** Diffusion, Permeability, Geomembranes, Composite Liner Systems, Performance evaluation

## 1 INTRODUCTION

The importance of the quantitative description of contaminant transport phenomena in liner systems appears to have increased considerably in recent years, in particular with respect to risk assessment for landfill construction and contaminated site containment, and equivalence or suitability considerations of different materials for liner systems.

Two contaminant and material dependent parameters are of fundamental importance in the description of the contaminant transport in a liner element. One is the partition coefficient, which represents the extent to which a contaminant from an aqueous solution can penetrate a liner material and be dissolved there, i.e. is distributed between the aqueous solution and the liner element or more generally is distributed between the liner material and an adjacent medium or another liner component. The other is the diffusion coefficient, which describes the degree of mobility of the dissolved contaminant within the liner material.

According to the second and third administrative provisions to the German waste avoidance and waste management act, concerning the technical standards for the treatment and disposal of waste (the so called TA Abfall and TA Siedlungsabfall), the composite liner comprising a geomembrane and a thick multilayered clay liner is the standard for municipal and hazardous solid waste landfills. Predominantly medium to high density polyethylenes (HDPE) are used for these purposes because these materials exhibit an extremely high chemical resistance and durability. The regulations in Germany require the certification of geomembranes for use in landfill liners and at present only this type of geomembrane is certified by the Federal Institute for Materials Research and Testing, BAM (BAM 1994).

In the following, the experimental results obtained from immersion tests for the determination of the partition and diffusion coefficients regarding the permeation of various contaminants, in particular from aqueous solutions, through HDPE geomembranes and composite liners, will be described. These experiments are the continuation of and supplement to

BAM's investigations in the field of contaminant transport in geomembranes already reported (August et al. 1984, 1992).

Special thermodynamically based calculation methods in engineering chemistry make it possible to calculate these parameters for a wide variety of undissociated contaminants in aqueous solution. Only this type of contaminant is of interest with respect to diffusion processes. Experiments lasting more than 10 years failed to yield any clues on solution or diffusion processes of hydrated cations and anions of dissociated molecules in aqueous solutions into geomembranes (Mueller et al. 1997b).

The experimental results for solubilities and partition coefficients will be compared with the calculated values. The comparison will indicate that these parameters can reliably be calculated for various kinds of contaminants. The calculation methods may therefore be used for the quantitative evaluation of contaminant transport through plastic liner and composite liner systems for landfills or the containment of contaminated sites.

## 2 THEORY

### 2.1 Partition Coefficient, Solubility and Diffusion Coefficient

If a geomembrane is submersed in an aqueous chemical solution, the molecules of the chemical may intrude into the plastic material. As the chemical concentration increases, increasing numbers of molecules will leave the geomembrane again. At a temperature  $T$  and pressure  $P$  a state of equilibrium between the amount of contaminant (mole fraction  $x_1$ ) of the chemical in the geomembrane and the amount of contaminant (mole fraction  $x_0$ ) in the aqueous solution, will be reached. The ratio of these two fractions is expressed by the partition coefficient:

$$\sigma' = x_1/x_0 \quad (1)$$

(The mole fraction of chemical dissolved in the plastic will be interpreted in the following as relating to one structural unit of

the polymer chain, e.g. CH<sub>2</sub> for polyethylene, and not the number of the polymer chains themselves).

In order to calculate  $\sigma'$  it is necessary to begin with the thermodynamic conditions of the state of equilibrium. The concentration partition at equilibrium is indicated by the chemical potential  $\mu(x, T, P)$  for the contaminant dissolved in water and that for it dissolved in plastic being equal. The dependency of the chemical potential of the dissolved contaminant on concentration is given by  $\mu(x, T, P) = \psi(T, P) + k_B T \log[\gamma(x, T, P)x]$ .  $k_B$  is the Boltzmann Constant,  $\psi$  is the chemical potential of the neat liquid chemical, being a function of T and P only.  $\gamma(x, T, P)$  is the activity coefficient which depends on the mole fraction, pressure and temperature. The function  $a = \gamma(x, T, P) \cdot x$  is called activity.

Thus in equilibrium the following holds:

$$\psi(T, P) + k_B T \log[\gamma_1(x_1)x_1] = \psi(T, P) + k_B T \log[\gamma_0(x_0)x_0] \quad (2)$$

from which it follows for the activities and concentrations of the solutions at equilibrium:

$$\gamma_1(x_1)x_1 = \gamma_0(x_0)x_0 \quad (3)$$

If the activities or the activity coefficients are known as a function of concentration, the two unknowns, partition coefficient  $\sigma'$  and mole fraction  $x_1$  in the geomembrane can be calculated from equations (1) and (3) for a particular  $x_0$  in the aqueous solution. At very low concentrations, the activity is proportional to concentration and, for a direct calculation of  $\sigma'$  using the proportionality constants  $\gamma_0$  and  $\gamma_1$ ,

$$\sigma' = \gamma_0 / \gamma_1 \quad (4)$$

can be assumed.

Usually, the concentration describing the contaminant content in a solution will be given by the volumetric concentration  $c$  (mass per volume) or by the mass fraction  $w$  (mass per mass). The corresponding partition coefficients are  $\sigma = c_1/c_0$  and  $\sigma'' = w_1/w_0$ . The relation of the partition coefficients is then given by:

$$\sigma' = x_1/x_0 \approx (V_p/V_L) \sigma \approx (M_p/M_L) \sigma'' \quad (5)$$

$V_L$  and  $V_p$  and  $M_L$  and  $M_p$  are respectively the mole volumes and mole masses of the water or the structural unit of the polymer.

If a geomembrane is immersed in the neat liquid chemical and the plastic is resistant to it some saturation concentration of the chemical dissolved by the plastic will be reached. The mass fraction (ratio of the mass of dissolved chemical to the mass of plastic) at saturation will be called the solubility  $s$ . An equation for the mole fraction  $x_p$  which corresponds to the solubility, can also be deduced directly from the equilibrium conditions (3). Since for the neat liquid chemical  $x_0 = 1$  and thus  $\gamma_0 = 1$ :

$$\gamma_1(x_p)x_p = 1 \quad (6)$$

must be true. Therefore, if the activity or the activity coefficient is known as a function of concentration, solubility can also be calculated according to (6).

Activities and activity coefficients and therefore the partition coefficients and solubilities can be calculated using the group-contribution methods. These methods consider the behaviour of chemicals in a solution to be determined additively by the properties of typical structural units of the dissolved molecules and by the interaction of these units with typical structural units of the solvent molecules. The structural units may be characterized by their properties volume, surface and interaction parameters with other units.

Two of these methods are used in the following. The partition coefficient can be determined directly by a method suggested by Piringier (1993), the so called Retention-Index method. The UNIFAC (Universal Functional Group Activity Coefficient) method is widely used and versatile but more complicated. An introduction is given by Reid et al. (1977). It is used to calculate the activities and activity coefficients of non-electrolytic liquid mixtures for various concentrations. Oishi and Prausnitz (1978) suggested an extension of this method which allows the activities of contaminants dissolved in amorphous polymers to be determined. Goydan, Reid and Tseng (1989) showed, that this method yields sufficiently exact results over a wide range of applications when compared with various similar methods for the determination of the solubility of organic contaminants in polymers.

Using group-contribution methods to analyze and parameterize a large amount of experimental results, Piringier (1993) derived the following empirical formula for the diffusion coefficient of contaminants in polymers at very low dilution:

$$D = \exp(A_p - 0,008 M_p - 10450 \frac{1}{T}) [m^2/s] \quad (7)$$

$M_p$  is the mole mass of the dissolved molecule, T is the absolute temperature measured in Kelvin and  $A_p$  is a materials parameter. For LDPE material the best fit to the data was obtained with  $A_p = 9$  and for high density PE materials with  $A_p = 5$  (Piringier 1993). For the medium density PE-copolymers used for the geomembranes we expect an intermediate value of  $A_p$  to give best results for the calculation of the diffusion coefficients.

The parameters  $\sigma$  and D can be determined experimentally using immersion tests. In an immersion test a sample of the geomembrane material of a particular geometry is immersed in the liquid chemical or its aqueous solution with the known, constant concentration  $c_0$ . The absorption of the chemical by the sample is measured from gradual mass increase  $\Delta G(t)$ . If the solubility of the chemical in the geomembrane material is limited, a saturation value  $\Delta G(\infty)$  for the increase in mass is reached during the test. For a diffusion process according to Fick's law with a constant diffusion coefficient D the increase in mass is proportional to  $(Dt)^2$  up to about 2/3 of the saturation

value. The proportionality factor depends on the geometry of the sample. For a plate with a large area compared to its thickness  $d$ :

$$\Delta G(t) = \Delta G(\infty) [4/(d \pi^{1/2})] (Dt)^{1/2} \quad (8)$$

The solubility  $s$  can be calculated for an immersion in the liquid chemical from the saturation value:

$$s = \Delta G(\infty) / G \quad (9)$$

The partition coefficient for immersion in the aqueous solution is determined from the concentration  $c(\infty) = \Delta G(\infty)/V$  of the chemical in the GM sample (density  $\rho_{GM}$ ), which is in equilibrium with the concentration of the chemical in the aqueous solution  $c_0$ :

$$\sigma = c(\infty) / c_0 = [(\Delta G(\infty) / G) \rho_{GM}] / c_0 \quad (10)$$

## 2.2 Permeability and Induction Time for Composite Liners

In the following we demonstrate the paramount importance of the partition coefficients for the contaminant transport in a liner. We show how these coefficients enter the formula for the steady state permeation rate and the induction time for the composite liner.

The concentration profile  $c(x)$  of the contaminant through the liner in the steady state can be split into different ranges:  $c_0$  is the initial concentration of the pollutant in the leachate,  $c_1(x)$  is the concentration profile in the geomembrane and  $c_2(x)$  that in the clay liner, we assume that the concentration beneath the liner should always be zero due to dilution by the groundwater. The concentration gradient which causes diffusion in the geomembrane, builds up by the adsorption and dissolution of contaminants on the surface of the geomembrane. The concentration conditions at the leachate/geomembrane interface ( $x=0$ ) as explained above are described by the partition coefficient  $\sigma_{0,1}$  thus:

$$c_1(0) = \sigma_{0,1} c_0 \quad (11)$$

In connection with the sealing layers geomembrane and mineral layer, a further parameter for the composite liner, i.e. partition coefficient  $\sigma_{2,1}$  for the interface between geomembrane and mineral layer ( $x = d_1$ ) is important:

$$c_1(d_1) = \sigma_{2,1} c_2(d_1) \quad (12)$$

In the simplest case  $\sigma_{0,1} = \sigma_{2,1}$ . Here it will be assumed that the partitioning of the contaminant between the geomembrane and leachate is similar to that between the geomembrane and the mineral layer pore water. Strictly speaking, however,  $\sigma_{2,1}$  depends on the properties of the interface between the two sealing components and  $c_1(d_1)$  and therefore it will differ from  $\sigma_{0,1}$ . In addition various chemicals in the leachate and in

contrast to the pure pore water effect the partition equilibrium.

For the diffusive transport of contaminants in the mineral layer pore water the effect of the pore structure on diffusion as well as the adsorbing effect of the "pore walls", i.e. the generally reversible adsorption of contaminants by chemical and physical bonding on the material of the mineral layer, should be considered in the diffusion equation. Pore structure will be described by a tortuosity factor  $\Gamma$ , by which the diffusion coefficient of the contaminant in water  $D_0$  is multiplied. Another partition coefficient  $k$  characterizes the contaminant partition between soil and soil water. Assuming once again linear equilibrium sorption, i.e. at any one time, for contaminant mass fraction  $c_3$  adsorbed by the soil particles and concentration  $c_2$  of the contaminants in the soil water,  $c_3 = k c_2$ , the following diffusion equations will be obtained:

$$R \frac{\partial c_2}{\partial t} = \Gamma D_0 \frac{\partial^2 c_2}{\partial x^2} \quad J_2 = -n \Gamma D_0 \frac{\partial c_2}{\partial x} \quad (13)$$

with the retardation coefficient  $R = 1 + \rho_d k/n$ , where  $\rho_d$  is the dry density of the mineral material and  $n$  its porosity.

In a mineral layer the permeation rate  $J_2$  and the induction time  $t_2$  are then given for an effective concentration  $c_0$  by:

$$J_2 = n \Gamma D_0 c_0 / d_2 \quad t_2 = R d_2^2 / 6 \Gamma D_0 \quad (14)$$

Under a steady contaminant supply the sorption in the mineral layer has no influence on the final permeation rate, it has however a substantial influence on the induction time. For a geomembrane the permeation rate  $J_1$  and induction time  $t_1$  of diffusive contaminant transport at a concentration  $c_0$  can be written as:

$$J_1 = \sigma_{0,1} D_1 c_0 / d_1 \quad t_1 = d_1^2 / 6 D_1 \quad (15)$$

Using permeability  $P$  as a material parameter, for the geomembrane and the mineral layer we define:

$$P_1 = \sigma_{0,1} D_1 \quad P_2 = n \Gamma D_0 \quad (16)$$

The permeability  $P$  and permeation rate  $J$  of the composite liner with a thickness  $d=d_1+d_2$  can now be easily calculated using the boundary conditions (11) and (12) from the conservation of contaminant fluxes in the steady state, i.e.  $J_1=J_2$ . This gives:

$$\frac{d}{P} = \frac{d_1}{P_1} + \frac{d_2}{(\sigma_{0,1}/\sigma_{2,1})P_2} \quad (17)$$

Finally the formula for the induction time of the whole system analogous to (17) should be given, which can also be easily calculated using a method suggested by J. C. Jaeger (Carslaw et al. 1959, Barrie et al. 1963). The induction time  $t$  of the composite liner is composed of the induction times  $t_1$  and  $t_2$  and

permeabilities  $P_1$  and  $P_2$  of its components as follows:

$$t = \frac{t_1 \left( \frac{d_1}{P_1} + \frac{3d_2}{(\sigma_{0,1}/\sigma_{2,1})P_2} \right) + t_2 \left( \frac{3d_1}{P_1} + \frac{d_2}{(\sigma_{0,1}/\sigma_{2,1})P_2} \right)}{\frac{d_1}{P_1} + \frac{d_2}{(\sigma_{0,1}/\sigma_{2,1})P_2}} \quad (18)$$

The permeation rate for the diffusion of a contaminant through the composite liner is determined according to (16) and (17) for given thicknesses ( $d_1 = 2.5$  mm and  $d_2 = 0.75$  m or 1.50 m for municipal waste landfills and hazardous waste landfills respectively) by diffusion coefficients  $D_1$  and  $D_0$ , partition coefficients  $\sigma_{0,1}$  and  $\sigma_{2,1}$  and soil parameters  $n$  and  $\Gamma$ . While parameters  $D_1$  and  $D_0$  and  $n$  and  $\Gamma$  vary by only approximately one order of magnitude for different contaminants and mineral materials, the partition coefficients  $\sigma$  of the various contaminants differ by many orders of magnitude. Thus the partition coefficient characterises the imperviousness of the composite liner for a variety of classes of contaminant. For example, the partition coefficient for cations and anions is practically zero since they cannot be dissolved out from the hydrated complex in the aqueous solution in the non-polar material polyethylene. As indicated previously, therefore, from the outset only undissociated organic and inorganic molecules have to be considered for diffusive contaminant transport.

Since the induction time depends on the square of the thickness, for a composite liner  $t_2 \gg t_1$ . Also the retardation capacity of the mineral layer may increase induction time considerably. The induction time  $t$  of the whole liner system is then determined according to (18) only by the thickness of the mineral layer and its sorption capacity. This does not apply for composite liners with particularly thin mineral layers such as GCLs.

This paper focuses on the determination of  $\sigma$  and  $D_1$ . A detailed discussion and evaluation of the other parameters mentioned above and therefore of contaminant transport in the composite liner is given elsewhere (Mueller et al. 1997b).

### 3 EXPERIMENT

The manufacturers and the resin specifications, thickness and crystallinity of the geomembranes used in the immersion tests and the identification number of the samples are listed in Table 1a. The corresponding parameters of the HDPE resins for certificated geomembranes are shown in Table 1b. The materials are high molecular weight, linear, medium density polyethylene with butene, hexene or octene co-polymer fractions. The first column of Tables 2a and 2b list the chemicals used as test liquids and as aqueous test liquid solutions for the immersion tests. Both non- or only weakly polar and polar organic test liquids were used.

Details of the experimental procedure and typical examples of mass gain versus time curves for samples immersed are given

elsewhere (Mueller et al. 1997a). The constant saturation value in the mass gain - time curve was used to calculate the mass fraction of the test liquid in the geomembrane, see (9). Tables 2a and 2b summarizes the results.

Table 1a. Properties (manufacturer, resin, thickness and crystallinity) of the test samples and sample numbers.

Sample number	Manufacturer	Product type	Thickness	Crystallinity <sup>2</sup>
48	AGRU GmbH	Hostalen GM 5040 T12	2.5 mm	(53.6 ± 0.5) %
139	GSE GmbH	Dowlex 2342 M	2.5 mm	(47.5 ± 0.5) %
a	Simona GmbH	unknown <sup>1</sup>	1.0 mm	(55.7 ± 0.5) %
b	SLT GmbH	Vestolen A 3512 R	2.0 mm	(51.3 ± 0.5) %

1) HDPE-resin of relatively high density (Dichte 0.954 g/cm<sup>3</sup>, MFI (190/5) 1.3 g/10min), no detailed data about the product available

2) with respect to a heat of melting of 293 J/g of fully crystallized HDPE

Table 1b. Characteristic data of the HDPE resins used for certificated geomembranes in landfill lining systems.

Product type	Density <sup>1</sup> [g/cm <sup>3</sup> ]	MFI <sup>1</sup> [g/10 min]	Ratio of MFI <sup>2</sup> [-]	carbon black <sup>1</sup> [wt.-%]
Hostalen GM 5040T12	0.946±0.002	0.85±0.15 (190/5)	19	2.15±0.15
Dowlex 2342 M	0.943±0.002	2.5±0.4 (190/5)	9	2.2±0.2
Fortiflex G36-24-149	0.947±0.003	23.0±3.0 (190/21.6)	18	2.35±0.25
Vestolen A 3512 R	0.942±0.003	1.6±0.2 (190/5)	9	2.1±0.3

1) Specification of the manufacturer according to the certification document, MFI: melt flow index according to DIN ISO 1133

2) Ratio of MFI (190/21.6) to MFI (190/5), measured at GM samples

The diffusion coefficient was determined according to (8) from the linear slope of the mass gain - square root of time curve valid for short times. The results are given in the second and third columns of Table 3a and 3b.

From the solubilities and diffusion coefficients determined from the immersion tests the expected permeation rates for the neat test liquids can be calculated according to (15). They are in good agreement with the directly measured rates obtained from permeation experiments. For trichloroethylene a rate of 50 g/m<sup>2</sup>d (Sample 48) and 56 g/m<sup>2</sup>d (Sample 139) was expected: measurement yielded 30 g/m<sup>2</sup>d and 61 g/m<sup>2</sup>d. For acetone a rate of 0.3 g/m<sup>2</sup>d (Sample 48 and Sample 139) was expected: measurement yielded 0.2 g/m<sup>2</sup>d on a 2.5 mm thick

geomembrane of Vestolen A 3512 R. For acetic acid a rate of 0.4 g/m<sup>2</sup>d was expected for sample a: measurement yielded a rate of 0.3 g/m<sup>2</sup>d.

The values for the aqueous solutions were corrected for the absorbed water

The agreement between permeation and immersion experiments is also proved by the data in the last column of Table 3a. Permeation experiments had been performed on specimens taken from sample a - see August et al. (1984). Diffusion coefficients (last column of Table 3a) were then determined according to (15) from the permeation rates using the solubility from Table 2a and 2b. They are in good agreement with the values obtained from immersion experiments.

The diffusion coefficients given here cannot be considered to be the diffusion coefficients of a single molecule of a dissolved contaminant in the amorphous phase of the polymer. They are rather average quantities parametrising permeation and absorption processes based on Fick's Laws assuming a concentration independent diffusion coefficient. The diffusion processes however exhibit a pronounced dependence on the concentration. This is clear from the non-linear slope of the mass gain - time curve for liquids with very high solubility.

The Table 3b gives the diffusion coefficients in geomembranes determined from permeation and immersion tests on aqueous

solutions. The values decrease with decreasing concentration even for polar contaminants which are only slightly concentrated in the geomembrane. This effect is especially clear for non-polar test liquids which can be well dissolved in the geomembrane. The diffusion coefficients from tests on aqueous solutions are approximately one order of magnitude smaller than values obtained from tests using neat test liquids.

The values for the aqueous solutions were corrected for the absorbed water

The chemicals are only dissolved in the amorphous regions of partially crystalline polymer. If a comparison is made with the calculated solubilities and partition coefficients for amorphous polyethylene, the mass gain for the dissolution of the chemical should only be related to the amorphous fraction of the sample. For this purpose the mass  $G_{\text{amorph}}$  of the amorphous phase in the geomembrane samples was determined from the degrees of crystallinity given in Table 1a. The partition coefficient  $\sigma$  was calculated from the saturation value of the mass gain for immersion in the dilute aqueous solution at concentration  $c_0$  according to (10) with  $G = G_{\text{amorph}}$  and the solubility for immersion in the liquid chemical according to (9) with  $G = G_{\text{amorph}}$ . The results for the solubilities and partition coefficients for the aqueous solutions corrected in this way are given in Tables 4 and 6.

concentrations to compare them with the measured values. For this purpose the value of activity  $a(x_0)$  was determined from the calculated activity curve for acetone in water, see Figure 1, for the specified concentration  $x_0$  of the aqueous solution. Figure 2 gives the activity curves for acetone in polyethylene. Since in equilibrium the activities are equal, the activity curve of acetone dissolved in the polymer yields the mass fraction  $w$  in the polyethylene at level of activity  $a(x_0)$ . For the aqueous solutions the calculated and measured values of the concentration in the polymer are in surprisingly good agreement. The calculations should therefore also yield reliable results for highly diluted aqueous solutions.

	0.486	0.008	0.006

Their activity coefficient was determined from the initial slope of the activity curve for  $x$  and  $w$  close to zero and the corresponding partition coefficient  $\sigma$  calculated according to (4) and (5). Table 6 shows a comparison of the experimental values measured and estimates with the results obtained by calculation. The estimated values are in square brackets. The estimated values were calculated as the ratio of solubility in the polymer (Table 2a and 2b) to solubility in water.

For aliphatic hydrocarbons the interaction parameters between the  $\text{CH}_2$  and the  $\text{H}_2\text{O}$  groups as given by Gmehling et. al. (1982, 1983), Tiegs et al. (1987) and Hansen et al. (1991) yield solubilities in water one or two orders of magnitude too high. Correspondingly partition coefficients estimated in this way would be much too small. For these cases it was necessary to fall back on the original interaction parameters given by Ried et al. 1977. The solubility in water is then in very close agreement with the measured values therefore the partition coefficients can be considered to be reliable.

#### 4 CALCULATIONS

The calculation methods applied are explained in great detail in the listed references, therefore they will not be extensively here. Activity  $a(x)$  of the aqueous solution of the test liquid with concentration (mole fraction)  $x$  was calculated using the UNIFAC method, see Reid et al. (1977) and the references given there. The activity  $a(w)$  of the test liquid dissolved in the polymer with a mass fraction  $w$  was calculated by the UNIFAC method as specifically extended for polymers by Oishi and Prausnitz (1978).

The amorphous regions of the polymer exhibit a large free volume. This has an effect on the molecules dissolved there which are spread throughout a greater free volume than in their

liquid phase. Therefore marked differences exist in the specific volumes of the liquid contaminant and that dissolved in the polymer which must be taken into account in the partition function of the solution and thus also in the activity. This is done in the extended UNIFAC method using an additional 'free volume' term, which depends on the density of the test liquid and of the polymer (Beret et al. 1975).

§) Calculated from the permeation rate, see August et al. (1984), and from the calculated partition coefficients of Table 6 according to (15)

The amorphous polyethylene was modelled by the structural unit  $\text{CH}_2$  ( $M_p = 14.03$  g/mol) with the corresponding volume and surface and also interaction parameters. For the calculation the theoretical density of the amorphous part was not used but rather the actual density of the partially crystalline polymer (see Table 1a). Under this assumption the best agreement with the experimental data was achieved. The group parameters for a wide variety of structural units are given by Gmehling et al. (1982,1983),Tiegs et al. (1987) and Hansen et al. (1991). Figures 1 and 2 show examples of the calculated activity curves. The solubility was determined from these activity curves according to (6). The results are summarized in Table 4.

For those test liquids in Table 4 whose calculated values are shown in square brackets the calculated activity curve according to the extended UNIFAC method approaches unity only

asymptotically, see annotation to reference (Beret et al. 1975). Therefore a substantial error occurs in the estimate of solubility. In these cases the following method was chosen. Based on the assumption that the calculations are most reliable at low concentrations the tangent to the activity curve at low concentrations was determined. The mass fraction at which the ordinate of this tangent line equals 1 was then used to estimate solubility. The values are given in square brackets in Table 4. Obviously they are in very close agreement with the measured values.

Table 4. Solubilities (mass fraction) calculated with the extended UNIFAC-method by Oishi and Prausnitz for the test liquids in amorphous polyethylene compared with the experimental results. The calculated values put in brackets are extrapolated from the activity curve at low concentrations.

Table 5 shows the calculations for polyethylene/aqueous acetone solution and polyethylene/acetic acid at various

O. G. Piringer suggested a simple group contribution method for the direct calculation of the partition coefficient  $\sigma$ . A detailed explanation can be found in (Piringer et. al. 1993). The method is based on the comparison of the retention times in gas chromatography and is denoted as the Retention-Index-Method. The polyolefin is simulated here by the non-polar material Silikon OV 101. Increments for important structural units in the non-polar material Silikon OV 101 and in water are given by Piringer (1993). The calculation results are given in Table 6. The partition coefficients calculated according to the UNIFAC method are in every case in fairly good agreement with those calculated by the Retention-Index method.

The diffusion coefficients for compounds dissolved at low concentration in the geomembrane might be estimated according to (7) with an appropriate choice of the materials parameter  $A_p$ . With  $A_p = 7.5$  a fairly good agreement with the measured values in Table 3b is obtained.

## 5 DISCUSSION

The polyethylenes investigated here containing linear polymer chains with 5 to 15 ethyl-, butyl or hexyl side chains per 1000 C atoms, exhibit a complex morphology of finely-distributed crystalline and amorphous regions. A sample of black HDPE geomembrane with a typical mass of 6 g contains additionally approximately 150 mg of finely distributed carbon black particles and a few tens of grams of antioxidants. The parameters given here 'average out' influences and interactions acting in complex surroundings.

This is valid first of all for diffusion coefficients. The dissolved molecules interact with each other and change the surroundings and the conditions for migration in the polymer, which can be observed as swelling. Therefore the diffusion coefficient should depend on the concentration. It can be seen from both immersion tests and from permeation rates that the diffusion coefficient is considerably smaller at small concentrations from aqueous solutions than under a load with neat test liquids. Above all, the induction times are much shorter under a load with neat test liquids than with aqueous solutions. For a permeation process with a diffusion coefficient  $D$  increasing as a function of the concentration according to a simple rule, e.g.  $D(c) = D_0 e^{bc}$ , the induction time can be calculated (Frisch 1957 and annotation this reference) and a strong reduction in induction time is indeed obtained in comparison to that which would be obtained according to (15) at a low concentration and diffusion coefficient  $D_0$ .

The diffusion coefficients at high dilution depend on polarity and in particular on the size of the dissolved molecule. It might be estimated for various temperatures with formula (7). For the organic compounds the diffusion coefficient typically lay at a few times  $10^{-13}$  m<sup>2</sup>/s. The partition coefficients in Table 6 show a completely different behaviour. They vary by nearly 10 orders of magnitude. This proves the statement made at the beginning, that the partition coefficient is the fundamental determining factor for a wide variety of permeation rates for the different

pollutant classes.

These numbers enable a few simple estimates of diffusion in the composite liner. The diffusion coefficients in the mineral layer lay typically between a few times  $10^{-11}$  m<sup>2</sup>/s and  $10^{-10}$  m<sup>2</sup>/s. The porosity is a few times  $10^4$ . The permeability is then according to (16) typically around  $10^{-11}$  m<sup>2</sup>/s. The thickness of the mineral layer is greater by a factor of 400 than that of the geomembrane. Since the diffusion coefficients in the geomembrane are less than  $10^{-12}$  m<sup>2</sup>/s, in spite of its small thickness its diffusion resistance according to (16) and (17) exceeds that of the mineral layer if the partition coefficient is less than 0.025. This is the case for all easily water soluble test liquids. The geomembrane therefore not only completely prevents ionic diffusion it also contributes greatly to the diffusion resistance for all easily water soluble non-dissociated molecules. Hence the geomembrane is an indispensable element of an efficient engineering barrier not only as a barrier to convective transport but also as a diffusion barrier for easily water soluble substances.

The diffusion resistance of the geomembrane for non-polar or only weakly polar hydrocarbons is however low. The imperviousness is essentially determined by the mineral component. An additional increase in the diffusion resistance can however be achieved through the conditions at the interfaces. Assuming that the partition coefficient  $\sigma_{2,1}$  between the soil water and the geomembrane is greater than that  $\sigma_{0,1}$  between the leachate and the geomembrane, i.e.  $\sigma_{0,1}/\sigma_{2,1} < 1$ , this increases according to (17) the diffusion resistance of the whole system. Sufficiently convincing measurements for this are not yet available. There are however various arguments supporting this assumption.

In spite of the complex morphology and composition of the polyethylenes investigated, as mentioned at the beginning it can be seen that even a simple modelling of the amorphous regions with the CH<sub>2</sub> structural unit and taking into account the contribution of the free volume to the activity, assuming that contaminants can be dissolved in amorphous regions alone, the solubility can be predicted over a range of some orders of magnitude with an accuracy of up to a factor of 2. The calculated partition coefficients are in close agreement with those measured for HDPE geomembrane in aqueous solutions.

The UNIFAC-method has the advantage that it might be used to calculate partition coefficients at moderate temperature typically for landfills and for multicomponent solutions. In the waste body, due to chemico-biological and in exceptional cases due to hydration and oxidation processes, temperatures up to about 80° C can occur. In the basal liner beneath a state of the art drainage layer however, temperatures of more than 40° C have never actually been found. A temperature increase from 23° C to 40° C results in a tenfold increase in the permeability of the HDPE geomembrane.

The results of the Retention-Index method agree with those of the UNIFAC method. The calculation with the former method is much easier because only the influence of non-polar and aqueous surroundings on larger structural features like aromatics, aldehydes, alcohols, branches, Cl side groups, etc.

has to be taken into account. Even the accuracy achieved with this assumption is obviously sufficient for risk estimation or system comparison for the application of geomembranes in the field of ground water protection.

$$t_{ind} = \frac{6(4e^{\beta c_1} - 1 + e^{2\beta c_1}(2\beta c_1 - 3))}{4(e^{\beta c_1} - 1)^3} \frac{d^2}{6D_0}$$

- The free volume term is determined by two parameters b and c ein. Parameter b is a proportionality constant of the order unity which enters the term for the reduced volume. With parameter c the rotational and vibrational external degree of freedom in addition to the translational degrees of freedom are taken into account. These are relevant for solvents with large molecules. Following the procedure of Oishi et al. (1978) and Goydan et al. (1989) we set b = 1.28 and c = 1.1. However especially for the large-chain hydrocarbons higher values of c might be more appropriate. Better agreement of the experimental value with calculated results are obtained for the solubility of the highmolecular hydrocarbons with greater values of c. However a detailed analyses of an optimized choice of the parameters for polyethylene is beyond the scope of this paper.

# Water And Organic Solvents Transport Parameters In Geomembranes.

L. Durin, N. Touze, C. Duquennoi

Cemagref, drainage and barrier engineering research division, B.P. 121, 92185 Antony cedex, FRANCE

**ABSTRACT:** To assess the efficacy of geomembranes against fluid transport, samples were tested in the presence of a concentration gradient and an hydraulic pressure gradient. Chemical diffusion tests were conducted by immersion of HDPE and EPR-PP in pure organic solvents such as acetone, dichloromethane and toluene. Water diffusion has been tested on various geomembranes such as HDPE, EPR-PP, PVC-P, EPDM, elastomeric bituminous and oxidized bituminous. Temperature influence on water diffusion rate was studied on PP, HDPE and PVC-P. Hydraulic permeation of water was studied on PVC-P, EPDM and a bituminous film with a permeation apparatus presented in this paper. Kinetic sorption curves are plotted from immersion tests. Diffusion coefficients and chemical permeation fluxes are calculated from experimental data. Immersion test is a valuable method for determining pure solvents diffusion coefficient if material swelling can be neglected. Application of Arrhenius Law to diffusion coefficient variation with temperature may be inaccurate. HDPE and EPR-PP seem to be more sensitive towards non polar solvents.

**KEYWORDS :** Geomembranes, Laboratory Tests, Permeability, Diffusion, Temperature Effects.

## 1 INTRODUCTION

Geomembranes are non porous materials which function is to act as a barrier against fluids such as water and pollutants. Various different methods have been used for estimating geomembrane behaviour towards fluid transport (August, 1984; Park, 1986). Transport phenomena in solids often refer to permeability, which is defined as the ability of a solid to be penetrated by a fluid. Distinction must be made between chemical and hydraulic permeability. Chemical permeability concerns the transport of molecules under a concentration gradient. Physical phenomena involved are the adsorption on surface, the diffusion through the geomembrane and the desorption. Hydraulic permeability is related to the transport of a under hydraulic pressure gradient.

Various studies aimed at determining mass flux from laboratory tests using pure (Haxo, 1990; Britton, 1989) or dilute organic solvents (Park, 1996). Authors often argue that when aqueous solutions are used, landfill conditions are better approached (Park, 1996). But few of them (Nguyen, 1996; Stessel, 1995) closely observed the influence of physical interaction between solvents and geomembranes on transport parameters evolution. Values obtained are rarely discussed considering their evolution along time. Nevertheless previous studies have shown that geomembrane ageing could also be controlled by transport phenomena (Durin et al. 1997, Duquennoi et al. 1995).

Because geomembranes are made of dense polymers, they are nonporous and laboratory experiments can last a long-time (at least 2 months). Two modes of transport (chemical and hydraulic permeation) through various geomembranes are compared in this paper by means of related parameters (diffusion coefficient, plasticizing coefficient, hydraulic and chemical permeation flow). It was aimed at determining if an increase of chemical gradient and of temperature could contribute to accelerate some processes without changes in phenomena. The last part of the paper describes a device used to evaluate water fluxes through geomembranes under hydraulic gradients (Eloy-

Giomi, 1993, Pelte, 1993, Touze, 1995). The method has become a standard in France to qualify the quality of geomembranes as far as hydraulic fluxes are concerned.

Three types of results are presented: (1) the effect of solvents type (organic and water) on diffusion coefficient value; (2) the effect of temperature on water diffusion; (3) the effect of water permeation under hydraulic pressure gradient.

## 2 DIFFUSION UNDER CONCENTRATION GRADIENT

### 2.1 Diffusion Coefficient Estimate

#### 2.1.1 Principle

Sorption tests through geomembranes can be described by an unidirectional Fickian diffusion in a medium bounded by two parallel planes (Crank, 1975). Solutions of second Fick's law (1) give the diffusion profile shape  $C(x, t)$  and permit the diffusion coefficient calculation from experimental profiles.

$$\frac{\partial C}{\partial t} = D \frac{\partial^2 C}{\partial x^2} \quad (1)$$

If the concentration of the diffusing solution adsorbed on the sample surface is called  $C_0$ , and the half-thickness of the sample is  $l$ , then boundary conditions for resolving (1) are (Crank 1975):

$$\begin{aligned} C &= C_0 & x &= -l, x = l \\ C &= C_1 & -l < x < l & \quad t = 0 \end{aligned}$$

For  $-l < x < l$  and  $t > 0$ , it gives (2):

$$\frac{C_x - C_1}{C_0 - C_1} = 1 - \frac{4}{\pi} \sum_{n=0}^{\infty} \frac{(-1)^n}{2n+1} \exp\left(-\frac{D(2n+1)^2 \pi^2 t}{4l^2}\right) \cos\left(\frac{(2n+1)\pi x}{2l}\right) \quad (2)$$

where  $D$  is the constant diffusion coefficient,  $t$  the time,  $n$  is a positive integer,  $C_x$  the concentration at the  $x$  distance from the surface.

If  $M_t$  is the quantity of diffusing matter in the membrane at time  $t$ , (2) leads to (3):

$$\frac{M_t}{M_\infty} = 1 - \frac{8}{\pi^2} \sum_{n=0}^{\infty} \frac{1}{(2n+1)^2} \exp\left[-D(2n+1)^2 \frac{\pi^2}{4l^2} t\right] \quad (3)$$

where  $M_\infty$  is the mass of diffusing matter absorbed when the sorption equilibrium is reached. Sorption ratio  $M_t / M_\infty$  is expressed as a function of time and the graph of sorption kinetic (Crank, 1975) is in general plotted with the reduced coordinates  $\left(\frac{M_t}{M_\infty}, \sqrt{\frac{Dt}{l^2}}\right)$ .

### 2.1.2 Sorption tests

Equation 2 is a trigonometric series which converges towards zero and infinity. When  $t$  tends to zero, it is assumed that the membrane surface reaches immediately equilibrium as soon as immersion begins ( $t = 0$ ). The diffusion coefficient  $D_0$  at the beginning of immersion can then be obtained from the half-sorption time  $t_{1/2}$  defined as

$\frac{M_{t_{1/2}}}{M_\infty} = \frac{1}{2}$ . If  $D_0$  is constant (Crank, 1975), equation 3 gives

$$D_0 \approx 0.0492 \times \frac{L^2}{t_{1/2}} \quad (4)$$

where  $L$  is the sample thickness.

When  $t$  tends towards infinity, it is considered that equilibrium is reached for a value of  $M_t / M_\infty$  equal to 90% of maximal sorption observed. Related time is called infinite time  $t_\infty$ . The diffusion coefficient  $D_\infty$  at equilibrium can be calculated from equation 3:

$$D_\infty = 0.212 \frac{l^2}{t_\infty} \quad (5)$$

Equations 4 and 5 give a good estimate of the diffusion coefficient if sorption is Fickian ( $D$  is a constant) and the geomembrane does not swell.

### 2.1.3 Evolution of diffusion coefficient with temperature.

Arrhenius law (6) says that an increase in temperature accelerates sorption rates:

$$D(T) = A \cdot \exp\left(-\frac{E}{RT}\right) \quad (6)$$

where  $A$  is a constant,  $E$  is the activation energy, independent from temperature  $T$ , and  $R$  the perfect-gas constant. The influence of a temperature variation on sorption was studied in order to determine if (6) could be used to estimate the diffusion coefficient at lower temperatures from results of tests conducted at high

temperature, assuming that the same value at the equilibrium could be reached faster in the latter case.

In the case of sorption tests conducted at three different absolute temperatures  $T_1 < T_2 < T_3$ , required times to reach the same value of sorption ratio are  $t_1 > t_2 > t_3$ . Then when (6) is verified one can obtain :

$$\ln\left(\frac{1}{t_2}\right) = \ln\left(\frac{1}{t_1}\right) + \frac{\frac{1}{T_2} - \frac{1}{T_1}}{\frac{1}{T_3} - \frac{1}{T_1}} \times \left(\ln\left(\frac{1}{t_3}\right) - \ln\left(\frac{1}{t_1}\right)\right) \quad (7)$$

## 2.2 Flow of Water and Solvents

If the diffusion coefficient  $D$  varies with the concentration, it can be described by Long's model (Favre, 1993):

$$D = D_0 \exp\left[\beta \left(\frac{M_t - M_{t=0}}{M_{t=0}}\right)\right] \quad (8)$$

where  $\beta$  is the plasticizing coefficient easily deduced from experimental diffusion coefficient value at equilibrium.

The chemical permeation flow,  $Q$ , under permanent regime is deduced from the conservation of mass. After integration along the sample half-thickness  $l$ , flow per unit volume,  $Q_v$ , is obtained from equation 9:

$$Q_v = \frac{-D_0}{\beta l \left[ \exp\left(\beta \left(\frac{M_t - M_0}{M_0}\right)_{x=l}\right) - \exp\left(\beta \left(\frac{M_t - M_0}{M_0}\right)_{x=0}\right) \right]} \quad (9)$$

Initial flow of chemical permeation per volume unit can be estimated for a membrane separating a medium with pure solvent at one face against void at the other face. Since the flow decreases during the experiment, because of the concentration gradient decreasing, initial flow is also the maximal during experiment.  $Q_v$  is easily converted in unit of mass,  $Q_m$  by:

$$Q_m = \rho Q_v \quad (10)$$

where  $\rho$  is the solvent density.

## 2.3 Experiments

### 2.3.1 Materials and methods

Table 1 presents the eight geomembranes tested. Crystallinity ratio for HDPE (High Density Polyethylene) was 80% and 20% for EPR-PP (Ethylene-propylene-rubber Polypropylene). Weighings were done with a balance (METTLER PE 360).

Table 1. Geomembranes tested with immersion tests.

	Bituminous	Bituminous	EDPM	HDPE	EPR-PP	EPR-PP	PVC
Thickness (mm)	4	3.9	1	2	1.5	1.2	1.5
Water (23, 40, 60°C)	×	×	×	×		×	×
Water (23°C)				×	×		
Acetone (23°C)				×	×		
Dichloromethane (23°C)				×	×		
Toluene (23°C)				×	×		

Selected solvents were nonpolar (toluene and dichloromethane), and polar (acetone and water). Five geomembrane samples were immersed in closed glass tanks containing 5 liters of pure solvent, under a temperature of 23°C. Sample dimensions at the beginning of experiment were 13 cm × 17 cm. Those dimensions were chosen in order to minimize edge effects. If L is the sample thickness and a is the radius of the circular aperture through which flow occurs, Crank (1975) states that edge effects on diffusion can be neglected if  $L/a \leq 0.2$ . Errors involved by such an approximation could lead to apparent differences between diffusion coefficient deduced from steady-state and time-lag measurements.

The tests of temperature influence on water sorption, were conducted with five 10 cm × 10 cm geomembrane samples immersed in glass tanks filled with one liter of distilled water. Experiments were conducted in incubators for immersions at 40°C and 60°C and in an air-conditioned room for 23°C tests.

In order to prevent any polymer degradation which would not be directly caused by solvent or water action, experiments were conducted in darkness, at a constant temperature and atmospheric pressure. At each selected time-lag, sample was removed, softly wiped with a special blotting paper and weighed. Kinetic curves ( $\frac{M_t - M_0}{M_0}; \sqrt{t}$ )

were plotted using the least square method assuming the experimental equation (deduced from equation 3):

$$\text{Abs.}\%(t) = \text{Abs.}\%(\infty) [1 - e^{-bt}] \quad (11)$$

with  $\text{Abs.}\%(t)$ , the percentage gain of matter absorbed at time t, b being a constant.

### 2.3.2 Results

#### 2.3.2.1 Immersion tests in solvents

Curve shapes show that the diffusion was Fickian. They present an asymptote when t tends towards infinity as showed in Figure 1, except for HDPE in water at 23°C for which equilibrium was not reached. The calculation method described above was followed and results are displayed in Table 2. Near the asymptote,  $M_t$  variations and errors on D decrease. There is always a difference between  $D_0$  and  $D_\infty$  as shown in Table 2. This can be attributed to the sample swelling which could increase edge effect. Every diffusion coefficient was under  $10^{-10} \text{ m}^2/\text{s}$  which was the maximum diffusion coefficient possible since pure solvents were used.

Stessel et al. (1995) have combined physical testing with chemical exposure. They showed that Hildebrand's solubility parameters could be a good indication of the permeability of a membrane to a liquid or vapour. They showed that HDPE Hildebrand's solubility was similar to the one of nonpolar solvents, helping melting process.

Figure 1. Kinetic sorption curves of PP (Fig. 1a) and HDPE (Fig. 1b) immersed in various solvents (TOL: toluene; DCM: dichloromethane; ACE: acetone), dotted line was calculated from (11).

Experiments showed in this paper seem to widen this hypothesis to PP since diffusion coefficients are higher in the case of immersion in non polar solvents (as dichloromethane and toluene).

Results also show that  $D_{\infty}$  is higher for PP than for HDPE. This can be attributed to the crystallinity which was lower for PP (20%) than for HDPE (80%). Results also show that  $D_{\infty}$  is smaller than  $D_0$  which is inconsistent with the hypothesis made on equation 2 ( $D$  is a constant along time).

Further research is conducted at present to verify the existence of a solvent-induced crystallization in polymer (Neogi, 1996) which could explain the difference between experimental and calculated curves particularly obvious in the case of PP immersed in dichloromethane (Figure 2.a). Values for water were not very accurate in the case of HDPE because equilibrium was not reached. The estimation of the absorbency for infinite time may be overestimated and this could explain the high diffusion coefficient for HDPE.

Table 2. Calculation of diffusion coefficient and chemical permeation flux from experimental data

	PP				HDPE			
	Water	Acetone	DCM	Toluene	Water	Acetone	DCM	Toluene
$D_0$ (m <sup>2</sup> /s)	$8 \cdot 10^{-15}$	$2 \cdot 10^{-12}$	$7.8 \cdot 10^{-11}$	$2.9 \cdot 10^{-11}$	$4.4 \cdot 10^{-13}$	$10^{-12}$	$10^{-11}$	$1.8 \cdot 10^{-11}$
$D_{\infty}$ (m <sup>2</sup> /s)	$1.5 \cdot 10^{-15}$	$4.5 \cdot 10^{-13}$	$1.6 \cdot 10^{-11}$	$6 \cdot 10^{-12}$	$9 \cdot 10^{-12}$	$2.6 \cdot 10^{-13}$	$2 \cdot 10^{-12}$	$4 \cdot 10^{-12}$
$Q_v$ (m <sup>3</sup> /m <sup>2</sup> /s)	$5.2 \cdot 10^{-12}$	$7 \cdot 10^{-11}$	$4 \cdot 10^{-8}$	$2.4 \cdot 10^{-8}$		$6 \cdot 10^{-12}$	$4.2 \cdot 10^{-10}$	$7.9 \cdot 10^{-10}$
$Q_m$ (g/m <sup>2</sup> /h)	0.0	0.2	193.4	75.6	0.0	2	2	2.5

Each flow was estimated by resolving equation 9. Integration was conducted on the half thickness, assuming the adsorption phase which precedes absorption was instantaneous and occurs on the first nanometers of the material. With a certain error we supposed that when sorption equilibrium was reached there was no concentration gradient between the surface and the inside of the polymer. Surface concentration at any time was then assumed to be equal to the concentration inside the sample at equilibrium. Results are presented in Table 2 with  $\frac{M_{\infty} - M_0}{M_0}(1) = 0$  and  $\frac{M_{\infty} - M_0}{M_0}(0) = \text{Abs.}(\infty)$ .

### 2.3.2.2 Immersion in water under various temperatures

Results obtained for the absorption of water at three different temperatures are presented on Figure 2. They have been obtained from another set of experiments. Diffusion coefficients and permeation fluxes could be determined at 23°C, for PP, HDPE and PVC-P, assuming that sorption equilibrium has been obtained. Curves shape seem to show that the diffusion was Fickian. For the other temperatures, sorption equilibrium has not been obtained, so that it was not possible to estimate diffusion coefficients. Results obtained are presented in Table 3. Diffusion coefficient values for HDPE, PP and PVC-P are somewhat strange for

water. PP has the lowest coefficient value; however a PP has a bigger amorphous phase than HDPE. Further research is necessary to determine if sorption equilibrium has really been reached, and to determine what is the role of the EPR contained in the PP geomembrane in the diffusion of water. For the bituminous and EDPM geomembranes, sorption curves exhibit an inflection point, indicating that the diffusion may not be Fickian. As the phenomenon responsible for this shape of curves has not yet been identified, diffusion coefficients could not be estimated.

An example of the diffusion coefficient variation with temperature is presented on Figure 3 for the PVC-P geomembrane. All results obtained have the same limitations, so that only one example is presented here. Figure 3 represents  $\ln(1/t)$  in function of  $1/T$ , for different percentages of absorption. Segments were based on the experimental points obtained at 23 and 60°C. The intermediate point, which was obtained at 40 °C, was presented with the uncertainty on its value. For most percentages of absorption, one can conclude that the three points are lined up. But the line slope varies in a significant manner with absorption, so that the assumption of a constant activation energy may not be accurate.

Table 3. Calculation of water diffusion coefficient and water permeation flux from experimental data (from Touze, 1995).

Geomembrane	$D_0$ (m <sup>2</sup> .s <sup>-1</sup> )	Plasticizing coefficient	Maximum percentage of sorbed water	$Q_v$ (m <sup>3</sup> .m <sup>2</sup> .s <sup>-1</sup> )	$Q_m$ (g.m <sup>-2</sup> .h <sup>-1</sup> )
HDPE	$1.38 \cdot 10^{-14}$	-1.68	$3.7 \cdot 10^{-2}$	$4.4 \cdot 10^{-12}$	$1.6 \cdot 10^{-5}$
PP	$6 \cdot 10^{-15}$	-0.44	0.59	$1.46 \cdot 10^{-11}$	$5.3 \cdot 10^{-5}$
PVC-P	$2.2 \cdot 10^{-14}$	-0.54	2.1	$8.21 \cdot 10^{-11}$	$2.9 \cdot 10^{-4}$

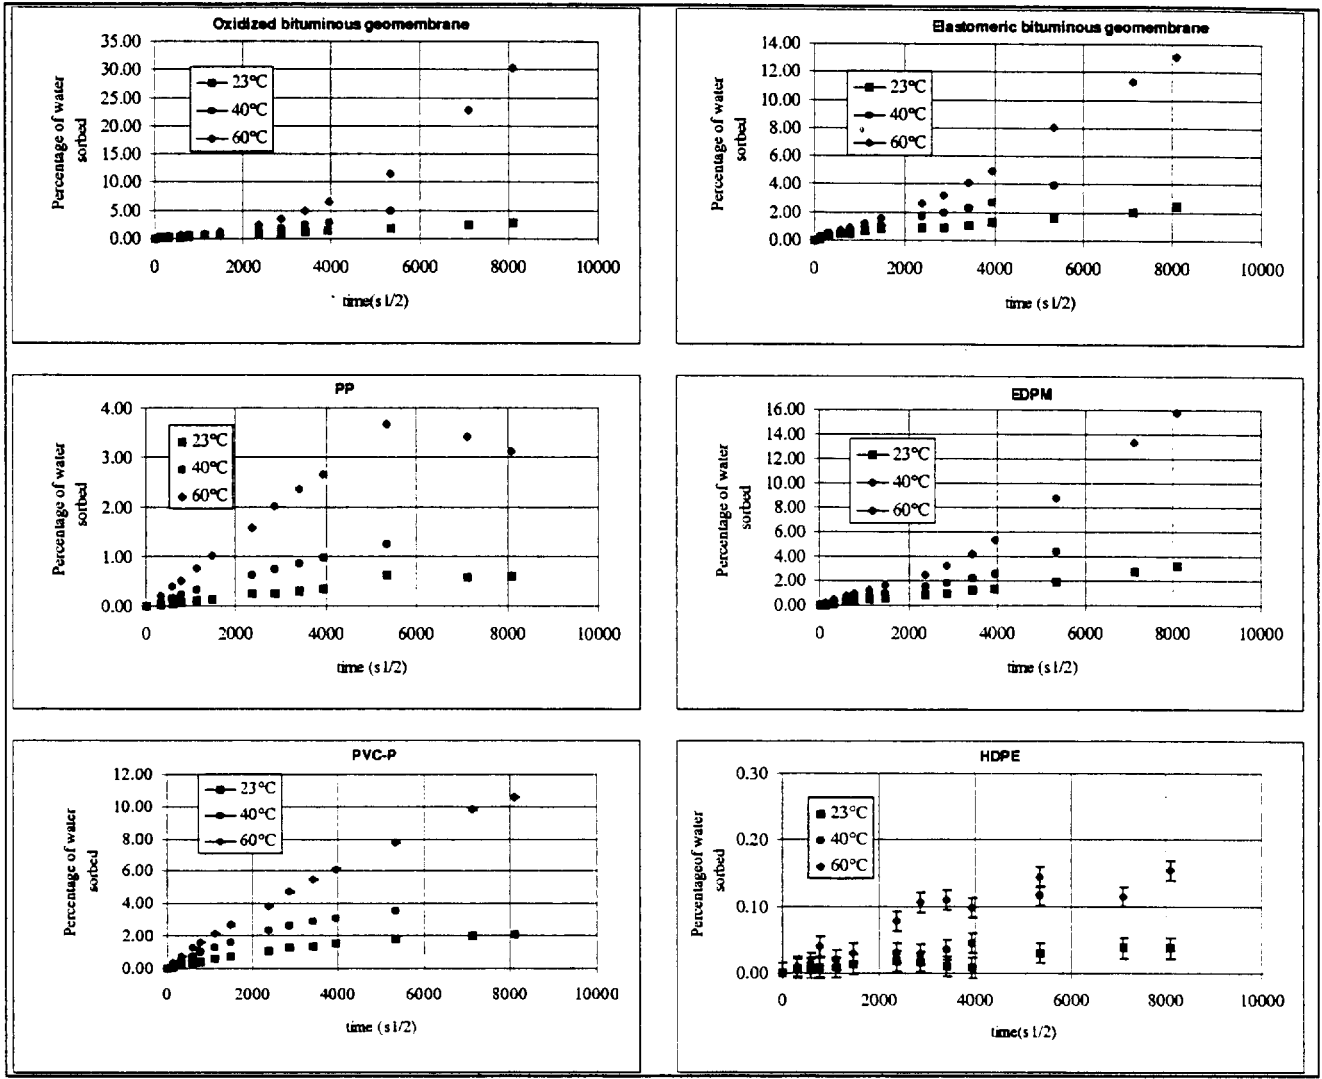

Figure 2. Kinetic sorption points for all the geomembranes tested in water, at 23, 40 and 60 °C.

3 HYDRAULIC PERMEATION

3.1 Principle of measurement

Hydraulic permeation tests aim at estimating the flow of liquid going through an undamaged geomembrane under a

hydraulic pressure gradient. As hydraulic conductivity is not an intrinsic parameter of geomembranes (Eloy-Giorni, 1993), we will not present any interpretation of our results in terms of hydraulic conductivity, assuming Darcy's Law is not valid in geomembranes.

From an engineering point of view, water hydraulic permeation is far more representative than water vapour permeation. Koerner (1986) identified several problems inherent to water hydraulic permeation tests. When conducted with high hydraulic heads, tests resulted in leaks and failed specimens, whereas tests conducted with low hydraulic heads resulted in long test times and evaporation problems. The technical solution to this problem is presented in the following.

3.2 Materials and methods

3.2.1 Materials tested

Three different kinds of materials were tested: a 1.5mm thick plastified polyvinyl chloride geomembrane (PVC-P), a

1 mm thick ethyl-propylen-diene monomer geomembrane (EDPM) and a 0.4 mm thick bituminous film.

### 3.2.2 The permeation apparatus

Tests were conducted in a stainless steel cell, composed of two parts gripping the geomembrane (see Figure 4). At the downstream side of the geomembrane was a porous stainless steel disc, allowing liquid transfer, but preventing geomembrane deformation and failure since the upstream pressure was greater than the downstream one.

Figure 4. Apparatus of measurement of fluxes through geomembranes under hydraulic pressure gradients

Precise measurement and regulation of pressure was achieved by the use of two numerical pressure transducers (PT). Each of them was linked to one chamber (the upstream, or the downstream one) by rigid stainless steel tubes. PT allow to impose the desired pressure, and to measure the volume variations, on each side of the geomembrane.

As temperature variations can cause variations of the fluid volume and dilatation of the apparatus components, seven temperature captors have been put on the PT and on the cell. The eighth captor measures the laboratory temperature. These captors were necessary because the temperature could vary in spite of the control of room temperature. The variation of volume measured by the PT can be written as follows :

$$\Delta V_i = \Delta V_i(T) + \Delta V_i^P, \quad i \in \{\text{upstream, downstream}\} \quad (12)$$

With  $\Delta V_i(T)$  the variation of volume due to temperature variations and  $\Delta V_i^P$  the volume variation really due to permeation.  $\Delta V_i(T)$  were determined during calibration phases, described below :

$$\Delta V_i(T) = \sum_j \alpha_{ij} \Delta T_j, \quad i \in \{\text{upstream, downstream}\} \quad (13)$$

$$1 \leq j \leq 8$$

### 3.2.3 Test procedure

A disc of geomembrane, 20 cm in diameter, was put in the cell, after a month of immersion in the fluid used for the test. We assumed that this period of immersion was enough to saturate the geomembrane with the fluid and to limit concentration controlled transfers which could occur during the test. Then, the downstream and upstream side of the apparatus (cell plus pressure transducer) were filled with liquid. A calibration for the downstream and upstream sides was done before the measurement of liquid fluxes.

Downstream calibration was conducted with the two gates linking the PT to the cell being opened, the upstream PT pressure reaches 110 kPa, and the one of the downstream PT reaches 100 kPa. It is thought that this difference of pressure was enough to prevent any deformation of the geomembrane, and small enough to prevent any transfer through the geomembrane. Then the upstream gate was closed, and during a period varying from three to seven days, volume and temperature variations were recorded (see Figure 5). If any liquid leakage occurs, from the inside of the cell to the outside, it could be detected during this calibration.

In the absence of liquid leakage, volume variations can be linked to temperature variations by (13).

Upstream calibration was done after the downstream calibration. Pressures to be reached by the upstream and downstream PT were respectively 200 and 190 kPa. Once those pressures have been reached, the downstream gate was closed. This calibration allows to obtain correlation coefficients between temperature and upstream volume variations.

It is assumed that the relation between temperature variations and volume variations during the measurement phase will be the same as during the calibration phases.

The measurement was made after the calibration phases. The downstream PT pressure was sent to 100 kPa and the upstream PT pressure was maintained at 200 kPa. (see Figure 5).

Uncertainty on the flux value  $Q$  measured depends on uncertainties on volume variations  $d\Delta V$ , temperature variations  $d\Delta T_i$ , geomembrane surface  $dA$ , and on time measurements,  $dt$  :

$$\frac{dQ}{Q} = \frac{dA}{A} + \frac{dt}{t} + \frac{d(\Delta V^P)}{\Delta V^P} \quad (14)$$

with

$$d(\Delta V^P) = d(\Delta V) + d\sum_j (\alpha_j d\Delta T_j) \quad (15)$$

Figure 5. Variation of pressure of the two pressure transducers during the different phases of a measurement

### 3.2.4 Results

Table 4 summarizes results obtained in three different laboratories on the same PVC-P geomembrane. All the tests have been conducted in similar cells. The devices used for measurements were different. Eloy-Giorni, (1993) used a radioactive tracers method, and Pelte (1993) used graduated tubes.

All fluxes were the same order of magnitude. The flux given by Eloy-Giorni (1993) is bigger than the other ones as it is the total flux. The flux we obtained (Touze, 1995) is given by an interval, taking in account the uncertainties of the measurement.

Results obtained for the other two materials were presented in Table 5. One can notice that the permeation flux for the EDPM geomembrane was the same order of

magnitude as the one obtained for the PVC-P geomembrane. The flux obtained with the bituminous film was three orders of magnitude bigger, under a pressure gradient 10 times smaller. So the apparatus designed allows to make the difference between products that can be used for bottom landfill liners with little risks, and others. As previously mentioned, the method of measurement is now a standard in France and products exhibiting a water flow less than  $10^{-4} \text{ m}^3 \cdot \text{m}^{-2} \cdot \text{day}^{-1}$  under a pressure gradient of 100 kPa are considered as safe. It is ten times less than the flow of water through a 1 m liner of clay with a hydraulic conductivity of  $10^{-9} \text{ ms}^{-1}$  under the same conditions. One can observe that even if there is a great uncertainty on the measurement for low values of flow, one can ensure that PVC and EDPM geomembranes tested are safe, following the given criterion.

Table 4. Comparison of literature values of water fluxes in a PVC-P geomembrane

Pressure gradient (kPa)	Total flux ( $\text{m}^3 \cdot \text{m}^{-2} \cdot \text{day}^{-1}$ ) (Eloy-Giorni, 1993)	Volumetric flux ( $\text{m}^3 \cdot \text{m}^{-2} \cdot \text{day}^{-1}$ ) (Pelte, 1993)	Volumetric flux ( $\text{m}^3 \cdot \text{m}^{-2} \cdot \text{day}^{-1}$ ) (Touze, 1995)
100	$1.7 \cdot 10^{-6}$	$3 \cdot 10^{-7}$	$J < 9,3 \cdot 10^{-7}$

Table 5. Permeation fluxes obtained on different materials tested

Material	EDPM geomembrane	Bituminous film
Pressure gradient (kPa)	100	10
Volumetric flux ( $\text{m}^3 \cdot \text{m}^{-2} \cdot \text{day}^{-1}$ )	$< 5.9 \cdot 10^{-7}$	$4 \cdot 10^{-3}$

## 4 CONCLUSIONS

As far as transport of water and organic solvents in geomembranes is concerned, the elementary mechanisms involved in chemical permeation are molecular sorption and diffusion, whereas mechanisms involved in hydraulic permeation are still unidentified.

- Chemical permeation flux values for non polar solvents represent the upper bound for all diffusive flux. It has to be considered that these values are calculated as

an initial flux for the maximum concentration gradient possible (pure solvent on one face, void on the other face). Further research is necessary to verify if swelling can be neglected when calculating mass flux and if the diffusion coefficient decrease along time could be caused by crystallinity ratio increase.

- Arrhenius law cannot be used with confidence to estimate the evolution of the diffusion coefficient of water in the geomembranes tested. Another limitation is

that the validity of Arrhenius law is based on the assumption that the maximum absorption coefficient (at equilibrium) was the same whatever the temperature was. This does not seem to be valid.

- The permeation apparatus described here permits to compare different geomembranes behaviour towards water permeation under a hydraulic gradient. The method of measurement is now a standard and permits to make sure that geomembranes used in bottom liners are safe from an hydraulic point of view, if undamaged. It could present an interest in the study of soluble ions transport through geomembrane. It is thought, but still not verified, that the macroscopically measured hydraulic permeation rates in undamaged geomembranes do not represent porous-medium-like transport phenomena but should rather be related to microscopic mechanisms similar to sorption and diffusion. The apparatus presented could help in improving the knowledge of the phenomena involved by testing different pressure gradients.

# LEAKAGE STUDY ACROSS AN OFFSHORE WASTE CONTAINMENT BUND

S.A. Tan

Senior Lecturer, Department of Civil Engineering, National University of Singapore

S.H. Chew

Lecturer, Department of Civil Engineering, National University of Singapore

G.P. Karunaratne

former Associate Professor, Department of Civil Engineering, National University of Singapore

**ABSTRACT:** This paper presents a study of potential leakage through an offshore waste containment bund from a FEM simulation of the steady state flow condition under the influence of the head difference between the waste pond and the open sea. It is assumed that under operating conditions, the waste pond may be kept at levels as high as 2m above mean sea level. For the study, the following liner systems are considered: (a) Dredge clay 2m thick ( $k=1 \times 10^{-8}$  m/s), (b) Geosynthetic clay liner 6 mm thick ( $k=1 \times 10^{-11}$  m/s), (c) Geomembrane liner 1 mm thick ( $k=1 \times 10^{-14}$  m/s) (d) Composite of Geosynthetic clay + 2m dredge clay (e) Composite of Geomembrane + 2m dredge clay. The results of the parametric study of the influence of bund hydraulic conductivity and the hydraulic head difference for the five alternatives are presented in the paper. Due to its very low comparative leakage potential, the system of geomembrane and 2m dredge clay layer cover on top of the geomembrane is used for the actual offshore waste containment bund design which is currently being constructed.

**KEYWORDS:** Containment, reservoir liners, modeling, performance evaluation

## 1 INTRODUCTION

Due to the scarcity of land for landfills, the Ministry of Environment of Singapore has embarked on the design and construction of an offshore waste disposal facility to cater for the end disposal of the incinerated residues of municipal and industrial wastes generated locally over the next 30 years. The facility involved the creation of a 30 ha offshore waste pond, by the bounding of the perimeter with 7 km of earth bunds in water depths varying from 10m at the shallow end to 20m at the deepest end from the offshore island of Pulau Semakau south of Singapore. For practical construction, the offshore bund will be created with stone revetments for shore protection, using geofabrics for separation and filtration between armour stones and hydraulic sand filling in the main body of the bund. However on the waste pond side of the bund, several geosynthetic liners were considered as possible protection layers to prevent leachate in the waste pond from contaminating the marine environment around the waste facility.

The southern coast of Singapore is in a low energy marine coastal environment due to the protection provided by the surrounding land masses. The fetch is generally short, and the directions of the maximum fetch rarely coincide with those of the strongest wind of about 8 m/s during the NE monsoon between December to March annually. Thus the average wave breaker height is less than 20 cm, and maximum wave height is less than 1 m, according to Chia et al, (1988). As there is no requirement for berthing facilities, the outer slope of the perimeter bund was designed using a conventional stone revetment structure of slope 1:3 with a 8 m berm for every 5 m rise in elevation from seabed levels, as shown in Fig. 1.

Detailed offshore site investigation was conducted at the proposed site for the offshore waste facility, and it was determined that the seabed soils consist mainly of 5m to 10m silty/clayey deposits on top of dense weathered sedimentary rocks of very low permeabilities, typical of the Jurong formation in the area. The silty/clayey deposits are from soft to firm consistency with very low permeabilities of less than  $10^{-10}$  m/s. Thus it is estimated that leakage through the seabed soils is a non-problem, as the offshore environment itself is a form of hydraulic barrier, with very low seepage gradient across the seabed soils underneath the waste facility, as shown by Lee et al, (1994).

## 2 LEAKAGE RATE EVALUATION

Giroud et al., (1994) have presented equations to evaluate the rate of leakage of liquids such as leachates through liners typically used in landfills including compacted clay liners (CCL), and several types of geosynthetic liners, geosynthetic clays liners (panels that consist of a layer of bentonite encapsulated between two geotextiles) and a composite where geomembrane is placed on low-permeability compacted clay or geosynthetic clay layer. The comparisons in Giroud's studies are only applicable to landfills where the head of leachate on top of the liner is small, i.e., typically less than 0.3m under one dimensional seepage condition. The relative effectiveness, and even ranking of the various liners compared in their study may be very different under the large liquid heads encountered in liquid impoundments (reservoirs), canals and dams.

For the two dimensional seepage analysis of an offshore containment bund, the finite element seepage program was

Fig.1 Typical Cross-Section of Offshore Containment Bund

used for the study. The software employed is SEEP/W by Geoslope, (1994), which is capable of modelling a 2D plane seepage analysis with saturated and unsaturated flows for both steady state and transient conditions. A typical cross-section of the offshore waste containment bund used is shown in Fig. 1. It consists of a rock bund revetment structure on the outer slopes of gradient 1:3, for shore protection purposes. The inner slopes are flatter with gradient of 1:5, and these slopes will be lined with approved liners. The liners under considerations are (i) 2m clay liner of dredged seabed clays placed directly on top of the hydraulic sand fill, (ii) geosynthetic clay liner covered by 2 m sand layer, (iii) geosynthetic clay liner covered by 2 m of dredged clays, (iv) geomembrane liner covered by 2 m sand layer, (v) geomembrane liner covered by 2 m of dredged clays. The analysis assumes that the dredged clay is 2 m thick with  $k=1 \times 10^{-8}$  m/s, as it cannot be compacted under water, the geosynthetic clay is 6 mm thick with  $k=1 \times 10^{-11}$  m/s, and the geomembrane is 1 mm thick with  $k=1 \times 10^{-14}$  m/s. All liner materials are assumed to be homogeneous and perfect, i.e no holes or cracks, zones of high permeability, or poor connection of panels and seams. The finite element mesh consists of 475, 8-noded quadrilateral isoparametric elements, with very thin elements to model the geosynthetic clay and geomembrane liners.

The hydraulic sand fill commonly used in Singapore reclamation projects are in the range of fine to coarse sands with very low silt contents. For bund construction, the silt contents are specified to be less than 5%, and for reclamation fill, the silt content must be less than 10%. Thus the range of possible sand permeabilities would be from as low as  $k=1 \times 10^{-6}$  m/s for fine sand with 10% fines, to as high as  $k=1 \times 10^{-3}$  m/s for coarse sand with less than 5% fines. The likely operative permeabilities for this project would be between  $k=1 \times 10^{-3}$  m/s to  $k=1 \times 10^{-4}$  m/s, with the latter as the most typical sand permeability to be encountered in the actual site.

The intended operating condition for the waste facility is to keep the pond levels at about mean sea level, which means theoretically, that there would be no net seepage from the waste pond to the sea, as there is no net head difference across the bund. For this comparative study, we assume steady-state condition, without consideration of the cyclical transient nature of the sea level due to the tides. With the sea kept at mean sea level, the seepage loss for the long term steady state condition of 2.0m, 1.5m, 1.0m, and 0.5m hydraulic head difference across the bund was considered in the study. The influence of tide on seepage loss across the bund using transient seepage analysis was reported by Tan et al, (1993).

### 3 COMPARISON OF LINERS

#### 3.1 Typical SEEP/W Results

Typical finite element steady state calculations involve iterations on the hydraulic conductivity functions which falls sharply as the sand desaturates into the negative pore water pressure zone of the unsaturated sand above the phreatic surface in the bund. For an all sand bund, convergence is rapid. For the sand bund with clay liner convergence may become difficult because of the sharp contrast in the hydraulic conductivities of the clay blanket and that of the sand bund. For all the finite element computations, a convergence tolerance of 0.001% difference on the norm of the nodal head vector between two successive iterations is applied. After convergence, the flux quantities across the bund is computed for four sections of the bund, one parallel to the inner slope and the remaining three vertical sections through the crest of the bund. All these flux values must be nearly the same when steady state seepage has been attained, as shown in a typical computation in Fig.1, where the leakage across a bund lined with a 6 mm thick Geosynthetic clay layer is calculated to be about  $2.8 \times 10^{-7}$  m<sup>3</sup>/s per m run of

bund.

Figure 2. Leakage rate as function of bund permeability

### 3.2 Leakage Rate Comparisons

The leakage rate values per m run of bund for varying bund fill permeability is shown in Fig.2. The results showed that with the use of liners, the leakage rate can be reduced significantly, especially for bund fill with the higher permeability. For the sand bund without liner (NL), the leakage rate is a linear function of bund permeability as expected from Darcy's law,  $Q=kiA$ . However when the inside slope of the bund is lined with either a clay or geosynthetic liner, this linear behavior appear not to apply. The leakage rate performance

becomes less dependent on the bund permeability for the liner cases.

Figure 3. Leakage ratio as function of bund permeability

When the leakage rate for liners is compared to the case without liners (NL), the leakage rate ratio is some kind of linear function of bund permeability. It is obvious that the leakage reduction is greater for the higher bund permeability. At a bund permeability of  $10^{-4}$  m/s, a geomembrane liner would produce 10,000 times less leakage, whereas a geosynthetic clay or 2m clay liner would result in about a 100-200 times less leakage

than an unlined bund.

Figure 4. Comparison of Clay liner with other liners for different bund permeability

Figure 5. Leakage rate ratio as function of bund head difference

From Fig.4, it appears that a geosynthetic clay liner or geosynthetic clay with a 2m clay blanket is only about 1 to 7 times better than a 2m clay liner. A geomembrane liner would produce about 50-200 times less leakage than a clay liner, whereas a composite geomembrane with a 2m clay blanket is about 200-500 times more effective than a 2m clay liner. Thus a geosynthetic clay liner is comparable to a thick clay liner, whereas a non defective geomembrane liner is much better than a clay liner.

The leakage performance of an unlined compared to a lined bund for a bund permeability of  $10^{-4}$  m/s, and a bund head difference of 0.5 m to 2.0 m is compared in Fig.5. It appears that a 2m clay liner is 200 times more effective than the unlined bund for head difference from 0.5-2.0m. The geosynthetic clay liner is 300-400 times better than the unlined bund, whereas geosynthetic clay with the 2m clay liner is 600-2500 times better, with decreasing effectiveness at higher head difference. The geomembrane liner is 8000-50000 times more effective,

whereas the geomembrane with the 2m clay liner is 20000-100000 times more effective than an unlined bund, with decreasing effectiveness at higher head difference.

Figure 6. Comparison of Clay liner with other liners for various bund head difference

In comparing clay liner with the geosynthetic liner as in Fig.6, it is apparent that geosynthetic clay has comparable leakage rate to a 2m clay liner. A geosynthetic clay layer with a clay liner would be about 5-30 times better than the clay liner. A geomembrane liner is 80-500 times better, while a geomembrane with a 2m clay liner is about 200-1000 times better than a 2m clay liner, with the lower ratio at a higher head

difference.

#### 4 CONCLUSIONS

The paper has presented a comparative evaluation of different liners for an offshore waste containment bund for the assumed operating conditions of bund permeabilities from  $k=1 \times 10^{-6}$  m/s to  $k=1 \times 10^{-3}$  m/s, for bund head difference from 0.5m-2.0m. The study showed that geosynthetic liners are better than clay liners for the reduction of seepage across the bund. It appears that a 6mm geosynthetic clay liner would perform slightly better than a 2m dredged clay liner, whereas a 1mm geomembrane is far superior to a 2m dredged clay liner. The relative performance of geosynthetic liners to clay liners increases with higher bund permeabilities and lower bund head difference. The use of a geomembrane liner with a 2m dredged clay liner would produce a bund with extremely low leakage rate, and the composite liner system would provide a multiple barrier defence that would enhance the system performance taking into account that the thin geomembrane layer cannot be laid in a defect free condition, especially in an offshore underwater condition.

The geomembrane chosen for this particular project is a high performance geocomposite geomembrane consisting of a high strength polyester base fabric, coated with a highly resistant ethylene interpolymer alloy. This geomembrane is about 1 mm (40 mils) thick and has a unit weight of 1290 g/m<sup>2</sup>, making it self sinking in the offshore laying environment.

**ABSTRACT:** This paper presents: (i) a new equation for calculating the rate of leakage through a composite liner due to geomembrane defects; (ii) a new equation that gives the rate of leakage through defects in a geomembrane placed on a semi-permeable medium; (iii) a new equation that gives the rate of leakage through a defect in a geomembrane liner taking into account the fact that the leachate collection material overlying the geomembrane hinders the flow of leachate toward the defect; and (iv) new equations for the design of leakage collection layers. Then, the paper presents a methodology based on these equations to select the optimal configuration of a double liner system.

**KEYWORDS:** Landfills, Liners, Geomembranes, Leachate, Leakage.

## 1 INTRODUCTION

The purpose of this paper is to provide information on new equations for the evaluation of the rate of leakage due to advective flow through defects in geomembranes included in liner systems and for the design of leakage collection layers. These equations were recently developed and published; references are made to the original publications for more details.

## 2 RATE OF LEAKAGE THROUGH COMPOSITE LINERS DUE TO GEOMEMBRANE DEFECTS

### 2.1 Presentation of the New Equation

In the context of this paper: (i) a composite liner consists of a synthetic component (a geomembrane) and a mineral component (a low-permeability soil or a GCL); and (ii) the mineral component is located beneath the geomembrane and is designated herein as "the low-permeability medium underlying the geomembrane". Semi-empirical equations are available to calculate the rate of leakage through a composite liner, due to geomembrane defects, when the leachate head on top of the liner is small compared to the thickness of the low-permeability medium underlying the geomembrane, whether the defect is small (Giroud et al. 1989) or large (Giroud et al. 1992). Equations are also available for the case where the leachate head on top of the liner is large compared to the thickness of the low-permeability medium underlying the geomembrane (Giroud et al. 1992, 1994); however, in such a case, graphs

are necessary to obtain the value of one of the terms of the equations, which is cumbersome. Giroud (1997) has shown that this term can be expressed analytically, which leads to entirely analytical expressions for the equations that give the rate of leakage through a composite liner, whether the leachate head on top of the liner is smaller or greater than the thickness of the low-permeability medium underlying the geomembrane. The equation in the case of a circular or quasi-circular defect is (Giroud 1997):

$$Q = C_{qo} \left[ 1 + 0.1(h/t_{UM})^{0.95} \right] a^{0.1} h^{0.9} k_{UM}^{0.74} \quad (1)$$

hence, for a circular defect:

$$Q = 0.976 C_{qo} \left[ 1 + 0.1(h/t_{UM})^{0.95} \right] d^{0.2} h^{0.9} k_{UM}^{0.74} \quad (2)$$

where:  $Q$  = leakage rate;  $a$  = defect area;  $d$  = defect diameter;  $h$  = leachate head on top of the liner;  $t_{UM}$  = thickness of the low-permeability medium underlying the geomembrane;  $k_{UM}$  = hydraulic conductivity of the low-permeability medium underlying the geomembrane; and  $C_{qo}$  = dimensionless coefficient that characterizes the quality of contact between the geomembrane and the underlying medium.

Equations 1 and 2 must be used with the following units:  $Q$  ( $m^3/s$ ),  $a$  ( $m^2$ ),  $d$  (m),  $h$  (m),  $t_{UM}$  (m), and  $k_{UM}$  (m/s). It should be noted that, when the leachate head on top of the liner is smaller than the thickness of the low-permeability medium underlying the geomembrane, the term in brackets in Equations 1 and 2 is approximately equal to 1. This term

is greater than 1 when the leachate head on top of the liner is greater than the thickness of the low-permeability medium underlying the geomembrane, which is often the case when this medium is a GCL.

Two typical values of  $C_{qo}$  are considered:  $C_{qogood}$ , the value of  $C_{qo}$  in the case of good contact; and  $C_{qopoor}$ , the value of  $C_{qo}$  in the case of poor contact. Definitions of good and poor contact are given by Giroud (1997). The following values were established by Giroud et al. (1989):

$$C_{qogood} = 0.21 \quad (3)$$

$$C_{qopoor} = 1.15 \quad (4)$$

Equations 1 and 2, and similar equations for rectangular defects and infinitely long defects given by Giroud (1997), supersede equations previously published by Giroud et al. (1992, 1994).

## 2.2 Limits of Validity of the Equations

The limits of validity of Equations 1 and 2 result from considerations such as: the experimental data supporting Equation 1, the restrictions to flow imposed by surface tension, and the range of applicability of Bernoulli's equation for free flow through an orifice. These limits can be summarized as follows (Giroud et al. 1997c):

- If the defect is circular, the defect diameter should be no less than 0.5 mm and not greater than 25 mm.
- The liquid head on top of the geomembrane should be equal to or less than 3 m.
- The hydraulic conductivity of the low-permeability medium underlying the geomembrane,  $k_{UM}$ , should be equal to or less than a certain value  $k_G$ . Giroud et al. (1997c) propose the following value for  $k_G$  in the case where the geomembrane defect is circular:

$$k_G = \left\{ 0.3891 d^{1.8} / \left[ C_{qo} \left( 1 + 0.1 (h/t_{UM})^{0.95} \right) h^{0.4} \right] \right\}^{1/0.74} \quad (5)$$

Values of  $k_G$  calculated using Equation 5 are given in Table 1.

Table 1. Maximum value,  $k_G$  (m/s), of the hydraulic conductivity of the medium underlying the geomembrane for Equations 1 and 2 to be valid in the case where  $C_{qo} = 0.21$  (good contact) and  $t_{UM} = 0.6$  m (from Giroud et al. 1997c).

## 3 RATE OF LEAKAGE THROUGH DEFECTS IN A GEOMEMBRANE ON A SEMI-PERMEABLE MEDIUM

### 3.1 Presentation of the New Equation

When a geomembrane is overlain and underlain by infinitely permeable media, the rate of leakage through a geomembrane defect is given by the classical Bernoulli's equation for free flow through an orifice:

$$Q = 0.6a \sqrt{2gh} = 0.15\pi d^2 \sqrt{2gh} = Q_B \quad (6)$$

As shown by Giroud et al. (1997c), Bernoulli's equation is valid if the hydraulic conductivity of the medium underlying the geomembrane is greater than:

$$k_B = 10^5 d^2 \quad \text{with } k_B \text{ (m/s) and } d \text{ (m)} \quad (7)$$

Values of  $k_B$  calculated using Equation 7 are given in Table 2. A comparison of Tables 1 and 2 reveals that  $k_G$  is always smaller than  $k_B$ . To evaluate the rate of leakage through defects in geomembranes underlain by a semi-permeable medium, i.e. when the hydraulic conductivity,  $k_{UM}$ , of the medium underlying the geomembrane is between  $k_G$  and  $k_B$ , Giroud et al. (1997c) have developed the interpolation method described below.

Interpolation between Equation 6 for flow through a defect in a geomembrane underlain by an infinitely permeable medium, and Equation 1 or 2 for flow through a defect in a geomembrane underlain by a low-permeability medium gives the following equation for the rate of leakage through defects in a geomembrane placed on a semi-permeable medium (Giroud et al. 1997c):

$$\log(Q_B/Q) = 0.74 \left[ \frac{\log(k_B/k_{UM})}{\log(k_B/k_G)} \right]^{\log(k_B/k_G)} \quad (8)$$

where  $Q_B$  is defined by Equation 6,  $k_B$  by Equation 7, and  $k_G$  by Equation 5.

Table 2. Hydraulic conductivity of the medium underlying the geomembrane below which Bernoulli's equation for free flow through an orifice is not theoretically valid,  $k_B$  (Equation 7), or not applicable for practical purposes,  $k_{UM\ min}$  (Equation 11) (from Giroud et al. 1997c).

Geomembrane defect diameter, d (mm)	0.5	1	2	3	5	10	11.284 (a = 1 cm <sup>2</sup> )
Theoretical, $k_B$ (m/s)	$2.5 \times 10^{-2}$	$1.0 \times 10^{-1}$	$4.0 \times 10^{-1}$	$9.0 \times 10^{-1}$	2.5	10	13
Practical, $k_{UM\ min}$ (m/s)	$2.5 \times 10^{-4}$	$1.0 \times 10^{-3}$	$4.0 \times 10^{-3}$	$9.0 \times 10^{-3}$	$2.5 \times 10^{-2}$	$1.0 \times 10^{-1}$	$1.3 \times 10^{-1}$

Combining Equations 5, 6, 7 and 8 gives:

$$\log Q = 0.3195 + 2 \log d + 0.5 \log h - 0.74 \left( \frac{5 + 2 \log d - \log k_{UM}}{n} \right)^n \quad (9)$$

where:

$$n = 5.5540 - 0.4324 \log d + 0.5405 \log h + 1.3514 \log C_{qo} + 1.3514 \log \left[ 1 + 0.1 \left( \frac{h}{t_{UM}} \right)^{0.95} \right] \quad (10)$$

The rate of leakage through a defect in a geomembrane underlain by a semi-permeable medium (whose hydraulic conductivity,  $k_{UM}$ , is greater than  $k_G$  and smaller than  $k_B$ ) can be calculated using Equation 9, which is equivalent to Equation 8. The genesis of the equation appears more clearly in Equation 8, whereas numerical calculations may be done more conveniently using Equation 9.

### 3.2 Example of Use of the Equation

Figure 1 shows a series of curves that represent the rate of leakage through a given geomembrane defect (diameter,  $d = 2$  mm) as a function of the hydraulic conductivity of the medium underlying the geomembrane for various leachate heads. Each curve in Figure 1 comprises three portions: the left-hand portion (straight line) represents Equation 2; the right-hand portion (plateau) represents Equation 6; and the central portion (curve) was interpolated using Equation 9. Both Equations 2 and 9 were used with  $C_{qo} = 0.21$  (Equation 3), i.e. assuming good contact between the geomembrane and the underlying medium. The limit value of the hydraulic conductivity between the left-hand portion and the central portion is  $k_G$  given by Equation 5 and Table 1; as shown in Table 1,  $k_G$  has a different value for each curve. The limit value of the hydraulic conductivity between the central portion and the right-hand portion is  $k_B$  given by Equation 7 and Table 2; as shown in Table 2,  $k_B$  has the same value for all curves related to the same value of  $d$ ; for example, for  $d = 2$  mm,  $k_B = 0.4$  m/s. Similar graphs for other values of  $d$  are given by Giroud et al. (1997c).

Figure 1. Rate of leakage through a 2 mm diameter defect in a geomembrane underlain by a medium, with a hydraulic conductivity  $k_{UM}$  and a thickness  $t_{UM}$ , overlain by a medium that is significantly more permeable than the underlying medium, for various values of the leachate head on top of the geomembrane,  $h$  (from Giroud et al. 1997c).

### 3.3 Limit of Applicability of Bernoulli's Equation

As indicated by Giroud et al. (1997c), Bernoulli's equation (Equation 6) provides a value of the leakage rate that is close to the value obtained using the interpolation method presented in Section 3.1, for values of the hydraulic conductivity of the medium underlying the geomembrane that are greater than  $k_{UM\ min}$  defined as  $k_B/100$ . Therefore, the practical limit of applicability of Bernoulli's equation is 100 times smaller than the theoretical limit of validity,  $k_B$ , hence, from Equation 7:

$$k_{UM\ min} = 10^3 d^2 \quad \text{with } k_{UM\ min} \text{ (m/s) and } d \text{ (m)} \quad (11)$$

Values of  $k_{UM\ min}$  calculated using Equation 11 are given in Table 2.

It is important to note that, for Bernoulli's equation to be applicable, the geomembrane must be not only underlain by a sufficiently permeable medium, but also overlain by a highly permeable medium. The required minimum hydraulic conductivity of the medium overlying the geomembrane is discussed in Section 4.

#### 4 RATE OF LEAKAGE THROUGH DEFECTS IN A GEOMEMBRANE OVERLAIN BY A PERMEABLE MEDIUM AND UNDERLAIN BY A HIGHLY PERMEABLE MEDIUM

##### 4.1 Presentation of the New Equation

As indicated in Section 3.1, when a geomembrane is overlain and underlain by infinitely permeable media, the rate of leakage through a geomembrane defect is given by the classical Bernoulli's equation for free flow through an orifice (Equation 6). Engineers designing landfills use Bernoulli's equation routinely without questioning its applicability. However, sometimes, absurd results are obtained, such as a calculated rate of leakage through a defect in a geomembrane liner greater than the total rate of liquid supply above the geomembrane.

The absurd results of the type indicated above are caused by an overestimation of the rate of leakage by Bernoulli's equation because this equation is based on the assumption that the hydraulic conductivity of the medium overlying the geomembrane is infinite. In reality, this hydraulic conductivity is not infinite; therefore, the flow of leachate toward the geomembrane defect is hindered and, as a result, the rate of leakage is less than in the ideal case of a geomembrane overlain by an infinitely permeable medium. Taking into account the fact that leachate does not flow freely toward the geomembrane defect, Giroud et al. (1997b) developed the following equation:

$$h = \left\{ \frac{a q_i}{2 k_{OM} \pi} + \frac{Q}{2 k_{OM} \pi} \left[ \ln \left( \frac{Q}{a q_i} \right) - 1 \right] + \frac{1}{4 g^2} \left( \frac{Q}{0.6 a} \right)^4 \right\}^{1/2} \quad (12)$$

where:  $q_i$  = rate of leachate supply on top of the medium overlying the geomembrane; and  $k_{OM}$  = hydraulic conductivity of the medium overlying the geomembrane.

It should be noted that, if  $k_{OM}$  is infinite, Equation 12 becomes identical to Equation 6, i.e. Bernoulli's equation for free flow through an orifice.

Equation 12 cannot be solved for  $Q$ . Therefore, iterations are necessary to determine  $Q$  when  $h$ ,  $a$ ,  $k_{OM}$  and  $q_i$  are known. Alternatively, graphical solutions can be used. An example is shown in Figure 2, and a series of similar graphical solutions is provided by Giroud et al. (1997b). Figure 2 shows that, in general, Bernoulli's equation overestimates the leakage rate. However, Figure 2 also shows that, for certain values of the leachate head on top of the geomembrane and the hydraulic conductivity of the medium overlying the geomembrane, Bernoulli's equation provides an excellent approximation of the leakage rate. This is further discussed in Section 4.2.

Figure 2. Graphical solution of Equation 12 for a geomembrane defect having a diameter of 2 mm.

##### 4.2 Limit of Applicability of Bernoulli's Equation

Comparing Equations 6 and 12, Giroud et al. (1997b) have shown that Bernoulli's equation gives the rate of leakage through a geomembrane defect with an error less than 5% if the hydraulic conductivity of the medium overlying the geomembrane,  $k_{OM}$ , is greater than:

$$k_{OM \text{ min } 5\%} = \frac{30 d^2}{h^{3/2}} \quad (13)$$

where the following units should be used:  $d$  (m),  $h$  (m) and  $k_{OM \text{ min}}$  (m/s).

It is interesting to note the consistency between two limits of applicability of Bernoulli's equation: the minimum value of the hydraulic conductivity of the medium *overlying* the geomembrane (given by Equation 13) and the minimum value of the hydraulic conductivity of the medium *underlying* the geomembrane (given by Equation 11). Equations 11 and 13 are consistent for  $h = 0.1$  m, which is remarkable because these two equations were established independently and are related to two different media.

##### 4.3 Relationship Between Liquid Supply and Leakage

For a given permeable medium (such as a leachate collection layer) overlying a geomembrane, the leachate head,  $h$ , and the leachate supply rate,  $q_i$ , are not independent. The leachate head depends on the leachate supply rate and varies as a function of the distance to the toe of the leachate collection layer slope. As shown by Giroud and Houlihan (1995), in a large number of cases, an excellent approximation of the average leachate head is given by the following equation:

$$h = \frac{q_i L}{2 k_{OM} \tan \beta} \quad (14)$$

where:  $\beta$  = slope angle of the permeable medium; and  $L$  = horizontal projection of the length of the permeable medium in the direction of the flow.

It is then possible to establish a direct relationship between the rate of leachate supply to the permeable medium,  $q_i$ , and the rate of leakage through the liner defect,  $Q$ . To that end, the leachate head,  $h$ , is eliminated by combining Equations 12 and 14, hence:

$$1 = (2/\pi) A [1 + C(\ln C - 1)] + B^2 (C/0.6)^4 \quad (15)$$

where  $A$ ,  $B$ , and  $C$  are dimensionless parameters defined as follows (Giroud et al. 1997b):

$$A = \frac{a k_{OM} \tan^2 \beta}{q_i L^2} \quad (16)$$

$$B = \frac{q_i k_{OM} \tan \beta}{gL} \quad (17)$$

$$C = \frac{Q}{a q_i} \quad (18)$$

Equation 15 provides a direct relationship between the rate of leachate supply,  $q_i$ , and the rate of leakage,  $Q$ . This direct relationship gives a definitive and quantitative answer to the following question often posed when practicing or teaching landfill liner design: is the rate of leakage through geomembrane defects greater if a geomembrane is overlain by a low-permeability leachate collection layer (which slows down the leachate flow toward the defects) or a high-permeability leachate collection layer (which reduces the leachate head over the geomembrane)? The answer to this question can be derived from Figure 3 which provides a graphical solution to Equation 15. Figure 3 shows that the rate of liquid migration through geomembrane defects decreases if  $A$  or  $B$  increases. From Equations 16 and 17, it appears that both  $A$  and  $B$  increase when  $L$  decreases and  $\beta$  and  $k_{OM}$  increase. The influence of  $L$  and  $\beta$  was already known through Equation 14: as  $L$  decreases or  $\beta$  increases, the leachate head decreases and, consequently, the leakage rate decreases. However, the influence of  $k_{OM}$  was not known because  $k_{OM}$  is a parameter in both Equations 12 and 14. Therefore, it is important to learn from the above discussion that, for a given situation defined by  $L$ ,  $\beta$  and  $q_i$ , the higher the hydraulic conductivity,  $k_{OM}$ , of the leachate collection layer, the lower the leakage rate. Therefore, the answer to the question posed above is that the rate of leakage through geomembrane defects is greater if a

geomembrane is overlain by a low-permeability leachate collection layer than by a high-permeability leachate collection layer. It should be noted that this conclusion is based on a demonstration that is limited, as is the scope of Section 4, to the case of geomembranes placed over a highly permeable medium. (However, the same conclusion would be reached if the geomembrane was placed on a low-permeability medium to form a composite liner because the rate of leachate migration through a composite liner is too small to have any significant impact on the leachate head on top of the liner. Therefore, in the case of a composite liner, it is obvious that the rate of leakage through geomembrane defects is greater if the leachate collection layer over the geomembrane has a low hydraulic conductivity than if it has a high hydraulic conductivity.)

Figure 3. Graphical solution of Equation 15.

## 5 LEACHATE FLOW IN LEAKAGE COLLECTION LAYERS DUE TO DEFECTS IN GEOMEMBRANE LINERS

### 5.1 Presentation of the New Equation

Sections 2, 3 and 4 were devoted to the evaluation of the rate of leakage through geomembrane defects, considering several cases of hydraulic conductivities of the media overlying and underlying the geomembrane. Section 5 addresses the flow of leachate in the leakage collection layer located between the two liners in a double liner system. Since only leakage through defects in the primary liner is considered herein, and since the number of defects is generally limited, the leachate generally flows only in portions of the leakage collection layer called the wetted zones. If the defects in the primary liner are sufficiently far apart, the wetted zones related to the various defects do not overlap, and the boundary of the wetted zone related to one defect is approximately a parabola, as shown below.

The leachate flows downslope in the leachate collection layer overlying the primary liner (Figure 4a). A very small fraction of this leachate passes through the primary liner defect, D (Figure 4a). The leachate that has passed through the defect in the primary liner, first flows more or less vertically (DA in Figure 4a) through the leakage collection layer upper part, which is unsaturated. Then, when the leachate reaches (at Point A) the saturated portion of the leakage collection layer, it flows in all directions in the plane of the leakage collection layer (Figure 4a). It is therefore logical to assume that the leachate phreatic surface in the leakage collection layer is a cone with its apex at Point A located vertically beneath the defect in the primary liner (Figure 4a). Furthermore, for leachate to flow in all directions, the hydraulic gradient must be approximately the same in all directions. Since the hydraulic gradient is closely related to the slope of the phreatic surface, it may then be assumed that the slope of the cone generatrices is the same in all directions. The slope of the phreatic surface (i.e. the slope of the cone generatrix) in the downslope direction is approximately known: it is close to the slope angle,  $\beta$ , since the flow thickness is small compared to the length of the leakage collection layer. Therefore, it is assumed that the angle between a horizontal plane and all generatrices of the cone that form the leachate phreatic surface is  $\beta$  (Figure 4a), i.e. the cone axis is vertical.

From the foregoing discussion, it appears that the wetted zone (Figure 4b) is parabolic since the intersection of a cone and a plane parallel to a generatrix of the cone is a parabola. However, the actual wetted zone is only approximately parabolic because several simplifying assumptions were made, as indicated above.

Giroud et al. (1997a) showed that a consequence of the conical shape of the phreatic surface is the following relationship between the rate of leachate migration through the primary liner defect,  $Q$ , the hydraulic conductivity of the leachate collection layer,  $k$ , and the thickness of leachate in the leakage collection layer beneath the defect,  $t_0$  (Figure 4a):

$$Q = k t_0^2 \quad (19)$$

$t_0$  is the maximum thickness of leachate in the leakage collection layer (i.e. the distance between Point A and the secondary liner), hence the condition for the leachate collection layer to not be filled with leachate:

$$t_0 = \sqrt{\frac{Q}{k}} \leq t_{LCL} \quad (20)$$

Equations 19 and 20 are extremely simple and do not depend on the size of the defect in the primary liner or on the slope of the leakage collection layer.

## 5.2 Equation of the Boundary of the Wetted Zone

Giroud et al. (1997a) established the equation of the parabola that defines the wetted zone related to a single geomembrane defect. This equation is conveniently expressed as the width of the parabola at the horizontal distance  $x$  (Figure 4b) from the geomembrane defect:

$$W = \frac{2 t_0}{\sin \beta} \sqrt{1 + \frac{2 x \sin \beta}{t_0}} = 2 L \mu \sqrt{1 + 2(x/L)/\mu} \quad (21)$$

where  $L$  = horizontal projection of the length of the leakage collection layer in the direction of the slope; and  $\mu$  is a dimensionless parameter defined as follows:

$$\mu = \frac{t_0}{L \sin \beta} \quad (22)$$

## 5.3 Wetted Fraction

Typically, there are several defects in a primary liner. The frequency of defects,  $F$ , is defined as the ratio of the number of defects in the liner and the surface area of the liner. For example, if there are four defects per hectare,  $F = 4/10,000 = 4 \times 10^{-4} \text{ m}^{-2}$ . The total wetted zone generated by the defects consists of the individual parabolic wetted zones for the various defects. The wetted fraction is defined as the ratio of

Figure 4. Leachate flow in the leachate collection layer, through a defect in the primary liner, and in the leakage collection layer: (a) cross section; (b) plan view.

the area of the total wetted zone and the surface area of the liner. The individual wetted zones may overlap; the smaller the defect frequency, the smaller the probability for the individual wetted zones to overlap. If the individual wetted zones do not overlap, which is the most frequent case since the defect frequency is generally small, two typical scenarios can be considered: (i) the worst scenario (Figure 5a) where all of the defects are located at the higher end of the primary liner slope, which results in the largest value for the wetted fraction; and (ii) the random scenario (Figure 5b) where the defects are located at random, which results in an average value for the wetted fraction. Using the equation of the parabola (Equation 21), Giroud et al. (1997a) calculated the wetted fraction,  $R_{w \text{ worst}}$  in the worst scenario, and  $R_{w \text{ rand}}$  in the random scenario:

$$R_{w \text{ worst}} = \lambda_{w \text{ worst}} F L^2 \quad (23)$$

where  $\lambda_{w \text{ worst}}$  is a dimensionless factor defined as follows:

$$\lambda_{w \text{ worst}} = \frac{2}{3} \mu^2 \left[ \left( 1 + \frac{2}{\mu} \right)^{3/2} - 1 \right] \quad (24)$$

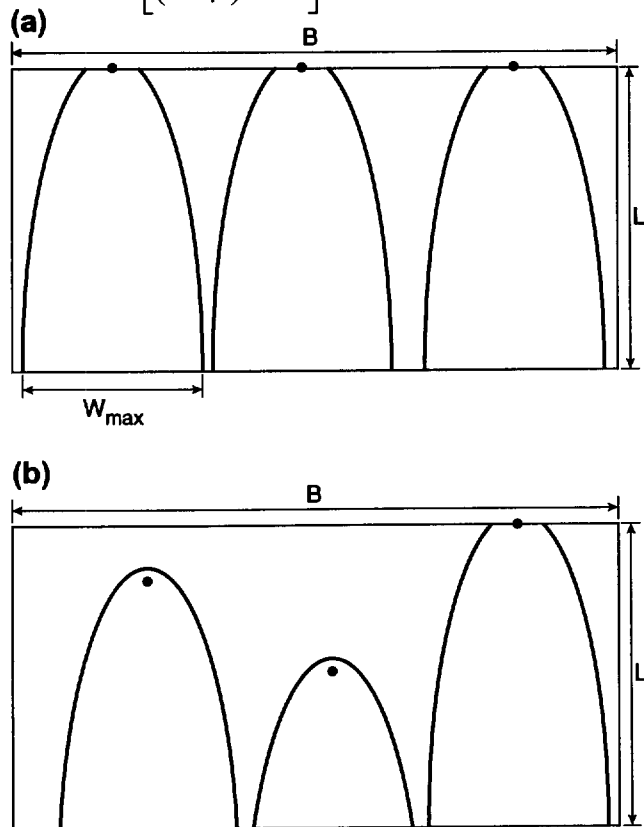

Figure 5. Leakage collection layer zones wetted by leachate migrating through several defects (•) in the primary liner, assuming no overlapping of wetted zones: (a) worst scenario where all of the defects are located at the high end of the primary liner slope; (b) random scenario where the defects are randomly distributed.

$$R_{w \text{ rand}} = \lambda_{w \text{ rand}} F L^2 \quad (25)$$

where  $\lambda_{w \text{ rand}}$  is a dimensionless factor defined as follows:

$$\lambda_{w \text{ rand}} = \frac{2}{15} \mu^3 \left[ \left( 1 + \frac{2}{\mu} \right)^{5/2} - 2 \right] \quad (\text{for } \mu \leq 2) \quad (26)$$

$$\lambda_{w \text{ rand}} = \frac{2}{15} \mu^3 \left[ \left( 1 + \frac{2}{\mu} \right)^{5/2} + \left( 1 - \frac{2}{\mu} \right)^{5/2} - 2 \right] \quad (\text{for } \mu \geq 2) \quad (27)$$

#### 5.4 Leachate Head on Top of the Secondary Liner

The leachate head on top of the secondary liner is zero outside the wetted zone. Inside the wetted zone, the leachate head varies from one point to another and an average value,  $h_{\text{avg}}$ , can be calculated. Based on the conical shape of the phreatic surface (Figure 4a) and using Equations 21 to 27, Giroud et al. (1997a) calculated the average leachate head on top of the secondary liner,  $h_{\text{avg worst}}$  in the worst scenario, and  $h_{\text{avg rand}}$  in the random scenario:

$$\frac{h_{\text{avg worst}}}{t_o \cos \beta} = \frac{3}{2 \mu \left[ \left( 1 + \frac{2}{\mu} \right)^{3/2} - 1 \right]} = \frac{\mu}{\lambda_{w \text{ worst}}} \quad (28)$$

$$\frac{h_{\text{avg rand}}}{t_o \cos \beta} = \frac{(5/3) + [15/(2\mu)] x_{\text{rand}} / L}{\mu \left[ \left( 1 + \frac{2}{\mu} \right)^{5/2} - 2 \right]} \quad (29)$$

It should be noted that  $h_{\text{avg rand}}$  is greater than  $h_{\text{avg worst}}$  because the wetted zone is smaller in the random scenario than in the worst scenario ( $R_{w \text{ rand}} < R_{w \text{ worst}}$ ). However, the total amount of leachate present at a given time in the leakage collection layer is greater in the worst case than in the random case.

As shown by Giroud et al. (1997a), if  $R_{w \text{ worst}}$  exceeds 2/3 or if  $R_{w \text{ rand}}$  exceeds 4/15, there is a high probability that the individual wetted zones will overlap. In this case, it would be extremely complex to determine the surface area of the wetted zone and, from a practical standpoint, it is preferable to use the approximate approach that consists of assuming that the entire surface area of the secondary liner is wetted (i.e.  $R_w = 1$ ). As shown by Giroud et al. (1997a), the values of the average leachate heads then become:

$$h_{\text{avg worst}} = \frac{F L Q}{k \tan \beta} \quad (30)$$

$$h_{\text{avg rand}} = \frac{F L Q}{2 k \tan \beta} \quad (31)$$

#### 5.4 Use of the Equations

To design a leakage collection layer, Equation 20 should be used. This extremely simple equation makes it possible to determine the required thickness of the leakage collection layer,  $t_{\text{LCL}}$ , as a function of the hydraulic conductivity of the leakage collection layer material,  $k$ , to accommodate a given leakage rate,  $Q$ .

To calculate the rate of leakage through the secondary liner (i.e. the rate of leakage into the ground), it is necessary to determine the head of leachate on top of the secondary liner. First, Equation 23 or 25 should be used to calculate the wetted fraction. If  $R_{w \text{ worst}}$  is less than 2/3 and  $R_{w \text{ rand}}$  is less than 4/15, Equations 28 and 29 can be used to calculate the leachate head in the worst and random case, respectively. If  $R_{w \text{ worst}}$  exceeds 2/3 or if  $R_{w \text{ rand}}$  exceeds 4/15, it should be assumed that the entire surface area of the secondary liner is wetted and Equations 30 and 31 must be used to calculate the average leachate head in the worst and the random case, respectively.

## 6 USE OF THE EQUATIONS TO SELECT THE OPTIMAL CONFIGURATION OF A DOUBLE LINER SYSTEM

The following methodology based on the equations presented in the preceding sections can be used to calculate the rate of leakage into the ground in the case of a double liner system: (i) calculate the rate of leakage through the primary liner; (ii) calculate the average head of leachate on top of the secondary liner; and (iii) calculate the rate of leakage through the secondary liner. Giroud et al. (1997d) used this methodology to compare two configurations of a double liner system: (i) in the first configuration, the primary liner is a geomembrane and the secondary liner is a geomembrane-GCL composite liner; and (ii) in the second configuration, the same two liners are in the inverse order, i.e. a geomembrane-GCL composite primary liner and a geomembrane secondary liner. They found that the rate of leakage into the ground is much less in the case of the second configuration, thereby showing that, from the viewpoint of minimizing advective flow of leachate, it is preferable to use the composite liner as the primary liner rather than as the secondary liner.

## 7 CONCLUSIONS

The new equations presented in this paper provide engineers designing landfills or evaluating landfill

performance with tools better than previously available. In particular:

- An entirely analytical method to calculate the rate of leakage through defects in the geomembrane component of a composite liner.
- An entirely analytical method to calculate the rate of leakage through defects in a geomembrane placed on a semi-permeable medium.
- An extension of Bernoulli's equation that eliminates the risk of absurd results such as those sometimes obtained with Bernoulli's equation, e.g. calculated leakage rate greater than the leachate supply rate.
- A set of equations that describe the flow of leachate in leakage collection layers and make it possible to design leakage collection layers and to calculate the leachate head on the secondary liner that is needed to calculate the rate of leakage through the secondary liner of a double liner system.

**ABSTRACT:** The Town of Babylon (State of New York, USA) constructed a lined landfill using a double composite liner with a leakage detection system between the upper (primary) and lower liner. The primary liner was a composite on the base and a geomembrane on the slope. A requirement of the landfill construction and operation permit is that leakage through the primary liner be less than 180 liters per hectare day (lphd). Monitoring prior to operation revealed liquid was removed from the leakage detection system at rates above 180 lphd. A detailed analysis of the available data revealed that while some of the liquid was construction water, the liquid was also attributable to leakage through the primary liner. The source of leakage was considered to be a possible hole 3 mm in diameter approximately 800 mm up the side slope.

**KEYWORDS:** Geomembranes, Leakage, Landfills, Double-liner Systems, Case Study

## 1 INTRODUCTION

The Town of Babylon (State of New York, USA) constructed a municipal solid waste landfill using a double liner system designed in accordance with the governing regulatory requirements. The liner system on the base of the landfill is a double composite liner with a leachate collection system (LCS) above the upper composite (primary) liner and a leakage detection system (LDS) between the primary liner and the lower composite (secondary) liner. The liner system on the slope is similar to that on the base except the primary liner consists only of a geomembrane. A requirement of the landfill construction and operation permit is that leakage through the top liner be less than 180 liter per hectare per day (lphd). This leakage rate is referred to as the action leakage rate or ALR. The action leakage rate is a concept introduced by the U.S. Environmental Protection Agency (USEPA) and is used by the New York State Department of Environmental Conservation (NYSDEC) as the rate of leakage from the LDS that triggers interaction between the owner or operator and the agency to determine the appropriate response action for the leakage. The USEPA requires an ALR only for hazardous waste landfills, while the NYSDEC requires an ALR for municipal solid waste landfills as well as hazardous waste landfills. Another permit requirement is the monitoring of the LDS flow rates for a period of 30 days prior to operation to establish satisfactory performance of the top liner, in addition to monitoring during and after the active life of

the landfill. The results of monitoring prior to operation is the subject of this paper.

During the pre-operation monitoring period, liquid was removed from the LDS of the two cells comprising the landfill at rates on the order of 300 lphd and 650 lphd. An evaluation of a number of landfills revealed that landfills with a CQA program consistent with standard industry practice had top liner leakage rates less than 500 lphd, and typically less than 200 lphd [Bonaparte and Gross, 1990]. Therefore, the 180 lphd requirement of the permit is achievable, but leakage rates above 180 lphd sometimes occur. A detailed evaluation of the measured leakage rates was performed since the leakage rate defined by the permit was exceeded. In the remainder of the paper the liner system is described, the results of pre-operation monitoring are presented, the monitoring results are analyzed to identify the sources of liquid removed from the LDS, and conclusions are drawn.

## 2 DESCRIPTION OF LINING SYSTEM

The lining system for the landfill incorporates both geosynthetic and low-permeability soil components. The liner system configurations on the landfill base and slope are depicted in Figure 1. The liner system was designed to meet the governing regulatory requirements of the State of New York. The specific liner system components on the base of the landfill are, from top to bottom: (i) 0.6-m thick protective sand layer ( $k \geq 10^{-5}$  m/s); (ii) geotextile filter; (iii) geonet drainage layer; (iv) 1.5-mm thick smooth high-density polyethylene

(HDPE) geomembrane; (v) geosynthetic clay liner (GCL); (vi) 0.3-m thick compacted clay liner ( $k \leq 10^{-7}$  m/s); (vii) geotextile filter; (viii) geonet drainage layer; (ix) 1.5-mm thick smooth HDPE geomembrane; (x) 0.6-m thick compacted clay liner ( $k \leq 10^{-9}$  m/s).

The liner system components on the slopes are from top to bottom: (i) 0.6-m thick protective sand layer ( $k \geq 10^{-5}$  m/s); (ii) geocomposite drainage layer consisting of a nonwoven geotextile heat-bonded to each side of a geonet; (iii) 60-mil thick textured HDPE geomembrane; (iv) geocomposite LDS; (v) 1.5-mm thick textured HDPE geomembrane; (vi) 0.6-m thick compacted clay liner ( $k \leq 10^{-9}$  m/s). The textured HDPE geomembrane and geocomposite drainage layers used for the side slope liner system extend approximate 1.5 m onto the base of the landfill. The GCL forming part of the composite primary liner on the base is extended 1 m up the slope.

The landfill is divided into two, 1.3 ha and 1.4 ha, cells subsequently referred to as the eastern and western cells. The lining system is continuous between the cells; however, the LCS and LDS of each cell are hydraulically separated by a berm. The LCS and LDS of each cell are pitched to drain to a sump area. Liquids collected in the sump area are pumped from the landfill. Separate pumps are used to drain the LCS and LDS.

### 3. LDS MONITORING RESULTS

The quantity of liquid removed from the LDSs of the eastern and western cells as part of pre-operation monitoring was recorded by accumulating flowmeters. The measured LDS flow rate in both cells exceeded the ALR of 180 lphd during initial monitoring. However, the ALR applies only to liquid leaking through the primary liner into the LDS. Liquid leaking through the top liner is not the only possible source for liquid being removed from the LDS. When using leakage data to evaluate the performance of a primary liner it is important to take other sources of liquid into account [Bonaparte and Gross, 1990]. Other possible sources of liquid are discussed below.

**Construction water** is liquid that became trapped in the LDS during construction and continues to drain from the LDS after construction. The considered landfill lining system incorporates a geonet LDS. The voids in the geonet on the base of each cell could contain on the order of 38,000 liters of liquid if saturated. The rate of removal of construction water will depend primarily upon the grade at which the geonet is installed and its transmissivity. The rate of drainage of construction water from the LDS was estimated to range from 30 to 3,000 lphd.

**Consolidation water** is liquid squeezed from the clay component of the primary clay liner. Consolidation is the result of load being placed on the lining system. Consolidation of the clay liner can occur under the weight of the protective cover over the top liner. The rate

of consolidation water which can be produced due to this load was estimated to be on the order of 0 to 100 lphd.

Figure 1. Liner System Configuration

**Infiltration** is liquid entering the LDS from outside the landfill or through the bottom liner. The rate will depend upon the source of infiltration (e.g., ground water surface water). The liner system is above the water table, and infiltration, if any, is expected to be negligible.

The daily liquid removal rate are plotted in Figure 2 for the eastern and western cells. The criteria used to evaluate liner system performance with respect to the 180 lphd ALR was the thirty-day average liquid removal rate. The first thirty-day average was calculated in June 1993. The western cell had a calculated 30-day average leakage rate of 240 lphd and the eastern cell had a leakage rate of 216 lphd on 24 June 1993. Since the thirty-day average

was above the 180 lphd threshold in both cells, it was concluded that either construction and consolidation water was not totally purged from the system, or there was a potential leak in the primary liner. On 10 July 1993 the pumps in the LCS sumps were turned off to allow precipitation to collect on the primary liner. This increase in hydraulic head on the primary liner created a small surcharge which accelerated the removal of any construction water, and would exaggerate conditions for leakage through the primary liner in the event a leak did exist.

The eastern cell did not perform as expected. As the hydraulic head increased on the primary liner, erratic liquid removal rates were measured. On 16 July, the daily rate of removal from the LDS reached 814 lphd (the 30-day average liquid removal rate was on the order of 260 lphd) and the hydraulic head was 610 mm (as measured in the eastern sump). From 17 July through 21 July the hydraulic head was increased to 740 mm, but the daily rate of liquid removal decreased to 198 lphd. This is what would be expected with the depletion of the construction and consolidation water. From 22 July through 18 August the hydraulic head increased to 1.01 m and the liquid removal rate started to increase. This increase was unexpected and could not be attributed to construction and consolidation waters.

The western cell performed as anticipated. As the hydraulic head increased on the primary liner, the rate of liquid removal from the LDS increased. On 17 July, the daily rate of removal from the LDS reached 308 lphd and the hydraulic head as measured in the western sump was 840 mm. From 18 July through 18 August the hydraulic head was increased to 1.27 m, but the daily rate of liquid removal gradually decreased to 49 lphd, as would be expected with the depletion of the construction and consolidation water. The western cell was determined to perform in accordance with the permit conditions and was not evaluated further.

#### 4. ANALYSIS OF DATA

As noted above, the liquid removal rate in the eastern cell increased significantly when the water level in the sump was raised above 740 mm. This increase in leakage rate was attributed to a hole in the top liner at least 740 mm vertical above the cell sump. At this elevation the hole was calculated to be above the GCL which extended a short distance (e.g., about 300 mm vertical) up the side slope. This observation was supported by the rapid response in the LDS to the height of liquid, which would be the case for leakage through a defect in a geomembrane overlying a free draining layer, as is the case on the slope. In order to estimate the size and location of the leak relative to the bottom of the cell, the data was analyzed using Bernoulli's equation for flow through an orifice [Giroud, 1984]:

$$Q = Ca\sqrt{2gh}$$

in which: Q = flow rate, C = dimension less coefficient related to the shape of the edge of the defect (assumed to be 0.6); a = area of orifice; g = gravity (9.81 m/s<sup>2</sup>); and h = height of liquid above the defect.

The conditions analyzed are shown in Figure 3. For two different water levels above the cell bottom, the rate of leakage is known; however, the height of liquid above the defect is unknown. Therefore, three unknowns exist: the height of liquid above the defect for each of the two different water levels, and the area of the defect. The available data and Bernoulli's equation were used to generate three equations with three unknowns. These equations are shown in Figure 3. Solving these equations yields an equivalent circular defect 3 mm in diameter located 785 mm vertical above the primary liner. The calculated height of the defect above the base is consistent with the elevation at which an increase in the leakage rate was observed.

Figure 2. Daily Liquid Removal

### Known Relationships

$$Q_1 = 0.6a\sqrt{2gh_1} = 5.957 \times 10^{-6} \text{ m}^3 / \text{s}$$

$$Q_2 = 0.6a\sqrt{2gh_2} = 8.497 \times 10^{-6} \text{ m}^3 / \text{s}$$

$$h_2 = h_1 + 102 \text{ mm}$$

### Calculated Hole Area

$$\text{HOLE AREA} = 7.154 \times 10^{-6} \text{ m}^2$$

$$\text{HOLE DIAMETER} = 3 \text{ mm}$$

$$h_1 = 98 \text{ mm (3.8 in)}$$

$$h_2 = 200 \text{ mm (7.8 in)}$$

$$h = 883 - 98 = 785 \text{ mm}$$

Figure 3. Summary of Leakage Analysis

The calculated defect size is approximately the same as the typical size defect that may occur in geomembranes installed with good CQA practice [Giroud and Bonaparte, 1989]. In addition, the defect is located well above the primary geomembrane on the base of the landfill. The operating requirements of the cell requires the hydraulic head on the primary liner to be less than 300 mm. Given the location of the defect, the operational requirements to maintain the hydraulic head in the LCS less than 300 mm, and the potential to damage the liner during repair, the recommendation was made to place the cell into operation.

## 5 SUMMARY AND CONCLUSIONS

The initial rate of liquid removal from the LDS of a double-lined landfill exceeded the permitted rate of 180 lphd in both the eastern and western cells of the facility. An investigation into the potential sources revealed the

liquid in the western cell was due to construction and consolidation water. The leakage in the eastern cell was initially attributed to construction and consolidation water; however, later some of the liquid was attributed to leakage through the geomembrane liner on the side slope. The leak was attributed to a possible 3 mm diameter hole on the side slope. At this distance up the slope the hole would not impact normal operations. Therefore, the recommendation was made to place the landfill into service without repairing the geomembrane. The case history presented in this paper demonstrates that:

- liquid removed from the LDS shortly after construction is not necessarily an indicator of primary liner performance;
- careful monitoring and analysis of LDS liquid removal is needed to distinguish between leakage and other sources of liquid;
- liquid removal rate data can be used to estimate the locations and size of geomembrane primary liner defects; and
- leakage can occur in liners constructed with good CQA practice.

# Comparison of Dye Testing and Electrical Leak Location Testing of a Solid Waste Liner System

G.T. Darilek

Principal Engineer, Leak Location Services, Inc., San Antonio, Texas, U.S.A.

L.V. Miller

Central Division Manager, Delaware Solid Waste Authority, Sandtown, Delaware, U.S.A.

**ABSTRACT:** Dye tracing and electrical leak location testing were independently conducted to detect and locate leaks in the primary geomembrane liner of two cells in a municipal landfill. Despite extensive quality control and quality assurance programs, water in the leak detection zone after construction indicated that the primary liner had a leak. Fluorescein dye tests were conducted by placing a fluorescent yellow/green dye in water impounded on the liner and then sampling the water drained from the leak detection zone for periods of at least 40 days. The samples of water were visually inspected and tested with a spectrophotometer. No dye was ever detected. An electrical leak location survey of the same areas located two leaks. One leak was a 90 x 76 mm (7.5 x 3 in.) hole that was near a leak detection drainage pipe. The other leak was a 25-mm (1-in.) diameter hole. The tests showed that dye testing was ineffective for detecting the presence of significant leaks in a liner system with sand above and below the leak. The electrical leak location method quickly and accurately located the leaks.

**KEY WORDS:** Leak detection, geomembranes, construction quality assurance, landfills, performance evaluation

## 1 INTRODUCTION

The lining system of a municipal solid waste landfill is the only barrier between the leachate generated and the local groundwater. The installation of the liner system is normally monitored with extensive quality control and quality assurance programs designed to insure that the specifications for materials and procedures for construction are met. Unfortunately, the completed lining system can be damaged during the installation of the leachate collection systems and the drainage/protection layers. Holes in the lining system can go undetected until long after landfilling in the area has started, making the location and repair of the holes almost impossible. Therefore, testing for leaks before waste is introduced can detect problems before they get worse.

The Delaware Solid Waste Authority (DSWA) initiated a post installation testing program that included dye tests and electrical leak location surveys for two cells of a disposal area with eight cells. The disposal area is comprised of two phases, each of which are divided into four drainage areas or cells. The tests on the two cells gave a good comparison of the two leak detection and location methods.

Figure 1 shows a cross section diagram of the typical cell construction. The diagram is not to scale. Each cell has dimensions of approximately 54 x 218 m (178 x 715 ft). The disposal area utilizes a double HDPE geomembrane liner system. The primary liner has a 600 mm (24 in.) protective drainage sand layer above the liner. The leak detection zone has a 300 mm (12 in.) layer of drainage sand between the liners. Leachate and leak detection pipe trenches formed in the primary liner and secondary liner respectively contain 150 mm (6 in.) perforated drainage pipes surrounded with ballast rock enveloped in a woven geotextile. The drainage pipes above the secondary and primary liners connect to common

headers which drain to separate internal sumps. All eight cells of the disposal area were dye tested. Only the last two cells were leak tested using the electrical leak location method.

## 2 DYE TESTS

The dye test included uniformly introducing a known concentration of fluorescent yellow/green fluorescein dye into the water impounded in each cell and then monitoring the water flowing into the leak detection sump for dye. Only one cell was tested at a time. The cells were filled with dyed water to a level just below the lowest berm. Because of the elevation of the lowest berm, only about half of each cell could be flooded. Therefore, the dye testing area in each cell was limited to approximately 50 x 125 m (160 x 410 ft). Samples of water were then collected from the secondary leak detection system and visually inspected under an ultraviolet lamp and analyzed using a spectrophotometer.

Cole-Parmer fluorescent yellow/green dye tracer was used to dye the primary water. The concentration of the dye in the water impounded on the primary liner was compared with the concentration of dye in the water collected in the secondary leak detection system using a Hach model DR/2000 spectrophotometer. The photometer was calibrated for absorbance of light at the 494 nanometer wavelength of the dye, and could detect the dye in concentrations of approximately 0.2 ppm. The minimum visible detectable concentration of the tracer using an ultraviolet lamp is one ppm. A higher initial dye concentration of 4 ppm was used to compensate for any moisture from construction in the leak detection system that would dilute the primary water and to compensate for biodegradation of the dye with time.

Figure 1. Typical Cross-Section View of Leachate and Leak Detection System

The maximum migration distance for the dye through the sand to a leak detection drainage pipe was approximately 14 m (46 ft). The minimum distance was approximately 1 m (3 ft). The estimated worst-case time necessary for the dye to migrate through the sand to the nearest part of the leak detection pipe was calculated using the equation from Giroud et al (1997):

$$t_{\text{travel}} = n x / (k \sin \beta \cos \beta); \quad (1)$$

where  $t_{\text{travel}}$  = leakage travel time;  
 $n$  = porosity of the sand;  
 $x$  = length of the leakage path;  
 $k$  = hydraulic conductivity; and  
 $\beta_L$  = slope of the leak detection layer.

The worst-case leakage travel time through the sand was calculated to be 38 days. The leakage travel time through the leak detection pipe was estimated to be a maximum of one day. Therefore, the dye tests were monitored for a minimum of 40 days. During the dye testing, two of the cells were tested in the summer where the increased temperature accelerated the biodegradation of the dye. Therefore, additional dye was added when the concentration of the dye decreased. Samples of the water in the leak detection sump were collected, analyzed, and stored twice a week.

### 3 RESULTS OF THE DYE TESTS

No dye was detected in any of the eight cells in the water collected from the leak detection zone using visual ultraviolet inspection and the spectrophotometer measurements. The absorbance of the water collected in the leak detection zone remained at a very low and constant level. The concentration of dye in the primary water decreased to the visible limit of 1 ppm in 16 to 28 days except for two cells that maintained a

visible concentration throughout the 40 days of monitoring. From previous tests, the dye in water that was not exposed to sunlight or high surface temperatures was much slower, requiring more than two months to degrade below the visible level.

### 4 ELECTRICAL LEAK LOCATION SURVEY

The electrical leak location method (Laine and Darilek, 1993) was used to search for leaks in two of the eight cells. The electrical leak location method is to apply a voltage across the liner and then detect the areas where electrical current flows through leaks in the insulating liner. Figure 2 shows a diagram of the principles of the method. Figure 3 shows an operator collecting the data. One electrode was placed in the sand on the primary liner. A second electrode was placed in the water at the end of a cleanout pipe in the leak detection zone. The electrodes were connected to a 300 VDC power supply. The geomembrane leak location survey was conducted by systematically making potential gradient measurements on the cover soil. Heavy vegetation on the sand layer along the survey lines was removed prior to the survey. Data was taken on survey lines spaced 760 mm (30 in.) apart. A measurement was taken every 760 mm with electrodes spaced 760 mm apart. The data was recorded using portable digital data loggers programmed so the operator could enter the survey parameters including file name, line number, starting position, position increment, and time interval between readings. The data collected with the digital data recorders was then downloaded to a laptop computer in the field and the data was plotted and analyzed for characteristic leak signals. The entire area of the two cells was surveyed using the electrical leak location method. The survey of 22,500 square m (5.5 acres) required eight man-days.

Figure 2. Principle of the Electrical Leak Location Method for Sand-Covered Geomembrane Liners

Figure 3. Geomembrane Electrical Leak Location Data Acquisition

## 5 RESULTS OF THE ELECTRICAL LEAK LOCATION SURVEY

Two leaks were found using the electrical leak location method. One leak was a 190 x 76 mm (7.5 x 3 in.) hole. It was excavated while the leak location survey crew was on the site. Figure 4 shows this leak in-situ with a 15 mm (6 in.) marker shown for scale. The second leak was a 25 mm (1 in.)

diameter hole. Figure 5 shows both leaks after they were cut from the parent material. A 300 mm (12 in.) scale is also shown in the photograph.

Considerable energy would be required to form leaks this large, so damage from machinery is suspected. The larger leak had scrape marks leading to the leak and the other edge of the leak had the torn piece of liner attached as a flap. The larger leak was found on the edge of a leachate collection trench, which was approximately 3 m (10 ft) from a leak detection drainage pipe under the primary liner. Visual observation of the excavated leak after a moderate rainfall showed approximately 75 mm (3 in.) of storm water flowing over the hole.

## 6 ANALYSIS

For the larger leak, the dye had to travel a distance of only 3 m (10 ft) through the sand on the primary liner, through the leak, through the sand in the leak detection zone, to the leak detection drainage pipe. The time required for this transit, again using equation (1), is approximately 8 days plus an additional day for the dye to flow down the leak detection drainage pipe. The absorbance of the primary water at the 8-day interval had decreased to 36 percent of the initial concentration, but was clearly visible. The absorbance of the water samples taken from the leak detection sump six, eight, and eleven days after the start of the test for that cell show no evidence of dye.

Since the completion of the construction of the disposal area, flow measurements were made of the water collected from each of the two phases. Each phase has four cells. The flow rate from Phase 2 has always been higher than Phase 1. This was originally believed to be due to the higher

Figure 4. 90 x 76 mm (7.5 x 3 in.) Leak Found Using the Electrical Leak Location Method

Figure 5. Samples of Geomembrane Liner Containing the Leaks Found Using the Electrical Leak Location Method

precipitation during the construction of Phase 2. Since landfilling has started in both phases the secondary flow rates have continued to decrease.

Prior to the repair of the holes, the flow rate was approximately 112 liters/10,000 sq m/day (lhd) (12 gallons/acre/day (gad)) for Phase 2 and 56 lhd (6 gad) for Phase 1. Since the repairs, the flow rate from Phase 2 has decreased to approximately 70 lhd (7.5 gad). The flow rate from Phase 1 has also continued to decrease to about 14 lhd (1.5 gad).

The secondary flow in Phase 2 dropped dramatically to approximately 70 lhd (7.5 gad) after patching the two holes. Because the flow before the leaks were repaired was approximately 112 lhd (12 gal/acre/day), the estimated leakage from the holes contributed 42 lhd (4.5 gad).

## 7 CONCLUSIONS

The tests showed that dye testing was ineffective for detecting the presence of significant leaks in a liner system with sand above and below the leak. Biodegradation of the dye significantly decreases the concentration of the dye during the long time required for water to flow to the leak detection sump. Considering that sand is a good filter for water, the failure of the dye test for the leak that was close to a leak detection drainage pipe may be because the sand adsorbed the dye from the water. Even if the dye tests would have indicated the presence of the leaks, the specific locations of the leaks would have been unknown.

The electrical leak location method not only detected the leaks, but also accurately located the leaks. The leaks were easily excavated for repair before waste was put in the disposal cell.

An electrical leak location survey for geomembrane liners is an effective method for detecting leaks present during the installation of the geomembrane liner or for detecting leaks caused by machinery while putting sand on the liner.

**ABSTRACT:** This paper presents an approach for evaluating the effectiveness of HDPE geomembrane liner protection. The approach is based on the use of multi-axial tension tests (ASTM D 5617) performed on geomembrane specimens after exposure to anticipated field conditions. A criterion based on the geomembrane mode of failure in the multi-axial tension test is used to determine if a certain type or level of mechanical damage is acceptable. An example from several studies conducted to evaluate the impact of a granular layer on a geomembrane is presented and discussed.

**KEY WORDS:** Geomembrane liner, Protection, Mechanical damage, Mode of failure, Multi-axial tension test.

## 1 INTRODUCTION

Geomembranes used in waste containment facilities are often overlain and/or underlain by granular drainage layers. Since coarse granular particles can potentially damage the geomembrane at points of contact, design measures are often taken to protect the geomembrane and limit damage to acceptable levels. Typical design measures include: requiring that certain characteristics of the granular material, such as maximum particle size, gradation, or angularity, are within specified limits; or including cushioning layers, such as geotextiles, between the geomembrane and the granular material. These design measures generally increase facility construction costs and there is therefore a need for designers to rationally evaluate their effectiveness.

The effectiveness of geomembrane protection measures is often evaluated through laboratory testing that is performed in two stages. The first stage is exposure, during which a geomembrane specimen is subjected to the anticipated field conditions of concern. The exposure conditions typically include anticipated stresses, temperatures, and loading durations. The second stage is evaluation, during which tests are performed to measure selected properties of the exposed geomembrane and the test results used to evaluate whether the degree of damage sustained by the geomembrane is acceptable. This paper provides information relevant to the evaluation stage of such testing. Specifically, the purpose of this paper is to discuss the use of multi-axial tension tests to evaluate

exposed high density polyethylene (HDPE) geomembranes and to present a criterion for assessing whether mechanical damage sustained by the geomembrane is within acceptable limits.

## 2 CRITERION FOR ACCEPTABLE DAMAGE

Consideration of acceptable levels of geomembrane damage is focused on the primary function of geomembranes used in waste containment facilities, i.e. to act as a hydraulic barrier. It is obvious that if punctures are observed in the geomembrane after the exposure stage of testing then the geomembrane will not function as an effective hydraulic barrier. In this case the level of damage is unacceptable and the evaluation stage of testing is not necessary. Other types of damage may decrease the ability of the geomembrane to resist rupture when subjected to the working loads and deformations that may develop throughout the life of the facility. The evaluation stage of testing is concerned with these other types of damage.

The ability of a geomembrane to resist rupture when subjected to loads and deformations results not from its strength, but from its ability to deform locally under concentrated loads and at locations where differential settlements occur. If the geomembrane has sufficient deformability, it can conform to the shape of adjacent material layers without the development of large internal stresses. This rationale leads to the following definition for acceptable levels of damage: for damage undergone by a geomembrane to be acceptable, the tensile strain

characteristics of the geomembrane must not be significantly affected.

The proposed criterion is based on the use of results from multi-axial tension tests performed in accordance with the American Society for Testing and Materials (ASTM) test standard D 5617. This test uses geomembrane specimens secured around the perimeter of a large diameter (greater than 450 mm) testing chamber. Pressure is applied to one side of the specimen to cause out-of-plane deformation. The pressure is increased until failure occurs due to rupture of the geomembrane. A virgin geomembrane with a uniform thickness must rupture at the top of the dome because this is the location where the stresses are highest. Since a large test specimen is used, the multi-axial tension test is more appropriate than many other small scale index tests. The mode of failure is an important characteristic with respect to the criterion proposed in this paper.

The important parameters that indicate the ability of a geomembrane to deform are the magnitude of tensile strain at yield and, to a lesser degree, the strain at break. However, the state-of-practice for predicting the stresses and strains in geomembranes used in waste containment facilities is not sufficiently detailed to justify a meaningful evaluation of the relative performance of geomembranes with slightly different stress-strain characteristics. Based on experience with multi-axial tension tests on mechanically damaged geomembranes, the authors have noted that the most significant indicator of damage for HDPE geomembranes may be when the geomembrane specimen ruptures at a location other than the top of the dome formed by the hydrostatically inflated geomembrane. If a geomembrane specimen ruptures at a location other than the top of the dome, this indicates that the specimen has been previously weakened at the location where the rupture occurs.

From the foregoing discussion, the following criterion has been developed: the mechanical damage undergone by a geomembrane is deemed unacceptable if the geomembrane specimen tested in a large diameter multi-axial tension test exhibits rupture at a location other than the center of the specimen and if this location is that of visible mechanical damage. The authors have used the approach and the criterion described above on several occasions and found that the proposed criterion always led to a clear and intuitively correct conclusion regarding what level of mechanical damage was acceptable.

In Section 3, an example from several studies conducted to evaluate the impact of a granular layer on a geomembrane is presented.

### 3 DESCRIPTION OF A TESTING PROGRAM

One of the studies conducted by the authors consisted of evaluating the need for a geotextile cushion between a

crushed rock layer and an HDPE geomembrane resting on a layer of compacted clay, thereby forming a composite liner to be used in an ore heap leach pad. The study included three steps:

- static compression loading to simulate the effects of the crushed rock layer on the geomembrane liner;
- visual examination of the geomembrane specimens after the compression tests to determine and record the locations of visible mechanical damage; and
- multi-axial tension tests to evaluate if the type or level of mechanical damage undergone by the geomembrane specimens was acceptable or not.

The materials used in the testing program consisted of a 1.5-mm thick HDPE geomembrane and four different proposed crushed rock materials designated A, B, C, and D. The particle-size distribution curves of the crushed rock materials are presented in Figure 1.

The static compression loading simulation was performed in a 450-mm diameter testing chamber. The size of the testing chamber was selected to be:

- more than five times the maximum particle size, which was 76 mm for material A, in order to eliminate the possible effects of arching which might have reduced the load applied to the geomembrane by transferring part of the load to the testing chamber; and
- less than the diameter (610 mm) of the pressure vessel used to perform the multi-axial tension test, in order to avoid the presence of locations where the geomembrane is damaged at or near the perimeter clamp, which could cause failures that are difficult to interpret.

One static compression loading was performed with each material A, B, C, and D. In each loading simulation, the geomembrane was underlain by a compacted clay layer to simulate the field conditions. The crushed rock material was then placed on the geomembrane and slightly tamped to produce a minimum of 100-mm thick uniform layer. A rigid steel platen was placed over the crushed rock material

Figure 1. Particle-size distribution curves of crushed rock materials.

and a compressive stress of 860 kPa was applied to the top of the testing chamber to simulate the maximum anticipated field loading of 55 m height of ore, assuming an ore unit weight of 15.6 kN/m<sup>3</sup>.

After 72 hours of sustained loading, the static compressive stress was removed and the geomembrane was carefully exhumed. The exhumed geomembrane was examined for any signs of damage and then subjected to a multi-axial tension test. The multi-axial tension tests were conducted on the geomembrane specimens generally within a few hours of exhumation. The multi-axial tension test was also conducted on a specimen of the virgin geomembrane in order to allow comparison between the failure modes and also obtain stress-strain data on the virgin geomembrane.

#### 4 SUMMARY AND DISCUSSION OF TEST RESULTS

##### 4.1 Visual Examination After Compression Tests

Visual observations and the photographic documentation (Figure 2) of the exhumed geomembranes are summarized in Table 1 and can be described as follows:

- The geomembrane that had been loaded with Material A showed significantly more damage than the other specimens. The imprints of the crushed rock material were visible at more than 50 locations on the upper surface of the geomembrane. Among these imprints, there were approximately 30 locations on the geomembrane surface which showed yield damage through the geomembrane thickness (i.e. where the imprints were also visible as protrusions on the lower surface of the geomembrane). However, no punctures were apparent at any of the contact points with Material A.
- The geomembrane specimen that had been loaded with Material B showed the least signs of damage. The

Table 2. Summary of multi-axial tension test results (see Note 1)

Test feature	Geomembrane specimen				
	Virgin	A	B	C	D
Maximum tensile stress ("Peak") (MPa)	17.9	19.8	19.0	18.0	18.2
Tensile strain at maximum stress (%)	11.2	7.3	11.2	11.2	11.2
Maximum tensile strain (%)	23.0	11.2	14.5	21.4	27.4
Tensile stress at maximum strain ("Break") (MPa)	15.1	18.1	18.9	15.5	14.7
Mode of rupture (see Note 2)	DXL	LOC	DXS	DXL	DXL

Note 1: The stress and strain values presented in Table 2 are from actual test data. They are more accurate than the values that can be obtained from the curves in Figure 3 (especially the tensile strain at maximum stress, which is difficult to obtain with precision from the curves due to the shape of the curves).

Note 2: DXL = Geomembrane rupture at the center of the specimen diametrically in the cross-roll direction with a large yield zone; DXS = Geomembrane rupture at the center of the specimen diametrically in the cross-roll direction with a small yield zone; and LOC = Geomembrane rupture localized at a point where the geomembrane was in contact with one of the stones in the loading test.

Figure 3: Multi-Axial Tension Test Stress-Strain Curves

- Material A significantly affected the geomembrane stress-strain curve (i.e. significantly lowering the tensile strain at peak) and significantly affected the mode of failure (i.e. geomembrane rupture at a point where the geomembrane had been damaged by a stone instead of being at specimen center).

It appears that the results of the multi-axial tension tests are consistent with the visual observations made on the geomembrane specimens following the compression loading simulation, which indicated the damage caused by Material A was far more severe than the damage caused by Materials B, C and D. Therefore, the results of the multi-axial tension tests are consistent with the criterion proposed in Section 2.

#### 4.3 Discussion of the Proposed Criterion

From the test results presented in Sections 4.1 and 4.2, it appears that the damage caused to the geomembrane by

Material A under the considered loading stress is unacceptable because it had two consequences that weakened the geomembrane and reduced its ability to resist mechanical actions during its service life: (i) it caused yield of the HDPE compound through the geomembrane thickness; and (ii) it caused a marked decrease in the yield strain of the geomembrane. In contrast, the damage caused by Materials B, C and D is acceptable.

Based on the above, an objective criterion for damage acceptability should be able to clearly distinguish between the geomembrane specimen that was loaded with Material A and the other geomembrane specimens. Several possibilities are considered:

- The maximum tensile stress (Table 2) does not provide any clear information.
- The tensile strain at maximum stress (Table 2) clearly distinguishes between the geomembrane specimen exposed to Material A and the other geomembrane specimens. Using the tensile strain at maximum stress as a criterion may therefore be appropriate. However, using the tensile strain at maximum stress as a criterion of geomembrane damage acceptability would have two drawbacks: (i) the peak of the stress-strain curves derived from multi-axial tension tests (Figure 3) is often not very marked and the determination of the strain at peak may be imprecise; and (ii) it would be difficult to develop a criterion that objectively distinguishes between an acceptable and an unacceptable strain reduction.
- The maximum tensile strain (Table 2) does not appear to provide results that are easy to interpret: damage to a geomembrane specimen results in an increase or a decrease of the maximum tensile strain.
- The tensile stress at maximum strain (Table 2) does not provide any clear indication.

imprints of the crushed rock material were visible at more than 100 locations on the upper surface of the geomembrane; however, none of these imprints resulted in yield damage through the geomembrane thickness as observed for the case of Material A.

- The geomembrane specimen that had been loaded with Material C showed moderate signs of damage by the overlying material. The imprints of the crushed rock material were visible at more than 50 locations on the surface of the geomembrane; however, none of these imprints resulted in yield damage through the geomembrane thickness as observed for the case of Material A. The imprints were slightly deeper and less uniform than those on the geomembrane specimen that had been loaded with Material B.
- The geomembrane specimen that had been loaded with Material D had a similar appearance as that loaded with Material B. The imprints of the crushed rock material were visible on more than 100 locations on the surface of the geomembrane; however, none of these imprints resulted in yield damage through the geomembrane thickness.

From the visual examination, it appears that Material A, caused significantly more damage than Materials B, C and D. From Figure 1, it appears that two characteristics that differentiate Material A from the three others and that may govern the ability of a granular material to cause a high degree of damage to a geomembrane are a large maximum particle size ( $d_{max}$ ) and a small value of the coefficient of uniformity,  $C_u$  (i.e. a very uniform particle size distribution curve). Indeed, these two parameters result in a smaller number of contacts between stones and geomembrane, hence higher contact forces for a given applied loading stress. This is confirmed by the number of imprints, which is less for Materials A and C than for Materials B and D (Table 1), and by the fact that Material A (large  $d_{max}$ , small  $C_u$ ) caused more damage than Material C (medium  $d_{max}$ , medium  $C_u$ ), which, in turn caused more damage than Materials B and D (medium  $d_{max}$ , very large  $C_u$ ). The angularity of the stones is another parameter that governs the ability of the stones to damage a geomembrane. However, no conclusion could be drawn from this testing program regarding this parameter since all four materials consisted of crushed stones of similar angularities.

## 4.2 Multi-axial Tension Tests

The results of the multi-axial tension tests, including the test performed on the virgin geomembrane specimen, are summarized in Table 2 and Figures 3 and 4. The interpretation of the results are as follows:

- The virgin geomembrane specimen and the geomembrane specimens that had been loaded with Materials C and D have similar stress-strain curves and the values of the maximum tensile strain, although different, are all between 20 and 30%. Also, they have the same mode of failure (Figure 4), i.e. rupture occurred at the center of the specimen, diametrically in the cross-roll direction, with a large yield zone.
- The geomembrane specimen that had been loaded with Material B has a stress-strain curve fairly similar to that of the virgin geomembrane, with approximately the same strain at peak (11.2%), but with a smaller strain at break. The failure mode (Figure 4) is rather similar to that of the virgin geomembrane, however, the yield zone is smaller in the case of the geomembrane specimen that had been loaded with Material B, which is consistent with the above comment about the strain at break.
- The geomembrane specimen that had been loaded with Material A has a strain at peak stress of approximately 7% whereas, in the four other cases, the strain at peak stress is approximately 11%. The mode of failure in the case of the geomembrane that had been loaded with Material A is distinctly different from the modes of failures with the four other geomembrane specimens (Figure 4). For Material A, the failure occurred at a point where the geomembrane had been damaged by a stone, in contrast with the four other specimens, where the failure occurred at the center of the specimen, i.e. independently from damage caused by the stones.

The above interpretations of the multi-axial tension tests may be summarized as follows:

- Materials C and D had essentially no effect on the geomembrane stress-strain curve and did not affect the mode of failure (i.e. geomembrane rupture at specimen center).
- Material B did not significantly affect the geomembrane stress-strain curve and did not affect the mode of failure (i.e. geomembrane rupture at specimen center).

Table 1. Summary of visual observations

Material	Holes	Imprints	Yield through	Yield size	Qualitative evaluation
A	None	>50	≈30	>2 mm×8 mm <5 mm×50 mm	Severe
B	None	>100	None	<1 mm×5 mm	Light
C	None	>50	None	<1 mm×5 mm	Light
D	None	>100	None	<3 mm diameter	Light

- The mode of rupture provides a clear distinction between the geomembrane specimen exposed to Material A and the other specimens, without the need for selection of a threshold property value separating acceptable from unacceptable damage.
- It may also be concluded that the damage, deemed unacceptable based on the mode-of-rupture criterion described above, also results in a decrease in tensile strain; however, the decrease in tensile strain does not provide an objective pass-or-fail criterion.

## 5 CONCLUSIONS

The paper has shown that a criterion based on the mode of rupture of a mechanically damaged geomembrane specimen subjected to a large-diameter multi-axial tension test provides a practical and defensible means to determine whether a certain type or level of mechanical damage is acceptable or not. The criterion is also consistent with the authors' observations from several mechanical damage studies.

**ABSTRACT:** Geomembrane liners at the base of solid waste landfills must be protected from stones and other sharp objects to properly act as liquid barriers. In Germany, where administrative instructions require very coarse grained drainage blankets above basal liners of solid waste landfills, special emphasis is placed on the selection of adequate protective layers. Their efficiency has to be demonstrated by tests according to the GDA-Recommendations of the German Geotechnical Society. The efficiency of six different geosynthetic protective layers was studied by large scale performance tests. The basal liner system, consisting of a compacted clay liner, a 2.5 mm thick HDPE-geomembrane, the protective layers and 0.3 m drainage stone of 16 to 32 mm were submitted to a uniformly distributed load increased step-wise up to 800 kPa. After more than two months loading, the geomembrane was exhumed and the deformations were examined by laser-measuring technique. The six protective layers lead to different results. All systems tested functioned successfully. A comparison of the performance observed by large scale testing and the assessment of the anticipated efficiency according to standard tests allows conclusions concerning the German protection efficiency test.

## 1 INTRODUCTION

Basal liner systems of solid waste landfills consist of impermeable geomembranes (GM) and mineral sealing layers such as compacted clay liners (CCL) in combination. There may be a single GM like in the German standard composite liner (Gartung 1996) or there may be two GMs, e.g. the double liner system employed in many landfills in the USA (Koerner 1994). In any case, there have to be leachate collection and removal facilities immediately above the basal seal to prevent increasing hydraulic heads above the liner. The dewatering systems typically comprise a drainage layer of gravel or crushed stone of 16 to 32 mm diameter.

Below the overburden of the waste deposit the coarse grained drainage material exerts very high local stresses on to the GM which could cause puncturing. So protection layers are installed between the coarse drainage aggregates and the GMs to prevent failure of the polymeric seal. The requirements to be met by the protection layers have been established on the basis of engineering judgment, and they have been supported by theoretical models. For the protection of the primary GM liner in the USA, Wilson-Fahmy, Narejo and Koerner (1994) carried out extensive studies. In Germany, where only one HDPE-GM of at least 2.5 mm thickness is used as a component of the composite basal liner, theoretical arguments for the criteria required for adequate long-term performance of protection layers have been presented by Seeger and Mueller (1996). In either country laboratory tests are performed for the evaluation of the suitability of protection layers. These tests which differ in both countries are modeling the function of the protection layer under simplified boundary conditions.

The adequacy of such „index“-tests is not known, because there is no real long-term field experience with the performance of protectors. As a contribution to the discussion of GM protection issues, results are presented here of some large scale model tests which were carried out at the LGA Geotechnical Institute at Nuremberg in Germany.

## 2 STANDARD PROTECTION EFFICIENCY TESTS

In the German standard test for the evaluation of the efficiency of protection layers, samples of the protector together with the GM of at least 300 mm, in our case 500 mm diameter, are submitted to loads in a device shown on Figure 1.

The coarse drainage aggregate above the protector consisted of natural river gravel 16 to 32 mm in the case reported here, and there was a 20 mm thick elastomer layer of 50 Shore hardness below the loaded test sample as specified in the GDA-Recommendations (1997). A vertical stress of 1,350 kPa at a temperature of 20°C was applied for 100 hours, and the resulting deformations at the lower surface of the GM were recorded by means of thin soft metal sheets. The deformed shape of the ductile metal sheets was transferred to plaster and after hardening, the micro-topography of the gypsum block was surveyed by laser to be evaluated with respect to the deduction of strains that occurred in the GM below the protecting geocomposite by data analysis. The results of the standard tests on the different products for protective layers reported here are presented on Table 2.

### 3 GEOSYNTHETICS FOR PROTECTION

The cushioning effect of protectors for GMs can be achieved by mineral layers such as sand, by geosynthetic sheets or by combinations of these two types of materials. Out of the great number of different products available, 6 geosynthetic protection layers were selected for the study reported here. They are listed on Table 1.

The geocomposite product no. 1 consists of rubber tire chips enveloped by geotextiles. No. 2 is a geocomposite routinely installed in many civil and environmental applications for drainage purposes, it was tested as a double layer protector. The geocomposites no. 3 and no. 4 are essentially mattresses filled with sand at the construction site. They are tailored to the needs of the particular landfill site and prefabricated. Protectors no. 5 and no. 6 are very robust mechanically bonded nonwovens. They are applied as single or double layers at the base of landfills, depending on the amount of overburden; in the study reported here, the efficiency of single and double layers was tested. The protection geocomposite on test fields no. 7 and no. 8 contains sand. The sand is filled into prefabricated geosynthetic sheets at the construction site.

### 4 LARGE SCALE TESTS

At the LGA Geotechnical Institute large scale model tests were carried out, primarily for the determination of the soil-structure interaction of HDPE drainage geopipes and the surrounding soil (Zanzinger and Gartung 1998). The model was 5.4 m long, 4.4 m wide and 2.0 meters high. At the base it consisted of a composite liner, CCL of 0.6 m and HDPE GM of 2.5 mm thickness. The GM was protected against puncturing by a layer of geosynthetic protectors. The total area of 24 m<sup>2</sup> was subdivided into 8 test fields covered with 6 different products. In two cases two test fields were provided with identical protectors. The

3	0.34	0.99	0.11	0.75
4	0.02*	0.19*	0.05	0.46
5	0.06	0.17	0.09	0.58
6	0.09	0.26	0.10	0.92
7	0.07	0.62	0.07	0.79
8 = 7	-	-	0.05	0.78

\* sample taken from a landfill construction site, tested at  $\sigma = 1,350$  kPa,  $\vartheta = 40^\circ$  C,  $t = 1,000$  h

drainage layer was composed of natural river gravel 16 to 32 mm, above which a mixture of sand-wood shavings was placed as a waste material substitute. The entire model was encapsulated with concrete slabs and tied together with high strength steel tension rods. So a uniformly distributed vertical stress representative of the over-burden of 60 m of solid waste could be applied via hydraulic flat jacks. Details of the loading procedure and the stress distribution within the model are given elsewhere (Zanzinger 1996).

For the quantitative determination of the performance of the protectors each test field was equipped with a 520 mm x 520 mm sheet of soft ductile metal at the lower surface of the GM in the zone of maximum vertical stresses below the foot of the structural arch which developed in the gravel adjacent to the geopipe. The recording procedure for the deformation measurement of the GM was the same as in the standard laboratory test. The metal sheet follows the deformation of the GM without any resistance, so also without developing any stress. After exhuming, the metal sheets depict the exact shape of the deformed GM. The micro-topography is then recorded by a plaster imprint which is surveyed with excellent precision by laser-measurements at 3 mm centers in two directions. As a result, a three dimensional image of the deformed GM is obtained. An example of the measured micro-topography is shown on the lower part of Figure 2.

Applying a detailed geometrical analysis to the deformation data, the distribution of strains in the GM is determined and plotted as shown on the upper part of Figure 2.

## 5 TEST RESULTS

Table 2 summarizes the most significant test results. It can be seen, that the average strains as well as the maximum strains determined in the standard laboratory test under a vertical stress of 1,350 kPa applied for 100 hours are somewhat smaller than the strains determined by the large scale test under a load representative of 60 m of waste

overburden applied for 6,500 hours (9 months). At test fields no. 7 and 8 where the protection is mainly achieved by about 20 mm of sand and the geotextiles are merely used as containers, hardly any differences between the two testing methods occurred.

Perhaps the most significant difference between the standard laboratory tests and the large scale test is their duration. The load was applied 65 times longer in the large

Figure 2. Image of the deformed GM and measured strain distribution

scale test than in the smaller lab tests. So it is conceivable that the larger deformations of the GM in the large scale test indicate the time dependent behavior of the polymeric geocomposites. But since there are also some other differences in the testing procedures, such as the stiffness of the base material: elastomer in one case, compacted clay in the other case and since the stress acting on the geomembrane in the large scale test is not exactly known, some other factors may also have contributed to the differences in the test results.

The performance of the sand filled geotextiles, test fields no. 3 and 4 and no. 7 and 8 is somewhat surprising. These systems which can certainly be considered suitable and durable because they employ mineral constituents, exhibit the largest values of maximum strains.

In case of the composite of test fields no. 3 and 4, the sand filled mattress with the greatest thickness and mass per unit area, the reason for the behavior can be assigned to the high degree of sand filling in the large scale test. The mattress transmits the vertical load along parallel lines. So the surface of the GM and below it the surface of the mineral sealing layer as well appear undulated. If the mattress is filled with less sand, this undulation can be minimized or avoided. This becomes evident, when the much smaller strains measured under conditions in the field (see Table 2, system no. 4: sample from a landfill side) are taken into account.

The protector no. 7 and 8 is thinner than the one of no. 3 / no. 4. The lower geotextile layer of the geocomposite is connected by welding points, and these welding points are stiffer than the surrounding elastic sections as matter of fact, the deformation of the GM is not caused by the drainage material above the protector but rather by the protector itself. So in the local region of the welding points there is an arching effect and the geomembrane is moving upwards.

These strains of the GM below sand filled protectors have to be regarded differently than those which are measured below pure geosynthetic protectors, because they are initiated by the structure of the protector. They are certainly tolerable at the recorded order of magnitude.

## 6 CONCLUSIONS

There is a difference in the maximum strains measured by standard protection efficiency tests and large scale field tests. If the large scale field tests are considered closer to actual field conditions, it turns out that the standard laboratory test underestimates the local maximum strains of the GM. So the lab test should be regarded as an index test rather than a performance test.

The local maximum strains of the geomembrane protected by geocomposites containing sand were greater than those of the tested geocomposites without mineral components. In all cases the maximum strains measured in the large scale test were less than 1 %. In our opinion all

geosynthetic protection layers tested in the study presented here, performed successfully and are suitable for use at the base of solid waste landfills.

## ACKNOWLEDGMENTS

The large scale tests for the study of the geopepe-soil interaction were financially supported by the Ministry of the Environment, the State of Bavaria. The support is gratefully acknowledged.

**ABSTRACT:** An adequate protective cover system is essential for preventing damage to the landfill geomembrane liner from impact, over-stressing, tearing, or puncturing during and after construction. The current method for ensuring protection of the geomembrane liner usually employs a soil layer that is 0.3 m thick, and in some cases uses a nonwoven geotextile between the soil and geomembrane for increased protection. The soil layer must possess a minimum hydraulic conductivity of  $1 \times 10^{-3}$  cm/s so that it also functions as a drainage layer. The optimal thickness and appropriate gradation of the soil to use in the protective cover and drainage layer have not been established. Furthermore, the optimal weight (or mass per unit area) of the geotextile has not been determined. In order to address these issues, field and laboratory tests were performed to determine the effects of soil gradation, presence of a geotextile, construction loading, and long-term waste loading on the geomembrane protection. The results of this testing demonstrated that a 0.3 m thick soil layer consisting of particles with  $D_{50}$  less than 30 mm and sphericity greater than 0.8 overlain on a  $270 \text{ g/m}^2$  nonwoven geotextile serves as an efficient protective cover system for a 1.5 mm thick HDPE geomembrane liner when it is constructed using construction equipment which exerts a ground pressure less than 30 kPa. This protective cover system was also found to be effective even under long-term waste loading up to a maximum pressure of 1400 kPa. However, a rational design approach taking into account site-specific conditions will provide the most optimal protective cover system for the geomembrane liners.

## 1 INTRODUCTION

An adequate protective cover system is essential for preventing damage to the landfill geomembrane liners from impact, over-stressing, tearing, or puncturing during and after construction. Currently, specific USEPA regulations on protective cover systems do not exist other than the stipulation that the leachate drainage layer which overlies directly above the geomembrane liner should be selected such that leachate head does not exceed 0.3 m. Some state landfill regulations additionally stipulate that the drainage layer material must possess a minimum hydraulic conductivity of  $1 \times 10^{-3}$  cm/s and a minimum thickness of 0.3 m. Many materials meet these requirements to be suitable for use in the drainage layer. These materials include soils, geosynthetics, recycled materials (e.g., shredded scrap tires), or a combination of these materials. Soils have been conventionally used; however, geosynthetics and recycled materials have also gained wide acceptance.

In addition to the efficient drainage of leachate, the designer must also assess the potential damage to the geomembrane liner during and after the construction of the drainage layer. Intuitively, there is a greater potential for geomembrane damage if a soil consisting of large size angular particles is used. Thus, the drainage layer material must be selected such that it serves a dual purpose, both as an efficient drainage medium and as an adequate geomembrane protective cover.

The common design practice is to use a soil layer to serve as a protective cover as well as a drainage layer. Optionally, a geotextile is placed above the geomembrane prior to the placement of the soil. The current approach to the selection of the soil type is mainly based on the minimum hydraulic conductivity requirement;

however, a wide range of soils can possess hydraulic conductivities equal to or greater than the required  $1 \times 10^{-3}$  cm/s. Therefore, an additional requirement which ensures maximum protection to the geomembrane liner is needed. In addition, the adequacy of using a 0.3 m thickness for the leachate drainage layer to serve as a protective cover is unknown. Furthermore, the necessity of using a geotextile above the geomembrane and, if necessary, the type of geotextile needed is unknown. Generally, protective cover systems are designed based on an empirical approach or the personal judgement of the designer. In order to develop a rational design approach, several researchers have performed both theoretical and experimental studies.

In this paper, an overview of previous studies performed on protective cover systems is provided first. Then, a summary of findings from a research study performed at the University of Illinois at Chicago (UIC) which involved both field and laboratory testing on protective cover systems is presented. Finally, a rational approach to the design of protective cover systems is outlined.

## 2 PREVIOUS STUDIES ON PROTECTIVE COVERS

Giroud (1992) evaluated the effects of placing a geotextile on the top, the bottom, or on both sides of the geomembrane on properties of the geomembrane. Puncture and impact tests were performed using a variety of 0.75 mm-thick geomembranes and 200, 400 and  $600 \text{ g/m}^2$  nonwoven needle punched geotextiles. These test results showed that using a geotextile either on top, bottom or on both sides increases the puncture and impact resistance over the geomembrane by itself. However, the combined effects of using a geotextile with soils over the

geomembrane were not investigated in this study.

Motan et al. (1993) performed laboratory testing using a pressure chamber in which a layer of angular gravel was formed by mounting particles with epoxy onto a plywood base, a geotextile was then placed, and finally a 1.5 mm thick smooth geomembrane was placed over the geotextile. Air pressure was applied in increments up to 815 kPa and then released. The geomembrane sample was removed and multi-axial tension tests were performed. This testing was repeated with geotextiles with four different weights of three different brands. Although beneficial effects of using a geotextile were observed, there was no consistent trend observed to conclude if one geotextile was better than the other. The testing conditions used in this study simulated protrusions from the subgrade. Only one particular soil was used and the soil particles were not allowed to move or reorient during the loading.

Koerner and his co-investigators reported a comprehensive investigation performed at Drexel University in order to determine the puncture protection of 1.5 mm thick HDPE geomembranes under different conditions and the results have been published in a three part comprehensive paper (Wilson-Fahmy et al., 1996; Narejo et al., 1996; Koerner et al., 1996). This investigation included a theoretical approach, an extensive laboratory experimental program, and a simplified design procedure. The theoretical approach is based on tensioned membrane theory and assumes axi-symmetric conditions on a geomembrane overlain on a single isolated protruding object rising above a firm subgrade. The effects of the height and top shape of the protrusion on the puncture resistance of geomembrane under the application of hydrostatic pressure were studied. The effects of the presence of geotextile between the geomembrane and the protrusion was also analyzed. Based on the comparison of pressures required for the initiation of yield conditions for a 1.5 mm thick HDPE geomembrane, it was concluded that an increase in the protrusion height, which is correlated to soil particle size, reduced the puncture resistance of the geomembrane. However, an increase in the radius of the protrusion shape, which reflects rounded or subrounded compared to angularly shaped particles, resulted in higher puncture resistance. In addition, it was determined that the effect of increasing the mass per unit area of the protection geotextile proved to significantly increase the puncture resistance of the geomembrane.

The above theoretical study was augmented with a laboratory testing program which involved: (1) hydrostatic pressure truncated cone puncture tests as per the standard test method ASTM D 5514, (2) similar tests except with cones substituted with isolated stones, (3) hydrostatic tests with geomembranes overlain on a bed of stones, and (4) geostatic tests which involved one truncated cone overlain by a geomembrane which in turn was overlain by a layer of sand and then was subjected to loading through the use of a rigid plate. The loading was gradually increased until failure of the geomembrane occurred. Some long-term tests were also conducted which involved loading to the fraction of its failure load and maintaining it for a long duration or until failure occurred. The different test variables considered in this testing program included different cone heights, different thicknesses of HDPE

geomembrane, and a 1.5 mm thick HDPE geomembrane with different protective geotextiles. The tests with isolated truncated cones or stones revealed that the geomembrane puncture resistance increases when: (1) the mass per unit area of the protective geotextile is greater, (2) protrusion heights are smaller, and (3) protrusion shapes are rounded as compared to angular. The arching and creep effects are also found to influence the geomembrane puncture resistance. All of these results are very useful in evaluating the geomembrane protection against isolated protrusions from the subgrade. In tests with a layer of packed stones, geomembrane failure could not be achieved; therefore, the signs of yield conditions were visually observed.

Using the puncture test data obtained using the isolated truncated cones and isolated stones, an empirical equation was suggested to calculate an allowable stress for a 1.5 mm thick HDPE geomembrane. This equation involves mass per unit area of the protective geotextile, protrusion height, and a series of modifying factors and partial factors of safety to account for the field conditions such as stone shape, packing density, soil arching, creep and chemical/biological degradation as well as a global factor of safety to account for uncertainties in the formulation.

The above study by Koerner and his co-investigators clearly documents the beneficial effects of using a geotextile to protect the geomembrane from damage due to isolated protrusions in the subgrade. The tests performed with a layer of stone closely simulated the protective cover and drainage layer over a geomembrane. However, the damage to the geomembrane in these tests was only assessed visually; therefore, quantification of the extent of physical changes that occurred for different stone types was subjective. The proposed design procedure is conservative because it is mainly based on the test results using isolated truncated cones or stones rather than test results using a bed of stone. Also, the values of different modification factors and partial factors of safety are required in using this procedure. In addition, the effects of construction loading are not addressed in this methodology.

Richardson (1996) investigated damage induced to a geomembrane when it is subjected to construction loading. A variety of geosynthetic cushions were evaluated to protect the geomembrane under two types of construction equipment loading conditions. A particular soil was employed with two different thicknesses 0.3 m and 0.6 m. It was found that even the lightest of geotextiles offered increased protection from scratches and dents. From laboratory wide width tensile testing, it was concluded that the recommended weight for a nonwoven geotextile, based on a factor of safety of three, was a 405 g/m<sup>2</sup> for a normal pressure of 345 kPa and linearly increased to approximately 1519 g/m<sup>2</sup> for a pressure of 2068 kPa. In this study, the yield strain and load correlated well with the visual damage to the geomembrane. However, other studies have found that physical changes to the geomembrane do not affect the yield strain and load, but the ultimate strain and load are affected (Reddy et al., 1996).

Among other countries, German regulations specify more stringent requirements on protective cover systems for the geomembrane liners (Brummermann et al., 1994). According to these regulations, if a strain as small as 0.25% is induced due to

local deformation of the geomembrane, the protective cover system is deemed unsuitable (Seeger and Muller, 1996). The yield stress of a 1.5 mm smooth geomembrane liner as determined by a wide strip tension test is approximately 18%. Even a third of this strain to reflect a factor of safety of 3 would be significantly higher than that of the German regulatory limit of 0.25%. Due to the strict regulations on the allowable strain in the geomembrane, the protective cover layer is constructed as a separate layer underneath the drainage layer. Three types of materials are commonly used for these protective cover layers: (1) nonwoven geotextiles with masses per unit area that are greater than 2000 g/m<sup>2</sup>, (2) sandfilled geotextiles or woven mattresses, and (3) nonwoven geotextiles with masses per unit area greater than 1200 g/m<sup>2</sup> that are covered with a coarse (0-8 mm) particle layer with a thickness of 15 cm or greater. Additionally, German systems use a geomembrane that has a 2.5 to 3 mm thickness and a drainage layer that employs a very coarse gravel that is graded from 16 to 32 mm (Seeger and Muller, 1996). Thus, it appears that the protective cover systems used in Germany are overly conservative.

### 3 RESEARCH ON PROTECTIVE COVERS AT UIC

Research conducted on protective covers for landfill geomembrane liners at UIC involved both field and laboratory testing to assess the performance of different protective cover conditions and to develop a rational design approach. An overview of the field and laboratory testing is provided in this section and the recommended rational design approach based on these test results is provided in the next section.

The procedures and results of field testing performed to evaluate different protective cover systems under construction loading have been described in detail by Reddy et al. (1996). This testing included seven test pads in order to determine the soil type, geotextile, and construction equipment that best protected the 1.5 mm thick smooth HDPE geomembrane liner. Two soils, a fine gravel and a medium gravel, were tested both with and without a 270 g/m<sup>2</sup> nonwoven geotextile. Two types of dozers, a light and a heavy dozer, were used for construction and reflected the typical field loading conditions. After the application of repetitive construction loading, geomembrane samples were exhumed, visually observed, and tested in the laboratory to assess the effects of physical changes on the properties of the tested geomembranes as compared to the virgin geomembrane. The laboratory tests performed on the exhumed geomembrane samples included wide strip tension, multi-axial tension, and water vapor transmission (WVT) tests. Typical results of multi-axial tension tests are presented in Figure 1.

These results showed that the physical changes in the geomembrane are reflected in the differences in the elongation at burst from multi-axial test and the ultimate strain and ultimate stress from wide strip tensile tests as compared to the values for the virgin geomembrane. The physical changes were significant for coarser soil and for heavy construction loading conditions. It was concluded from this study that a 270 g/m<sup>2</sup> nonwoven geotextile can significantly protect the geomembrane from

construction loading even when using construction equipment exerting a pressure of 46 kPa is used.

The field testing was complemented with a laboratory testing program in order to assess the protective cover systems under simulated long-term waste loading conditions. These tests were performed in a specially constructed simulation test setup. The details of the test setup and testing procedures have been given by Reddy and Saichek (1997). For these tests, an elastomer, which possessed compressibility similar to that measured for a typical compacted clay, was laid at the bottom of the test setup, and then a geomembrane was laid on the top of the elastomer. Different protective systems were installed over the geomembrane with different soils both with and without a geotextile. The soils used ranged from sand to gravel corresponding to D<sub>50</sub> values of 0.65 to 30 mm, respectively. The sphericity values ranged from 0.798 for the crushed gravel to 0.846 for the fine gravel. A rigid plate was placed on the cover system and incremental loading up to 1400 kPa was applied. The load was maintained constant for 48 hours and then gradually released. The geomembrane was then carefully exhumed and visually observed. Multi-axial tension, wide strip tension and WVT tests were performed similar to the field testing program in order to characterize the physical changes that the geomembrane had undergone due to loading. These test results also revealed that physical changes were reflected in the elongation at burst from multi-axial tests, and the ultimate stress and strain from wide strip tension tests. Overall, these long-term simulation testing results showed a similar trend in that a 270 g/m<sup>2</sup> geotextile adequately protected the geomembrane even when it was subjected to a high pressure of 1400 kPa. For long-term testing performed without a geotextile, the geomembrane elongation at burst and, generally, the stress and strain at break also decreased as the soil particle size increased. Figure 2 shows the changes in the elongation at burst observed as a function of mean particle size. The results for the tests incorporating a 270 g/m<sup>2</sup> geotextile are also shown in this figure. These results demonstrate that larger size particles cause more extensive physical changes as compared to smaller size particles, and the beneficial effects of incorporating a geotextile weighing 270 g/m<sup>2</sup> is clearly evident.

It should be noted that although valuable information has been obtained from this study, additional field and laboratory testing using distinctly different soils, types of geotextiles, and loading conditions is essential in order to create an extensive database which can then be utilized to develop design charts.

### 4 RATIONAL DESIGN APPROACH

In order to construct a protective cover system which will perform the functions of efficient drainage and adequate protection of the geomembrane, a rational design approach is outlined below:

Step 1: Obtain information on the subgrade and the liner components. Particularly, the type and thickness of the geomembrane must be known before the protective cover design can proceed.

Step 2: Select the type of material which will serve as both the protective cover and drainage layer. Potential materials can be

Figure 1. Evaluation of Field Performance of Protective Cover Systems Under Construction Loading

Figure 2. Evaluation of Protective Cover Systems Under Long-Term Waste Loading Conditions

either soils, geosynthetics, recycled materials, or a combination of these materials. For this paper, soils are considered as the suitable choice of materials. The different soil sources in the vicinity of the project site should be identified, and costs associated with procuring soils from these sources should also be obtained.

**Step 3:** Characterize the soils which have potential for use as protective and drainage materials as well as being cost-effective. The characterization must include particle shape, grain size distribution, density, hydraulic conductivity, durability, and shear strength. The soil must possess a minimum hydraulic conductivity of  $1 \times 10^{-3}$  cm/s and be compatible with the leachate characteristics of the expected waste material in order to be further considered.

**Step 4:** Determine the clogging potential of the soil. Standard filtration, retention, and clogging procedures can be followed as detailed by Koerner (1994). In addition to investigating physical clogging, biological activity should also be studied. Logically, soils containing relatively large voids and a high permeability are less likely to become clogged by finer particles or biological growth.

**Step 5:** Perform a protective performance evaluation of the potential soils under both construction and long-term loading conditions. This evaluation provides the necessary thickness of the soil and the necessity of using a geotextile. The UIC research results showed that a 0.3 m thick soil layer consisting particles with  $D_{50}$  in the range of 0.65 to 13 mm and sphericity greater than 0.8 placed over a  $270 \text{ g/m}^2$  nonwoven geotextile will provide adequate protection against low ground pressure (<30 kPa) construction equipment as well as long-term waste loading pressures up to 1400 kPa. These results may be used as an initial guidance for the selection of soil gradation; however, a site-specific testing program using the procedures developed at UIC (Reddy et al., 1996; Reddy and Saichek, 1997) is highly desirable.

**Step 6:** Evaluate the selected system for stability on the slopes to ensure that no sliding will take place within any material layer or along any interface.

**Step 7:** Stipulate QC and QA procedures in order to ensure that the materials, equipment, and construction procedures meet the specifications. The composition and placement of the first few lifts of waste should also be monitored to ensure that possibly damaging waste products, such as old concrete reinforcement bars, are not located directly on top of the protective cover soil.

## 5 SUMMARY

The current practice for geomembrane protection is to use a 0.3 m thick soil layer with or without an underlying geotextile. The protective soil layer also serves as the leachate drainage layer and must possess a hydraulic conductivity greater than  $1 \times 10^{-3}$  cm/s. Employing an excessively thick layer of protective cover soil is uneconomical, and using a layer that is too thin increases the susceptibility of the geomembrane to damage. The type of soil, particularly the shape and size of the particles, also influences the degree of protection offered to the geomembrane. In addition, the beneficial effects of the geotextile below the soil layer have not been well quantified.

Comprehensive field and laboratory testing undertaken at UIC was aimed at determining the adequacy of different cover systems during construction and under long-term waste loading conditions to protect a smooth 1.5 mm high density polyethylene (HDPE) geomembrane. The field investigation involved the testing of cover systems that were comprised of different soils with or without a geotextile and were subjected to various construction loads. The laboratory investigation involved the development of a simulation test apparatus and testing of various protective cover systems under incremental loads to simulate increasing waste heights. The laboratory simulated protective cover systems were comprised of a soil layer with varied soil type both with and without a geotextile. Damage to the geomembrane liner was quantified by performing water vapor transmission (WVT), multi-axial tension, and wide strip tension tests on the geomembrane samples exhumed after both field and laboratory simulation testing. These test results allowed the evaluation of the relative protective performance of different protective cover systems tested in this study.

The protective performance was found to depend on the soil type, incorporation of a geotextile, construction loading, and long-term waste loading. The geomembrane protection was found to be significantly dependent on the soil particle size. A 0.3 m thick layer of soil consisting of particles with  $D_{50}$  less than 30 mm and sphericity greater than 0.8 provided greater protection. Incorporation of a  $270 \text{ g/m}^2$  nonwoven geotextile significantly enhanced geomembrane protection. Additionally, the use of construction equipment with ground pressure less than 30 kPa caused less damage to the geomembrane. Protective cover systems meeting these criteria are found to perform satisfactorily under long-term waste loading up to 1400 kPa. Finally, a site-specific testing should be conducted, where possible, to determine the most efficient and economical protective cover system.

## ACKNOWLEDGMENTS

Financial support for this project was provided by Waste Management Inc. The National Seal Company made their laboratory facilities and personnel available for the geomembrane testing. The assistance of John Siebken of the National Seal Company is gratefully acknowledged. The authors are thankful to S. Motan, S. Bandi, M. Finy, and J. Rohr for providing valuable comments during the course of this research.

**ABSTRACT;** Geomembranes such as HDPE and EPDM are used as a liner in waste landfill. When they experience deformation during service life time by differential settlement of subgrade soil or by the localized settlement around pieces of aggregate beneath the liner, tensile stress creates within the geomembrane. Non-woven geotextiles are also laid over and/or beneath it in order to protect against puncture from the gravel or sharp-edged material in waste. In this paper, first, a relation between amount of elongation  $S$ , creating maximum tensile stress  $\sigma_{max}$  and frictional coefficients  $\mu$  between geomembrane and the adjacent material is derived based on theory of elasticity. Next, model tests such that a geomembrane was laid on subgrade and the subgrade was forced to subside locally are presented. The tests' results showed that placing a geotextile between geomembrane and sand gave a meaningful effect on decreasing a tensile strain creating within geomembrane.

**KEY WORDS:** Geomembrane, Geotextile, Tensile Strain, Differential Settlement, Laboratory Test, Theory of Elasticity

## 1 INTRODUCTION

Geomembranes such as HDPE and EPDM are important component of a liner in waste landfill. When they experience deformation during service life time by differential settlement of subgrade soil or by the localized settlement around pieces of aggregate beneath the liner, tensile stress creates within the geomembrane. If the elongation is larger, creating maximum tensile stress may become larger and bring a rupture of the geomembrane. However the strain distribution and/or strain is, the authors think, is dependent on not only an elastic modulus and a thickness of geomembrane but also a frictional resistance between geomembrane and above/beneath materials. The frictional resistance is function of constrained stress (surcharge presser acting on it) and frictional coefficient between materials

Non-woven geotextiles are usually placed overand/or beneath the geomembrane for a purpose of protection from a puncture of it induced by the gravel or sharp-edged material in waste. Fortunately, a frictional coefficient between geotextile and geomembrane is usually much lower than that on intersurface between geomembrane and soil (Ingold; 1991). Therefor, placing a geotextile over and beneath is thought to have a function of decreasing the maximum strain even if gross elongation is same.

In this paper, the authors derive an elastic formula relating maximum stress (strain), surcharge pressure and frictional coefficient to a given elongation. Then they show the results of experiment where the modeled subgrade overlaid by geomembrane was forced to subside locally.

## 2 ELASTIC FORMULA

Fig. 1 Schematic drawing of geomembrane embedded in soil

Let us consider a situation that a geomembrane having a thickness of  $t$  and an elastic modulus of  $E$  is embedded in ground and one edge of the geomembrane is pulled by a force of  $T = \sigma_{max} \cdot t$  as shown in Fig. 1. The geomembrane should experience frictional resistance of  $\mu_U \cdot \sigma_n$  and  $\mu_L \cdot \sigma_n$  on top and bottom surfaces, respectively. Assuming that strain creates within an extent of  $L$  from the edge, the relation between tensile stress  $\sigma_x$ , strain  $\epsilon_x$  and infinitesimal deformation  $ds_x$  at point  $x \leq L$  is expressed as

$$\frac{ds_x}{dx} = \epsilon_x = \frac{\sigma_x}{E} \quad (1)$$

A equilibrium equation of force at point  $x$  is given by

$$\sigma_x \cdot t = \sigma_{max} \cdot t - \int_0^x (\mu_U + \mu_L) \cdot \sigma_n \cdot dx \quad (2)$$

Substituting Eq.(2) into Eq.(1) and then integrating  $ds_x$  over an extent of  $L$ , we can obtain an elastic formula (3) representing elongation  $S$  (Imaizumi et al., 1996).

$$S = \frac{(\sigma_{max} \cdot t)^2}{2 \cdot E \cdot (\mu_{tl} + \mu_L) \cdot \sigma_n} \quad (3)$$

The basic concept of this formula is thought to be just same as that of Co-energy presented by Giroud (1994).

Eq.(3) can be rewritten as Eqs.(4) and (5) for maximum stress  $\sigma_{max}$  and maximum strain  $\epsilon_{max}$ , respectively.

$$\sigma_{max} = \frac{\{2 \cdot S \cdot E \cdot (\mu_{tl} + \mu_L) \cdot \sigma_n\}^{0.5}}{t^{0.5}} \quad (4)$$

$$\epsilon_{max} = \frac{\{2 \cdot S \cdot (\mu_{tl} + \mu_L) \cdot \sigma_n\}^{0.5}}{(E \cdot t)^{0.5}} \quad (5)$$

From these equations, it is clearly pointed out that decreasing a frictional coefficient on intersurface between the geomembrane and the adjacent material can decrease the maximum tensile stress creating within it when same elongation of geomembrane is required..

### 3 EXPERIMENT

#### 3.1 Materials used

Dried Toyoura sand was used for both modeled base layer and protection layer over geomembrane liner. Two types of geomembrane, smooth surfaced HDPE and slightly textured EPDM, were used for a modeled liner. Two types of nonwoven geotextiles, continuous one with a thickness of 5 mm and stapled one with a thickness of 10 mm, were used for a protection layer beneath a liner. Mechanical properties of the geosynthetics are listed in Table 1. HDPE has a tensile strength about 3 times stronger and elastic modulus about 15 times larger than EPDM. Stapled nonwoven has the lowest strength among them.

Table 1. Mechanical properties of Geosynthetics

Type	Elastic Modulus (MN/m <sup>2</sup> )	Tensile Strength (MN/m <sup>2</sup> )	Yield strain (%)
HDPE	588.4	33.34	14
EPDM	39.2	9.81	640
C-N-GT	8.9	6.18	-
S-N-GT	0.13	0.33	-

C-N-GT; Continuous nonwoven geotextile  
S-N-GT; Stapled nonwoven geotextile

Table 2. Peak frictional coefficient between materials

	Toyoura		
	Sand	C-N-GT	S-N-GT
HDPE	0.36	0.16	0.16
EPDM	1.13	0.54	0.49

The amounts of frictional coefficients on intersurface between geomembrane and sand and geomembrane and geotextile were tested using direct shear test (Imaizumi et al. 1994) and are listed in Table 3. The value of frictional coefficient of HDPE geomembrane for geotextile is about 44 % lower than that for sand, and that of EPDM for geotextile is about 45 % lower than for sand.

Fig. 2 Setting up of geomembrane in a container

Fig. 3 Positions of strain gauges on geomembrane

#### 3.2 Testing Set-up and procedures

Modeled liner in landfill was constructed in container having a width of 200 mm, a length of 800 mm and a depth of 250 mm. A part of steel base with a length of 150 mm from its left end in the container can be forced to subside by electric screw jack (see Fig. 2).

First, Toyoura sand was rain-poured from a height of 750 mm to become a relative density of 95 %. The thickness of sand layer is 100 mm. Then a geomembrane with a width of 196 mm and a length of 750 mm was placed of which end was fixed to I-shaped steel mounted on subsiding base. In order to measure creating strain within a geomembrane, 16 strain gauges in total were pasted on top and bottom sides of geomembrane. Their pasting points are shown in Fig. 3.

After sand for a protection layer with a thickness of 150 mm was installed by a similar procedure employed for base layer, rubber-bag for air pressure was placed over the sand and steel cap was fixed to the container through bolts. In

some cases, nonwoven geotextile was placed beneath the geomembrane for protection.

The level of surcharge pressure was applied ranging from 98 to 196 kN/m<sup>2</sup> through air pressure rubber-bag. Then the subsiding part of steel base was forced to fall at moving rate of 1 mm/min. till it dropped by 40 mm. The strains creating in a geomembrane were measured through strain gauges at each 0.50 mm of base settlement and stored in diskette through data logger and personal computer.

#### 4 RESULTS AND CONSIDERATION

Axial strain was estimated as a mean value of measures of upper and bottom strains. Then gross elongation was calculated by integrating the estimated axial strains over entire length of geomembrane.

##### 4-1 Effect of type of geomembrane on strain distribution

Fig. 4 shows strain distributions of HDPE and EPDM without any protection layer of geotextile at gross elongation of 0.4 mm under a surcharge pressure of 98 kN/m<sup>2</sup>. In both cases, the amount of strain near the constrained left end is higher and decreases toward the other end, that is from point No.1 to point No.8, although point No.1 is not always highest. The point indicating the highest strain level is No.2 or No.3. This point is just over the edge of subsiding steel base. So, some additional pressure from arching behavior of soil may constrain the geomembrane and prevent inner geomembrane from stretching. Otherwise it is considered for some experimental error to be included.

Fig. 4 Strain distribution of HDPE and EPDM without geotextiles

This result shows that the strain does not create uniformly along the geomembrane when the underlying base ground settles differently, while some designing for geomembrane liner assumes that the strain would distribute uniformly. The shape of distribution is almost similar as

one above mentioned in elastic consideration and presented by Giroud (1994).

In Fig. 4, HDPE has somewhat wider distribution and lower level of strain than EPDM. This difference seems to attribute to the difference of their rigidity and frictional property between sand. EPDM having lower rigidity about one-fifteenth of HDPE and larger coefficient about 3 times is apt to concentrate the strain.

##### 4-2 Effect of level of frictional coefficient or normal stress on strain distribution

Figs. 5 and 6 show comparison of strain distribution of geomembrane with continuous nonwoven geotextile to that without geotextile. When the geotextile was placed beneath the geomembrane, strains distribute over wider extent and its level situated just above subsiding base is lower. This trend is much distinct in case of EPDM. Therefore, placing a geotextile beneath a geomembrane is effective to decrease the maximum induced by differential settlement.

Fig. 5 Strain distribution of HDPE with and without continuous nonwoven geotextile

Fig. 6 Strain distribution of EPDM with and without continuous nonwoven geotextiles

Figs. 7 and 8 show the distributions of strain in case of changing a level of surcharge stress. In case of HDPE without geotextile, a trend that a shape of distribution becomes narrow with increasing of surcharge pressure is barely found. In case of EPDM with stapled nonwoven geotextile, the trend is practically recognized.

Fig. 7 Strain distribution of HDPE at surcharge pressure of 98, 147 and 196 kN/m<sup>2</sup>

Fig. 8 Strain distribution of EPDM with stapled nonwoven geotextile at surcharge pressure of 98 and 196 kN/m<sup>2</sup>

## 5 CONCLUSIONS

- (1) Based on theory of elasticity, it is found that a amount of elongation of embedded geomembrane is functions of not only thickness and elastic modulus but also frictional coefficient and constrained stress.
- (2) EPDM having smaller rigidity and larger frictional coefficient have more localized strain distribution than HDPE.
- (3) Placing a geotextile beneath a geomembrane functions to decrease maximum induced stress practically.
- (4) Lager level of surcharge seems to make strain distribution localized.

In order to obtain more clear conclusion, the tests should be continued modifying a testing device and procedure.

## 6 ACKNOWLEDGMENT

The authors express their thanks Miss M.Abo for her helping the experiments in earnest. The financial support provided by Grant-in-Aid for Scientific Research (B) from The Ministry of Education, Science, Sports and Culture is also gratefully acknowledged

# Laboratory Study of High Density Polyethylene Geomembrane Waves

Te-Yang Soong

Research Engineer, Geosynthetic Research Institute, Drexel University, Philadelphia, Pennsylvania, USA

Robert M. Koerner

Professor and Director, Geosynthetic Research Institute, Drexel University, Philadelphia, Pennsylvania, USA

**ABSTRACT:** The behavior of waves of the type seen in field deployed HDPE geomembranes was evaluated in laboratory tests. Four experimental variables were evaluated: normal stress, original wave height, geomembrane thickness and temperature. Twenty-five separate tests were conducted, each for 1,000 hours duration. Contact between the geomembrane and the subgrade soil was not achieved in any of the tests performed. The results suggest that if waves are to be avoided, the geomembrane must essentially be flat on the underlying subgrade before backfilling. Furthermore, tensile strains were monitored in each test with resulting values as high as 4.9%.

## 1 INTRODUCTION

Geomembranes form the essential material component in many liner systems which require a liquid and/or vapor barrier. Such applications are landfill liners, landfill covers, liquid impoundment liners and other waste pile liners. The usual assumption in the placement of such liners (particularly for composite geomembrane/clay liners) is that they lay flat on the soil subgrade beneath them. Unfortunately, this is often not the case. Waves, or wrinkles, of different sizes often occur in the as-placed and seamed geomembranes, see Figure 1.

Figure 1. Photograph of waves in a field deployed and seamed geomembrane before backfilling or covering.

These waves have given the geomembrane community a certain amount of concern as to their behavior and/or fate after soil backfilling and/or covering by other geosynthetic materials. Figure 2 illustrates some possible deformation scenarios of geomembrane. The usual concerns expressed by many regulators, owners, engineers and installers are the following:

Figure 2. Deformation scenarios in geomembrane waves

- Intimate contact is not achieved. This allows for a potential leak through the geomembrane to spread over a relatively larger area as opposed to the area of the hole itself.
- Locations of large curvature suggest high stress concentrations. Such locations are susceptible with respect to stress cracking and/or a decrease in lifetime.
- The creation of "mini dams" which result in a less efficient removal of the liquid, as well as higher heads on the geomembrane.
- Cyclic heating and cooling might cause desiccation of underlying clayey subgrade soils.

The concern as to the ultimate fate of geomembrane waves should certainly receive attention insofar as a firm understanding of the problem. However, to date, all analyses and investigations into geomembrane waves have been semi-qualitative, e.g., see Giroud and Morel (1992) and Giroud (1995). A quantitative approach which evaluates the ultimate fate of geomembrane waves in a systematic and controllable manner is the focus of this study which is laboratory oriented. It is important to state that this study does not attempt to quantify the performance of geomembranes in the field stemming from the existence, or nonexistence, of such waves. What it does attempt to

quantify is the behavior of the waves as a function of the following four variables; normal stress, original wave height, thickness of geomembrane, and temperature.

Due to its common use in most environmentally related applications, high density polyethylene (HDPE) geomembranes were used throughout the study. In particular, one manufacturer's commercially available geomembrane was used. The only variation in material was the thickness of the specimens, which was one of the experimental variables. In all other cases, the thickness was maintained at 1.5 mm which is a commonly used value in many applications.

## 2 EXPERIMENTAL SETUP AND MONITORING

Four rigid boxes having dimensions of 300 mm long  $\times$  300 mm wide  $\times$  300 mm high were used to conduct the experiments. The front was fitted with a thick Plexiglas "window" to visually track and trace the profile of the wave's behavior. The waves were created by using geomembrane specimens longer than the inner length of the test box. After each specimen was placed in the box, sand backfilling was started from the end to the center of the box in a symmetrical manner. Consequently, the "slack" was "pushed" toward the center and, as a result, a reasonably symmetric wave was formed. The justification of using the relatively small test setups to simulate situations in the field are presented in an separate paper, see Soong and Koerner (1998). Along with steel reaction frames and a hydraulic pressurizing system, these boxes allow a application of normal pressure up to 1,500 kPa. This is equivalent to a solid waste landfill of approximately 125 m in height, i.e., a so-called "megafill". In addition, all four boxes can be simultaneously housed in a environmental room where constant environmental conditions can be maintained within ranges of 0 to 55°C temperature and 0 to 98% relative humidity. Photographs of a test box and the environmental room used in this study are shown in Figure 3. As seen in the figure, a data acquisition system was also available for strain gage measurements.

The experimental monitoring includes two parts: profile-tracing of the actual wave specimens and strain gage measurements. The latter part was used to quantify the tensile strains induced at different locations on the geomembrane wave specimens under various experimental conditions. The strain gages used in this study were electrical resistance (foil-type) strain gages having resistance of 120-ohms and gage length of 12.7 mm. With proper configuration, this particular type of gage measures strain within the range of  $\pm 5\%$  to an approximate accuracy of 0.25%. The installation procedure recommended by the gage manufacturer was followed. The surface cleaning and preparation was considered most critical in this regard.

Figure 3. Photographs of one of the test boxes and the environmental room used in this study.

## 3 EXPERIMENTAL DESIGN

Four series of 1,000-hour experiments were designed and performed to evaluate the effect of the four experimental variables on the behavior of HDPE geomembrane waves. Table 1 presents the experimental design for normal stress, original height of wave, thickness of geomembrane, and temperature. As seen, the effects of different variables were evaluated by varying one particular parameter while holding the others constant. In all cases, smooth HDPE geomembranes were used and strain gages were attached to the wave specimens at different locations with constant readout over the duration of the tests.

Table 1. Experiments conducted in this study

Parameter Evaluated	Experimental conditions			
	Normal Stress (kPa)	Wave Height (mm)	Geomembrane Thickness (mm)	Testing Temp. (°C)
Normal Stress	180	60	1.5	23
	360			
	700			
	1100			
Original Wave Height	700	14	1.5	23
		20		
		40		
		60		
Geomembrane thickness	700	60	1.0	23
			1.5	
			2.0	
			2.5	
Testing Temp.	700	14	1.5	23
		20		42
		40		55
		60		

## 4 EXPERIMENTAL RESULTS

The results of the experiments will be given on an individual variable basis. The original and final (after 1,000 hours) shapes of the geomembrane waves along with the locations of strain gages will be presented in graphic form. Values of the maximum strain measured, along with wave heights and height-to-width ratios, corresponding to each of the tests will be given in table form.

### 4.1 Effect of Normal Stress

As listed in Table 1, a 1.5-mm thick HDPE geomembrane wave specimens with a 60-mm original wave height was subjected to four different normal stresses, namely; 180, 360, 700, and 1,100 kPa. The temperature was maintained at 23°C for all experiments over the entire duration of the experiments, i.e., 1,000 hours. The original (same for all specimens) and the final shapes of all test specimens, obtained via profile-tracing through the Plexiglas window, are shown in Figure 4.

Six strain gages, numbered from 1 to 6, were originally bonded at the locations shown on the uppermost curve in Figure 4 for all specimens. Gages 1 to 3 were on the upper surface near the center and gages 4 to 6 were bonded on the lower side of the geomembrane near the edges. This was necessary since the gages respond more accurately under tension than compression.

Figure 4. Original and final shapes of wave specimens under varying normal stress (gridlines have dimensions of 10 mm  $\times$  10 mm).

A typical strain gage measurement result of the test conducted under a normal stress of 700 kPa is shown in Figure 5 where the measured strain is plotted against time. It is seen that the upper portion of this particular wave specimen experienced considerable strain with a maximum tensile strain of 3.4% recorded near the crest of wave. Table 2 summarizes such information for this series of experiments.

As shown in Table 2 the final wave height decreases with increasing normal stress. However, the height-to-width ratio increases with increasing normal stress, even more significantly. It was seen that the effect on the height-to-width ratio is essentially doubled in comparison

Figure 5. Strain measurement results of test conducted at 700 kPa

Table 2. Summarized results - Effect of normal stress

Normal Stress (kPa)	Final Wave Ht. (mm)	Final H/W <sup>1</sup> Ratio	Max. Strain (%)	Gage(s) of Max. Strain
0 (original)	60	0.47	+ 1.7 <sup>2</sup>	#1
180	47	0.47	+ 1.8	#1
360	42	0.51	+ 2.0	#1
700	38	0.58	+ 3.0	#1, 2 & 3
1100	34	0.62	+ 3.2	#2 & 5

1. Height-to-width ratio

2. "+" for tension, "-" for compression

with the effect on the final wave height. Since high height-to-width ratios generally indicate large curvatures and locations of high stress concentration, the overall effect of high normal stress is obviously unfavorable.

The maximum strain recorded in each experiment shows that tensile strain increases as normal stress increases. This is expected since the H/W values increase with greater curvature. Nevertheless, the geomembrane is tensioned significantly less than its yield point. (Note that the tensile yield strain for this geomembrane is in the range of 15 to 25% depending on the temperature.) Therefore, tensile yield is not challenged in any way.

### 4.2 Effect of Original Wave Height

The second series of 1,000-hour experiments was designed to evaluate the effect of the original wave height on the behavior of HDPE geomembrane waves. Five tests using 1.5 mm-thick wave specimens were conducted. The original wave heights were 14, 20, 40, 60, and 80 mm, respectively. All specimens were subjected to a constant normal stress of 700 kPa and maintained at a constant temperature of 23°C over the entire duration of the experiment. The original and final (after 1,000 hours) shapes of the test specimens are shown in Figure 6.

Figure 6. Original and final shapes of wave specimens with varying original height (gridlines have dimensions of 10 mm × 10 mm).

Table 3 was developed to summarize the test results. As seen, there was an approximate 40% reduction in height after 1,000 hours for all waves. As to the final H/W ratio, it increases with increasing original wave height. Note that for waves originally higher than 60 mm, the final H/W ratios exceeded a value of 0.5. There was no sign of achieving intimate contact between the specimen and the underlying subgrade after 1,000 hours, even for the wave with the smallest original height. With regard to the maximum strain recorded, an increasing trend is also seen with increasing original height.

Table 3. Summarized results - Effect of wave height

Original Wave Ht. (mm)	Original H/W <sup>1</sup> Ratio	Final Wave Ht. (mm)	Final H/W <sup>1</sup> Ratio	Max. Strain (%)	Gage(s) of Max. Strain
14	0.17	8	0.14	+ 0.2 <sup>2</sup>	#1
20	0.15	12	0.18	+ 1.2	#3
40	0.27	25	0.38	+ 2.4	#2 & 4
60	0.33	38	0.58	+ 3.0	#1, 2 & 3
80	0.33	47	0.65	+ 3.4	#2 & 4

1. Height-to-width ratio
2. "+" for tension, "-" for compression

#### 4.3 Effect of Geomembrane thickness

The third series of the experiments was designed to evaluate the effect of geomembrane thickness on the behavior of

HDPE geomembrane waves. Four tests using HDPE geomembrane wave specimens with thicknesses of 1.0, 1.5, 2.0, and 2.5 mm were conducted. The original heights of all specimens were approximately 60 mm. Owing to the various stiffness of the geomembranes having different thicknesses, a constant value of original H/W ratio could not be maintained, see Table 4. All specimens were subjected to a constant normal stress of 700 kPa and maintained at a constant temperature of 23°C over the entire duration of the experiments. The original and final (after 1,000 hours) shapes of the test specimens are shown in Figure 7.

Figure 7. Original and final shapes of wave specimens with varying thickness (gridlines have dimensions of 10 mm × 10 mm).

The summarized results generated by this series of tests, including both the strain gage and the profile-tracing monitoring, are presented in Table 4.

Table 4. Summarized results - Effect of GM thickness

GM Thickness (mm)	Final Wave Ht. <sup>1</sup> (mm)	Original H/W <sup>2</sup> Ratio	Final H/W <sup>2</sup> Ratio	Max. Strain (%)	Gage(s) of Max. Strain
1.0	27	0.24	0.52	+ 2.5 <sup>3</sup>	#5
1.5	38	0.34	0.58	+ 3.0	#1, 2 & 3
2.0	33	0.18	0.34	+ 3.1	#1, 2, 4 & 5
2.5	38	0.21	0.32	+ 3.3	#2, 3, 4 & 5

1. Original wave height = 60 mm
2. Height-to-width ratio
3. "+" for tension, "-" for compression

As shown in Table 4, with the only exception being the 1.0 mm-thick geomembrane wave, the following observations were made. First, the thickness of geomembrane has very little effect on the final height of geomembrane waves. There was an approximate 40% reduction in height after 1,000 hours for all waves. In other words, the original height essentially determined the final height of the geomembrane waves. Second, the geomembrane thickness did show a significant effect on the final H/W ratio of the waves. That is to say, the final H/W ratio decreases with increasing geomembrane thickness. The latter observation can be interpreted in an alternative manner. That is, for waves with the same original height, thicker geomembranes resulted in smaller but wider voids beneath the wave. Third, the maximum strain recorded in each experiment shows that tensile strain increases as the thickness of geomembrane increases.

#### 4.4 Effect of Testing Temperature

The fourth series of experiments was performed to evaluate the effect of testing temperature on the behavior of HDPE geomembrane waves. Three sets of experiments, each consisting of 1.5-mm HDPE geomembrane waves with original heights of 14, 20, 40, and 60 mm, were conducted at temperatures of 23, 42 and 55°C.

The original shape of all waves were formed at 23°C with approximately 100 mm of sand backfill over them. Temperature was then increased, as necessary, to the desired value. This was meant to replicate field situations where the exposed geomembranes experience an increase in temperature after placement and seaming. The test boxes were then filled with sand, followed by a decrease in temperature back to 23°C, to simulate the decrease in sheet temperature of the field deployed geomembranes after the geotextile protection and drainage layers are placed. After approximately 24 hours, a constant normal stress of 700 kPa was applied. After another hour, temperature was increased from 23°C to the desired value and maintained for the rest of the experiment. The last step was intended to simulate a possible increase in the sheet temperature over the lifetime of landfills.

The original and final shapes of the test specimens, at three different temperatures, are shown in Figure 8. The summarized results generated from both parts of the monitoring is presented in Table 5. The values of maximum strain listed in the table correspond to the maximum final (after 1,000 hours) strain.

As seen in Table 5, temperature has only marginal effect on the final wave height and the final H/W ratio. For waves originally shorter than 40 mm, the maximum measured strain increases with increasing temperature. For waves originally higher than 40 mm, however, the maximum strain shows no clear trend with increasing temperature.

Figure 8. Original and final shapes of wave specimens having various original heights monitored at different temperatures (gridlines have dimensions of 10 mm × 10 mm).

Table 5. Summarized results - Effect of temperature

Original Ht. (mm)/ H/W <sup>1</sup> ratio	Temp. (°C)	Final Wave Ht. (mm)	Final H/W <sup>1</sup> Ratio	Max. Strain (%)	Gage(s) of Max. Strain
14 / 0.17	23	8	0.14	+ 0.2 <sup>2</sup>	#1
	42	10	0.19	+ 0.6	#4
	55	5	0.20	+ 1.3	#2
20 / 0.15	23	12	0.18	+ 1.2	#3
	42	14	0.21	+ 1.6	#4
	55	12	0.30	+ 2.1	#4
40 / 0.27	23	25	0.38	+ 2.4	#2 & 3
	42	25	0.42	+ 3.2	#3
	55	25	0.40	+ 2.1	#1
60 / 0.33	23	38	0.58	+ 3.0	#1, 2, 3 & 5

	55	28	0.55	+ 4.9	#1, 2 & 5

1. Height-to-width ratio

2. "+" for tension, "-" for compression

## 5 SUMMARY OF TEST RESULTS

Summarizing remarks, subdivided according to the physical manifestation of the wave, are as follows:

### Regarding the wave heights:

- Wave heights decrease with increasing normal stress.
- An average of 40% reduction in wave heights was observed after 1,000 hours.
- Varying thicknesses of geomembranes had only a marginal effect on the final wave heights.
- Varying temperatures (after the wave was formed) had only a slight effect on the final wave heights.
- The final wave heights recorded from all experiments varied from 5 to 47 mm.
- Contact with the subgrade was not achieved after 1,000 hours, even for the smallest wave at the highest testing temperature.

### Regarding the height-to-width (H/W) ratio:

- The height-to-width ratio of the waves increased (approximately linearly) with increasing normal stress.
- The height-to-width ratio of the waves increased (approximately linearly) with increasing original wave heights.
- The height-to-width ratio of the waves decreased (approximately linearly) with increasing geomembrane thickness.
- Varying temperatures had only a marginal effect on the final height-to-width ratio of the waves.
- The final height-to-width ratios of the waves recorded from all experiments varied from 0.14 to 0.65.

### Regarding the tensile strain at the end of the experiments:

- The tensile strain at the maximum point of curvature of the waves increased (approximately linearly) with increasing normal stress.
- The tensile strain at the maximum point of curvature of the waves increased (approximately logarithmically) with increasing original wave height of the waves.
- The tensile strain at the maximum point of curvature of the waves increased (linearly) with increasing geomembrane thickness.
- The tensile strain at the maximum point of curvature of the waves increased with increasing testing temperatures for waves originally smaller than 40 mm.
- The tensile strain at the maximum point of curvature of the waves showed no clear trend with increasing testing temperatures for waves originally higher than 40 mm.
- The tensile strains recorded from all experiments were as high as 4.9%.

## 6 CONCLUSIONS

The above summarized observations have resulted in the following conclusions:

- Geomembrane waves, which are induced in the field during placement and subsequently maintained during seaming, distort greatly upon the application of even a nominal normal stress. The distortion accentuates the height-to-width ratio of the wave.
- Over the 1,000-hour experimental time of stress application for the main series of tests, the waves did significantly decrease (approximately 40%), however, they never disappeared.
- The maximum tensile stresses occur at locations of maximum tensile strain. These locations are on the anticipated side of the waves, i.e., tension along the upper surface of the wave near its crest and tension along the lower surfaces where the wave curvature changes to accommodate the horizontal subgrade beneath the wave. Note that compressive stresses occur on the opposite side of the geomembrane but they are of less concern than tensile stresses.
- The maximum tensile strain measured in this series of twenty-five 1,000-hour experiments was 4.9%. Note that yield of HDPE geomembranes is in the range of 15 to 25% strain (depending on the temperature), thus yielding of the geomembrane is not suggested.
- It is important to note that this study did not address the possible implications of the waves, their possible leakage scenarios, nor long-term performance of the geomembranes involved.

## 7 ACKNOWLEDGMENT

The funding for the preparation of this paper was provided by the U.S. EPA. Financial support via David A. Carson under contract CR-821448 is sincerely appreciated. Some additional funding was provided by the Geosynthetic Institute's consortium of member organizations.

# Installation Procedure and Welding of Geomembranes in the Construction of Composite Landfill Liner Systems - Focus on "Riegelbauweise" -

Ulrich B. Aversch, Dipl.-Ing.

Institut für Baumaschinen und Baubetrieb, RWTH Aachen, Aachen, Germany

Rolf Th. Schicketanz, Dipl.-Ing.

Ingenieurbüro Schicketanz, Aachen, Germany

**ABSTRACT:** For an optimal composite sealing system one has to achieve, among others, that the geomembrane lies on the mineral layer in a so called "intimate contact". This requires a practically flat placement of the geomembranes over the whole area. The problems which you have to deal with when placing the geomembranes are to get the manufacturing conditioned imperfections under control as well as the waves in the geomembranes caused by sun or global radiation in order to achieve a flat surface before putting loads on the whole surface. This can be done by the "Riegelbauweise" ("Fixing Berm Construction Method" FBCM). Procedural and equipment parameters are presented.

**KEYWORDS:** Geomembrane Wrinkling, Installation, Intimate Contact, Riegelbauweise

## 1 INTRODUCTION

Landfills will continue to be indispensable in the foreseeable future. In order to avoid emissions the entire landfill area must be totally sealed and for this purpose cappings, side and base liners are used. The German guidelines "TA Abfall (1991)" and "TA Siedlungsabfall (1993)" advocate that landfill cappings and base liners consist of a combination of a mineral layer covered by a geomembrane (composite liner).

The composite liner consists of a minimum 75 cm mineral layer, as designed for a domestic waste landfill, or a minimum 150 cm mineral layer for a hazardous waste landfill, and a geomembrane (HDPE, thickness  $\geq 2.5$  mm).

This is supplemented by a drainage system consisting of a protective and a drainage layer. The protective layer might be composed of heavy-weight geotextiles ( $3.000 \text{ g/m}^2$ ) or of a combination of protective geotextile ( $1.200 \text{ g/m}^2$ ) overlaid with sand (0/8 mm) in a thickness of 15 cm. The drainage layer usually consists of graded permeable gravel (for example 16/32 mm). The composite liner and the drainage system together make up a landfill liner system, specially for base sealings (Figure 1).

The requirements on such a liner system, climatic considerations and the resulting scheduling commitments demand a meticulously drawn up structural and operational design for the implementation of the construction work and, in particular, for the utilisation of plant and machinery (Dornbusch et al. 1996).

Figure 1. Composite landfill liner system for hazardous waste (Germany).

## 2 PROCEDURAL AND EQUIPMENT PARAMETERS

The choice of effective plant and procedures is crucial for the technical and economic success of any building operation. This includes the scaling and performance-related coordination of the equipment line which must correspond to the particular requirements.

The various procedural steps in constructing a composite liner with a drainage system and the corresponding machinery are described in Aversch 1995 and are summarized in Figure 2 in the form of a process and an equipment line.

This paper focusses on the final procedural steps, beginning with the "Surface Treatment".

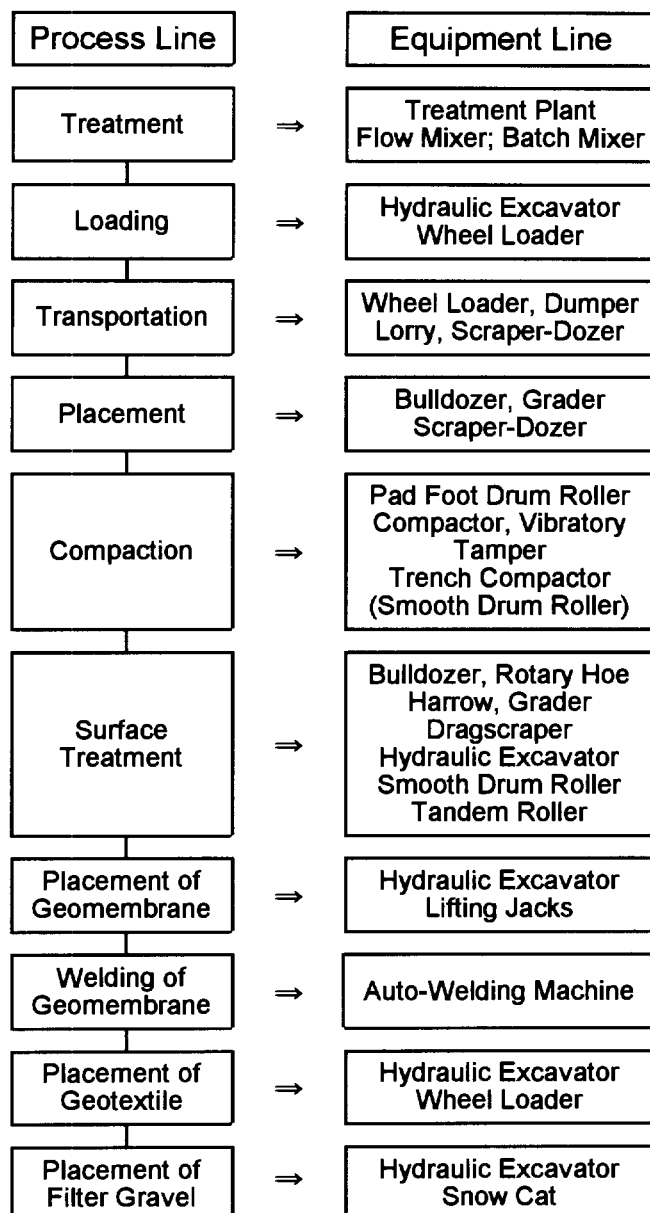

Figure 2. Process and equipment line.

## 3 SURFACE TREATMENT

The creation or rather the smoothing of the surface of a mineral layer poses the greatest difficulties for both personnel and machines. In order to obtain the intimate contact between the mineral layer and the geomembrane for the composite sealing effect, the clay surface must be plane, smooth and free of foreign matter, gravel or other objects. The surface of the mineral layer should not contain single grains of more than 10 mm diameter. Such grains must be fully embedded in the clay matrix. No mineral grains with sharp edges are allowed at the surface. According to the geomembrane approval directive set by BAM 1992 (Bundesanstalt für Materialforschung und -prüfung, Federal Institute for Materials Research and Testing), the surface of the compacted mineral layer must be absolutely clear of any abrupt changes in the surface structure. The BAM requirements allow for steps of at most 5 mm and level deviations of maximum 20 mm beneath a 4-m slat (screed) placed on top of the layer. Intolerable are deep dry-cracks, a wet or dusty-dry surface of the mineral layer during the installation of geomembrane, even when the required thickness of the mineral layer is achieved (Schicketanz 1992).

These requirements on the clay surface demand the utmost care in the implementation of the construction. This operational step can take up the same amount of time as the installation and compaction of an entire three-layer mineral liner (Aversch 1993).

Pad foot imprints cannot be levelled out by a smooth drum roller, even when using heavy models. Smoothing of the surface of a mineral layer according to the requirements demands a special procedural implementation. The following combination of techniques is favourable: the top layer must be superelevated (about the height of the pad feet), then compacted by foot drum roller. The additional millimeters will then be taken down by heavy levelling machines. For the smoothing process suitable machines are bulldozers without grousers (bogdozer model), graders or drag scrapers pulled by light tractors. The lighter the machine, the less damage will be done to the compacted clay layer, i.e. by track imprints.

Due to the possible development of shearing (which poses a threat to stability on embankments) and the subsequent breakdown in homogeneity, it is questionable to add further in-situ treatment of the earthen material by rotary hoe and harrow before the final surface treatment. However, this technique eliminates all disrupting imprints or surface roughness and a pre-smoothed surface of crumbly consistence is achieved.

A surface prepared in such a way has to be further treated by a combination of smooth rollers, consisting of heavy rollers (9-13 t) with smooth drum and ballon tyres, and light tandem rollers. Initially, one roller with smooth drum compacts the prepared surface; this can be carried out dynamically or statically. Further roughnesses, such as small hollows and wheel-prints of the rollers can only be removed using light compacting machines; any further passes using heavy rollers will create new defects. Suitable machines are tandem rollers with smooth drums and, possibly, dynamic vibration. The edges due to the shifting of the roller can be virtually avoided if the drums are displaced slightly with

Figure 3. Equipment line for the construction of a mineral layer.

each transition (about 1/3 of the breadth of the drum). One possible process line for the implementation of the above procedural steps is shown in Figure 3.

#### 4 INSTALLATION OF GEOMEMBRANES

The installation of geomembranes poses another challenge to personnel, because they cannot drive over the clay surface with heavy machines and even inappropriate footwear might leave intolerable imprints. The heavy, rolled-up geomembrane can therefore only be brought in on and placed from on-site roads outside the construction section. Hydraulic excavators are most useful for this purpose. Spreader bars attached to the boom can pick up the geomembrane rolls from both sides of the steel cylinder core. The hydraulic excavator can access the geomembrane across the trench to the construction section from outside. The geomembrane can be unrolled either by lifting the rolls onto jacks at the construction section side and pulling down on the geomembrane manually, while maintaining a smooth underside or the entire roll with its core can be unrolled onto the construction section (with auxiliary support using ropes on embankments). Both installation techniques involve manual work.

Wheel loaders can generally be used for transporting the geomembranes on site, but because of their limited reach are less suitable than hydraulic excavators with long cantilevers or telescopic booms.

#### 5 WELDING OF GEOMEMBRANES

The geomembranes are welded at the edges with auto welding machines according to the DVS-Guideline 2225, Part 4 (1996). They become plasticised by an electrically heated and controlled heating wedge, and the edges are then pressed together by two pressure rollers and welded. The machine is entirely controlled by micro-processor. Furthermore, all the welding parameters and quality assurance data are memorized, such as welding speed, wedge temperature, welding pressure, ambient temperature, temperature of the membrane surface, date, time, machine number and installation contractor, company's logo and number of weld or site. The machines should have a serial interface so that a site's overall installation design can be monitored and depicted by PC with a graphics program (long-term documentation, database). In addition it is possible to monitor all the welds visually with the limiting values on screen simultaneously, and thus defects can be located immediately.

The need for simple landfill base geometries must be reiterated here as this will reduce the number of welds required.

#### 6 INTIMATE CONTACT WITH MINERAL LAYER ("RIEGELBAUWEISE")

The required flatness of the geomembranes has often been a matter of controversy (Figure 4). The geomembrane sealing

component has to be in full surface contact with the next sealing component - the mineral layer - so that the surcharges lead to an intimate contact. It is possible to observe many different on-site techniques being applied in order to achieve this result. Despite all the problems mentioned previously, it is possible to achieve an evenly placed geomembrane on a flat surface if the personnel and contract management are efficient and the installation is carried out conscientiously.

Figure 4. Example of a wavy geomembrane.

Intimate contact between the mineral layer and the geomembrane requires a flat placement of the geomembrane over the entire area. This can be achieved using the "Riegelbauweise" ("Fixing Berm Construction Method" FBCM) which has been developed and described by Schicketanz et al. 1991.

HDPE has a heat expansion coefficient of a factor of approx. 20 times higher than, for example, steel. This expansion can be used to attain complete flatness of the geomembrane in the cooler evening hours which could never be achieved by mechanical means.

The imperfections caused by the production and delivery of geomembranes as well as the waves in the geomembrane caused by sun or global radiation have to be under control in order to achieve a flat surface before the surface can be covered with the protective and drainage material.

According to the method of "Riegelbauweise" (FBCM) the geomembranes are placed following a layout-plan of placement in the morning on the prepared mineral liner surface. After about 1 hour (to adapt to the ambient temperature) the geomembranes are adjusted and stretched a little to eliminate the waves in the geomembrane condition on delivery and unrolling. Then the geomembranes are fixed with sandbags to prevent wind suction etc. After welding and testing of the seams and cleaning of the geomembrane surface, the geosynthetic protecting layer is spread.

Before it gets cooler in the evening, so called cross-"fixing-berms", consisting of protecting sand layer or drainage gravel, are placed on the geosynthetic protecting layer at the ends of the geomembranes and at special locations (e.g. hollows, grooves, toes) to fix the geomembranes and keep them in position. The fixing berms

should not exceed a distance of more than 30 to 50 m in order to avoid transverse contraction of the geomembranes. In the evening the lower temperature causes the geomembrane to become flat and subsequently the whole area can be spread with the protecting or drainage mineral layer either during the same night or in the early morning of the next day to prevent the built-up of condensed water underneath the geomembranes as well as the formation of new waves (figure 5).

The grading of the mineral protective layer to the designed level and the placement of the drainage layer is carried out some days later during normal day time, since a direct heat effect on the geomembranes is prevented by the complete coverage and thus also no new waves can form.

The installation of geomembranes in composite liners to cover the entire surface evenly is made possible by the utilisation of the physical characteristics of the geomembrane, and if the welders are experienced in their work, they can weld the geomembranes without creating any pockets in spite of the waves which invariably exist. This has been confirmed by on-site observations and is to be seen in figure 6 to 8.

Figure 6. Example of a flat geomembrane on a landfill slope.

Figure 7. Example of a flat geomembrane on a landfill bottom.

Figure 5. Flat placement of geomembrane by "Riegelbauweise".

Figure 8. Example of a flat geomembrane on a landfill bottom.

## 7 STRESS LOAD ANALYSIS

The highest surface temperature measured in Germany on geomembranes of 2.5 mm thickness under direct sun exposure was not more than 60°C.

Since the fixing berms are placed later in the afternoon on the already cooling geomembranes, one can consider the temperature of the fixed geomembranes to be approx. 40°C. When covering the flat geomembrane with geosynthetics and protective sand layer or filter gravel, the temperature is usually not less than 15°C. With a temperature difference of  $\Delta T = 25 \text{ K}$  and a coefficient of linear thermal expansion of  $1.7 \times 10^{-4}/\text{K}$  the geomembrane will contain a strain of about 0.425%. At an accepted modulus of elasticity of about 600 MPa (MDPE) the induced stress is approximately 2.55 MPa, about 15% of the yield stress (about 17.5 MPa) of a common BAM-approved MDPE geomembrane (Seeger, S. and Mueller, W. 1996). This very low contraction stress level will additionally be reduced by stress relaxation while the geomembrane is in service. The service temperature of the geomembrane can - due to the increased leachate temperature - for the first 10 years be reckoned with up to about 35°C.

Therefore and on account of the MDPE resins used in Germany for geomembranes we see no danger of stress cracking or other kinds of failures when applying the "Riegelbauweise".

## 8 INSTALLATION OF PROTECTIVE LAYER AND DRAINAGE BLANKET

Analogous to the geomembrane, the protective geotextile can only be accessed to the placement area from the outside because it is not possible to allow heavy machinery to drive on the mineral layer or on the geomembrane. Correspondingly, there exists no actual installation equipment. Hydraulic excavators with articulated or telescopic booms are suitable.

This procedural step causes further implementation problems because geomembrane and geotextile cannot be accessed by heavy machinery. Bulldozers are therefore not

very suitable because of their high machine weight and shearing force which would impact on a geotextile or geomembrane; if a bulldozer is used it should be a bog-dozer model with plastic tracks.

The extensive installation of filter gravel by hydraulic excavator and excavator mats is out-dated because of its inefficiency. The use of hydraulic excavators with telescopic or articulated booms is feasible. They can reach the placement area from outside or from special construction roads on the placement area which are higher than 1.0 m, that is laterally, with the help of a long cantilever (range about 12 m). Because of its excellent levelling capacities the hydraulic excavator with a telescopic boom and power levelling shovel (cutting breadth 2.5 m) has proved useful on various sites.

A competitive alternative to hydraulic excavators are snowcats. The machines, originally designed for winter sports, have a low dead weight (2-6 t) and broad tracks (2 x 1.5 m), so that only low shearing forces and ground pressures (0.040 - 0.050 kg/cm<sup>2</sup>) are transmitted to the geotextile and geomembrane and no waviness in the geotextile or geomembrane will arise due to the installation of the protective layer. By way of comparison: a bulldozer exerts a ten times higher specific ground pressure than a snowcat.

Snowcats have proved effective on site. Even in slopes, especially if geogrids are installed, filter gravel can be pushed and placed easily and economically.

## 9 GEOSYNTHETIC CLAY LINERS (GCL)

At present the possible consequences of wrinkled geomembranes in combination with underlying GCLs are still under discussion. Some experts fear, that leakage paths may form or, moreover, hydrated bentonite might migrate into the hollows under the wrinkles.

Especially this fact reinforces the need of a flat installation of geomembranes to prevent wrinkles as much as possible to prevent any kind of flow path between the mineral sealing system and the geomembrane.

If wrinkles cannot be prevented during the installation phase it should be required to strengthen the internal shear strength of needle-punched GCLs to increase the internal shear strength and prevent the movement of bentonite laterally in the GCL. The use of non reinforced GCLs or partly reinforced GCLs (e.g. stitch bonded) would be critical for this application. Heerten et al. (1995) have demonstrated in their publication that there is a correlation between peel strength of the GCL and internal shear strength. Various testing programs have proven that GCLs can transmit a high shear strength in a needle-punched product without showing any creep behavior or pulling out of the fibers.

In any case, it is suggested - especially in base seals - to use GCLs with an appropriate peel resistance value and in addition have the geomembrane installed in such a way that wrinkles are avoided. Furtheron it is suggested that above items are construction quality controlled and should be already considered in the design phase and during the tender.

The choice of effective plant and procedures is crucial for a technically and economically successful construction project, along with the scaling of the equipment to correspond to requirements and the coordination of the equipment according to capacities.

Suggestions for a feasible equipment line for the construction of a composite liner incorporating a protective and a drainage system have been made above. The implementation of such a landfill liner system is highly demanding of personnel and machinery and requires the efficient implementation of construction procedures. In addition, various marginal conditions and risks as well as exacting schedule requirements increase the demands and thus exacerbate an already tense situation. The requirements which have to be met by a landfill liner system, weather factors and the resulting scheduling commitments, demand careful planning and sequential organisation of the construction work and particularly in the choice of machinery. Approved effectiveness of machinery, personnel and procedures are part of the performance-related requirements.

The landfill designer has to provide simple, even, non-curved geometries for the landfill base. Landfill designers should not seek to increase landfill volume by means of complex geometries, because in this way quality is reduced and the use of effective technology is prevented.

It is possible to construct a successful and economical composite liner with intimate contact of the layers by using the "Riegelbauweise" (FBCM), if it is carried out carefully and by well experienced personnel under effective management by the contractor.

# BENTONITE MIGRATION IN GEOSYNTHETIC CLAY LINERS

Timothy D. Stark

Associate Professor, Department of Civil Engineering, University of Illinois at Urbana-Champaign, Urbana, Illinois, USA

**ABSTRACT:** Since the introduction of geosynthetic clay liners (GCLs) to waste containment facilities, one of the major concerns about their use has been the hydraulic equivalency to a compacted clay liner. Field observations and laboratory test results show that the thickness, or mass per unit area, of hydrated GCLs can decrease under normal stress, especially around zones of stress concentration, such as a sump or wrinkles in an overlying geomembrane. In a liner system, this decrease in GCL thickness can lead to an increase in fluid flux, regulatory non-compliance, and a decrease in leachate attenuation capacity and containment time. In a cover system, a reduced thickness of bentonite may lead to an increase in infiltration or gas migration through the GCL. Suggestions for protecting hydrated bentonite from stress concentrations are presented.

**KEYWORDS:** Geosynthetic Clay Liners, Flow Rates, Fluid Barrier, Permeability, Shear Strength

## 1 INTRODUCTION

In recent years, geosynthetic clay liners (GCLs) are increasingly being selected to replace compacted clay liners (CCLs) in composite liner and cover systems for waste containment facilities. Some of the advantages of GCLs over CCLs are: (1) lower and more predictable cost, (2) prefabricated/manufactured quality, (3) easier and faster construction, (4) reduced need for field hydraulic conductivity testing, (5) availability of engineering properties, (6) more resistance to the effects of wetting/drying and freeze/thaw cycles, (7) increased airspace resulting from smaller thickness, and (8) easier repair. Some of the disadvantages of GCLs versus CCLs include: (1) a potential for lower internal and interface shear strength, (2) a possible large post-peak shear strength loss in reinforced GCLs, (3) lower puncture resistance, (4) smaller leachate attenuation capacity, (5) shorter containment time, and (6) possibly higher long-term flux because of a reduction in hydrated bentonite thickness under the applied normal stress (Anderson and Allen 1995 and Anderson 1996). Koerner and Daniel (1995) concluded that GCLs can be considered hydraulically equivalent to CCLs if puncture and bentonite thinning do not occur.

## 2 BENTONITE MIGRATION IN GCLs

Field experiences, including the GCL slope stability research project in Cincinnati, Ohio (Koerner et al. 1996), show that bentonite will absorb moisture because of its high matric suction potential. An increase in water content is accompanied by an increase in compressibility regardless of the normal stress at which hydration occurs (Terzaghi et al. 1996).

Koerner and Narejo (1995) showed that if a circular piston is applied to a hydrated GCL, the bentonite will flow away from the load and the hydrated thickness of the GCL beneath the applied load will decrease. They concluded that

the soil covering a GCL must have a thickness ( $H$ ) greater than or equal to the diameter ( $D$ ) of the loaded area to adequately protect the GCL. Fox et al. (1996) presented results of similar GCL bearing capacity tests using three cover soils: a clean sand, a fine gravel, and a medium gravel. They recommended an  $H/D$  ratio between 1 and 2 to protect the GCL for this range of cover soils. The U.S. Army Corps of Engineers (United States 1995) requires a minimum cover soil thickness of 0.45 m, instead of an  $H/D$  ratio, before construction equipment can operate on top of a GCL.

The thickness of hydrated bentonite also may decrease under nonuniform normal stresses that may be imposed by the waste placed above the liner system. Stress concentrations in a liner system can cause hydrated bentonite to migrate to zones of lower stress. Stress concentrations are ubiquitous in a liner system, especially around a sump, under leachate collection pipes, at the edge of an anchor trench, at slope transitions, and around slope benches. Bentonite migration may be particularly important in sump areas because high hydraulic heads in a sump can increase leakage rates. In fact, Tedder (1997) recommended additional protection for sump areas. Stress concentrations can also be induced in a cover or liner system by a subgrade that contains stones or is uneven and/or contains ruts prior to GCL placement. Another possible mechanism for stress concentration development is local differential settlement caused by natural variations in foundation compressibility and shear strength, i.e., bearing capacity.

## 3 MIGRATION AT GEOMEMBRANE WRINKLES

The presence of wrinkles in an overlying geomembrane creates zones of nonuniform normal stress, which can cause hydrated bentonite to migrate into the airspace under the wrinkle. Figure 1 presents a typical pattern of wrinkles in a recently installed black, smooth high density polyethylene (HDPE) geomembrane. It can be seen that the liner has a

number of wrinkles, especially around the sump located in the foreground. (Note: sandbags in middle of photograph for scale.) The photograph was taken in the morning which probably reduced the number of wrinkles. In addition, there are a number of places around the sump and subsequent piping that lead to stress concentrations.

Figure 1. Typical pattern of wrinkles in a smooth HDPE geomembrane liner and around a sump.

Koerner (1996) and Soong and Koerner (1997) discussed the progress of a current research project investigating the fate of wrinkles in geomembranes. Current results indicate that the shape of a wrinkle or wave can change with time and normal stress, but the height does not appear to reduce substantially under a range of normal stresses. In addition, Eith and Koerner (1996) and Koerner et al. (1997) described a municipal solid waste landfill double liner system that was exhumed after eight years of service. The double liner system was constructed in 1988 and exhumed for a lateral expansion. After exhumation, a number of large wrinkles were found in the geomembrane. These observations show that wrinkles are not removed after installation, and can be long-term zones of nonuniform normal stress acting on an

underlying GCL. The lack of intimate contact due to wrinkles can result in hydrated bentonite migrating into the airspace under the wrinkle.

Anderson and Allen (1995) and Anderson (1996) showed that the thickness of a hydrated GCL can be reduced significantly in the vicinity of a geomembrane wrinkle. A normal stress of 958 kPa was applied to a hydrated GCL in the presence of a geomembrane wrinkle using a one-dimensional compression apparatus. These tests were conducted using a steel and plexiglass consolidometer measuring 0.3 m by 0.3 m. Two needle-punched GCLs were used in these compression tests. Both products consisted of woven upper geotextiles and nonwoven lower geotextiles. The non-woven geotextile of the GCL was placed on a horizontal layer of compacted sand while the woven geotextile was in contact with the geomembrane.

Both GCLs were hydrated under a normal stress of 9.6 kPa for 72 hours. The moisture content of the bentonite after hydration ranged from 100 to 150%. A 1.5 mm thick smooth HDPE geomembrane with a 50 mm wrinkle, as suggested by Giroud (1995), was placed on top of the GCL. Sand was then compacted along the sides and top of the wrinkle.

The normal stress was applied using a loading frame with a load cell at an average rate of 4.5 kN/min in one-dimensional compression. The normal force was increased for approximately 3.5 hours until a normal stress of 958 kPa was achieved. This normal stress was maintained for 3 hours and observations of the bentonite behavior were made. The shape or width of the wrinkle changed slightly but it did not disappear due to the normal stress of 958 kPa.

The hydrated bentonite migrated toward the void under the geomembrane wrinkle where the normal stress was at or near zero. The thickness of the GCLs under the wrinkle was 20 to 25 mm while the thickness farthest away from the wrinkle was less than 2.5 mm. The nominal manufactured thickness of the GCL was 7.0 mm. In addition, the upper woven geotextile separated from the GCL under the wrinkle and conformed to the shape of the wrinkle. This was caused by the additional pressure of the migrating bentonite breaking or pulling the needle-punched fibers out from the woven geotextile in the low confining stress area under the wrinkle. Along the edges of the GCL, where the bentonite was in compression, the needle-punched fibers remained intact.

In summary, the test results presented by Anderson and Allen (1995) indicate that migration of hydrated bentonite toward the area under a wrinkle in the 1.5 mm thick smooth HDPE geomembrane can occur. The migration of bentonite into the wrinkles of a geomembrane also has been observed at an operating landfill in Ohio (Evans 1997).

The migration of hydrated bentonite has implications for meeting regulatory requirements, including mass of bentonite per unit area and hydraulic performance. Thus, it

seems prudent to ensure a minimum long-term thickness or mass per unit area of hydrated bentonite to maintain hydraulic performance, leachate attenuation capacity, and leachate containment time in a GCL liner system. In a cover system, a minimum long-term thickness of hydrated bentonite should be maintained to reduce water infiltration and/or gas migration out of the landfill. The reduced thickness in a cover could be caused by vehicle traffic, slope transitions or benches, and geomembrane wrinkles.

#### 4 POSSIBLE SOLUTIONS

A number of possible solutions were considered to eliminate or reduce the potential migration of hydrated bentonite in a liner system. One possible solution is to use a CCL because of the low compressibility of the highly compacted soil. Another solution is to encapsulate the bentonite between two geomembranes to reduce the amount of hydration and the resulting increase in compressibility. This can be accomplished with planar geomembranes or geomembranes with protrusions. Multiple layers of GCL also can be installed at known points of stress concentration, e.g., sumps and changes in slope. The multiple layers of GCL initially provide a thicker layer of bentonite. Another possible solution involves reducing stress concentrations in the subgrade by smoothing changes in the geometry, reducing ruts, and removing rocks. The geomembrane also should be installed with a limited number of wrinkles. This can be accomplished by using geomembranes that are light-colored (white), exhibit a high friction coefficient (textured), and/or are flexible (Giroud 1995).

#### 5 MODIFICATION OF EXISTING GCLs

Another technique to ensure a minimum long-term thickness of hydrated bentonite is to modify existing GCLs to include an internal structure or stabilizer element. The stabilizer element would reduce the compression, and thus lateral squeezing, of hydrated bentonite in response to the stress concentrations in a liner or cover system. The internal structure would also protect the bentonite from concentrated stresses applied during handling, stockpiling, and construction, and may provide additional resistance to accidental puncture. Confining the bentonite in an internal structure will provide better assurance of the thickness or integrity of the bentonite. This protection is already provided in some bentonite waterproofing applications. It is anticipated that the bentonite would fill the entire depth of the internal structure. Therefore, the initial thickness of the GCL, or internal structure, would correspond to the desired bentonite thickness.

The modified GCL described herein utilizes a geonet as the internal structure or stabilizer element. This modified

GCL is fabricated by bonding one nonwoven geotextile to the geonet, filling the geonet with bentonite, and bonding the second geotextile. The internal structure facilitates bonding of the geotextiles and protects the bentonite, or other impermeable material, from the overlying normal stress. Heat bonding usually results in a strong bond between a geotextile and geonet, which has been observed for geosynthetic drainage composites. This bonding significantly reduces the potential for internal failure or shear through the bentonite. The internal structure also provides some puncture and tensile resistance to the GCL. If additional tensile resistance is required, the geonet could be replaced with a thick geogrid. Other variations of the modified GCL include the use of an internal configuration or structure that differs from a geonet or using a geomembrane that incorporates an internal structure (Stark 1997).

##### 5.1 Hydraulic Conductivity of Modified GCL

Stalcup and Rad (1994) conducted a falling head hydraulic conductivity test in accordance with ASTM D5084 (Standard 1993a) to evaluate the hydraulic conductivity of the modified GCL. The modified GCL described herein consisted of two 265 g/m<sup>2</sup> nonwoven geotextiles heat bonded to a geonet. The geonet was filled with 5 kg/m<sup>2</sup> of bentonite.

The modified GCL was consolidated at a confining stress of 35 kPa and then hydrated. The hydraulic conductivity value of  $4 \times 10^{-11}$  m/sec was measured using falling head hydraulic gradients ranging from 27 to 5. This value is in agreement with values (2 to  $5 \times 10^{-11}$  m/s) reported for existing fabric encased GCLs (Geotechnical Fabrics Report 1997).

##### 5.2 Shear Strength of Modified GCL

Swan (1994) conducted 0.3 m by 0.3 m direct shear tests in accordance with ASTM D5321 (Standard 1993b) to evaluate the shear strength of the modified GCL. The modified GCL was hydrated and sheared at the same normal stress. Two normal stresses, 100 and 290 kPa, were used in the tests. The modified GCL was allowed to hydrate for 24 hours under tap water immersion. The shear stress was applied at the rate of 1.0 mm/minute, as indicated in ASTM D5321. In both tests, failure occurred between the upper geotextile and a special direct shear gripping surface. The bond between the upper and lower geotextiles and the geonet did not fail or show any degradation. Table 1 presents the peak shear stress and secant friction angle for each test. These angles of internal friction correspond to a linear failure envelope that passes through the origin and the peak shear stress. The resulting friction angles are large, and comparable to the peak friction angle of a textured geomembrane/nonwoven geotextile (265 g/m<sup>2</sup>) interface

(Stark et al. 1996).

Table 1. Direct shear test results on modified GCL.

Normal stress (kPa)	Peak shear stress (kPa)	Peak secant friction angle (degrees)
100	115	49
200	174	31

Figure 2 presents the shear force-displacement relationships from the two 0.3 m by 0.3 m direct shear tests on the modified GCL. No post-peak strength loss was observed in the test at a normal stress of 100 kPa. In fact, the shear force-displacement relationship increases with increasing shear displacement due to necking or stretching of the geonet. The test at a normal stress of 290 kPa exhibited a reduction in shear force and friction angle of approximately 6 kN and 9 degrees, respectively. The post-peak strength loss is mainly attributed to the pulling out and/or tearing of the filaments from the nonwoven geotextile during shear (Stark et al. 1996). The geonet also necked or stretched during this test.

Figure 2. Shear strength of modified GCL after hydration (after Swan 1994).

### 5.3 Compressibility of Modified GCL

One-dimensional compression tests were conducted on the modified GCL in the 0.3 m by 0.3 m consolidometer used by Anderson and Allen (1995). The tests were conducted in the presence of a geomembrane wrinkle to demonstrate protection of the hydrated bentonite. The testing was performed both with and without bentonite in the geonet to distinguish between bentonite and geosynthetic compressibility.

For comparison purposes, the normal stress (958 kPa) and duration of the maximum normal stress (3 hours) used in the previously described tests by Anderson and Allen (1995) were used to test the modified GCL. However, to better simulate landfill loading rates, the normal stress was

applied at an average rate of about 2.5 kPa/min, instead of 4.5 kPa/min, until a normal stress of 958 kPa was achieved. As a result, approximately 6 hours of loading was required to obtain a normal stress of 958 kPa. However, this loading rate is still probably faster than actual landfilling.

Both modified GCL specimens were hydrated using the procedure described by Anderson and Allen (1995). The water content of the bentonite in the modified GCL after hydration was 172%. The specimen without bentonite was also hydrated, but moisture contents of the geosynthetics were not measured. After the normal stress was removed, the specimens with and without bentonite were measured to determine the variation of thickness across the specimen in the presence of a wrinkle.

#### 5.3.1 Modified GCL with bentonite

Table 2 presents the thicknesses of the GCL specimen with bentonite before and after loading to a normal stress of 958 kPa. The thickness of the GCL prior to hydration under a normal stress of 9.6 kPa for 72 hours was about 5.5 mm.

The thickness of the modified GCL increased slightly from approximately 5.5 mm to 5.8 and 5.9 mm along the right and left edges, respectively, during the hydration phase of the test. This is attributed to bentonite swelling into the nonwoven geotextile at a normal stress of 9.6 kPa. The thickness also increased slightly under the wrinkle at the center of the specimen. It is anticipated that this increase in thickness is also due to expansion of the bentonite during hydration.

Table 2. Thickness of modified GCL with bentonite.

Test Condition	Thickness at left edge (mm)	Thickness under wrinkle at center (mm)	Thickness at right edge (mm)
After hydration & prior to loading	5.9	5.7	5.8
After application of normal stress of 958 kPa	5.4	10.1	5.5
Change in thickness after loading	-0.5	+4.4	-0.3

Under a normal stress of 958 kPa, the GCL thickness at the outer edges decreased slightly to approximately the original thickness of 5.5 mm. This decrease is attributed to compression of the geotextile, compression of the geonet,

and possible squeezing of hydrated bentonite through the upper nonwoven geotextile toward the wrinkle or into the underlying bentonite. The bentonite probably initially migrated into the upper nonwoven geotextile during hydration under a normal stress of 9.6 kPa.

The interesting behavior occurred under the wrinkle near the center of the specimen where the thickness increased by 4.4 mm. Examination of the specimen after testing indicated that the increase in thickness was caused by bentonite swelling vertically into the nonwoven geotextile, the geotextile and geonet not being compressed under the wrinkle, and the geonet being slightly compressed along the edges and forcing hydrated bentonite toward the wrinkle area. It is also possible that hydrated bentonite in the nonwoven geotextile was squeezed or pushed from the left and right edges to the area under the wrinkle. It is important to note that the nonwoven geotextile remained bonded to the top of the geonet in the vicinity of the wrinkle instead of separating from the GCL as was observed in tests performed on a needle-punched GCL by Anderson and Allen (1995).

In summary, the modified GCL maintained a minimum thickness of 5.4 mm (near the initial thickness of 5.5 mm) after hydration and loading to a normal stress of 958 kPa in the presence of a geomembrane wrinkle.

### 5.3.2 Modified GCL without bentonite

Table 3 presents the thickness of the modified GCL specimen without bentonite before and after loading. The thickness of the GCL after hydration for 72 hours under a normal stress of 9.6 kPa was approximately 5.6 mm. As expected, the thickness of the modified GCL remained approximately constant during the hydration phase of the test because no bentonite was placed in the geonet. After loading to a normal stress of 958 kPa, the thickness at the left and right edges of the modified GCL showed little, if any, compression which is similar to the modified GCL with bentonite. The GCL thickness under the wrinkle remained essentially unchanged.

Comparison of Tables 2 and 3 shows that the modified GCL with and without bentonite exhibited similar thicknesses along the edges after loading to a normal stress of 958 kPa. The only discrepancy appears to be the area under the wrinkle where some hydrated bentonite swelled into the nonwoven geotextile and may have been pushed from the edges through the nonwoven geotextile to the wrinkle area.

In summary, the use of an internal structure in a GCL may provide some assurance of the minimum thickness or mass per unit area of the bentonite after installation. The long-term thickness can be prescribed by using an internal structure height that meets the desired thickness or mass per unit area. In addition, stress concentrations caused by handling, installation, uneven subgrades, rocks, sumps, piping, slope transitions, and geomembrane wrinkles will

not have to be reduced or modified because the bentonite is protected by the internal structure. The modified GCL also utilizes materials already approved and accepted for waste containment facilities.

Table 3. Thickness of modified GCL without bentonite.

Test Condition	Thickness at left edge (mm)	Thickness under wrinkle at center (mm)	Thickness at right edge (mm)
After hydration & prior to loading	5.6	5.5	5.7
After application of normal stress of 958 kPa	5.4	5.7	5.3
Change in thickness after loading	-0.2	+0.2	-0.4

## 6 CONCLUSIONS

Hydrated bentonite can migrate to areas of lower normal stress due to stress concentrations. Stress concentrations are ubiquitous in a liner system, especially around a sump and pipe locations, at the edge of an anchor trench, around slope transitions and slope benches, under geomembrane wrinkles, and above an uneven subgrade or rock. Possible solutions to eliminate or reduce the migration of hydrated bentonite include using a compacted clay liner, encapsulating the bentonite between two geomembranes to reduce the amount of hydration and the resulting increase in compressibility, installing multiple layers of GCL at known stress concentrations, eliminating stress concentrations in the subgrade by smoothing changes in geometry, reducing ruts and removing rocks, and/or installing geomembranes with a limited number of wrinkles. The number of wrinkles could be reduced using a geomembrane that is light-colored (white), exhibits a high coefficient of friction (textured), and/or is flexible (Giroud 1995). Another alternative is to modify existing GCLs to include an internal structure or stabilizer element as described herein. The stabilizer element appears to protect the bentonite from stress concentrations thereby reducing bentonite migration and provide additional puncture resistance.

# Thermal Treatment of HDPE Geomembrane Sheets

Jacek Mlynarek, SAGEOS Geosynthetic Technology Center, Canada

Michel Marcotte, SOLMERS International Consultants, Canada

Pierre Sarazin, SAGEOS Geosynthetic Technology Center, Canada

**ABSTRACT:** To produce HDPE geomembrane sheets, heat is mixed with polymer pellets. The produced melt is then forced through an extruder and cooled down. Since thermoplastic material are known to have memory, heat treatment can access this memory and spell out some important information about the future behavior of the produced sheet, in particular if heat welded seams behavior is concerned. From the hypothesis that seam behavior will be controlled by parent material behavior under the same condition, different HDPE sheets were subjected to thermal treatment and their reaction measured. From more than 1500 tests, film blown extrusion sheets showed less reaction to thermal treatment. Moreover, the variability of their reaction through out the sheet itself is much less than the one of flat extruded sheets. DSC analysis confirmed these differences while tensile tests cannot see any significant differences. In that respect, thickness variation is an important parameter. It was found that thin geomembranes swell more significantly than the thicker ones. Finally, results reveals that thermal treatment procedure can be applied to identify type of extrusion process of any given HDPE geomembranes.

**KEYWORDS:** geomembrane, HDPE extrusion, thermal treatment

## 1 INTRODUCTION

In the past 15 years, worldwide landfill technology has rapidly adopted the use of high density polyethylene (HDPE) as a low permeability liners. This geomembrane material covers today most of the marketplace related to flexible membrane liners (FML). Since most of their use is concentrated in environmental protection facilities, their long term behavior is then of the utmost importance.

To create continuous liners over a large surface, HDPE geomembrane sheets are produced in continuously enlarged width and field welded through polymer fusion. As heat comes in the first stage of sheets production, heat is again supplied at the sheets' interface as welding procedure goes on. Heat supply is then one of the major component of any HDPE geomembrane sheet.

Today the geosynthetic society works intensively to understand basic properties of HDPE geomembranes as well as their long term behavior. It is understood that long term performance of liners could substantially be affected by inappropriate or excessive welding conditions such as too high roller pressure, overheating of the sheets and thermal shock within or in the vicinity of the fused area (Rollin et al, 1989). So

sheet's reaction to heat transfer and thickness variation as of some importance.

Struve (1993) has explained in details seven categories of parameters that affect wedge welding of geomembranes. All of them are related either to welding process, ambient weather, on-site conditions or technical ability of the operators to control wedge welder parameters. None of Struve's categories refer to behavior of the sheet itself (stress relaxation, molecules orientation). Koerner (1993) underlines a large number of operational variables, mentioning that « the type of the geomembrane, its thickness, its texture, the temperature of the sheet, and the orientation of the sheet probably all play a part in some respect ».

None of the reviewed authors had shown the influence of heat transfer to sheet itself except if this heat transfer exceed what the material can support. As a consequence, it seems that the only intrinsic property of the geomembrane sheet really taken into consideration for the selection of welding conditions (pressure and heat transfer) is geomembrane's thickness (Rollin & Fayoux, 1991, Struve, 1993). Maybe because only part of geomembrane thickness (20% to 30% according to Maranda, 1995) participates in welding process.

All engineers agree on the importance of welding temperature on the quality of a final seam. None however ask how geomembrane itself responds to this welding temperature e.g. what is its thermal reaction, understood as relaxation of stresses and/or of molecular orientation during heat application. This property took very little attention of geosynthetic scientists. Huneault (1992), Maranda (1995), Vermeersch et al. (1995) and Marcotte et al. (1995) have assumed that thermal behavior of geomembrane itself is an important factor in selection of geomembrane welding conditions. They carried out a thermal treatment test of samples taken from the seam area and from geomembrane sheet adjacent to the seams. The test was based on the dimensional stability tests. The results indicated that there are difference between thermal behavior of different seams samples.

In this paper the authors present results of a research on thermal treatment ( $T^2$ ) of HDPE geomembrane sheets. This research was undertaken in an effort to verify if geomembranes  $T^2$  behavior differ from one geomembrane to another and if it could play a role during welding and influencing,  $T^2$  behavior of seams.

Results of  $T^2$  testing of HDPE geomembranes are presented and discussed in this paper. The testing program was focused on geomembrane sheets only. At this step of research seams were excluded from the program.

## 2 THERMAL TREATMENT ( $T^2$ ) TEST

The test consists of immersion of the geomembrane samples into a hot (145°C) silicone bath placed in an oven under controlled temperature conditions and for a given time. Standard minimum time of immersion was 5 minutes while standard maximum time of immersion was 120 minutes. The initial size of samples was 6 cm x 1 cm, with the length (6 cm) taken in the machine direction, while width is in the transverse direction. Thickness of sample was also measured prior to immersion. At selected intervals of time of immersion samples were removed from the bath and then air cooled to room temperature. Their dimensions in machine direction (MD), transverse direction (TD) and sheet thickness (ST) were measured. The observed dimensional changes were analyzed and the deformation values were calculated using the following equation :

$$D_X (\%) = ((X_{\text{final}} - X_{\text{initial}})/X_{\text{initial}}) \times 100 \quad (1)$$

where :  $D_X$  = deformation of parameter X (MD, TD or ST)

Samples location on the width of geomembranes sheet is shown in Figure 1.

Figure 1. Location of samples on geomembrane sheets

In addition to thermal treatment testing some samples were analyzed by Differential Scanning Calorimetry thermal analysis procedure. Their tensile property was tested by ASTM D638-91.

Seven (7) commercially available HDPE geomembranes of 40, 60 and 80 mils of thickness have been selected for this testing program. Their properties specified by manufacturers are given in Table 1. Three (3) of them were produced by flat extrusion process and four (4) by blown film process. More than 1 500 samples have been tested during the program.

## 3 RESULTS

### 3.1 Thermal Treatment ( $T^2$ ) Test

Figure 2 shows a shape of samples of three geomembranes after 120 minutes of testing according to  $T^2$  procedure.

Figures 3 shows distribution of dimensional deformations of three parameters : machine direction, transverse direction and thickness. It can be noticed that thermal treatment ( $T^2$ ) behavior of blow film extruded geomembrane is much more uniform than the one manufactured by flat extrusion process. Also,

differences are observed between two flat extruded geomembranes.

Table 1. Properties of tested geomembranes as specified by manufacturers

ID*	Width (m)	Yield Strength (kN/m)	Break Strength (kN/m)	Elongation Yield/Break (kN/m)	Seams Shear (kN/m)	Seams Peel (kN/m)	Extrusion Process
-----	-----------	-----------------------	-----------------------	-------------------------------	--------------------	-------------------	-------------------

40 mils geomembranes

A	-	15.1	28	13/560	14.2	11.4	Blown
B	4.5	15.4	26.6	13/700	14	10.5	Flat

Figure 2. Samples of 40 mils geomembranes after 120 minutes of thermal treatment

Figure 3. Thermal treatment results (dimensional deformation) in relation to sample position on the geomembrane sheet ; a) machine direction, b) transverse direction, c) thickness

Photos of samples after  $T^2$  in relation to sample location on the width of geomembrane sheet are presented in Figure 4. Figure 4a shows samples of flat extrusion process manufactured geomembrane while Figure 4b shows samples of blown film manufactured one. One column on these Figures represents samples taken at the same area of sampling. Three physical phenomena were observed during sampling. First, a

high shrinkage in machine direction was observed. It is clearly seen in Figure 2, where samples after T<sup>2</sup> are compare to original dimensions of the sample. Second, swelling process was observed in all samples. Finally, less pronounced changes were observed in transverse direction of each specimen as can be observed in Figure 2. Third, a variation of deformation in transverse direction was noted on the thickness of samples, as can be see in Figure 2, geomembrane C.

Figure 5 shows changes of dimensional deformation with time for machine direction dimension (Figure 5a) and for thickness (Figure 5b). These Figures also indicates the differences in TT behavior for different initial thickness of geomembranes. It can be noted that the dimensional deformation changes of the 80 mils geomembrane are less pronounced than the ones of the 40 mils geomembrane.

### 3.2 Tensile test (ASTM D638-91)

Samples of two geomembranes, identified as B (flat extrusion) and C (blown film) were analyzed for their tensile behavior. The series of ASTM D638-91 tests were carried out on samples collected from the edge and from the center of geomembranes.

Tables 3 and 4 summarize tensile tests results for both geomembranes.

Table 3. Tensile test (ASTM D638-91) results of two geomembranes, C (blown film) and B (flat extrusion) - edge samples

### 3.3 Differential Scanning Calorimetry

DSC analysis was applied to measure the fusion temperature of two geomembranes. Samples for testing were taken from two locations on the geomembrane width, the edge and the center. Typical curves of DSC analysis for samples of flat extruded geomembrane B are shown in Figure 6 while values of fusion temperature are summarized in Table 5.

Table 5. Values of fusion temperature

Geomembranes ID	Peak Fusion Temperature ( °C)	
	Edge	Center
Geomembrane A (Blown Film Extrusion)	130.1	130.1
Geomembrane B (Flat Extrusion)	131.1	127.3

Figure 6. Examples of DSC curves for samples of geomembrane B

## 4 DISCUSSION

### 4.1 General

The specification of tested geomembranes, given by manufacturers, are very similar, as shown in Table 1. Also, simple statistical analysis of standard deviation of tensile results obtained during this program indicates that there is no significant difference between tensile property (ASTM D638) of HDPE geomembranes.

However,  $T^2$  indicates significant difference in thermal behavior of tested geomembranes. The visual observation indicates clearly that a shape of sample at the end of  $T^2$  depends on type of process as well as, in particular in case of flat extruded geomembrane, on position of samples on geomembrane sheets - Figure 4a. It can be also noted that the dimensional changes are very rapid at the beginning of thermal treatment and slows down with time, showing a tendency to equilibrium after about 60 minutes of treatment.

These differences in thermal treatment behavior of the geomembranes were never taken into consideration in selection of welding parameters.

### 4.2 Differences between geomembranes

$T^2$  deformation ratio distribution curves (Figure 3) indicate a significant difference in thermal behavior of blown film and flat extruded geomembranes.

Large differences in transverse direction and thickness deformation ratio can be noted for tested geomembranes (Table 2 and Figure 2). Machine direction deformation ratio varies very little, between -82% to -84%. The deformation ratio data indicates that the tested geomembranes react differently to temperature applications e.g. their thermal treatment behavior is different.

Simple statistical analysis of tensile test data presented in Tables 3 and 4 indicates that there is fair statistical discrepancy for the strength at yield in the transverse direction measurements between two geomembranes. There is no statistical difference between all other tensile testing parameters of both geomembranes.

### 4.3 Differences on the width of geomembranes

Blown film extruded geomembranes (manufacturers A and C) do not show large differences in deformation

ratio on the width of sheet, Figure 3 and Table 2 for all three, machine direction, transverse direction and thickness). On the other hand, flat extrusion geomembranes (manufacturers B and D) show different  $T^2$  behavior at the edge and in the center of the geomembrane sheet as shown in Figure 3.

The transverse direction (TD) and thickness deformations varied significantly as can be noticed in Table 2. Transverse direction deformation varies between 25% to 100% for the samples taken at the edge of geomembranes and between -5% to 25% for the samples from the center of the sheet. The negative value of the deformation of the sample in the center of the sheet could be an effect of the medium plane shrinkage. Thickness varies even more drastically, at the edge its deformation ratio for the same initial thickness of geomembranes varies between 200% to 500% while in the center sample between 375% to 500%.

Statistical analysis of tensile tests data indicates that there is no significant discrepancies between tensile behavior of geomembrane samples taken from the edge and from the center of tested geomembranes.

DSC analysis confirms the differences in thermal behavior of geomembranes noted during  $T^2$  tests (Table 5). Similarly to  $T^2$  results, a nonuniform behavior on the width of geomembrane sheet is observed for flat extruded geomembrane. As can be seen in Table 5, fusion temperature of the samples taken from the edge of the sheet is 131.1°C, while the center samples have fusion temperature 127.3°C. The DSC values of the blown film extruded geomembrane indicates uniform thermal behavior of the width of the geomembrane. A slight difference in fusion temperature of two geomembranes can also be noted in Table 5.

### 4.4 Thickness of geomembrane

The thinner geomembranes generate a higher deformation ratio than the thicker ones. Thus, it can be concluded that the relaxation of thermal stresses in these geomembranes are easier.

## 5 CONCLUSIONS

1. The typical specification of HDPE geomembranes, given by well known manufacturers, shows no important differences between HDPE geomembranes sheets. Tensile test results are very

similar for all the tested HDPE geomembranes from different manufacturers, indicating no significant differences between geomembranes.

2. The study reveals important difference in reaction to thermal treatment (thermal stresses relaxation) of different HDPE geomembranes. These differences, were never taken into consideration in selection of welding parameters.
3. Blown film extruded geomembranes indicates quite uniform reaction to both T<sup>2</sup> and DSC analysis. The deformation ratios and the fusion temperature values are very similar for the samples taken from different locations of the geomembranes.
4. On the other hand, flat extruded geomembranes show significant differences in thermal behavior of the samples taken at the edge and at the center of the geomembrane. These differences are confirmed by DSC tests.
5. T<sup>2</sup> confirms that the thickness is an important parameter in thermal behavior of geomembranes. It was found that the thin geomembranes swell under thermal treatment more significantly than the thicker ones.
6. Finally, results reveals that T<sup>2</sup> procedure can be applied to confirm the type of extrusion process of any given HDPE geomembranes.

## 6 RECOMMANDATIONS

More factual data is needed to understand thermal behavior of geomembranes to confirm authors observations.

Influence of thermal treatment (thermal stresses relaxation) on HDPE geomembranes seams is still little unknown. It is clear, however, that this behavior can have an influence on seaming process. It is thus recommended to relate the observed thermal treatment behavior of HDPE geomembranes to their seams quality.

## ACKNOWLEDGEMENTS

This research project was complete funded by SAGEOS Geosynthetic Technologies Center in collaboration with Ecole Universitaire d'Ingenieurs of Lille in France. The authors gratefully acknowledge material support from geomembrane manufacturers Agru America, Columbia Geosystems, GSE and National Seal. Special

acknowledgments are forwarded to Prof. J.Morcellet and Dr. D. Gueugnault of Ecole Universitaire d'Ingenieurs of Lille for their contribution in the research program reported in this paper.

# The Influence of the Welding Parameters for HDPE Geomembranes

A.L. Rollin and F. Montgrain, Solmers International, Longueuil, Canada

P. Lafleur and L. Maranda, École Polytechnique, Montréal, Canada

**ABSTRACT:** When in service, particularly in landfills, High Density Polyethylene (HDPE) may present fractures at the edge of seams upon the welding conditions used and their durability is questioned. Seams were performed in situ using a hot wedge welding machine and two commercial HDPE geomembranes 1,5mm (60 mils) thick. The evaluation of seams quality and its adjacent sheet has been performed by measuring properties using eight (8) different tests: seam shear and peel strengths; sheet crystallinity by the differential scanning calorimeter technique and by the gradient column method; residual stress in seam and membrane samples by dimensional changes in hot air and in silicone oil; seam brittleness level by the impact test developed at École Polytechnique and a high-sensitivity impact standard test. Temperature profile has been obtained simulating heat transfer involving a hot wedge machine using the method of finite differences. The simulation of the temperature profile indicated that the polymer sheet melts on about 20 to 30% of its thickness. Thermal gradients were found to be excessively high around the boundary of the melted zone, of the order of 50°C/mm of sheet width. It has been shown that the stress goes from compression in the weld to tension in the sheet indicating that the welding process does not induce stresses in the geomembrane but rather a stress gradient. Since it is known to be precursor of the stress-cracking phenomenon. Recommendations are made on the need to still improve welding machines and monitor welding. The measurement of the stress gradient build during seaming using the hot oil bath testing procedure should be investigated throughout to adapt it to HDPE geomembranes.

## 1 INTRODUCTION

### 1.1 The Concern

Often engineering structures fail because a geomembrane contains an unexpected flaw that is introduced, or gradually develops and becomes of a critical size that can cause rapid unexpected failure (Peggs 1994). Controlling welding process variables is then vital to achieving consistent wedge welds (Struve 1993). The various welding machines must monitor the desired variables to achieve consistent results over the widest possible range of field conditions and good well trained technicians must ensure that their machine performed well. It has been shown that seam quality is significantly influenced by speed, welding temperature, surface conditions and applied pressure (Peggs 1990, Rollin 1889a and b, Rollin 1991a, Rollin 1993, Rollin 1994, Struve 1993). These parameters may also significantly affect the long term behavior of the adjacent geomembrane. Thus, seam assessment criteria should include parameters for the adjacent geomembrane.

### 1.2 Seams

Sheets of two commercial HDPE geomembranes 1,5mm thick (shown in Table 1) were seamed in situ using a hot wedge welding machine (Maranda 1995) and the welding parameters were selected to span a wide range of acceptable conditions (Struve 1993): condition I being

identified normal and conditions II to IV being closer to non-acceptable limits. The welding procedure was performed under controlled conditions with the same machine such that the parameters influencing the seam quality are the welding speed, the welding temperature and the applied pressure as presented in Table 2.

Table 1. HDPE sheet properties

Sheet property/identification	GM A	GM B
Thickness (mm)	1,65	1,5
Tensile strength: yield point		
machine direction (MPa)	20,52	19,23
width direction (Mpa)	20,41	18,58

Table 2. Welding conditions

Welding conditions	Speed (m/min)	Temp. (°C)	Pressure
I	3	400	normal
II	2	400	normal
III	3	450	normal
IV	3	450	high

The influence of these welding parameters in the seam and in its adjacent sheet could be obtained by testing samples taken in the seams and in the sheet at distances from the center of the seam as shown schematically in Figure 1. It should be noted that samples collected at locations 1 and 2 are approximately 3,0mm thick.

Figure 1. Schematic of a seam sample

## 2. EXPERIMENTAL

The evaluation of the seams and their adjacent membrane has been performed by measuring properties using eight (8) different methods. Firstly, a shear and a peel tests were performed on samples of produced seams to assess their acceptability as evaluated in the field by measuring their shear and peel strengths and identifying the location and the nature of the break. The ASTM D816 and D4437 modified test procedures were performed at a rate of 50mm/min. A total of 120 samples were tested and the results of the peel strength are presented in Table 3 and compared to Struve 1993 results. In all cases the Film Tear Bond criteria was respected.

Table 3. Seam peel resistance results

Peel resistance (N/mm)	GM A	GM B	Struve, 1993
minimum strength	21,6	17,7	19,3
maximum strength	26,6	21,6	24,4

It is generally accepted to identify the quality of an HDPE seam by calculating the critical ratio of the measured strength to the sheet strength at its yield point. As proposed (Peggs 1985) this factor should be greater than 90% for the shear resistance and 80% for the peel resistance. The calculated ratios for the shear test are all above the criteria and below for the peel test as presented in Table 4.

Table 4. Seam shear and pell resistance ratios

Seam shear resistance ratio (%)	GM A	GM B
I	99,7	102,9
II	103,4	101,3
III	101,1	101,8
IV	103,1	103,2
Seam peel resistance ratio (%)		
I	76,8	71,9
II	76,9	66,3
III	79,7	71,6
IV	74,1	65,6

The sheet crystallinity of the samples as a function of its location from the center of the welds has been calculated using a Scanning Differential Calorimeter (see Figure 2) and the density column method ASTM D1505 (see Figure 3). Forty (40) samples were tested at a rate of 10°C/min in

the SDC. The results indicate similar percentage of crystallinity in both membranes ranging from 75 to 79%.

Figure 2. Sheet crystallinity by SDC

Two hundred (200) samples have been tested using the density column standard ASTM procedure. The results indicate a crystallinity ranging from 76,5 to 78,2% with a slight decrease in crystallinity at the seam edge located at 1cm from the weld center. It is interesting to note that this location corresponds to the melted polymer zone limit occurring during the welding process.

Figure 3. Sheet crystallinity by density column method.

Residual stresses in samples were identified using two dimensional stability tests: in hot air ASTM D1204 and in hot silicone bath. Samples of 10cm long and 1cm wide were placed in a oven at 130°C for an hour and samples of 6cm long in hot silicone oil at 140°C for 300s. The measured changes in the transverse direction (X axis) were in all cases the most drastic for both membranes (see Figure 4 for hot oil results) while the changes in the machine direction (Y axis) and the thickness (Z axis) were less pronounced (see Figures 5 and 6 for hot oil bath results). In Figure 4, the stresses go from compression in the weld to tension in the sheet indicating that probably the welding process did not induced stresses in the membrane but rather a stress gradient. This stress gradient is probably resulting from the relaxation of stresses within the sheet, stresses induced during the manufacturing process and not from the welding process. In any event this stress gradient is most probably responsible for seam brittleness.

Figure 4. Transverse direction dimension variation

Obtained results indicated that the stress relaxation within the sheets were responsible for a decrease in the machine direction (sample width) of approximately 70% while the thickness increased by 2,5 times its value. The presence of the stress gradient in samples located at 1cm and 2cm from the weld center can be observed on Figures 5 and 6.

Figure 5. Machine direction dimension variation

Figure 6. Thickness direction dimension variation

Seam brittleness can be detected using an impact test (Rollin 1991b). Samples were submitted to two impact test procedures: the Dynatup instrument and the impact test developed at Ecole Polytechnique (Rollin 1991b). The results are presented in Figures 7 and 8

Figure 7. Dynatup apparatus impact test results

In the Dynatup device, an hemisphere rod of 12mm in diameter is dropped on a 76,2mm x 76,2mm sample with an impact energy ranging from 15 to 30J. The obtained results indicate that a greater impact energy has been necessary to rupture the samples within the weld than within the sheet itself. Visual observations of rupture samples indicated that the mechanism of rupture was ductile.

Figure 8. Ecole Polytechnique impact test results

Similarly the median impact energy necessary to rupture 1,5mm thick geomembranes GMA and GMB samples obtained with selected welding conditions (I to IV) are compared with already published data (Struve 1993, Rollin 1993). Overall, the results obtained over such a wide range of welding parameters are consistent. The higher values obtained of serie V are certainly related to improved machine design.

Thermal shock to HDPE sheet during welding can initiate stress cracking. In order to obtain the temperature gradients imposed on geomembrane during the welding process, temperature profile has been obtained simulating heat transfert involving a hot wedge machine and using the method of finite differences as shown schematically in Figure 9.

Figure 9. Heat transfer through the membrane

The temperature profile within the sheet at a specific time is function of the welding speed and the wedge temperature. Using the thermal conductivity equation in two dimensions for a transitional regime (1281 points), setting the heat transfer to both sheets identical and using a typical 75mm long and 37mm wide brass wedge, temperature profiles were obtained for a wide range of welding speed and temperature. The conductivity of the membrane was set at 0,48 W/m-°C (the HDPE conductivity is not affected by the black carbon content (Mesloh 1990)), of the wedge at 147 W/m-°C and at 0,0426 W/m-°C for air.

Figure 10. Simulated temperature profile

Temperature profiles such as the one presented in Figure 10 could be obtained for a wide range of welding speed and wedge temperature. From the temperature profile representing condition I, it can easily be found that the sheet melting thickness during the welding procedure ranges from 20 to 30% of its thickness and that the melted polymer limit correspond to edge of the wedge. The maximum temperature of 165 °C is located close to the

wedge and a large thermal gradient of the order of 50°C/mm of sheet width is located between 1,5 to 2,0cm from the center of the weld. The sheet surface temperature is approximately 55°C at a welding speed of 3m/min and raises to 75°C for a welding speed of 2m/min. The simulated temperature profiles indicated that excessive thermal gradients are generated at the boundary of the melted zone.

### 3. CONCLUSIONS

From the results obtained in this experimental study, the following conclusions can be drawn:

- the hot wedge welding process of HDPE geomembranes is responsible for stresses relaxation in manufactured sheets leading in the generation of large thermal gradients at the edge of the seams
- during the hot wedge welding process only a small fraction of the polymeric sheet is melted: 0,3mm in its thickness and 0,5mm at the edge of the weld
- the measurement of the dimensional variations of seams in hot oil bath or in an oven simulates best the welding process and is very sensitive to locate residual stresses in manufactured sheets
- the results obtained from most test procedures did not clearly differentiated between the welding conditions
- the simulated temperature profiles indicated that excessive thermal gradients are generated at the boundary of the melted zone and that a minimal fraction of the polymer is melted during the welding process

Recommendations are made on the need to still improve welding machines and to monitor welding parameters to lower the thermal gradient at the seam edge. The dimensional variations test standard should be investigated throughoutly since it can be performed easily. It would be interesting in the future to corrolate the impact energy measured by the impact test with the stress gradient generated with the hot oil bath testing procedure.

### ACKNOWLEDGEMENTS

The authors would like to thank Dr. J. Mlynarek and O. Veermersh from Sageos for their support during the testing phase of the project. The authors also acknowledge the efforts of Materiaux Techniques Cote personal for their involment in supplying products and welding the many geomembranes sheets. Finally a special thank is dedicated to Mr. Fred Struve whose comments materially improved the manuscript.

# Assessment of Seam Quality and Optimization of the Welding Process of HDPE Geomembranes

G. Lüders

Bundesanstalt für Materialforschung und -prüfung, Berlin, Germany

**ABSTRACTS:** Using GM's made of two different commercial resins 50 double track fusion seam test samples were produced by systematic variation of some welding parameters. The results of short term and long term peel tests were correlated with the ratio of the thickness reduction of the seam  $s_f$  to the thickness of the molten surface layer  $L_o$ . The ratio  $s_f / L_o$  is an important process parameter, reflecting the interaction of welding parameters. Thus, all seams appear to be quite acceptable in the short term test, independent of the ratio  $s_f / L_o$ . However, the long term tests revealed peeling of the seams and the time to failure  $t_f$  strongly depends on  $s_f / L_o$ . We found a pronounced maximum in the failure time at  $s_f / L_o = 0.7$ , where the lifetime was improved by a factor of 5 to 10. It is therefore shown that the long term peel test is appropriate to evaluate the quality even of acceptable seams. An optimization of the welding process is possible. Time plots of peeling, micrographs of the fracture surface and annealing experiments indicate that the time to failure depends on the structural and thermal homogeneity of the seam at given welding conditions.

**KEYWORDS:** Geomembranes, weld seams, peel separation, failures, quality assurance

## 1 INTRODUCTION

In the construction of composite landfill liners, HDPE geomembrane sheets are placed and welded together one by one over the mineral layer to form a single large-area geomembrane liner. Appendix E of German TA Abfall (1991) and TA Siedlungsabfall (1993) states the suitability of the geomembrane and the welding technology must be verified under a process of certification. The relevant BAM Guidelines (BAM 1992), which are based in the main on the requirements of DVS 2225 (DVS 1991-1996), consider welding to be the only suitable seaming method. The Clarification section of the BAM Guidelines states that a suitable test method and further knowledge on the mechanical long-term performance of the weld seams and their dependencies on the welding parameters are still required to enable seam quality to be evaluated.

In the following paper the initial results of our investigations will be detailed with regard only to the welding parameters used in one and the same hot wedge welder of a construction-site-tested type. These are connected to earlier long-term peel tests in which peel of the weld area was observed but no relationship between failure time and welding parameters could be established (Bielefeld et al. 1991).

## 2 REMARKS ON WELD SEAM BEHAVIOUR UNDER DESTRUCTIVE LOADING

As is well known, short-term mechanical testing methods such as tensile shear tests per DVS 2203 (DVS 1985), are not able to differentiate appropriately the strength of overlap weld seams. It is not the weld area itself but the base material adjacent to the seam edge which always suffers brittle or yield failure; this is because the weld area is stiffened locally and the test periods are not long enough to activate any processing-related defects in the seam plane (Knausenberger et al. 1983). The process which enables the determination of seam quality in tensile tests on hole-notched hot wedge butt weld seams, i.e. a tensile load

perpendicular to and hole-notching in the weld plane, is not feasible for overlap weld seams in geomembranes. In long-term tensile tests, too geomembrane weld seams always fail in the base material near the seam edge. Establishing a relationship between failure time and seam geometry and welding parameters is difficult for a number of reasons (Bielefeld et al. 1991). Peel tests per DVS 2225 can basically only differentiate between 'good' (meeting the requirements) and 'poor' seams, however they can be used on construction sites and form part of QC/QA. In peel tests, too, the weld area remains undisturbed while the base material elongates at the seam edge. The maximum tensile force is measured, from which yield stress can be calculated. The weld area only peels if welding conditions are far below the requirements of the Guidelines, based on extensive practical experience. It is only this type of 'poor' seam which permits measurement of peel resistance.

What seam quality evaluation should (or must) be based on still remains to be determined (Müller and Lüders 1995):

- Seam edge break with an undisturbed weld area under practice-relevant (long-term) tensile loading, or
- failure of the weld area under long-term peel loading.

The general belief that peel forces do not occur in the field during landfill construction and operation and are therefore irrelevant in practice have lately been proved incorrect by the discovery of peeled seams in excavated geomembrane samples (Peggs et al. 1994). Analytical considerations on seam performance in short-term peel tests have revealed that the stress maximum in seam edge yield related to the yield stress in the base material, known as the Film Tearing Bond (FTB per NSF 1993), fails to provide any information on seam quality. Its evaluation must, therefore, be based on the failure, i.e. peel, of the weld area (Peggs 1996).

### 3 EXPERIMENTS

#### 3.1 Geomembranes

Two BAM certified geomembranes, based on ethylene-butene copolymer (GM1) and ethylene-octene-copolymer (GM2) both with a narrow molecular mass distribution were used in the tests (Table 1).

Table 1. Materials properties (in part, manufacturer's data)

GM		1	2
Density	[g/cm <sup>3</sup> ]	0.942	0.943
MFI 190/5 <sup>1</sup>	[g/10 min]	1.6	2.5
MFR 190/21.6 / 190/5		9	9
M <sub>w</sub> /M <sub>n</sub>		4.8	3.4
Carbon black	[% by mass]	2.1	2.2
Yield stress	[N/mm <sup>2</sup> ]	18	16.8
T <sub>c</sub> (DSC-peakmaximum)	[° C]	125	124
Thickness	[mm]	2.5	2.5

<sup>1</sup> Melt flow index at 190 °C under a 5 kg loading

#### 3.2 Weld Seam Sample Preparation

Welding was performed using a hot wedge welding machine of a construction-site-tested type known world-wide. Roller pressure and speed were transferred mechanically to the two part-seams by rollers above and below the geomembrane. Welding parameters were recorded using a data acquisition system with memory cards and evaluated using DOS software.

- Two 'open' thermo-elements in the hot wedge (HW) contact areas to measure the interface temperature of the geomembrane emerging at the HW tip during test welding (not quite correct!).
- The lower limit of the gap difference between the rollers on the left and right part-seams was 0,05 mm
- Width of the part seams 15 mm; total length of a weld seam: 9m; range of length applied 1m to 8.5m selected from the seam length range for which, according to the welding records, the roller pressure was constant and equal to the nominal value.
- Test specimens from the weld seam samples were sawned across the seam and finally planed down on each side to a width of 15 mm ± 0.05.

#### 3.3 Long-term Peel Test

The investigation was aimed at finding the relationship of failure time as a function of the welding parameters and not at determining the absolute values of failure time. Preliminary tests indicated that there was no significant difference in parameter dependency between the two part seams. Thus it was

possible to concentrate the investigation on one specific part-seam ( GM1 on part seam 1, GM2 on part seam 2 ). Weld seam failure time was determined on at least six test specimens, taken from different parts of the seam at at least 40cm intervals.

Testing was carried out in mechanical advantage test set-ups with horizontal load lever compensation in water at 80°C containing 2% by mass surfactant and time/elongation recorded. Following a 10 minute pre-loading period at 10% of the main load, the test load was applied automatically (test start). Breaking with no deformation over the long term is not representative of realistic conditions for seam peel so a test load high enough to obtain relatively short failure times could be chosen. A 4 N/mm linear load was chosen for GM1 and 6 N/mm for GM2, which prevented yield in the seam edge and ensured uniform seam failure due to a fast peel. The results obtained exhibited a normal distribution. The arithmetic mean of a minimum of 6 (maximum 18) measurement results was used as the failure time.

### 4 RESULTS TO THE RELATIONSHIP BETWEEN FAILURE TIME AND REDUCTION IN THICKNESS

Failure time was investigated in long-term peel tests on weld seams which differed in the combination of their welding parameters. Seam variants produced at

- hot wedge temperatures T<sub>HW</sub> 280; 350; 400 and 450°C
- roller pressures F 800; 1100 and 1400N
- welding speeds V 0.8; 1.5 and 2.5 m/min

were tested. In short-term peel tests per DVS 2225 all but one seam yielded at the seam edge and thus they comply with the requirements.

Seam strength measured as peel resistance always increases with decreasing thickness until the minimum melt flow is reached (Potente 1977). Beyond this (s<sub>t</sub> = 0.1 - 0.2mm) the seam peels no further and at this point yield stresses at the seam edge, which are of course independent of the reduction in thickness and without exception lay on a high plateau, can be measured. Because peel in the weld area and yield at the seam edge are two completely different failure types the results are not therefore suitable either for establishing a definition of a welding factor, or for including this in a closed relationship with the welding parameters (Michel 1995).

Seam strength measured as failure time reacts to every change in process conditions. The reduction in thickness behaves in parallel or inversely with failure time, i.e. the relationship is undefined similar to the that with failure time in tensile shear tests (Bielefeld 1991). For a meaningful relationship between seam quality, measured as failure time in peel tests, and process parameters to be formulated, the reduction in thickness alone is not suitable. A new reference quantity is therefore needed. With regard to butt welded seams, the so-called the ratio in thickness reduction is used (Michel 1988).

When applied to hot wedge welding, the reduction in thickness s<sub>t</sub> is, analytically speaking, the distance by which the gap between the two rollers is reduced until the selected roller pressure F reaches equilibrium with the flow resistance of the molten material of the two sheets (Figure 1). Flow resistance can be compared with normal stress σ<sub>22</sub> when molten material

Reduction of the thickness $s_t$ with roller pressure $F =$ flow resistance	
Flow resistance = (normal stress $\sigma_{22}$ ) = $f(V, L_o)$	
Reduction in thickness $s_t = f(F, V, T)$	Melt depth $L_o = f(T, V (t_H))$
rheological process conditions	thermal process conditions
$s_t / L_o$ Ratio in thickness reduction	

Figure 1. Scheme to explain terms in the ratio in thickness reduction

is exposed to a shear stress  $\sigma_{21}$  e.g. in a cone-plate-viscometer. It is perpendicular to the shear plane and equals force  $F$ , required to prevent the cone and the plate from drifting apart, i.e. to keep their distance constant. In equilibrium with roller pressure  $F$ , flow resistance is a function of speed  $V$  and melt depth  $L_o$ .

The melt depth depends on the HW temperature and the pre-heat period  $t_H$ , i.e. on speed, too. It can be therefore considered as the result of the thermal history of the geomembrane. The melt depth predetermines not only the melt depth in the geomembrane, however, but also, simultaneously, the most important initial geometric condition for the melt flow in the seaming phase.

The ratio of the reduction in thickness to melt depth - the ratio in thickness reduction  $s_t / L_o$  - is then approximately the ratio of the thickness of extruded to input melt under the above equilibrium conditions in the seaming phase, i.e. a measure for melt flow. Thus the ratio in thickness reduction ought to represent a parameter for the combination of all the process conditions to which seam properties could be related. Whether this is actually the case in a welding process, in which rheological and thermal conditions are determined by partly freely chosen and partly dynamically adjusted parameters, will be investigated following.

## 5. THE RATIO IN THICKNESS REDUCTION $s_t / L_o$ USED TO OPTIMISATION OF THE WELDING PROCESS

While microscopic measurements are not appropriate to measure the input molten layer Fourier's equation for non-steady heat conduction in the following derivation (Michel 1995) was applied to calculate melt depth  $L_o$ .

$$L_o = 1.905(1 - \theta_c) \sqrt{a_{eff} t_H} \quad (1)$$

where:

$$\theta_c = \frac{T_c - T_{GM}}{T_{HWP} - T_{GM}}$$

$T_c$  = crystalline melting point for HDPE (table 1);  $T_{GM}$  = geomembrane temperature;  $T_{HWP}$  = temperature at the hot wedge tip (HWP), depending on the selected speed and nominal value  $T_{HW}$  (used as interface temperature);  $\theta_c$  = temperature (dimensionless);  $t_H$  = pre-head period, calculated for a 7cm effective HW length;  $a_{eff}$  = effective thermal conductivity, according to (Potente 1977); 1.905 = correction factor.

Failure time values measured in long-term peel tests and the ratio  $f_o$  of the yield stress from short-term peel tests to the yield stress in the base material are plotted in Figure 2 as a function of the ratio in thickness reduction.

Figure 2. Failure time  $t_r$  in long-term peel test and yield stress ratio  $f_o$  in short-term peel test as a function of the ratio in thickness reduction  $s_t / L_o$

Over almost the whole range of  $s_1/L_0$  between 0 and 1 the yield stress ratio exhibits a high plateau at  $f_0 = 0.9$ , as is already well known (Michel 1995). However the failure time obtained as an average of all values reaches a maximum at  $s_1/L_0 = 0.7$  for both resins. Compared to the shortest failure time measured the life time was improved by a factor of 5 to 10. For butt weld seams a maximum was found at  $s_1/L_0 = 0.75$  (Michel 1988). This agreement is surprising considering the rather different seam geometries and processes involved in the two welding methods. Since the loci of maximum of the failure time coincide for weld seams of both materials (GM1 and GM2),  $s_1/L_0 = 0.7$  can be considered as an invariable optimization value for HDPE, i.e. in the range around this  $s_1/L_0$  value (e.g. 0.5-0.9 in Figure 2) the interaction of the selected welding parameters is optimum with regard to the production of the seams investigated. An analysis of the dependency of the failure time on each of the adjustable parameters (T, V, F) alone turned out not to be appropriate. For the welding practice it is on the other hand of importance to determine the optimum values for the adjustable parameters F and V in order to keep the  $s_1/L_0$ -value in the above optimum range. Thus the dependency of the failure times on V and F is shown in figure 3 and 4 by assigning the respective values for V and F to each of the data point of figure 2 (as in figure 2 each data point is given by its failure time and the corresponding  $s_1/L_0$ -value).

Figure 3 shows the areas characterized by the average seam melt depth  $L_0$  with failure times contained in them and placed according to the corresponding  $s_1/L_0$  values.

Figure 3. Failure time  $t_r$  as a function of the ratio in thickness reduction  $s_1/L_0$  with melt depth  $L_0$  as a parameter

It can be seen that seams with long failure time require melt depths between 0.75mm and 0.90mm, i.e. reaching the failure time maximum depends decisively on the pre-heat conditions - pre-heat period and temperature.

In Figure 4 it can be seen clearly that failure time attributed to roller pressures  $F=800$  and  $1100$  N and velocities  $V=1.5$  and  $0.8$  m/min exhibits high values in the marked  $s_1/L_0$  range between 0.5 and 0.9.

(a)

(b)

Figure 4. Failure time  $t_r$  as a function of the ratio in thickness reduction  $s_1/L_0$ : (a) with roller pressure F as a curve parameter, (b) with speed V as a curve parameter

To formulate the optimum parameter combination in Table 2 temperature must be taken directly as a welding parameter, because it does not represent an optimization variable.

Table 2. Optimum parameter combinations

GM	$s_f/L_o$	$L_o$ [mm]	F [N]	V [m / min]	$T_{HW}$ [°C]	$t_f$ increase [h]
1	0.55	0.75	800	1.5	400	24- 34
	0.78	0.90	1100	0.8	350	24- 32
2	0.50	0.75	800	1.5	400	286-430
	0.75	0.90	1100	0.8	350	286-597

The wider the  $s_f/L_o$  basis of the maxima attributed to the single parameters, the easier the optimization. They can be then made easily to coincide, thus the corresponding parameter combination can be determined by the same reduction in thickness ratio. The results in Table 2 indicate that low to medium roller pressure values and velocities result in the greatest failure times. This does not exclude however that other parameter combinations, in particular when they are graded more closely than in this work may provide even better results. Pre-requisite is however that the actual pre-heat conditions ensure adjusting the reduction in thickness ratio. This is no more the case at e.g. 2.5m/min (Figure 4b, GM1, open triangle). Here the pre-heat time is so short that the geomembrane cannot be molten deep enough (Figure 3,  $L_o = 0.5mm$ , open circle). An 'optimum' ratio in thickness reduction can then be achieved though with an extremely high roller pressure, but the failure time is only increased slightly (Figure 4a, 1400 N, GM1, open triangle †, 1600 N, GM2, rhombus). A calculative estimation suggests that the effective HW length must be a minimum of 11cm to achieve  $L_o = 0.75mm$  at 2.5m/min.

On the other hand Figure 3 indicates clearly (GM2, solid triangle †) that failure time also remains short at  $L_o = 0.75mm$  when roller pressure was too low (Figure 4a,  $F = 600 N$ , solid triangle †). In order to increase melt flow of  $s_f/L_o = 0.1$  with regard to failure time optimization, either  $L_o$  must be increased up to 0.9mm (solid triangle † in Figures 3 and 4a) or even better F must be increased up to 800 or 1100 N.

## 6 ADDITIONAL REMARKS ON THE RELATIONSHIP BETWEEN SEAM PROPERTIES AND FAILURE TIME

The causes of the quality-determining properties of a weld seam deviating from those of the base material are nearly always attributed to the consequences of a thermo-rheological restructuring process. The positional variable secondary crystallisation in the thermally effected zone (Kamenowa et al.) and the flow-induced crystallisation in the zone influenced by shear (Kojima 1979; Aciemo et al. 1978) leave a morphologically unhomogeneous seam area weakened by the complex effect of frozen-in stresses (Ehrenstein 1979). Failure was consistently predicted in the fibrillar shear structure in the

molten/solid transition zone for butt weld seams (Egen 1985) and also observed in peeled weld seams (Bielefeld 1991; Gehde 1992). The question of whether or not this failure criterion holds for weld seams of all parameter combinations was investigated.

In Figure 5 e.g. failure time of annealed weld seams (2h and 120°C) is compared with the failure time of non-annealed weld seams (GM1, Figure 4a). The annealing effect depends on the  $s_f/L_o$  position and is maximum at high roller pressures.

Figure 5. Failure time  $t_{tr}$  of annealed (T) and non-annealed weld seams of GM1 as a function of the ratio in thickness reduction  $s_f/L_o$  with roller pressure as a curve parameter 2h/120°C

The time plot of peeling measured as clamp distance against time is uniform for all seam samples with high failure time (Figure 6a). Scattering increases with decreasing failure time. The steep increase becomes unsteady and is often characterized by a step at the beginning (Figure 6b).

Figure 6. Distance between the clamps  $\epsilon$  in the peel test as a function of time: (a) GM2 seam samples of high failure time  $t_f$  and high melt depth  $L_o$ ; (b) GM2 seam samples of low  $t_f$  and small  $L_o$ .

Simple microscopic illustration of the fracture interfaces of peeled seams shows that there are inhomogeneities there which are characteristic of some parameter combinations (Figures 8a-d). The results illustrated here exemplarily provide indications for seam quality, which is explained in a summarised way using the scheme in Figure 7.

Figure 7. Melt flow in the weld area (schematic)

In the final phase of the welding process orientations left behind by melt flow in the loading plane freeze quickly. Considering the melt flow illustrated schematically by arrows it becomes clear that the more the (bright) transitional area is affected by the relative movement of the (dark) molten mass towards the seam edge, the more widespread the development of fibrillar shear structures. At high roller pressure and a low temperature orientation spreads as far as into the bead (a in Figure 7) which is then often split at the end of the peel process in the centre (Figure 8d).

8a. Fracture surface of a GM1 seam sample [16x];  $s_r/L_o=0.69$   $t_f=24\text{h}$ ; detail: transition seam centre to side; welding direction ↓

8b Fracture surface of a GM1 seam sample [10x];  $s_r/L_o=0.04$   $t_f=6 \text{ h}$ ; V ↑↑; detail: seam centre vortexing and lacking in molten material; welding direction -

8c. Fracture surface of a GM1 seam sample [6.5x];  $s_r/L_o=0.17$   $t_f=3.5 \text{ h}$ ; F ↑↑; detail: seam centre containing no molten material; welding direction ↓

Because of the heat content transported to the seam edge by the molten material a relaxation back into the spherulitic structure and regaining of strength isotropy can be expected (b in Figure 7).

This is not only of special importance in seams with small melt depth  $L_0$ , where it may explain the step in plots of Figure 6a. It could also explain that seams with sufficient high heat content ( $L_0$ ;  $T$ ;  $V$ ) after brittle groove cracking in the root of the bead notch the peel front runs frequently into the geomembranes material or the material of the residual cross section exhibits yielding (Figure 6b), i.e. the behavior of the weld area in the peel test becomes similar to that of the geomembranes material due to the more extensive annealing after welding.

At high velocity, vortexing occur in the molten mass (c in Figure 8, Figure 7b), as has already been suggested as elastic turbulence for extreme flow conditions in butt weld seams [20]. In all three cases the molten mass may be displaced from the centre of the seam (Figure 7c). On peeling only adhesion ruptures can be then observed in the centre of the seam between two each other close adjacent interfaces.

The farther the ratio in thickness reduction from the position of the failure time maximum, the greater the extent of structural and thermal inhomogeneity. Correspondingly, seams with long failure times peel evenly and leave bright fracture interfaces, finely structured probably by crazing (Figure 7a). With decreasing failure time mixed failure increasingly prevails, consisting of extensive yielding of more or less flat, spliced ribbons and adhesion ruptures in plane areas which exhibit a large number of faults and a shortage of molten material due to vortexing and/or high orientation. In such cases seams fail both in and near the weld plane.

## 7 SUMMARY AND CONCLUSIONS

Hot wedge weld seams in long-term peel tests always fail due to peel in the weld area. Failure time and access to the open seam ensure an assessment of seam quality.

The absolute values of failure time depend closely on the geomembrane's material. They are between one and 40 hours at 80°C in water with 2% surfactant (GM1, 4N/mm), however they may reach in spite of high loads even several hundred hours (GM2, 6N/mm). The relationship between failure time and welding parameters can be illustrated convincingly by using the ratio of the experimentally obtained reduction in thickness  $s_r$  to the calculated melt depth  $L_0$  of the geomembrane, i.e. the ratio in thickness reduction  $s_r / L_0$  as a reference figure. The  $s_r / L_0$  locus of failure time maxima with the parameters melt depth, roller pressure and speed may serve to optimize welding conditions and process-relevant seam quality assessment. It can also be used to recognize the limitations of hot wedge welding, such as

- principal limitations: the pre-heat conditions cannot be freely chosen but must be adjusted to the welding speed and
- practical limitations for the actual material and the welding machine used.

For seam quality standard  $s_r / L_0 = 0.7$  can be used which has been experimentally established as an invariant optimization quantity for HDPE. Parameter combinations near this value, i.e. falling in the range 0.5 to 0.9, are supposed to provide only

seams of good quality. Whether or not this finding holds under construction site conditions, it will be investigated in the future.

Failure time and failure performance depend closely on the type and extent of melt flow. Peel performance and annealing in seams suggest the consequences of rheologic phenomena, such as frozen-in orientation and melt vortexing in the seam centre and the displacement of molten material from the seam centre. The farther the  $s_r / L_0$  value from the optimum range 0.5-0.9, the stronger these phenomena.

A structural and thermal inhomogeneity over the seam width indicates that in such cases the seam strength also differs widely. It is, as a rule, higher in the lateral segments of the weld area into which molten material flows, thus making heat available to reduce orientation by relaxation.

# AUTOMATIC ULTRASOUND SEAM TESTER FOR BITUMINOUS GEOMEMBRANES - DEVELOPMENT AND FIELD RESULTS

B. Breul

Colas S.A., Direction Recherche et Développement, 92653 Boulogne Billancourt, France

J. Carroget

Colas S.A. Laboratoire Central de Recherche, 78114 Magny les Hameaux, France

R. Herment

Société des Pétroles Shell, Direction Bitumes, 92563 Rueil Malmaison, France

**ABSTRACT:** Bituminous geomembranes have been tested with hand-held ultrasonic equipment for twenty years. Colas has developed a mechanised seam tester for seam widths of up to 20cm, offering greater precision, reliability and speed. It consists of a 20cm-wide horizontal cylinder in which 24 ultrasound pick-ups bathe in a liquid medium. The rubber membrane conforms to irregular surfaces and is constantly wetted to provide intimate contact with the geomembrane. A VDU displays the data. Testing proceeds at a rate of 100 metres of seam per hour, compared with 50-80m per day with manual apparatus. The machine will work equally well on sloping linings. Readings are made every millimetre as the it progresses. Flaw detection resolution is 5mm<sup>2</sup> but the software only registers flaws larger than 1.5 cm<sup>2</sup>.

**KEYWORDS:** , Ultrasound, Seams, Testing, Geomembranes, Quality Control.

## 1 COLETANCHE® REINFORCED BITUMINOUS GEOMEMBRANE

Colétanche reinforced bituminous geomembrane is manufactured in 4m-wide rolls and consists basically of a needle-punched infinite polyester fibre geotextile impregnated with RI00/40 blown bitumen or a bitumen/elastomer mix. Thickness ranges from 3.3mm to 5.6mm. The geomembrane therefore meets French Standard NFP 84500, which requires that a geomembrane must be more than 1mm thick and more than 1.5m wide with a permeability coefficient expressed as the flow passing through it of less than 10<sup>-4</sup> m<sup>3</sup>/m<sup>2</sup> per day. The rolls are unwound on site with a 20cm overlap for the hot air seam.

The permeability coefficient of this geomembrane is very low over the whole width (the Darcy K coefficient is less than 10<sup>-13</sup> m/s) but when assessing overall in-place watertightness, one must consider any damage sustained by the geomembrane as it is laid, and seam quality. Since the bituminous geomembrane is thick and reinforced, it displays excellent resistance to puncturing by the granular covering material frequently applied as protection. It is also robust in terms of chance damage during the laying process, such as puncturing by a stone wedged in the sole of a workman's boot, a frequent source of damage to thinner membranes<sup>1</sup>. This means that it is very often sufficient simply to test seams to ensure that the whole waterproofing system meets the specification<sup>2</sup>.

Seam testing is also relevant to PVC, HDPE, EPDM and other types of geomembranes although not for geosynthetic clay liners which are not geomembranes under the NFP

84500 definition because they cannot be welded together. Geomembrane seam testing methods include the electric comb, double weld with central channel, and vacuum and ultrasound apparatus. The last-mentioned method yields what can be considered an X-ray image of the seam, immediately identifying flaws that need repairing.

## 2 MANUAL ULTRASOUND TESTING

Bituminous geomembrane seams have been tested for the last twenty years with hand-held ultrasound apparatus<sup>3</sup> working in the 1-3 MHz frequency band. Figure 1 illustrates the return echoes that are picked up and displayed on the oscilloscope when there is no discontinuity in the ultrasonic waves crossing the seam between the emitter and receiver. Figure 2 shows the echo pattern when the seam is flawed.

## 3 AUTOMATED ULTRASOUND TESTING

### 3.1. Test Machine

The CAC 94 automatic machine was designed in 1994 for automatic testing of seams widths up to 20cm. It weighs 200kg and has two steering wheels and two drive wheels. It tows a horizontal rubber cylinder, 21cm wide, filled with a conducting liquid, and contains 24 ultrasound pick-ups, set back 1cm from the cylinder wall so that they are unaffected as the rubber deforms when travelling over irregular surfaces. A spray bar meters a wetting agent ensuring

continuity between the ultrasound gear and the test seam. The positions of the flaws detected are marked on the membrane. The machine also carries a computer with liquid crystal screen.

Figure 1. No Flaw

This machine progresses at a rate of 100m per hour, as compared with 50-80m per day with hand-held apparatus.

Figure 2. One Flaw

### 3.2 Procedure

Figures 3, 4 and 5 show the interfaces encountered by the ultrasound waves:

A: Transducer/conducting liquid interface

B: Wetting agent/top membrane interface

C: Top membrane/bottom membrane interface

D: Bottom membrane/underlying soil interface.

Figure 3 shows the echo received from a sound seam, while figure 4 is the echo from a flaw at interface C. Figure 5 shows the display when no wetting agent is used. Readings are made every millimetre as the machine moves along the seam. Each transducer sweeps a strip parallel to the direction of travel. Each strip is subdivided into virtual rectangles for ease of processing and recording. This produces a grid map, with each rectangle measuring 9mm x 5mm approx. Adjacent flaws must aggregate more than 1.5 cm<sup>2</sup> in size, otherwise they are ignored by the software.

## 4 VALIDATION PROCEDURE

The machine was validated by comparing the results from manual and automatic testing of a seam 1.5m long and 20cm wide into which 0.2mm-thick brass inserts of various shapes had been placed. The inserts produce the same signature as an air bubble of the same area. The inserts ranged in size from 50 cm<sup>2</sup> to 1.5 cm<sup>2</sup> and were scattered in random fashion in the seam.

It was found that the map produced by the automatic machine resembled a radiographic image whereas the manual procedure aggregated multiple adjacent flaws into a single flaw, and sometimes failed to detect flaws that were known to exist (Table 1, figure 6).

## 5 PRACTICAL APPLICATIONS

### 5.1 Preparation

Before use on site, transducer response is checked by using a standard plate of constant thickness and acoustic impedance. The machine is then calibrated on a single thickness of the geomembrane as delivered to site in order to check that transducer response always indicates a flawed seam.

### 5.2 Examples of Field Use

The machine has been used both on the flat and on sloping linings such as at the Strasbourg municipal solid waste incinerator bottom ash stabilising yard in 1996. At the 38m-high Ortolo rockfill dam in Corsica with bituminous geomembrane upstream facing sloping 1 vertical for 1.7 horizontal, the machine was winched up from the toe to the dam crest; seams were 70m long.

Figure 3 : NO FLAW

Figure 4 : ONE FLAW

Figure 4 : NO WETTING AGENT

In all, field tests have revealed seam flaws needing repair amount to 1-2 ‰ of total seam footage.

6

## CONCLUSIONS

Seam quality control using the CAC mechanised seam tester is now standard practice. The stated goals of precision, reliability and rapidity have been achieved. It would appear that this test has led to an improvement in seaming quality.

# Evaluating the Stress Crack Resistance of HDPE Seams

R.W. Thomas

Vice President and Technical Director, TRI/Environmental, Inc., Austin, Texas, USA

**ABSTRACT:** Forty three (43) field seams were collected over the construction seasons of 1995 and 1996 in the United States. The seams were made from sheet supplied by at least 4 different manufacturers, were both smooth and textured, and included fusion and extrusion welds. The seams also ranged in thickness from 1 to 2 mm and were made by at least 5 different types of welding machines. The stress crack resistance of these seams was determined by a constant load test at 80°C. Results showed that 30% of the seams failed in less than 100 hours and that extrusion seams were more susceptible to crack formation than fusion seams. The main failure modes for the seams were also determined. Fusion seams broke primarily through the top sheet at the root of the squeeze-out bead. Extrusion seams showed five different failure modes but the most prevalent one was a crack directly through the extruded bead. This mode of failure raises important questions about the stress crack resistance of the welding rod used to make extrusion seams.

**KEYWORDS:** HDPE, Geomembranes, Laboratory Tests, Stress Cracking, Seams

## 1 INTRODUCTION

The phenomenon of slow crack growth (stress cracking) in HDPE geomembranes has been studied for over ten years and is still not well understood. Certain resin characteristics like density, molecular weight, molecular weight distribution and co-monomer type and distribution are believed to affect stress crack resistance, but it is not known exactly how. Therefore, this is one property of HDPE that needs to be continually monitored for quality assurance and to minimize the potential for field fractures. The main way to evaluate a materials stress crack resistance is with ASTM D5397, "Evaluation of Stress Crack Resistance of Polyolefin Geomembranes Using Notched Constant Tensile Load Test". This test is one of the best tools available for evaluating the stress crack resistance of smooth geomembranes and its development has directly led to improved resins and a reduction in the numbers of stress cracks that have occurred in the field.

The test has several limitations, however. First, it has limited use as a QC/QA tool because it is a relatively long test. The most common performance requirement for an acceptable geomembrane is a failure time greater than 200 hours under a load of 30% of the yield strength when tested by the appendix to D5397. This is over eight days which is too long for a QC/QA test. One way to accelerate the test is by increasing the temperature (Hsuan 1995, Thomas 1997).

Secondly, this test cannot be performed on textured geomembranes or seams. Tests on textured sheet are important because the texturing processes create flaws in the surface of the sheet and it is important to know if these flaws can lead to stress cracks. Tests on seams are important because historically, nearly all of the stress cracks found in the field started at a seam.

A modification of ASTM D5397 was developed several years ago in Germany by workers at a Federal Institute called Bundesanstalt für Materialforschung and prüfung, or BAM (Müller 1992). This test was subsequently used in the USA to

study stress cracking of textured geomembranes (Thomas 1993), and different types of seams (Thomas 1993, 1994, 1995). The test has been called the BAM test, and is a constant load stress crack test that is run at a higher temperature (80°C vs. 50°C), uses a specimen with more surface area (10 cm<sup>2</sup> vs 0.5 cm<sup>2</sup>) and does not involve a notch.

The purpose of this study was to use the BAM test to study the stress crack resistance of selected HDPE seams installed in the USA during the construction seasons of 1995 and 1996.

## 2 EXPERIMENTAL PROCEDURES

### 2.1 Seam Samples

Forty three (43) seam samples were collected from sites all over the USA. It is believed that they are a fairly good representation of the types of seams being made. Specific information is not known about all of the seams, except for the site they were from. However, it is known that they included sheet made from at least 4 different manufacturers and the seams were made by at least 5 different brands of welders. Otherwise, the exact resin, sheet manufacturer, installer, and welding machine were not known. All of the seams studied passed destructive peel and shear tests.

Thirty eight (38) seams were made from 1.5 mm (0.06 in) sheet, two were made from 1.0 mm (0.04 in) sheet, and three were made from 2.0 mm (0.08 in) sheet.

The seams were divided into four main classes. They were smooth/fusion, textured/fusion, smooth/extrusion, and textured/extrusion. Seams joining smooth sheet to textured sheet were considered to be textured seams. The numbers of each type are given in Table 1. An attempt was made to keep a balanced sample set, but this was not possible. It was more difficult to obtain extrusion seams because they are tested less frequently than fusion seams.

Table 1. Types of field seams evaluated.

Seam Type	Number of Samples
Smooth/Fusion	15
Textured/Fusion	11
Smooth/Extrusion	7
Textured/Extrusion	10

## 2.2 The BAM Stress Crack Test

The test specimens were rectangular bars, cut with a die and of the dimensions 1.25 cm x 15.2 cm (0.5 in x 6.0 in). They were mounted in modular lever arm devices, each capable of holding 5 specimens. The stress crack solution was 5% Igepal CA-720 in DI water, the test temperature was  $80 \pm 1^\circ\text{C}$ , and the applied stress was 4.0 MPa (580 psi).

The test was run by first mounting five replicate specimens in shear into a test device. This means that the top sheet was placed in one clamp and the bottom sheet on the other end of the seam placed in the other clamp. Then, the device was mounted onto the side of a constant temperature bath containing the stress crack solution. After about five minutes, the loads were applied to the lever arms and the timers on the devices set to zero. Placing the load on the specimens within five minutes is believed to allow them to become loaded more gradually, since they had not yet reached the test temperature. As each specimen failed, it tripped a switch causing the timer to stop. If no specimens failed within a specified time, the experiment was terminated.

## 3 RESULTS AND DISCUSSION

### 3.1 Failure Times

In nearly all cases, the average reported is the result of five test specimens. In two cases, specimens slipped from the grips, so the remaining 3 or 4 failed specimens were averaged. The average failure times of the 43 seams ranged from 17 to over 500 hours. Since the main focus of this paper was on fast failure times it was decided after a few months to terminate the tests once they reached 300 hours. The variability in the average failure times was relatively constant among the different sample types. A summary of the results in terms of failure time ranges is shown in Table 2.

These results clearly show that extrusion seams are more susceptible to cracking than fusion seams. Most of the fusion seams lasted over 300 hours while only a few of the extrusion seams did. Also, most of the extrusion seams failed in less than 200 hours, with 41% failing in less than 100 hours. Overall, 13 of 43, or 30% of the seams tested failed in less than 100 hours. Eight of the 13 failed in 50 hours or less.

Table 2. Summary of average failure times (43 samples).

Failure Time(hrs)	Smooth Fusion	Textured Fusion	Smooth Extrusion	Textured Extrusion
<100	3 (20%)	3 (27%)	5 (71%)	2 (20%)
100-200	1 (7%)	2 (18%)	1 (14%)	4 (40%)
200-300	3 (20%)	0 (0%)	0 (0%)	2 (20%)
>300	8 (53%)	6 (55%)	1 (14%)	2 (20%)

Two important questions that need to be addressed are:

1. Why do some seams fail more quickly than others?, and
2. How good is good enough?

The first question is related to a number of factors which affect the stress crack resistance of the seams. First, the stress crack resistance of the base sheet is an important consideration. The generally accepted minimum value for a geomembrane is 200 hrs, when tested by the Appendix to ASTM D5397. Most of the resins on the US market today have average stress crack values from 500 to 1000 hours. There are also a couple of resins that can easily exceed 2000 hours in this test. It has been shown that seams made from great resins will be less susceptible to stress cracks than seams made from average resins (Thomas 1995).

A second factor which affects the stress crack resistance of the seams is the welding process itself. During seaming, events can occur which may affect stress crack resistance. It has already been shown that the geometry of the hot wedge and drive wheels is an important factor (Thomas 1995). Additionally, the wedge temperature, drive roller pressure, and welding speed are important variables. During extrusion seaming, the surface of the sheet is ground and preheated before the extrusion bead is put in place. Over-grinding can leave stress crack initiation sites in the joint, as can overheating. The quality of the welding rod is another variable. It may or may not be made from the same resin as the sheet. And, even if it is, its stress crack resistance can be compromised by high temperatures or long dwell times in the extrusion gun.

A belief held by the author is that, in general, one can hardly do anything to hurt an excellent resin, but average resins can produce seams that might be considered unacceptable. Again, it is important to decide what level of performance is desired. Obviously, a seam that lasts 200 hours in this test is better than one that lasts 100 hours, but how does one know that a 100 hour seam is not acceptable?

The answer to this question is important because even though seam samples can fail in an accelerated test does not mean the seams will fail in the field. On the other hand, it would seem prudent to expect some minimum performance to further reduce the potential for field failures. Fast failure times might also be indicative of correctable quality problems in the seams.

One way to consider how long a seam should last is by comparing seam results with results from ASTM D5397 performed at 80°C (Thomas 1997). Results from that study showed that the test is accelerated by at least 8 times when run at 80°C and a load of 20% of the yield stress. That means that 200 hours in the notched test at 50°C is about equal to 25 hours in the test at 80°C. Obviously, if a seam breaks as quickly as a notched sample, the seam would essentially be like a defect equivalent to a razor blade cut to a depth of 20% of the thickness of the sheet. So, one would expect a seam sample to last much longer than a sample with a notch in it. Therefore, a seam requirement of 100 hours in the BAM test would suggest that the seam was 4 times more resistant than the minimum required notched sheet stress crack resistance. The stress crack resistance of the seam is definitely a result of both the stress crack resistance of the sheet and the amount of stress placed into the seam during the seaming process (Thomas 1995). That means that the 100 hours minimum time could be reached by a good resin with a significant amount of internal stress in the seam, or a minimally acceptable sheet made into a seam with very little internal stress. Either way, 100 hours seems to be a reasonable and obtainable value.

### 3.2 Failure Modes

The modes of failures for all of the specimens that broke were examined independently from the failure times. The failure times are greatly influenced by the resin, but the locus of failure can provide valuable information about the “weak link” in the seam. The crack will start at some location under stress that contains a flaw.

There were three different failure modes associated with double track fusion seams. They were: 1) a crack in the top sheet at the base of the squeeze-out bead, 2) the same location in the bottom sheet, and 3) a crack forming in the sheet away from the weld. Only one sample cracked in the sheet. It was a textured sheet seam and the fact that it failed in the sheet suggested that the sheet itself was more susceptible to cracks than the seam. The crack appeared to start at a thin spot in the geomembrane. The distribution of the failures modes found in the fusion seams is shown in Table 3. It is clear from these results that most of the fusion seams tested failed in the top sheet. This was true for both smooth and textured seams.

Table 3. Fusion seam failure modes (42 specimens).

Failure Mode	Number (% of Total)
Top sheet at squeeze out	27 (64%)
Bottom sheet at squeeze out	10 (24%)
In the sheet	5 (12%)

The total number of specimens available for failure mode analysis was 42 even though there should have been 60 since 12 fusion samples with 5 replicates failed in less than 300 hours. However, three sets of seams tested early in the study were discarded and three individual specimens slipped from the grips.

There were five different failure modes observed for extrusion seams. They were: 1) failure through the extrusion bead, 2) failure through the top sheet under the extruded bead, 3) failure through the top sheet at the edge of the extruded bead, 4) failure through the bottom sheet under the bead, and 5) failure through the bottom sheet at the edge of the extruded bead.

The distribution of these failure modes through the samples tested is shown in Table 4.

Table 4. Extrusion seam failure modes (70 specimens).

Failure Mode	Number (% of Total)
Through the extrudate	43 (61%)
Top sheet under bead	4 (6%)
Top sheet at edge of bead	3 (4%)
Bottom sheet under bead	12 (17%)
Bottom sheet at edge of bead	8 (11%)

The most common and surprising failure mode was directly through the extruded bead. This occurred over 60% of the time and was more common in smooth seams than textured seams (80% vs. 48%). The most surprising fact about this failure mode was the length of some of the cracks. There were beads that were over 7.6 mm (0.3 in) tall. This failure mode suggests that the stress crack resistance of the welding rod itself needs to be considered. It is possible that either a different resin is being used to make the rod, or the rod is somehow damaged during the extrusion process.

Failures through the top sheet either under the bead or at the edge of the bead were relatively rare. There were only 7 specimens that failed this way and 6 of them were textured.

Failures in the bottom sheet either under the bead or at the edge of the bead were the second most common modes. Most of these were found in textured sheet (15 vs. 5). In fact, there were no failures in smooth sheet that occurred at the edge of the bead, they all failed at a location under the bead. Close examination of one of the samples that failed under the bead showed that the cracks grew from grinder marks that had not been remelted during the extrusion process.

The failures at the edge of the extrusion bead in textured sheet may have been a result of sheet thinning in that area. It is reasonable to assume that if the sheet thins, it would have a higher stress causing cracks to grow there more quickly.

Of the failures cataloged above, the ones that failed in less than 100 hours are examined again in Table 5. These results give an indication why the seams failed so quickly.

Table 5. Failure modes of 13 seams failing in <100 hours.

Seam Type	Failure Mode
Sm./Fusion (3)	100% - top sheet at squeeze out
Tex./Fusion (3)	66% - top sheet at squeeze out 33% - in the sheet
Sm./Extrusion (5)	100% - through the extrudate
Tex./Extrusion (2)	50% - bottom sheet under bead 50% - bottom sheet edge of bead

Close examination of these 13 seams shows that causes of early failures can be found in most cases. The smooth/fusion seams all failed by a crack in the top sheet at the base of the squeeze out bead. It was discovered that one failed because of a bad resin. The failure time of the sheet by the notched stress crack test was 65 hours, which is much less than the required 200 hours. The other two appeared to be overheated. One was a 1.0 mm (0.04 in) seam that had large ripples throughout the seam. The other was a 1.5 mm (0.06 in) seam that had been distorted to the point that the cross-section of the seam was shaped like a stretched out letter Z.

Two of the textured/fusion seams failed in the top sheet at the root of the squeeze out and the other failed in the sheet. The seams looked acceptable, but it was possible that there were thin spots at the edges. The seam that failed in the sheet was made from a textured sheet that appeared to have many thin spots. It also failed quickly ( $51 \pm 4$  hours), which indicates that the stress crack resistance of the textured sheet itself should be considered.

All of the smooth/extrusion seams failed through the extruded bead. This mode of failure proves that the stress crack resistance of the welding rod needs to be controlled. All of these seams would probably have surpassed 100 hours with a higher quality welding rod.

The textured/extrusion seams all failed in the bottom sheet, with half cracking at the edge of the bead and half cracking under the bead. It appeared as if sheet thinning was the cause of the failures at the edge and overheating caused cracks under the bead. The sample that cracked under the bead showed puckering underneath the bottom sheet.

This brief analysis suggested that the seams that failed in less than 100 hours all had some type of quality defect. This supports the selection of 100 hours as a minimum acceptable failure time. It is strongly believed that all of these times can be easily improved by learning more about the relationship between the seaming process and the stress crack resistance of the resulting seams.

#### 4 SUMMARY AND CONCLUSIONS

This paper presented results of stress crack tests performed on 43 field seams made in the USA during the construction seasons of 1995 and 1996. The failure times and the different failure modes were reported. The results obtained lead to the following conclusions.

1. Extrusion seams are more likely to fail by stress cracking than fusion seams. This is extremely important when one considers the appropriateness of cutting holes in fusion seams to test them and repairing the resulting hole with an extrusion seam.
2. The main failure mode for extrusion seams was a crack through the extruded bead. This means that the stress crack resistance of the welding rod is a new and important consideration.
3. Seams that failed in less than 100 hours likely had quality defects that can be corrected.
4. The BAM test has proven to be a very effective tool for evaluating the quality of seams. More work is required to discover why seams break quickly and how to make seams that survive longer in this test. Longer times in the BAM test will certainly improve the reliability of a geomembrane over its service lifetime.

**ABSTRACT:** The objective of this paper is to analyse the effects of aging on geomembrane durability and to design an accelerated test (few months duration). This test takes into account the different aging parameters without changing the aging mechanisms observed on site. Different analysis and mechanical tests are considered to characterize the geomembrane changes. Results show good agreement with observations on site.

**KEYWORDS:** Geomembrane, Mechanical properties, Stress cracking, Polymeric aging.

## 1 INTRODUCTION

Geomembranes have been used almost all over the world for about three decades. During these years the variability of applications of geomembranes has been constantly increasing. Nowadays, the environment in which geomembranes are used is very different from an application the another.

Among all the problems encountered by engineers and scientists in this context of technological diversity, the question of durability is one of the most important in terms of engineering and scientific complexity.

The problem of geomembrane durability has been addressed by researchers like Haxo (1989) and Koerner (1990). Their pioneering work, besides setting the bases for future research, enabled considerable enhancements in material developpement and engineering practice. But not all has been done! To the simple question "how long will this particular geomembrane perform in this particular case of application?", no simple answer can be found, and moreover, no widely accepted method can be found to answer it. Most of the time, and particularly when environmental issues are at stake, the answer is crucial.

The lack of a ready-made method to evaluate the durability of geomembranes is mainly due to the fact that in many cases, physical, chemical and biological stresses of the geomembrane and their effects on the material are not very well known. This, in turn, is due to the lack of measurements, either of the stresses themselves or of their separate aging effects on the geomembrane geomembranes.

An objective of the study presented herein is to set up

the bases of a method to accelerate the aging of by increasing the value of pertinent individual form of stresses. Our final goal is to predict the durability of geomembranes under given conditions.

The research program involved four french laboratories: CEMAGREF (Agricultural and Environmental Engineering Research Institute), INERIS (National Institute for Industrial Environment and Risks) and LIRIGM (Research Laboratory on Geology and Mechanics, Grenoble University), LRPC (Regional Research Laboratory of Civil Engineering of Lyon), under financial support from ADEME (National Agency for Environmental Protection and Energy Saving).

## 2 AGING OF GEOMEMBRANES: THEORETICAL FRAMEWORK.

### 2.1 Definitions

The following definitions and theoretical framework to aging studies are based on well-established methods in the field of polymer aging (Verdu, 1984). These methods have been validated and successfully applied in such domains as automobile, electronic equipment, pipes, etc...

Aging is defined as a slow and irreversible evolution of material properties under environmental stresses.

Durability should not be confused with aging. It is the ability of a material or a structure to withstand aging in such a way that its properties remain in the limits of acceptability for a given use.

The service life of a material or a structure is the time during which its properties remain in the limits of acceptability for a given use. In order to estimate the service life of a geomembrane, it is not only necessary to predict its aging but to define the limits of acceptability of its properties.

Natural aging is defined as aging under condition in use.

Artificial aging is defined as aging in a specific, controlled device, either in the laboratory or on site. The quality of artificial aging depends on its closeness to natural aging.

Artificially accelerated aging is defined as accelerated aging by the means of artificial conditions. Aging mechanisms are supposed to be similar to those occurring in field condition but in an accelerated way.

Aging environment is a set of external factors likely to influence aging of a material or a structure.

It has to be underlined that aging depends on numerous environmental parameters: some parameters can be isolated and others are interacting.

The typical example to illustrate this lack of data concerns the long-term behavior of geomembranes used in landfill barriers. The physico-chemical environment to which a geomembrane is exposed at a landfill bottom is generally reducing and light-free. These conditions are thought to be favorable to geomembrane durability, because polymers are usually affected by photo-oxidation aging processes which can reasonably be neglected here. On the other hand, the leachate in which the geomembrane is continuously immersed is a complex aqueous solution of low concentration chemicals which have a potentially long-term deteriorating effect on geomembranes, especially when combined with mechanical stress and temperature. This already complex situation is furthermore complicated by the extreme difficulty of *in situ* observations : solicitation measurements are very scarce and sample collection and analysis is impossible most of the time. It is therefore necessary to develop tests in which aging mechanisms are similar to those occurring in field conditions but in an accelerated way.

The effect of interacting chemical and mechanical stresses can be illustrated by the now famous example of stress cracking of High density polyethylene (HDPE) (Hsuan et al., 1993) further developed in part 3 of the present article.

### 3 ACCELERATED AGING: TESTS AND RESULTS

Results presented herein concern HDPE geomembrane 2 mm thick and flexible polypropylene (FPP) geomembranes. The main reason for this presentation is that full results and interpretations are available on the HDPE material and that FPP is quite new.

Chemical, thermal and mechanical aging conditions have been selected on the base of literature. Different geomembrane types have all been immersed in the same immersion medium at 23 and 60 °C, under constant uniaxial tensile strain (5% for HDPE and 10% for FPP). The synthetic immersion medium (SIM, presented in table 1) is an aqueous solution of selected active chemicals, considered as a collection of aging-triggering agents. The SIM is designed to age the geomembranes without modifying natural aging mechanisms, each solvent representing a chemical family, known to be interacting with geomembranes.

Table 1. Initial SIM composition

Compound	Concentration
Cyclohexanone	30 g/l
Phenol	3 g/l
Perchloroethylene	0.1 g/l
Xylene	0.1 g/l
Heptane	0.1 g/l
Surfactant	10 g/l
pH	2

Samples are regularly taken out from the tanks (every 2 months with a maximum immersion time of 8 months). Samples are then weighted (before and after drying at 60°C (or 30°C for samples immersed at 23°C) during 48 hours) and tested using analytical and mechanical methods.

#### 3.1. Results On HDPE Samples

Physico chemical analysis was presented in "Accelerated aging tests for geomembranes used in landfills" (Maisonneuve et al., 1997). As it is thought that aging first affects the surface of geomembrane, such analysis cannot detect changes at the surface of the material because the polymer is melting due to the high temperature during analysis. Surface analyses would be more appropriate. More thorough experiments are underway. Only Oxidative Induction Times (OIT) which gives the time for oxidation in isothermal conditions decreased (table 2). It shows a loss of antioxidants.

Duquenois et al. (1995) also noticed a small loss of ester-type antioxidant after 27 months, in leachate at 50°C.

Tensile tests and shear tests show a decrease in strength at yield (table 2) and an increase in strain at yield with aging on both seamed and non seamed samples.

To confirm this result, the relaxation modulus has been assessed by measuring the stress in a sample maintained at a fixed strain. The residual modulus is higher in stressed non-immersed samples at 23°C than in stressed samples

immersed in the SIM at 60°C for the same fixed strain (table 2).

It can be induced by the internal lubrication in the polymer due to the absorption of components.

Moreover, we also detect an increase in strain for samples immersed in water at 60°C, during the same time, but no change happens for samples in SIM, at 23°C. This change is an important result because Giroud (1984) has demonstrated that failures of HDPE geomembranes are governed by the yield strain on the order of 10%.

Castaldo (Eurogeo,1996) noticed similar mechanical variation for 3 different HDPE immersed in a synthetic medium at elevated temperature (50°C and 70°C).

A possible interpretation of these observations is that modification of mechanical properties at yield described above depends first of temperature.

Table 2. Variations between 8 months aged HDPE samples and reference HDPE samples for different tests and analyses

Tests	Variations* (%) in	
	water, 60°C	SIM, 60°C
tensile test		
strength at yield	1	-0.5
strain at yield	3.2	5.4
shear test		
strength at yield	3	-15.2
strain at yield	4	10.8
peel test	No significant results	
relaxation	modulus	air, 23°C
		SIM, 60°C
	non seamed sample	-70.7
	seamed sample	-79.5
mass	before drying	0.1
	after drying	0
thickness	No significant results	
density	No significant results	
permeation	Soon available results	
DSC	No significant results	
OIT	Time to oxydation	-56
TG	Soon available results	
MFI	No significant results	

\* Aged samples are immersed 8 months in pure water and in SIM, at 60°C; they are then tested after drying 48h at 60°C. The relaxation test compares stressed sample in air and in SIM during 8 months.

A very important phenomenon to be considered for semi-cristalline polymers in the visco-elastic state (like

HDPE) is stress cracking. To induce it, notched samples are immersed in different media (SIM, surfactant in solution or pure water) under constant stress. Two types of break can be developed:

- Ductile break obtained with a stress large enough to produce a fast yield point: Interlamellar chain tension produces intra-cristallite break.

- Brittle break obtained with a smaller stress: Break occurs in the amorphous zone (inter-cristallite break).

Our first results on HDPE immersed in SIM show the transition from brittle break to ductile break which occurs at about 40% of the stress at yield. When comparing results obtained with SIM and with water, the influence of the immersion medium is noticeable: No break was observed in water after 2000h, whereas break occurred after 10h for HDPE in SIM for the same stress level.

The immersion medium has a growing reactivity with high pH, a low viscosity and a low surface tension (Courard, 1996). We can compare our result to results found by Hsuan et al (1993) : they compare the effect of different incubation media. The medium composed by 10% IGEPAL Co630 in 90% tap water will be seen to be a very aggressive incubation liquid compared to other fluidslike 100% tap water or air (i.e. no liquid immersion).

To induce stress cracking in field, it must have a point at which a crack can initiate (simulated by notched sample in laboratory). Condition of a crack initiation point could be an imperfection scratch, carbon black agglomeration or other anomaly but will most likely be at the location of a seam (Carson,92).

These data clearly show solvent absorption by the geomembrane, increased both by temperature and the SIM.

### 3.2 Results On FPP Samples

This geomembrane is a rubber modified polypropylene and it is very difficult to characterize the molecular properties because the different components interact during physico chemical analysis: it is then impossible to separate them. In this particular case, physico chemical analysis do not appear to be good indicators of aging. More thorough experiments are underway.

Figure 2. HDPE and FPP tensile test.

Like HDPE, we focused our research on mechanical tests. The yield point is not as distinct as in HDPE (figure 2) because of the Ethylene Propylene Rubber included in PP. However, in tensile tests, we observed a decrease of the pseudo- yield strength, as in HDPE.

Mass variation, measured after 2 months immersion tests are presented table 3.

Table 3. Mass variation on FPP

T = 23°C	T = 60°C
SIM	SIM
+ 5 % before drying	+ 5 % before drying
+ 2% after drying	- 0.5% after drying
Water	Water
+ 1% before drying	+ 2% before drying
0% after drying	0% after drying

Absorption is noticeable for samples immersed in SIM and water. In water immersion, the variation is reversible. In SIM, at 60°C, the mass is inferior to initial mass, the copolymer seem to be attacked by the solvents. In SIM, at 23°C, solvents are still present in the copolymer after drying, the heat to extract solvents during drying is probably not important enough.

#### 4 CONCLUSION

Physico chemical analysis did not evidence aging phenomena on HDPE and FPP, except for the loss of antioxidants.

We suppose that for both HDPE and FPP, modification of mechanical properties at yield first depends on temperature.

Stress cracking tests show the importance of the immersion medium to develop cracks. This phenomenon is very important because break is obtained under the same conditions on site and during our experiments.

Solvent absorption by immersed samples depends both on temperature and on immersion medium.

HDPE and FPP geomembranes have a good resistance to the applied stresses. Additional analyses are necessary to correlate mechanical stresses with a change in structure.

Similar modification are noticed on accelerated aging geomembrane and on 'natural' aging geomembrane: this accelerated aging process seems to be a good way to understand the long term behavior of geomembranes. Next step consists on determining accelerated aging factors by comparing the effects of accelerated aging to the effects of aging on site. Other materials and sollicitations should also be considered.

#### ACKNOWLEDGEMENTS

This study was partially financed by ADEME and could be achieved. The aging study on HDPE and on FPP was conducted at INERIS laboratory (which supported a PhD work with ADEME on this subject) and at IRIGM, university of Grenoble (France).

**ABSTRACT:** The U. S. Department of Interior, Bureau of Reclamation (Reclamation) began investigating the long term properties of flexible polypropylene (fPP) geomembranes as early as 1989. This paper presents the performance of fPP geomembranes at two field test sites in which the geomembranes were either covered by soil or partially exposed to direct sunlight. The buried fPP continues to have good mechanical properties after 6 years. The particular stabilization package used in the exposed fPP was found to be inadequate to prevent ultraviolet (UV) degradation. The exposed section of the geomembrane showed cracking after 26 months. Furthermore, the UV degradation was substantiated in a laboratory acceleration test using a UV weatherometer. This indicates that UV weatherometer exposure and subsequent testing can be used for screening to evaluate the UV resistance of differently formulated fPP geomembranes.

**KEYWORDS:** flexible polypropylene, geomembrane, ultraviolet resistance,

## 1 INTRODUCTION

In 1989 Reclamation began a study on the laboratory evaluation of a new type of geomembrane that was being developed. This new geomembrane is a co-polymer of propylene and ethylene (Kilius and Shah, 1995). It is generically referred to as flexible polypropylene (fPP). The laboratory studies gave rise to two separate field installations. The fPP geomembrane involved in these two case histories was supplied by one manufacturer who also formulated the stabilization package.

The first field installation by Reclamation of a fPP geomembrane was in April, 1992. A 0.75 mm (30 mil) thick geomembrane was used as liner in a test section of a canal near Belle Fourche, South Dakota, United States. The geomembrane was placed directly on the soil subgrade and covered with 0.4 m (16 in) of soil. Thus the geomembrane was fully covered during the duration of the test program. Coupons were retrieved from the test section after 3, 4 and 6 years. The possible changes in physical and mechanical properties were evaluated.

The second field installation was in May 1994. A 1 mm (40 mil) thick fPP geomembrane was used as a liner in a salinity gradient solar pond near El Paso, Texas, United States. Details of the concept and principles of solar pond behavior have been described by Lichtwardt and Comer, 1996. The geomembrane in the upper portion of the pond was not covered and thus it was exposed directly to the ambient environment. The geomembrane in the lower portion of the pond was covered by a brine solution which varied in concentration, with fresh water on the surface and concentrated brine on the bottom. The geomembrane at the bottom of the pond reached temperatures as high as 90°C. In order to monitor the geomembrane properties during the

testing period, test strips were installed on the northern slope of the pond. The strips were retrieved at different time intervals so that the change in material properties could be evaluated. Additionally, laboratory acceleration tests were performed on this 1.0 mm thick geomembrane in order to evaluate the long-term behavior of fPP material. Two accelerated incubation protocols were carried out: water incubation at elevated temperatures and accelerated weathering incubation using an ultraviolet weatherometer.

This paper presents the results obtained from both field sites so that the performance of fPP geomembranes under two different service conditions can be compared and contrasted. In addition, data obtained from the laboratory and field coupons will be compared in order to assess the merit of the respective acceleration tests.

## 2 fPP GEOMEMBRANE USED AS A CANAL LINER

Belle Fourche Irrigation District Personnel prepared a previously determined leaking 150m (500 ft) long section of the Belle Fourche canal for placement of a geomembrane. This preparation included removing all protrusions (e.g., stress) in the subgrade which were larger than 20 mm (3/4 in.). A fPP geomembrane was selected for this test site to examine its long term performance in a canal lining application. The fPP was factory fabricated into panels so that the only seaming required was a transverse weld between ends of the adjacent panels. Panels were folded, rolled, and placed on pallets which were delivered to the job site.

The 0.75 mm (30 mil) unreinforced fPP was hand-placed in the canal as shown in Figure 1. The ends of the

Figure 1 - Hand-placed the fPP geomembrane in the canal.

adjacent panels were to be wedge welded. However, problems were encountered welding the fPP geomembrane in the sun using a welder which was originally designed to weld high density polyethylene (HDPE) geomembranes. Therefore, the panels were welded using a hot air gun aided by a hand-held roller. These seams were determined to be adequate since canal linings are not generally required to provide 100 percent seepage control.

Following placement of the geomembrane, coupons were attached to the geomembrane both above and below the water for monitoring purpose. The geomembrane was then covered by a protective layer comprised of 0.2 m (8 in) of soil topped by 0.2m of sand and gravel so as to provide for erosion resistance.

### 2.1 Test results of field coupons

Transport of water in this location is provided during the summer months only. Therefore, the test coupons were removed following 2, 3 and 5 irrigation cycles, i.e., 3, 4 and 6 years of duration. The results of mechanical property testing are reported in Table 1.

The mechanical properties of tensile, tear, and seam peel and shear have not changed significantly over the 6 years that the fPP has been buried. Whether the soil covered geomembrane is above the water line or beneath it does not seem to have an effect on the mechanical properties. The unreinforced fPP continues to have excellent elongation properties and adequate tensile and seam properties.

Water district personnel report that the fPP geomembrane has stopped the seepage problems that were present prior to the installation.

Table 1. Properties of Belle Fourche buried fPP geomembrane sheets and seams. (values are the average of 5 replicates)

Year	1994	1995	1997
<b>Geomembrane sheet</b>

### 3 fPP GEOMEMBRANE USED AS A SOLAR POND LINER

Five test sample strips were installed on the north slope of the solar pond noted in the introduction. However, the strips were placed 6 months after the pond being constructed. The length of the strips extends from the anchor trench to the bottom of the pond so that coupons from different zones of the pond can be taken for analysis. Parallel to the field study, coupons of the geomembrane were evaluated by two laboratory accelerated incubation methods: UV degradation and thermo-oxidation. Both field and laboratory coupons were tested for their tensile properties and melt flow rate (MFR). Table 2 gives the method used for each test and the parameters that were monitored. The results obtained from the field and laboratory coupons are presented in this section.

Table 2. Tests and test parameters used in the solar pond study.

Test	ASTM Method	Test Parameter
Tensile	D 638 Type IV	break stress/break strain
Melt Flow Rate	D 1238	value at 2.16 Kg/230°C

#### 3.1 Test results of retrieved field coupons

The field sample strips were retrieved after 6 and 12 months duration. Coupons were taken from six different zones along the length of the strip. The zone location and exposure condition of the coupons are described in Table 3.

Table 3. Description of the field coupons

Code	Zone	Exposure Conditions
1	Trench	ambient temperature/no UV
2	Exposed	ambient temperature/UV
3	Upper Liquid	water/ambient temperature/limited UV
4	Middle Liquid	brine solution at 30-50°C
5	Lower Liquid	brine solution at 50-70°C
6	Base Storage	brine solution at 70-93°C

Tensile tests were only performed in the machine direction of the geomembrane. For each coupon, five tensile replicates and three MFR replicates were tested. The average values were compared to their corresponding original value to obtain the percent retained value. Figure 2 shows the percent retained of each test at six different zones as described in Table 3. After 12 months, both tensile properties and MFR value of the geomembrane remained largely unchanged, although MFR values at the exposed zone are higher than the other zone locations.

However, after 26 months of service, before the 24 month old strip sample being retrieved, cracking was observed on the geomembrane in the exposed zone, i.e., Zone 2. This indicates that the geomembrane was undergoing UV degradation. Coupons were cut from the geomembrane in this particular zone for property evaluation. The change in properties is shown in Figure 3. The tensile break stress and break strain have dropped approximately 50% whereas the melt flow rate value increased 400%. On the other hand, the geomembrane that was covered either by soil or solution did not show any cracking, and their properties remained almost the same.

Figure 2. Properties retained of field coupons at different locations.

### 3.2 Test results of laboratory coupons

The long term durability of this particular fPP geomembrane was evaluated after exposure to two laboratory accelerated procedures: water incubation at elevated temperatures and ultraviolet exposure.

Figure 3 - Properties retained of field coupons in Zone 2.

#### 3.2.1 Water incubation study

The water incubation test was meant to simulate the effect of high temperature on the geomembrane in a liquid medium. Water was used instead of the brine solution due to the difficulty of maintaining the salt concentration. Coupons were incubated in separate water baths at temperatures of 55, 65, 75 and 85°C. The incubated coupons were removed from the baths on three month intervals. Tensile and MFR tests were performed on the retrieved coupons. Figure 4 shows the property retained values of the geomembrane coupons during the 12 months of incubation at 85°C. There is essentially no change in the properties, since the change is within the variation of the test method itself. Similar behavior was observed at the three lower incubation temperatures.

Figure 4. Changes in properties of geomembrane incubated in water bath at 85°C.

#### 3.2.2 UV exposure study

To simulate field conditions of the geomembrane located in the exposure zone (Zone 2 of Table 3), geomembrane coupons were incubated in a fluorescent UV weatherometer. The incubation procedure was according to ASTM D 5208. The condition of the incubation was set to be 5 hours of UV light at 60°C followed by a 3 hours

Figure 5. Changes in properties of UV exposed coupons

condensation at 50°C. Coupons were removed from the apparatus after 500, 1000, 3500 and 7500 hours of incubation time. Tensile and MFR tests were performed on the removed coupons. The test results are presented by plotting the property retained against the incubation time, as shown in Figure 5.

The tensile break stress and break strain do not show changes until 3500 hours after which their values decrease significantly. For the MFR value, it gradually increases after 1000 hours. It was impossible to measure the MFR value for the 7500 hour coupon due to its rapid flow. The increase in MFR value indicates that a chain scission reaction is taking place in the polymer. The UV degradation probably started between 3500 and 7500 hours. Furthermore, many regions in the 7500 hours coupons became so brittle that cracking resulted during cutting of the test specimens. Thus, the break stress and break strain at 7500 hr could be much lower than values that are shown in Figure 5.

### 3.3 Correlation between field and laboratory studies

In the water incubation study, test results are consistent between the laboratory coupons and field-retrieved coupons, even though the immersion solutions are not the same. After 12 months incubation, there was no substantial change in either tensile properties or MFR values at temperatures as high as 85°C.

For the UV acceleration study, cracking was noticed in coupons exposed for 7500 hr. Also cracking was observed in the field after 18 months. This suggests that the UV degradation of the geomembrane can be estimated using the fluorescent UV weatherometer. The correlation between the UV acceleration test and the field condition can be quantified based on the total UV radiation energy as described by Hsuan and Koerner, 1993. The calculation procedure is presented as follows:

- Step 1 - Determine the total UV radiation energy in the 295-385 nm range at the field site. Since the site is located at El Paso, Texas, this value is estimated using data published by South Florida Test Service for their Arizona site (South Florida, 1993). From May 1993 to June 1995, the total UV energy was measured to be 696 MJ/m<sup>2</sup>. This value is considered to be the approximate amount of energy that the field

exposed geomembrane was subjected to during its 26 months of service life.

- Step 2 - Calculate the total UV energy being generated by the weatherometer during 7500 hours of incubation. The weatherometer is equipped with UVA-340 lamps with peak emission at 343 nm. The UV energy from 295-400 nm is 39 W/m<sup>2</sup>. The actual UV light time in 7500 hours = 7500 \* 5/8 = 4687 hr. The total energy generated = 4687 hr \* 39 W/m<sup>2</sup> = 658 MJ/m<sup>2</sup>.
- Step 3 - Compare the results of the previous two steps where it is seen that the field (696 MJ/m<sup>2</sup>) is quite close to the laboratory (658 MJ/m<sup>2</sup>) which is encouraging insofar as laboratory simulation studies are concerned.

## 4 CONCLUSION

In the two case histories reported in this paper, buried and exposed fPP geomembrane were monitored for changes in the as-received properties. The buried fPP canal liner continues to retain essentially all of its mechanical properties after 6 years of service. The field performance indicates that the geomembrane has stopped the seepage problems that were present prior to the installation. For the exposed fPP geomembrane, cracking was observed after 26 months, indicating that this particular stabilization package is inadequate to protect the geomembrane under the site ambient environment. An accelerated laboratory test using a UV weatherometer showed good correlation to the field performance. Thus, it seems that the UV weatherometer could be used to evaluate different UV stabilization packages being used in the fPP geomembrane.

## ACKNOWLEDGMENTS

Laboratory testing by the Bureau of Reclamation was performed by John Schaffer of the Materials Engineering and Research Laboratory. Linda Konrath was supported by the NSF Research Experience for Undergraduates, Project number CMS-9312772.

President, I-CORP INTERNATIONAL, Ocean Ridge, Florida, USA

**ABSTRACT:** A fracture mechanics methodology for predicting the life expectancy of PE geomembrane liners under service conditions is presented. The approach builds upon the experience and success gained in developing a lifetime assessment capability for PE natural gas pipes. It combines slow crack growth testing with fracture mechanics analyses to predict the life expectancy of the liner. Correlations for the time for initiation of crack growth and the crack growth rate with the stress intensity factor are developed. It is demonstrated that the bidirectional shifting method and shift functions, developed for PE pipes, can also be used to quantify the influence of temperature on the failure process in PE geomembranes. The correlation for the crack growth rate can be integrated for the field loads to predict the liner's life expectancy. This approach can be used to establish the admissible initial defect size for a prescribed loading and service life, and as a basis for specifying inspection requirements, and quality control and assurance standards.

**KEYWORDS:** Geomembranes, Stress Cracking, Fractures, Temperature Effects, Failures

## 1 INTRODUCTION

Geomembranes are used to line evaporation, ash and other ponds of electrical power stations in the United States, Canada and Europe in addition to solid waste and hazardous waste landfills. Geomembranes are often used as the primary barrier to prevent intrusion of contaminants into the adjoining soil and ground water. Therefore, long-term durability is essential to the reliable performance of these barriers.

Premature failures of a number of uncovered liquid impoundment and solid waste lining systems in North America and Europe have occurred (Peggs et al. 1988). In many instances these failures could be traced to cracking originating at scratches and gouges produced during the installation of the geomembrane, near seams or at other stress risers. Frequently, the driving force for the failure of liners in uncovered ponds is due to thermal contraction stresses that may result from large changes in ambient temperature with the onset of the winter season if proper precautions are not exercised in the design and installation of the geomembrane.

While several different materials have been used in geomembranes, high density polyethylene (HDPE) is often the material of choice because of its better chemical resistance to degradation by harsh chemicals and aggressive leachates. Like other polymers, polyethylene is a viscoelastic material and, therefore, is susceptible to time-dependent failures at stresses significantly less than its yield strength. Stress rupture tests are frequently performed to evaluate the susceptibility of a geomembrane material to

time-dependent failure. A typical test is the notched constant tensile load (NCTL) test (ASTM 1993). In this test a dumbbell shaped face-notched specimen is subjected to a constant tensile load in the presence of a surfactant (e.g., Igepal) at an elevated temperature, and the time to failure as a function of the applied stress is measured. Examples of the application of this test method to HDPE geomembrane materials along with data can be found in Hsuan et al. (1993) and Lord et al. (1993). Failure at the higher stress levels is characterized by a ductile collapse of the remaining ligament or net section. By contrast, the failure at lower stresses exhibits little ductility at the macroscopic level and generally results from slow crack growth (SCG). The latter failures are often referred to as brittle because of their slit-like appearance even though there is evidence of ductility at the microscopic level.

To date, no quantitative relationship between the time to failure in an NCTL test and the actual service life of a geomembrane liner has been established. Until recently, a similar situation existed for the time-dependent failure of PE natural gas distribution pipes which exhibit the same type of service failures as geomembrane liners. Over the last decade a fracture mechanics methodology has evolved under support from the Gas Research Institute that permits making lifetime forecasts for medium and high density PE gas pipes and fusion joints for the system operating conditions (e.g., internal pressure and temperature) (Kanninen et al. 1990, Popelar, S.F. et al. 1991, Pfeil et al. 1993). In this methodology slow crack growth tests, performed on laboratory fracture specimens, are used to develop empirical relations for the time for initiation of

crack growth and the rate of crack growth as a function of a measure of the crack driving force and temperature. In these tests, temperature and stress are used to accelerate the failure process. The influence of temperature on the crack growth resistance and the life expectancy is quantified through bidirectional shifting (Popelar, S.F. et al. 1993, Pfeil et al. 1993). These data and the crack driving force for defects in the pipe or its joints are used to determine the life expectancy of the component for prescribed operating conditions.

Because of the many similarities between the time-dependent failure in PE geomembrane liners and gas pipes, it is reasonable to expect that the technology developed for predicting the life expectancy of medium and high density PE gas pipes and butt fusion joints can be extended to geomembrane applications. The objective of this paper is to demonstrate that the accelerated testing and fracture mechanics methodology developed for PE natural gas distribution systems can be extended to make realistic and useful forecasts for the durability of geomembranes at service conditions. A long-range goal is to identify manufacturing, seaming, construction, quality assurance, and maintenance procedures that will help ensure the failure-free, long-term service performance of geomembranes.

## 2 FRACTURE MECHANICS METHODOLOGY

### 2.1 Stress Intensity Factor

The stress and strain fields exhibit a  $r^{-1/2}$  singularity at the tip of a crack in a linear viscoelastic continuum (Kanninen and Popelar 1985). The strength of these fields is determined by the stress intensity factor  $K$  which depends linearly upon the applied load and is a function of the crack length and the geometry of the cracked body. Expressions for stress intensity factors of different flawed bodies can be found in fracture mechanics handbooks (e.g., Tada et al. 1985). Strain concentrations at the crack tip in a polymer usually result in the formation of a narrow rarefied (crazed) zone emanating from the tip. Crack growth proceeds by systematic formation and failure of the crazed zone. This zone is not explicitly included in the development of expressions for the crack tip fields. If the size of the crazed zone is small compared to the size of the region over which the singular fields dominate, then it can be argued that whatever happens within the crazed zone must be controlled by the singular crack tip fields. The local crack tip fields will be identical in two flawed bodies for the same loading mode (e.g., Mode I) if their stress intensity factors are equal. Therefore, the crack growth time history in one body can be expected to be the same as that in a second body of the same material, thickness and temperature if their stress intensity factors are equal. Hence, data gathered from one body (e.g., the test specimen) can be transferred to the second body

(e.g., the geomembrane liner) to predict the crack growth history in the latter under its loading.

In general, the stress intensity factor can be expressed as

$$K = \frac{P}{W} \sqrt{\pi a} Y(a/W) \quad (1)$$

where  $P$  is the applied load per unit width,  $a$  is the crack length,  $W$  is the thickness or dimension of the body in the direction of potential crack growth, and  $Y(a/W)$  is a dimensionless function that depends upon the geometry of the cracked body.

### 2.2 Life Prediction

Suppose that the crack growth rate  $da/dt$  and the time  $t_i$  for initiation of crack growth determined in laboratory SCG tests conducted at temperature  $T$  can be correlated with the stress intensity factor and can be expressed functionally as

$$\frac{da}{dt} = F(K; T) \quad (2)$$

and

$$t_i = G(K_o; T) \quad (3)$$

where  $K_o$  is the initial stress intensity factor corresponding to the initial crack length  $a_o$ . Laboratory tests are frequently conducted at temperatures greater than the anticipated service temperature in order to accelerate the crack growth process. Provided that the fracture mode remains brittle, stresses greater than those experienced in the field are often applied in laboratory tests to further accelerate the failure process. The stress intensity factor accounts for different stress levels.

Popelar, C.F. et al. (1990) and Popelar, C.H. et al. (1991), (1993) have demonstrated that material property data for medium and high density PE natural gas pipe materials gathered at temperature  $T$  can be translated to an arbitrary reference temperature  $T_r$  (e.g., the service temperature) through bidirectional shifting. Bidirectional shifting of SCG data requires that time  $t$  and the stress intensity factor  $K$  be replaced by the reduced time  $t/a_T$  and  $Kb_T$ , respectively. The horizontal  $a_T$  and vertical  $b_T$  shift functions are given, respectively, by

$$a_T = \exp[-0.109(T - T_r)] \quad (4)$$

and

$$b_T = \exp[0.0116(T - T_r)] \quad (5)$$

where  $T$  and  $T_R$  are expressed in degrees Celsius or Kelvin (Popelar, C.F. et al. 1990). The horizontal shifting is based upon the classical time-temperature superposition principle for the rate process phenomenon in thermorheologically simple materials. Because of its semicrystalline nature, PE is a thermorheologically complex material. Vertical shifting is required in addition to horizontal shifting to account for variations in its mechanical properties (e.g., slow crack growth resistance) resulting from changes in its crystallinity with temperature. Consequently, Equations (2) and (3) for the crack growth rate and time for initiation of crack growth at the arbitrary temperature  $T_R$  become

$$\frac{da}{dt} = a_T F(Kb_T; T) \quad (6)$$

and

$$t_i = G(K_o b_T; T) / a_T \quad (7)$$

Equation (6) can be viewed as the nonlinear equation of motion for the crack tip and Equation (7) provides the initial condition. The integration of Equation (6) subject to the initial condition of Equation (7) provides the failure time

$$t_f = t_i + \frac{1}{a_T} \int_{a_o}^{a_f} \frac{da}{F(Kb_T; T)} \quad (8)$$

at the reference temperature for isothermal loading wherein  $t_i$  is given by Equation (7) and  $a_f$  is the final flaw size that may be determined from a criterion for unstable crack growth. Equation (8) can be used to predict the life expectancy of a geomembrane for a prescribed loading and initial flaw size  $a_o$  or, conversely, to determine the permissible initial flaw size for a prescribed design life and loading history. The methodology provides a rigorous approach for establishing a quality assurance program which currently relies upon rules of thumb for which there may be no theoretical basis (e.g., scratches and gouges deeper than ten percent of the geomembrane thickness are not permitted).

The task of making estimates for the life expectancy of geomembranes reduces to one of establishing the correlations in Equations (2) and (3), demonstrating that they hold irrespective of the load and initial flaw size, and justifying the use of the shift functions of Equations (4) and (5). The process of establishing these correlations is described in the following sections.

### 3 SLOW CRACK GROWTH TESTS

The 2-mm thick material used in the tests is a HDPE material taken from a liner that served as an uncovered cap of a mixed waste landfill. It had an NCTL ductile/brittle

transition time of approximately 20 hours at 50°C in a 10 percent Igepal solution.

Blanks, 102-mm long by 12.7-mm wide, were cut from this material. A centrally located face notch was sliced into the specimen at a very slow rate with a scalpel blade to minimize damage. The notch depth was systematically varied from 28% to 57% of the liner thickness. The notches were oriented parallel to the extrusion direction.

Grips were attached to the specimens so that the test section was 75-mm long. Figure 1 is a schematic of the SCG test setup which is located in a precision oven for performing controlled elevated temperature tests. The specimen is dead loaded through the core of a liner variable differential transformer (LVDT) which is used to measure the load-point displacement of the specimen that is automatically recorded with an A/D board and a PC. Tests were performed for different combinations of load, initial notch depth and temperature.

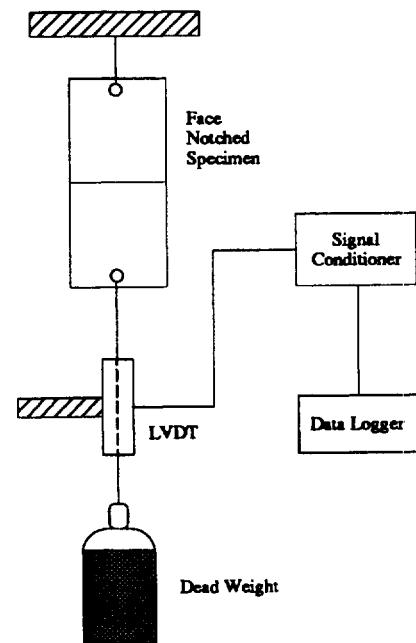

Figure 1. Schematic of slow crack growth test setup.

Figure 2 depicts a typical measured variation of the load-point displacement with time for a test conducted at 81°C. A careful examination of the record reveals an inflection point nearly 25 hours after loading. Empirical data show this point to be the time for initiation of crack growth. Prior to this time the displacement is due to viscoelastic creep of the specimen, and afterwards the displacement is due primarily to crack growth and secondarily to creep. Failure of the specimen occurred approximately 53 hours after loading. Depending upon the initial value of the stress intensity factor and test temperature, typical test durations may vary from a few days to several weeks or more.

Figure 2. Typical measured load-point displacement history.

Figure 3. Crack length history deduced from measured load-point displacement record of Figure 2.

#### 4 SLOW CRACK GROWTH RESULTS

Prior to crack initiation, the SCG test can be viewed as a creep test from which the creep compliance of the material can be determined. This creep compliance is used in a quasi nonlinear viscoelastic fracture model (Popelar, S.F. et al. 1993) of the specimen to deduce the crack growth history from the measured load-point displacement record. Figure 3 shows the crack growth history deduced from the load-point displacement record in Figure 2. The validity of this approach was established by comparing the measured crack length at the end of the test with the deduced length. The local slope of the curve in Figure 3 provides the crack growth rate  $da/dt$ , and the crack length and load determine the corresponding stress intensity factor  $K$  per Equation (1).

Figure 4 shows the correlation of the stress intensity factor with the crack speed for tests conducted at 61°C and 81°C. The straight lines represent the best least square power law fit to the respective data. While there is some scatter in the data, the stress intensity factor appears to be an appropriate fracture mechanics parameter for characterizing SCG — considering that results are for a variety of loads and initial notch lengths. Figure 5 depicts the correlation of the time for initiation of crack growth  $t_i$  with the initial stress intensity factor  $K_0$  from tests at 61°C and 81°C. The accelerating influence of an elevated temperature on the crack growth rate and the initiation time is clear from these figures.

The bidirectional shifting method, using the shift functions established for PE gas pipe materials, can be used to develop master curves. Figures 6 and 7 depict, respectively, the resulting master curves at a reference temperature of 81°C for the crack growth rate and the time

Figure 4. Correlation of the stress intensity factor and the crack growth rate at 61°C and 81°C.

for initiation of crack extension. These master curves exhibit good coherence with the shifted 61°C data interspersed with the 81°C data. Note that the reference temperature is completely arbitrary and has no influence upon the coherence of the master curve. The straight lines are best least square fits to the data and are given by

$$da/dt = F(K; 81^\circ\text{C}) = 6.8K^{5.3} \quad (9)$$

and

$$t_i = G(K_0; 81^\circ\text{C}) = 5.44 \times 10^{-4} K_0^{-6.9} \quad (10)$$

liner's installation temperature is 50°C. While the ambient temperature was assumed to remain constant in this example, seasonal changes can be included. In this case not only will the thermal stress and, hence, the crack driving force vary with time, but also the shift functions will vary with time. These time-dependencies must be taken into consideration when integrating the equation of motion for the crack tip, Equation (6).

The purpose of Figure 8 is simply to illustrate the fracture mechanics methodology and several simplifications were made in developing it. The influence of stresses other than thermal ones is neglected and will further reduce the life expectancy. The mean data for the initiation time and crack growth rate were used. A more detailed statistical analysis could be used to provide predictions for a prescribed confidence level which may additionally reduce the life expectancy by as much as a decade.

## 5 CONCLUSIONS

An investigation of SCG in a HDPE geomembrane material has been performed. A fracture mechanics methodology for predicting the life expectancy of geomembranes for service conditions has been developed and demonstrated for a surface crack that grows through the thickness of the liner. The methodology, which is based upon earlier developments for PE natural gas pipes, can be used to predict the life expectancy of a liner for prescribed service loads and size of an initial defect, or to determine the permissible initial defect size for prescribed service loading and life. SCG tests at different temperatures were conducted for specimens having various initial notch depths and loads. Correlations between the stress intensity factor and the time for initiation of crack extension, and the crack growth rate demonstrate that the stress intensity factor is an appropriate measure of the crack driving force in this HDPE material. Coherent master curves for the initiation time and crack growth rate were obtained using the bidirectional shifting method and shift functions developed for PE pipes. The accelerated testing approach, presented herein, permits developing critical SCG data for making long-term durability assessments (e.g., lifetime forecasts on the order of 100 years or more) relatively quickly. An example was presented that demonstrated how the methodology may be used to establish a rational basis for specifying inspection requirements and quality control and assurance standards. Finally, it is through a methodology of the type presented herein that the long-term performance of PE geomembranes can be quantified.

# Temperature Effect on the Stress Crack Resistance of High Density Polyethylene Geomembranes

Y. G. Hsuan

GRI, Drexel University, Philadelphia, PA 19104

**ABSTRACT:** The current status of stress crack resistance testing of HDPE geomembranes is the single point notched constant tensile load (SP-NCTL) test per ASTM D 5397-appendix. Since more than 200 hours is required to arrive at an acceptance decision, the quest is to use higher temperature to reduce the testing time. The results of this study indicate that the testing temperature can be increased to 70°C to obtain the maximum acceleration on the failure time. Using this temperature, instead of the current standard temperature of 50°C, results in an additional acceleration factor of 4.7 over the factors inherent in the test method itself. Using 70°C it is possible that a quality control procedure can be crafted to give a "go/no go" result within 48 hours.

**KEYWORDS:** stress crack resistance, slow crack growth, polyethylene, geomembrane.

## 1 INTRODUCTION

Stress cracking as defined in ASTM D883 is "an external or internal crack in a plastic caused by a tensile stress less than its short-term mechanical strength". The stress cracking mechanism can be divided into two categories: rapid crack propagation and slow crack growth. Cracking that is caused by the rapid crack growth mechanism takes place extremely fast and generally extends to a large area by shattering in a dendritic pattern. This type of failure does not commonly occur in the high density polyethylene (HDPE) geomembrane unless subzero temperatures exist (Peggs 1990). Comparatively, cracking that is induced by the slow crack growth mechanism proceeds relatively slowly and is generally limited in its extent. The crack propagation rate varies with the material, magnitude of the tensile stress and temperature. Cracks caused by slow crack growth have been observed in HDPE geomembranes used as surface impoundment liners. (Hsuan, et. al., 1993; Peggs and Carlson, 1988). Such field observations indicate the importance of slow crack growth resistance of HDPE geomembranes with respect to their long term performance. An effective test method should be utilized to assess such property in the minimum amount of testing time.

In the United States, the ASTM D 5397 "Notched Constant Tensile Load (NCTL) Test" is the standard method to evaluate slow crack growth resistance, generally called the stress crack resistance (SCR), of HDPE geomembranes. The incubation conditions specified in the method include a constant temperature immersion at 50°C and a specific incubation solution which consists of 10% surfactant (Igepal® CO-630) mixed with 90% tap water. Both the temperature and incubation solution have an accelerating effect on the crack propagation rate, in particular the temperature (Lord et. al., 1993). However, in the HDPE polyethylene pressure gas pipe industry, 80°C is the commonly used incubation temperature to accelerate crack growth rates (Brown 1993). For HDPE geomembranes, Thomas and Siebken (1997) performed the NCTL test at

80°C using a different surfactant (CA-720). They have found a good correlation between test results at 50°C and 80°C incubation. However, there was no available data at the intermediate temperatures.

This paper presents the result of a series of NCTL tests performed at temperatures of 50, 60, 70 and 80°C in an incubation medium of 10% CA-720 and 90% water. Two different geomembranes were evaluated to verify the effect of temperature on crack growth rate in such a surfactant solution environment.

## 2 TEST MATERIALS

Two commercially available HDPE geomembranes were included in this study. They are designated as Samples A and B. The nominal thickness of both samples is 1.5 mm. The geomembranes were produced by different manufacturers and by different processes: blown sheet and flat sheet extrusion. The density, crystallinity and melt index values are given in Table 1.

Table 1. Material properties of Samples A and B.

Property	ASTM Method	Sample A	Sample B
Density (g/ml)	D 1505	0.9492	0.9490
Melt Index (g/10 min.)	D 1238	0.29	0.15
Heat of Fusion* (J/kg)	D 4037	123	124

\* Heat of Fusion is directly proportional to crystallinity of the polymer

## 3 TEMPERATURE EFFECT ON TENSILE YIELD BEHAVIOR

The tensile yield properties of the geomembranes was evaluated according to ASTM D 638 Type IV. These data are necessary since the NCTL test is performed at given percentages of the yield stress. Furthermore, the yield stress

varies with temperature and it must be evaluated accordingly. Tests were performed in an environmental chamber in order to achieve the designated temperatures which varied from 20 to 80°C.

Thomas and Siebken (1997) found that the yield stress decreased as the test temperature increased in a linear relationship. Similar behavior was also obtained for the two geomembranes used in this study. Figure 1 shows the effect of temperature on the yield stress of Samples A and B. The slope of the line, which may be related to the percent crystallinity of the polyethylene, is 0.23 MPa/°C.

Figure 1. Tensile yield stress at different temperatures.

Besides lowering the yield strength, the increase in temperature actually influences the yielding behavior of the test specimens. Figure 2 shows the stress/strain curves of Sample A at different test temperatures. The yield region consists of two peaks, referred to as double yielding. This complex yielding behavior was observed in a variety of polyethylene copolymers by Lucas et. al. (1995). As temperature is increased, the first yield peak gradually diminishes whereas the second yield peak becomes more

Figure 2. The yield behavior at different temperatures

pronounced. In both geomembrane samples, the second peak became the predominant yield peak at temperatures above 70°C. Lucas et. al. (1995) have proposed that the first peak corresponds to the yielding of original perfect crystallites in the material. The second peak is induced by the yielding of the newly formed crystallites. As the test temperature increases, the energy requirement for secondary recrystallization is reduced. A greater amount of less perfect crystallites can be melted and recrystallized. As a result, an enhanced second yield peak is obtained, particularly above 70°C.

In this study, the first yield peak was used to analyze the temperature effect on the yield stress, and it was also utilized to calculate the applied stress of NCTL tests.

#### 4 TEMPERATURE EFFECT ON STRESS CRACK RESISTANCE

The stress crack resistance (SCR) of Samples A and B were evaluated by the NCTL test. This section presents the test details and results of the NCTL tests.

##### 4.1 NCTL Test Procedures

The NCTL test was performed according to ASTM D5397 at temperatures of 50, 60, 70 and 80°C. The incubation solution used in the test consisted of 10% surfactant with 90% of water. Instead of a minimum of 10 applied stresses as required in the standard method, only the lower stresses that induce brittle failure were utilized. This included applied stresses ranging from 15 to 30% of the yield stress at room temperature. Three specimens were tested at each stress level. The failure time of each specimen was recorded to the nearest 0.1 hour. The average failure time was used in the data analysis.

Due to the high elevated testing temperatures used in the study, a different surfactant was used than the one specified in the standard method. As explained by Thomas and Siebken (1997), the surfactant CO-630, which is a type of ethoxylated alkylphenol compound, becomes immiscible with water in a temperature range of 52-56°C. Thus another type of ethoxylated alkylphenol, CA-720, was selected due to its high immiscible temperature range, that being 86-90°C. Furthermore, CA-720 is rather sensitive to NaCl. If it is mixed with 10% NaCl solution, the immiscible temperature range drops to 56-60°C. To minimize such effect, deionized water was used throughout the study.

##### 4.2 NCTL Test Results and Analysis

The NCTL test data are presented by plotting percent yield stress against average failure time on a log-log scale. Figures 3 and 4 present the brittle response curves for Samples A and B, respectively. The slopes of these curves are very similar, indicating that the same failure mechanism took place in all tests.

Figure 3. NCTL test response curves for Sample A.

Figure 4. NCTL test response curves for Sample B.

In the above curves, the failure time decreased as the testing temperature increased, indicating that crack propagation was accelerated by the temperature. However, the acceleration seems to slow down between 70 and 80°C in comparison to the lower temperatures. The actual temperature effect on the failure time is unable to be evaluated by presenting the data using percent yield stress at room temperature, as shown in Figures 3 and 4. This is because the yield stress also decreased as temperature increased.

To determine the temperature dependence on the time to failure, the applied stress at each test temperature is normalized to the corresponding yield stress at that temperature. The normalized stress ( $\sigma/\sigma_y$ ) data is plotted against average failure time on a log-log scale as shown in Figures 5 and 6 for Samples A and B, respectively. The resulting curves are somewhat different to those appearing in Figures 3 and 4. The 70 and 80°C lines overlap one another. This implies that there is no temperature acceleration at elevated temperatures above 70°C. In other words, at a same percent yield stress, a similar failure time will be obtained at temperatures of 70 and 80°C and presumably (although not evaluated) still higher temperatures.

Figure 5. Normalized stress vs. failure time for Sample A.

Figure 6. Normalized stress vs. failure time for Sample B.

Conversely, from 50 to 70°C, temperature clearly accelerates the crack growth rate. The relationship between temperature and failure time can be expressed by the Arrhenius equation, shown as Equation 1. Figure 7 presents an Arrhenius plot at four different normalized stresses for both Samples A and B. A linear relationship is obtained. The same behavior was also found for Sample B. The activation energy of the failure mechanism is found from the slope of the lines to be 73.5 kJ/mol.

$$t_f = A \exp(E/RT) \quad (1)$$

where:

- $t_f$  = failure time (minutes)
- A = constant
- E = activation energy (= 73.5 kJ/mol)
- R = gas constant (8.31 J/mol.K)
- T = temperature (K)

Similar tests were performed by Lu and Brown (1990) on a HDPE pipe resin in forced air ovens at temperatures from 24 to 80°C. A linear relationship between failure time and inverse temperature was obtained up to 70°C. Also the linearity ceased at 80°C for the low applied stresses. The failure time at 80°C was somewhat similar to that obtained

at 70°C. This may suggest that the unexpected SCR behavior found at 80°C test on geomembranes was not induced by this particular test environment but by the change in the material, such as secondary recrystallization. Tests performed in both water and air could verify whether the unexpected behavior observed at 80°C is due to internal or external factors. Such experiments are currently ongoing.

Figure 7. Failure time against inverse temperature at different normalized stresses for Samples A and B.

Regarding the temperature acceleration factor (AF), at the same normalized stress value of 0.5, the average AF of two tested samples between 50°C and 70°C is 4.7. Using the current SCR specification (GRI-GM 10, 1997), a minimum failure time of 200 hours at 30% yield stress of room temperature at test temperature of 50°C is required. After being normalized to the yield stress at corresponding test temperature, the 30% becomes 50% of the yield stress at 50°C. Thus at the same normalized stress, i.e., 50% yield stress at 70°C, the failure time will be 4.7 times faster, reducing the testing time to 43 hours. (Note that the 50% yield stress at 70°C is approximately equal to 20% of the yield stress at room temperature).

## 5 SUMMARY AND CONCLUSION

The effect of temperature on SCR of two HDPE geomembrane samples was evaluated at temperatures of 50, 60, 70 and 80°C using the brittle region of the NCTL test. Additionally, tensile tests were performed at these temperatures to obtain the corresponding yield stress (which decreased linearly as temperature increased).

For the NCTL test results, the failure time decreased as temperature increased. From 50 to 70°C, the failure time increased exponentially with the temperature. However, the acceleration seems to cease between 70 and 80°C.

The results of this study indicate that the maximum temperature that can provide acceleration in performing the NCTL test is 70°C. At the same normalized stress value,

the failure time at 70°C is 4.7 times faster than that at 50°C.

## ACKNOWLEDGMENT

The funding of this research was provided by the Geosynthetic Institute's Consortium of Member Organizations. The author also appreciates the assistance of Mr. Derrick Whitaker in performing the tensile tests. # Antioxidant Depletion During Thermal Oxidation of High Density Polyethylene Geomembranes

Y. G. Hsuan  
GRI, Drexel University, Philadelphia, PA 19104

Z. Guan  
GRI, Drexel University, Philadelphia, PA 19104

**ABSTRACT:** In this study, forced air oven aging was utilized as the acceleration procedure to simulate the thermo-oxidation process in five high density polyethylene (HDPE) geomembranes containing different antioxidant packages. The geomembrane coupons were incubated at four different temperatures; 115, 95, 75 and 65°C. After a predetermined period of time, incubated coupons were removed from the oven and subsequently evaluated for the consumption of antioxidants, along with possible changes of physical and mechanical properties. The consumption of antioxidants with time was monitored by both standard oxidative induction time (Std-OIT) and high pressure oxidative induction time (HP-OIT) tests. The results indicate that both OIT tests can effectively track the consumption of antioxidants that consist of hindered phenols and phosphites. However, for antioxidant packages that contain thiosynergists or hindered amines, the HP-OIT is the appropriate test. The study also demonstrates that the tensile break properties of the geomembrane remain unchanged until all the antioxidants are consumed. Based on the reduction rate of OIT, the depletion time of antioxidants at a 20°C site temperature was extrapolated using the Arrhenius equation. The average depletion time of hindered phenol and phosphite types of antioxidants is 80 years. The addition of thiosynergists and hindered amines further extended the depletion time in an amount which is still under investigation.

**KEYWORDS:** oxidative induction time, aging, polyethylene, geomembrane, oxidation.

## 1 INTRODUCTION

High density polyethylene (HDPE) geomembranes have been widely used as liquid barriers in landfill applications for both liners and covers. Since geomembranes in such applications are typically covered by soil or by other geosynthetics; neither sunlight nor elevated temperatures are of concern. However, oxidation remains as a key degradation mechanism regarding the long-term durability of the material. For protection against oxidation during the service period, antioxidants are added into the formulation of the geomembrane. As long as antioxidants are present in the material, the physical and mechanical properties of the geomembrane can be preserved (Hsuan and Koerner, 1997). Thus the long term performance of HDPE geomembranes is greatly dependent on the depletion time of the antioxidants.

There are many different types of antioxidants and each performs somewhat differently. Oven aging is the most commonly used laboratory incubation method to investigate the performance of antioxidants in polymers (Gray, 1990; Gugumus, 1996). Coupons are incubated in forced air ovens at elevated temperatures for a sufficient time so as to deplete the antioxidants and start the oxidative degradation process. At that time, the physical and mechanical properties of the material begin to degrade. The temperature of the ovens should be high enough to increase the reaction in order to obtain results within a reasonable time frame, but cannot be too high that the reaction mechanism and material's structure are altered. Temperatures as high as 110°C to 120°C have been utilized in evaluating HDPE geomembranes by researchers (Gray, 1990; Thomas and Ancelet, 1993; Yim and Godin, 1993).

In this study, five different commercially available HDPE geomembranes were incubated in four ovens at

temperatures of 115, 95, 75, and 65°C. The incubated coupons were periodically removed from the ovens and were then evaluated for their remaining antioxidants using two types of oxidative induction time (OIT) tests together with the physical and mechanical properties.

## 2 INCUBATION TEST PROCEDURES

The oven aging incubation procedure was performed according to ASTM D5271. Coupons with dimensions 100 mm wide and 180 mm long were taken from each geomembrane sample. The coupons were freely hanging in forced air ovens maintained at temperatures of 115, 95, 75, and 65°C.

Specimens were taken from the incubated coupons at a monthly intervals for antioxidant evaluation. They were taken at three month intervals for physical and mechanical tests.

## 3 EVALUATION TESTS

Properties of the incubated coupons were monitored by thermal analytical, physical and mechanical tests. Table 1 shows the tests that were included in this study.

Table 1. Test used to evaluate incubated geomembranes.

Test	ASTM Method	Property Evaluated
Std-OIT	D3895	Amount of antioxidant
HP-OIT	D5885	Amount of antioxidant
Melt Index	D1238	Molecular weight
Tensile	D638 - IV	Stress and strain

The depletion of antioxidants were monitored by two OIT tests. OIT is the time required for the geomembrane test specimen to be oxidized under a specific pressure and temperature. For the same antioxidant package (type and amount), the OIT is proportional to the quantity of the antioxidant (Howard, 1973). However, for different antioxidant packages, direct comparison between two single OIT values can be misleading and caution must be used.

Once the polymer starts to oxidize, there will be either a cross-linking reaction or a chain scission reaction taking place, resulting in a change in molecular weight. The melt index test is a qualitative method to assess molecular weight of polymers. A decrease in melt index value indicates an increase in the molecular weight (i.e., crosslinking) and vice versa. Melt index tests were performed only at the incubating temperatures of 115 and 95°C.

As the oxidation proceeds further, it will eventually induce changes in the engineering properties such as tensile properties. Five tensile parameters are included in the analysis: modulus, yield stress and yield strain, and break stress and break strain. It should be recognized that break strain has the greatest sensitivity towards molecular changes in the polymer. Again, only coupons at the two higher incubation temperatures were tested for tensile properties.

#### 4 TEST MATERIALS

Five commercially available HDPE geomembranes were included in the study. They are designated as Samples A to E. All samples have a nominal thickness of 1.5 mm. The five geomembranes were produced by four manufacturers. They included both blown sheet and flat sheet extrusion processes. The physical and chemical properties of the original unaged material were evaluated and the data is presented in Table 2.

Table 2. Average properties of original geomembrane

Sample	Anti-oxidant <sup>1</sup>	MI <sup>2</sup> (g/10 min)	Std-OIT <sup>3</sup> (min)	HP-OIT <sup>4</sup> (min)
A	a	0.23	122±7%	262±6%
B	a	0.15	129±1%	280±1%
C	a	0.29	156±5%	368±3%
D	b	0.15	1267%	1125±12%
E	c	0.46	144±9%	1499±9%

Note:

- a = hindered phenols & phosphites  
b = hindered phenols, phosphites & thiosynergists  
c = hindered phenols, phosphites & hindered amines
- MI = melt index
- Std-OIT = Standard OIT
- HP-OIT = High pressure OIT

Regarding the antioxidant package in each geomembrane, only the type (not the quantity) of each antioxidant component was known.

The original Std-OIT values were very similar in all five samples even though they contained different antioxidant packages. Contrary, a large difference in the HP-OIT values was observed. The thiosynergists and hindered amines led

to a much higher OIT value in Samples D and E. This is because these two antioxidants have a maximum effective temperature below 200°C (Fay and King, 1993). Subsequently, their performance cannot be properly evaluated by the Std-OIT test which uses an isothermal temperature of 200°C. On the other hand, at an isothermal temperature of 150°C in the HP-OIT test, the presence of these two types of antioxidants was able to be assessed. Thus, the HP-OIT is the proper test for antioxidant packages containing thiosynergists or hindered amines.

#### 5 TEST RESULTS AND DISCUSSION

Since the focus of this paper is on the depletion of the antioxidants, the OIT results will be emphasized.

##### 5.1 Results of Std-OIT and HP-OIT Tests

The test data indicate that the normalized Std-OIT decreased exponentially over time regardless the antioxidant package type, see Figures 1 and 2. The reduction behavior was very similar for Samples A, B and C. On the other hand, the OIT depletion rate of Samples D and E increased greatly at incubation temperatures 95°C and 115°C, particularly for Sample D.

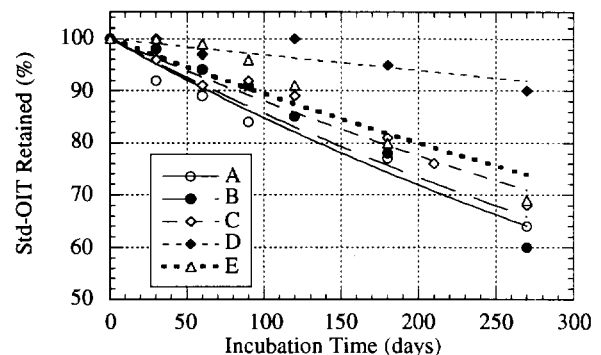

Figure 1. Change in percent retained of Std-OIT values at an incubation temperature of 65°C

Figure 2. Changes in percent retained of Std-OIT values at an incubation temperature of 95°C

In comparison, the HP-OIT exhibited different responses depending on the antioxidant package, as shown in Figures 3 and 4. Samples A, B and C which contained the same antioxidant types behaved similarly; their OIT values decreased exponentially with incubation time at all incubation temperatures.

Figure 3. Changes in percent retained of HP-OIT values at an incubation temperature of 65°C.

Figure 4. Changes in percent retained of HP-OIT values at an incubation temperature of 95°C.

Similar to the Std-OIT, Sample D which consists of thiosynergists also showed a rapid depletion in OIT values at 95°C and 115°C incubation temperatures. However, the OIT value maintained almost unchanged after the significantly drop in the first 90 days. The rapid reduction in OIT values at 95°C and 115°C suggest that substantial amount of thiosynergist was quickly consumed at these two elevated incubation temperatures. Since the depletion occurred within such short period, as indicated by the HP-OIT results, volatilization probably was the primary consumption mechanism rather than oxidation. There may be a high concentration of thiosynergists near the surface of the coupons. The depletion rate for the remaining additives seems to be relatively slow and is sufficient to protect the geomembrane from being oxidized.

For Sample E, which contained hindered amines, its OIT value decreased exponentially with time but at a much

slower rate than samples with only phosphite and hindered phenols.

## 5.2 Comparing Std-OIT, HP-OIT and Other Material Properties

In order to demonstrate the importance of the antioxidants toward the long term physical and mechanical properties of the geomembrane, changes in MI value and tensile properties are compared to the two OIT results at incubation temperatures of 115 and 95°C.

Since Samples A, B and C contain the same antioxidant types, their properties behaved in a similar manner throughout the incubation period. Sample A was selected to represent this group of three samples. Figures 5 and 6 depict the change of each property with incubation time at 95°C and 115°C, respectively.

Figure 5. Changes in properties with incubation time at 95°C for Sample A.

Figure 6. Changes in properties with incubation time at 115°C for Sample A.

Based on Figures 5 and 6, the behavior of this group of geomembranes can be summarized as follows:

- The depletion of antioxidants using both Std-OIT and HP-OIT measurements were very similar. Actually, a linear correlation was found between them. Thus either

one of the tests can be used to evaluate these types of antioxidant packages.

- Regarding the correlation between OIT and tensile properties, the data at 115°C indicates that tensile break properties remain essentially unchanged as long as antioxidants are still present. After 180 days, the tensile break properties dropped significantly when both OIT values approached zero.
- As for the MI value, it behaved differently at these two incubation temperatures. At 115°C, the MI value decreased steadily with time even though the OIT was still at a fairly high value. Such behavior was also observed by Thomas and Ancelet (1993) under similar test environment. However, at 95°C, the MI value remained largely unchanged while the Std-OIT value decreased to 20%. Hsuan and Koerner (1997) observed essentially no changes in MI value as the Std-OIT decreased to less than 10% at temperature of 85°C in a soil incubation condition. The decrease in MI value at 115°C probably was due to cross linking resulted from oxidation reactions. Since the onset of the melting peak begins at about 60°C and reaches the peak at 128°C, some amount of the crystalline phase are in the molten stage at 115°C. Such change in microstructure can substantially enhanced the oxidation degradation which most likely not occurs at the low service temperature. Thus the incubation temperature at 115°C seems to be too high to evaluate the durability of HDPE geomembranes.
- Regarding the MI value in evaluation of polymer degradation, it probably has a higher sensitive than the tensile test. However, it may be difficult to establish a correlation with the tensile behavior. Data from longer incubation times could verify this hypothesis.

For Samples D and E, their change of properties with time at 115°C are given in Figures 7 and 8, respectively. The Std-OIT and HP-OIT behaved very differently for both samples. In Sample D, the Std-OIT value gradually decreased to less than 5% in 270 days, whereas the HP-OIT value maintained at 20% after the initial rapid reduction. In spite of the low Std-OIT value, the tensile properties remained unchanged. Sample E is somewhat similar to Sample D in their Std-OIT results. After 270 days, the Std-OIT value reached 2% while the HP-OIT value was still at 60%. Clearly, the presence of hindered amines was being detected by the HP-OIT. At the same time, the tensile properties showed no significant changes. The test data further confirmed that the HP-OIT test reflects more the "true" state of the antioxidants present in these two geomembranes. The Std-OIT test measures mainly the depletion of the hindered phenol and phosphite antioxidants.

Regarding the MI value, again a reduction was only detected at 115°C in both samples. Sample D showed the least decrease in the MI value than all other four geomembranes.

Figure 7. Changes in properties with incubation time at 115°C for Sample D

Figure 8. Changes in properties with incubation time at 115°C for Sample E.

## 6 ANTIOXIDANT DEPLETION TIME

The significance of antioxidants to the longevity of the geomembranes has been qualitatively illustrated. It is of value to use this data to quantify the depletion time of the antioxidants, since within this time period, the engineering properties of the geomembrane are unchanged. In this section, the methodology used to predict the depletion time of the antioxidants is based on OIT reduction rates obtained from three elevated incubation temperatures. Data obtained from the 115°C is not included due to the possible changes in the material's structure as stated earlier. Furthermore, Samples D and E were not analyzed. The evaporation of the antioxidants in Sample D, make the high temperature data not possible to be analyzed. For Sample E, the current reduction in the HP-OIT value at the lower incubation temperatures are too small to actually predict the depletion rates.

For Samples A, B and C, the depletion of OIT decreased exponentially with time. The generalized equation for OIT depletion curves as those shown in Figures 1 and 2 can be expressed by Equation (1). The depletion rate of the OIT at each incubation temperature can be determined by curve fitting.

$$\text{OIT} = P * \exp(- S*t) \quad (1)$$

where:

$$\text{OIT} = \text{OIT time (min.)}$$

- P = original OIT of the geomembrane (min.)  
 S = OIT depletion rate (min./day)  
 t = incubation time (days)

The next step is to extrapolate the OIT depletion rate to a lower (and site specific temperature), using the Arrhenius equation described in Equations (3) and (4).

$$S = A \cdot \exp(-E/RT) \quad (3)$$

$$\ln(S) = \ln(A) + (-E/R) \cdot (1/T) \quad (4)$$

- where: S = OIT depletion rate  
 E = Activation energy of the antioxidant depletion reaction under this test condition (kJ/mol)  
 R = gas constant (8.31 J/mol.K)  
 T = test temperature in absolute Kelvin (degrees K)  
 A = constant

A linear relationship is established between  $\ln(S)$  and inverse temperature. Figure 9 shows the Arrhenius plots for the Std-OIT testing of Samples A, B and C. Similar behavior is also obtained for the HP-OIT.

Figure 9. Arrhenius plot for Std-OIT test data.

The resulting activation energies of these samples are very similar regardless the type of OIT test, since similar reactions are being evaluated. The average activation energy value (slope of the lines in Figure 9) is 36 kJ/mol.

Based on the resulting Arrhenius equations, the OIT depletion rates at a typical site specific temperature can be extrapolated. To select a site specific temperature, Koerner, G.R., et. al. (1995) and Yazadini, et. al. (1995) found that the temperatures at the base of two municipal landfills in Pennsylvania and California vary between 19 and 22°C. Thus 20°C was used as the extrapolation temperature to calculate depletion rate using Equation 4. Using the obtained depletion rate, the required time to deplete all the antioxidants in the coupons at 20°C was calculated using Equation 1. However, before proceeding with the calculation, two boundary conditions must be established. They are the intrinsic OIT values that a pure unstabilized (i.e., no antioxidants) HDPE resin can possess in the two

respective OIT tests. Both Std-OIT and HP-OIT tests were performed on a pure HDPE resin. The Std-OIT was measured to be 0.5 minutes and HP-OIT to be 20 minutes. These two values are taken to be the OIT values when essentially all of the antioxidants in the incubated HDPE geomembranes are consumed (i.e., the OIT time in Equation 1). Table 3 shows the time required to consume all antioxidants from the three coupons at 20°C. In other words, these are the predicted antioxidant depletion times at temperature of 20°C under the simulated test conditions presented in this study.

Table 3. Required time to consume all the antioxidants

Sample	Antioxidant Depletion Time (year)	
	Std-OIT	HP-OIT
A	60	70
B	80	50
C	100	110

The predicted lifetimes from both Std-OIT and HP-OIT tests are reasonably close, although Sample B showed a unexpected low value using the HP-OIT test. The overall average lifetime of this antioxidant package under the test environment is 80 years. This is substantially shorter than the predicted value obtained from a separate incubation test that simulated a landfill liner condition. In that case, a 200 year depletion time was found (Hsuan and Koerner, 1997). This difference can be contributed by two factors. One is caused by the different oxygen concentrations between the two incubation environments. In the forced air oven, the concentration of oxygen is relatively high (21%) and is constantly being circulated. Comparatively, the oxygen is limited in a simulated landfill incubation test. Second is due to the evaporation of the antioxidants. The constant air circulation in the forced air oven can accelerate the antioxidant diffused out from the polymer as well as oxygen diffused into the polymer. Thus the forced air oven incubation procedure is a very severe test condition. It does not represent typical field situations, since at least one side of the geomembrane is always in contact with soil even for exposed applications.

Nevertheless, the air oven incubation is an ideal index test procedure for the evaluation of different antioxidant packages and for manufacturing quality control purposes. It can achieve the desired result within a relatively short time.

## 7. SUMMARY AND CONCLUSION

The consumption of antioxidants in five commercially HDPE geomembranes incubated in forced air ovens at elevated temperatures of 115, 95, 75 and 65°C was assessed. The results can be summarized as follows:

- The OIT test is ideally suited to track the depletion of antioxidants in the geomembrane. The OIT value decreased exponentially with incubation time in most of the tested geomembranes.

- For geomembrane Samples A, B and C that contain combination of hindered phenols and phosphites, the Std-OIT test can be used as well as the HP-OIT test. For geomembrane Samples D and E that contain either thiosynergists or hindered amine, the HP-OIT is the appropriate test.
- The 115°C incubation temperature is too high for aging evaluation. In addition, geomembranes that consist of thiosynergists, should not be incubated at temperatures 95°C and above due to the rapid evaporation of the thiosynergists.
- The antioxidants in the geomembrane must be completely consumed before the physical and mechanical properties begin to change.
- The antioxidant depletion time was predicted using the Arrhenius equation and found to be approximately 80 years for Samples A, B and C.
- For Samples D and E, which contained thiosynergists or hindered amines, the depletion time appears to be longer in comparison to Samples A, B and C. The depletion times of these two antioxidant packages are still under investigation.
- The time of 80 years for depletion of antioxidants is shorter than the results obtained from a separate study using a simulated landfill incubation setup. In that study, the predicted antioxidant depletion time is 200 years. The differences in these two values is caused by the amount of oxygen available. In this study, oxygen is constantly circulating in the forced air oven. While this incubation method is appropriate for research into different types of antioxidants or for manufacturing quality control, it does not represent in-situ condition.

Due to the significance of the antioxidant to the long-term durability of geomembranes, the performance of the antioxidants in the geomembrane should be properly evaluated by the user community (designers and/or owners). Since the Std-OIT and HP-OIT tests can effectively monitor the overall amount of antioxidants present in the geomembrane, the consumption rate of different antioxidant types can be compared and verified after the geomembrane is incubated in a properly designed procedure.

In a recently developed manufacturing quality control specification for HDPE geomembranes (GRI, 1997), the antioxidant packages are being evaluated. A minimum of 100 minutes of Std-OIT or 400 minutes of HP-OIT is recommended. Also the consumption rate of the antioxidant is limited to 55% for Std-OIT and 88% for HP-OIT, after the geomembrane is exposed in a forced air oven at a temperature of 85°C for 90 days.

# Selecting A Geomembrane Material

Ian D. Peggs

I-CORP INTERNATIONAL, Inc.; Ocean Ridge, FL, USA

Rick Thiel

Thiel Engineering; Oregon House, CA, USA

**ABSTRACT:** As the number of available geomembrane materials Polyethelene (PE), Poly (vinyl chloride) (PVC), Polypropylene (PP), Chlorosulfonated Polyethylene (CSPE), Polyester (PET), Polyurethane (PUR), and their alloys) increases and their range of applications widens, it is becoming more important that the proper selection of material, and even resin within one material type, be made. This cannot be done on an emotional basis, nor can it be done without a thorough knowledge of geomembrane performance. A technically based protocol is presented for selecting a material for each specific geomembrane application. The important parameters for each geomembrane application are identified and rated on a scale of 1 to 5 in terms of their significance to the project. The candidate materials are then rated on a scale of 1 to 10 for each of the parameters. The two ratings are multiplied and then totaled for each material to provide a technically based overall rating of geomembrane materials for the specific project. Examples are provided for different types of facilities, which highlight the materials, operations and maintenance characteristics that influence the performance of geomembranes in different lining applications.

**KEYWORDS:** Geomembrane, liner, design-by-function

## 1 INTRODUCTION

The selection of a geomembrane material for landfill or liquid impoundment lining systems is often based on the prescriptions of federal, state or provincial regulations, or is based on the selection of the material that will most easily proceed through appropriate permitting processes. For the past several years high density polyethylene (HDPE) has enjoyed the position of geomembrane-of-choice and, in fact, "HDPE" has become almost synonymous with the word "geomembrane". However, in a few instances, such as for the containment of black liquor at pulp mills (Peggs et al, 1993), for the containment of nitric acid and due to inadequate specification of resin properties, this has led to liner failures. In such instances alternative materials or resins would have provided better service, but the knowledge or appropriate mechanisms for the selection of the better materials or resins were not in place or were ignored.

The conditions under which geomembranes are used in lining systems are wide and varied. Geomembranes are required to provide service as the only, primary, or secondary liner of basal lining systems. The single, or primary geomembrane may be exposed to ultraviolet radiation or may be covered

with soil, or it may be covered with a wide range of liquid chemicals. The primary geomembrane may be placed on an imported well-prepared soil layer, while a secondary geomembrane (never exposed to UV radiation except during installation) may be placed on a not-so-well-prepared (rough) natural subgrade. While the primary geomembrane may be constantly exposed to a chemical the secondary geomembrane will not, or should not. If the primary geomembrane is exposed to UV radiation, it may also be exposed to wide variations in temperature (if liquid levels are varied) while the secondary geomembrane is not exposed to such wide changes in temperature. Thus, the service conditions experienced by primary and secondary geomembranes in the same basal liner may be quite different. There are similar, and more, differences required for the performance of geomembranes in landfill caps and floating covers, when compared to basal liners. Geomembranes in caps are subjected to differential settlement, permanent shear stresses, temperature variations, and perhaps vegetation root penetration that basal liner are not. They must be able to tolerate deformation far more readily than basal liners. Then there are different requirements for geomembranes used as canal liners, dam facings, vertical cut-off walls, fuel

farm secondary containment, and portable storage for fuel and water.

There are many geomembrane materials available today - HDPE, Very Low Density Polyethylene (VLDPE), Linear Low Density Polyethylene (LLDPE), coextruded PEs, Poly (Vinyl chloride) (PVC), PVC alloys, Polypropylene (PP) (reinforced and unreinforced), Ethylene Propylene Diene Monomer (EPDM), Chlorosulfonated Polyethylene (CSPE), Bitumen (roll and spray products), Polysulfide (PS), Polyurethane (PUR) (roll and spray products), and Polyester (PET) - all with different performance characteristics. With this wide range it is inappropriate to assume that one material, even a regulatory prescribed one, will provide optimum, even adequate, performance. Even though many regulations and project specifications allow "proven equal" materials, the time and expense of proving equality are more than most facility owners are willing to incur. Thus, innovation and progress are stifled.

It is also necessary to understand that, just as there are many different geomembrane polymers, so there are many different HDPE resins with different performance characteristics. While all of these have very similar conventional strength, density, and deformation characteristics, their long term mechanical durabilities (stress rupture resistance) can vary by a factor of more than 1000. Thus, specifying "HDPE" alone is akin to requiring a bridge to be made simply out of "steel". One needs to be much more specific to obtain adequate or optimum performance from the installed facility.

Therefore, a technical approach based on polymer performance, geomechanics, constructibility, and other factors has been developed for the selection of the most appropriate geomembrane for each project specific application. Cost considerations then become a secondary, rather than the primary, reason for material selection. By using this approach the increasing number of geomembrane failures that are occurring might be reversed.

## 2 METHODOLOGY

The first step in the process is to identify all of the factors that are important for the successful performance of the geomembrane in the specific application in the specific project. As previously indicated, such factors will be different for primary and secondary liners, caps, and floating covers. Not

only should basic material mechanical, physical, and chemical performance be considered, so also must installation conditions (temperature, wind), time between installation and designed service conditions, operational requirements, and maintenance requirements. Will the landfill liner/cover be left exposed before waste is placed? Will select waste be placed as the first layer? Will the liquid level be constant, or high in winter and low in summer, or vice versa? Will the owners want to make their own repairs? A complete listing should be made of all of these requirements.

The second step is to identify the relative significance of each of these parameters (requirements) on a scale of 1 to 5, with 5 being "most significant" and 1 being "of little (but still some) significance". Thus, UV resistance for an exposed leachate lagoon liner will receive a 5 rating, while for a secondary basal liner it will receive a 1, unless for some reason, during installation, sections of it were to be left exposed for some time, when it might receive a 2. Clearly, these ratings are somewhat subjective and are based on the experience of the rater.

Some of the factors and their relative significances in solid waste and liquid impoundment facilities are listed in Tables 1 and 2 respectively. Note that that these should not be considered complete for any real facility since environmental conditions have not been defined. Also note the differences between primary and secondary geomembrane liner requirements.

When all the significant parameters for each of the geomembrane components have been identified and rated, a number of candidate geomembrane materials (three to five) should be identified. Clearly, experience and judgment are usually required to develop the initial 'short list' of candidate geomembranes. Cost should not be a factor at this stage of the selection process.

The performance of each of these candidate materials is then rated against each of the required parameters on a scale from 1 (poor) to 10 (excellent). A scale of 1 to 10 for only 3 or 5 materials allows emphasis to be given to extremely good or poor performance as required. The complete parameter/material rating system can be presented as shown in Table 3.

The significance and performance ratings (1 to 5 and 1 to 10) are multiplied to provide an adjusted rating for each parameter/material combination. All of the adjusted ratings for each material are then totaled to

generate the final material rating. The highest value identifies the most technically appropriate material for that specific geomembrane application. Only now should factors such as cost be considered. And with this system, one generates a means of partially demonstrating "equivalency" of different materials.

As with any contrived rating system, experience and judgment are required in the final evaluation. There may be some technical parameters of overriding importance that are not adequately reflected in a subjective tabular rating. For example, achieving a minimum acceptable factor of safety for slope stability is often a fundamental design criteria that must be met with no compromise. In this case there is an absolute pass/fail criterion that candidate geomembranes must meet to qualify for further evaluation. Slope stability analyses on a specific project may reveal that only an aggressively textured geomembrane will be able to satisfy the requirements, and that textured polyethylene geomembranes are the only material available that is manufactured with such surfaces. But then the significance of that factor on the stress rupture resistance may have to be given more weight as well. Thus, the tabular matrix would then shift its emphasis from a range of fundamental polymer types, to a range of available polyethylene properties.

### 3 EXAMPLES

Four situations, all of which are contrived, and all of which are intentionally incomplete (so as not to become "prescriptions"), are described below.

**CASE 1 - THE PRIMARY AND SECONDARY GEOMEMBRANES OF AN MSW LANDFILL.** The secondary geomembrane will be placed on a coarse stony subgrade in a cold winter with the primary placed on a GCL in the following hot summer. The primary geomembrane will be covered immediately. Local regulators are aware of PP, and PVC, but are most comfortable with HDPE.

In this case the secondary geomembrane will have to tolerate subgrade scratching damage during installation and will have to tolerate puncture strains from the coarse subgrade. It will have to have some resistance to UV radiation since it may be exposed for up to 6 months. It will also have to have a low expansion coefficient so that excessive wrinkles are not formed at the high summer temperatures when it will be covered.

The evaluation presented in Table 4 indicates HDPE is most acceptable for the primary geomembrane, while PP is most suited for the secondary geomembrane.

While it is an accepted fact that a composite liner constructed from a geomembrane and mineral layer/GCL produce the optimum lining system, similar recognition has not effectively been given to the benefits of using two different materials in double geomembrane lining systems, where the negative aspects of the primary geomembrane are complemented by the positive aspects of the secondary. Thus the chemical resistance and strength of an HDPE geomembrane can be complemented by the strain tolerance, low expansion coefficient, flexibility, and stress cracking resistance of a more flexible geomembrane. The secondary geomembrane does not require the same chemical resistance since it is not constantly exposed to the contained liquid, but it will conform better to the subgrade because of its flexibility (providing a better composite action than will HDPE). In cold environments compensation wrinkles in a flexible secondary geomembrane will not present a problem when placing an HDPE primary geomembrane, also with compensation wrinkles, on top of it, as might happen if the primary HDPE geomembrane were placed on top of a wrinkled secondary HDPE geomembrane. There is much to be said for having primary and secondary geomembranes made from different materials. (Note that the decision to use different materials for primary and secondary liners may also need to take into account the need to weld the primary and secondary liners together in the anchor trench to prevent water from entering the leak detection system. This is a site-specific issue that could be incorporated into the rating procedure.)

**CASE 2 - THE EXPOSED PRIMARY GEOMEMBRANE IN A PULP MILL BLACK LIQUOR POND** that will be installed in the summer in a location where winter temperatures can reach -40°C. The pond will mostly be empty except for three-week plant maintenance periods. "Detergents" will not be skimmed off the liquor. The black liquor enters the pond site at a temperature of 82°C.

Although efforts are made to reduce the temperature of the black liquor by cascading or spraying it into the pond, the liquid is still relatively warm. But is this necessary if exposed black liners regularly experience temperatures of 80°C in the summer sun? Chemical resistance to the liquor is of extreme importance as is the concern of thermal contraction of the geomembrane at low winter temperatures. Compensation wrinkles may need to be built-in in the summer installation.

Table 5 indicates PP and CSPE appear to be technically the most suitable materials.

**CASE 3 - A CO-DISPOSAL (MSW/CDD) LANDFILL CLOSURE CAP** where temperatures vary somewhat but are never very high. Installation occurs in the summer. The waste is subject to differential settlement. There is an active landfill gas removal system incorporated in the lining system. The geomembrane is placed on a GCL on 3:1 slopes.

The cap will have to tolerate the strains of differential settlement, and the stresses induced by some temperature changes. Maximum temperatures are not so high that loss of plasticizers from PVC is of concern.

Table 6 indicates that PVC is technically the optimum geomembrane. However, slope stability analyses indicate that the interface friction between PVC and the underlying GCL is not adequate to meet the minimum required factor of safety of 1.5. In this case, consideration of a well-textured LLDPE is warranted if its interface shear strength is able to meet the requirements.

**CASE 4 - AN UNDERGROUND CONCRETE RESERVOIR** for storage of irrigation water for a golf course. There are many square concrete pillars supporting the roof. All corners between pillars and floor, and walls and floor, are right angles. There are cracks in the floor.

Table 7 indicates that a spray on polyurea liner is the optimum liner for this application.

Clearly these examples have been contrived to generate different solutions and should not be considered complete, either in the parameters of significance, nor in the selection of candidate geomembrane materials, but they do provide examples of the types of thought processes and evaluations that are required for the successful selection and functioning of a geomembrane. There is not one geomembrane material that will be suited for all applications.

Even though this methodology may lead the specifier to an appropriate geomembrane material, care still needs to be taken in the details of the final specification. For example, when specifying HDPE, the stress rupture performance characteristics (stress cracking resistance) should be matched with the criticality of the specific lining installation.

Finally, it should be noted that there are many benefits to be gained from using different, but

complementary, materials for the primary and secondary geomembranes of double lining systems.

#### 4 CONCLUSIONS

A simple technically based procedure has been developed for the selection of the most appropriate geomembrane material for project specific applications. The procedure takes into account the operational and maintenance requirements of the facility as well as the mechanical, physical, and chemical performance characteristics of the material.

The procedure also provides information for a basic assessment of technical equivalency of different materials.

As with all engineering construction materials, experience, judgment, and a knowledge of the performance of such materials in such applications is essential in order to mobilize the optimum performance of the finished product.

**ABSTRACT:** This paper presents the preliminary study on heat-insulating performance of the geomembrane composite. The authors find that generally the thermal diffusivity of the geomembrane composite is slightly smaller than that of the concrete and 10~30 times smaller than that of simple geomembrane, and will decrease with the increase of thickness of geotextile associated with geomembrane. In this paper, a typical dike is presented as a application case for checking the heat-insulating effect of geomembrane composite. It is expected that the geomembrane composite will be used in the place of the concrete as the heat-insulating layer in civil engineering.

**KEYWORDS:** Geomembrane composite, Thermal diffusivity, Laboratory test, Heat insulation

## 1 INTRODUCTION

Geomembrane composite is a material composed by the geomembrane and geotextile. Since it has multi-functions such as seepage prevention and drainage, geomembrane composite was successfully widely applied in civil engineering in China, such as, in the main cofferdam at Shuikou Hydroelectric Station (Tao, 1989), in Lijiaqing earth dam (Tao, 1990), in the Core of Zhushou Reservoir dam (Tao, 1993), in the Xiaolingtou Rock-fill dam (Tao, 1996) to replace the clay or concrete impervious barrier and sand cushion.

The geomembrane composite is usually associated with the geotextile (in general needle-punched geotextile). The geotextile associated with the geomembrane is of fiber structure, thus is non-homogeneous, porous and anisotropic. These characteristics make the geotextile to have good heat-insulation performance, so that the geomembrane composite has both geomembrane and geotextile properties as well as impervious and heat-insulation functions. Formerly, the people have not attached importance to this special property of the geotextile.

The aim of this paper is to investigate whether the geomembrane composite is able to be used as heat-insulation layer in civil engineering.

Analytic results indicate that the seepage-prevention and heat-insulation effect of the geomembrane composite is fairly significant. So, the geomembrane composite can be used as a new type of engineering material to replace the concrete impervious and heat-insulation liner in civil engineering. It is a new application field in civil engineering for the geomembrane composite.

## 2 HEAT CONDUCTION EQUATION AND THERMAL DIFFUSIVITY

### 2.1 Heat Conduction Equation

Based on the heat conduction theory and energy conservation law, differential equation of heat conduction in terms of rectangular coordinates for the non-homogeneous and anisotropic area with inner heat source is

$$\frac{\partial t}{\partial \tau} = \left( a_x \frac{\partial^2 t}{\partial x^2} + a_y \frac{\partial^2 t}{\partial y^2} + a_z \frac{\partial^2 t}{\partial z^2} \right) + \frac{A}{C_p \rho} \quad (1)$$

where  $t$ —temperature;  $\tau$ —time;  $a$ —thermal diffusivity;  $A$ —inner heat generated per unit volume;  $\rho$ —density;  $C_p$ —specific heat at constant pressure.

From Eq.(1) it can be seen that the main characteristic for heat conduction is thermal diffusivity,  $a$ , which is defined by

$$a = \frac{\lambda}{\rho C_p}$$

where  $\lambda$  denotes the thermal conductivity.

The parameter,  $a$ , denoted the area where inner heat propagates per unit time. Since  $\rho$  is the mass density, the specific heat  $C_p$  must have the dimension of heat per unit mass and per temperature difference. If the specific heat is based on unit weight, the specific weight  $\gamma$  must be used in place of  $\rho$ . Therefore the dimension of the thermal diffusivity,  $a$ , is  $m^2/h$ .

Thus, it follows the research on thermal diffusivity of geomembrane composite first in laboratory.

### 2.2 Thermal Diffusivity of Geomembrane Composite

Geomembrane composite is a kind of thin plate material, according to the transient thermal diffusivity theory of infinite plate (Chapman, 1974), a test apparatus which is suitable for transient thermal diffusivity of infinite plate is developed. The test apparatus consists of water tanker composed by a heating chamber and a measuring chamber, of a auto-temperature controlling

Table 1 Test results of thermal diffusivity

No.	Specifications	Thermal diffusivity (m <sup>2</sup> / h)
1	Single geomembrane PVC with a thickness of 0.5 mm	0.06211
2	0.5 mm PVC with 250 g / m <sup>2</sup> NPGT on both sides	0.00798
3	0.5 mm PVC GM with 300 g / m <sup>2</sup> NPGT on both sides	0.00502
4	0.5 mm PVC GM with 400 g / m <sup>2</sup> NPGT on both sides	0.00358
5	0.5 mm PVC GM with 450 g / m <sup>2</sup> NPGT on both sides	0.00269
6	0.5 mm PVC GM with 500 g / m <sup>2</sup> NPGT on both sides	0.00207
7	Single geomembrane PVC with a thickness of 0.7 mm	0.05946
8	0.7 mm PVC GM with 300 g / m <sup>2</sup> NPGT on both sides	0.00475
9	0.7 mm PVC GM with 500 g / m <sup>2</sup> NPGT on both sides	0.00201
10	Concrete with a thickness of 100 mm	0.002995

Note: GM— geomembrane composite; NPGT— needle-punched nonwoven geotextile.

system, and of a auto-detecting system. Geomanbrane composite No.2~ No.6, No.8 and No.9, and single geomembrane No.1, No.7 are used in the tests as shown in Table 1.

The thermal diffusivity of the concrete plate (No.10) obtained by use of the test apparatus above-mentioned is 0.002995 m<sup>2</sup> / h, it is similar to that (0.0032 m<sup>2</sup> / h) obtained by use of "Measuring Apparatus for thermal diffusivity of Concrete" in "The Hydraulic Concrete Test Codes" approved by the Ministry of Water Resources and Electric Power of China in June 1982. Therefore, the test apparatus developed for determining the thermal diffusivity of geomembrane composite is reliable.

From Table 1, it can be seen that

— The thermal diffusivity of geomembrane composite is similar to that of concrete and it is relatively small and generally belongs to 10<sup>-3</sup> m<sup>2</sup> / h;

— The thermal diffusivity of geomembrane composite decreases with increase of thickness (or mass per unit area) of the geotextile associated with the

geomembrane;

— For the single geomembrane, the thermal diffusivity is the largest, it decreases slightly with increase of thickness of the geomembrane.

### 3 HEAT-INSULATING PERFORMANCE OF GEOMANBRANE COMPOSITE

As a calculation example, the authors take a dike installed between the intake and outlet of a power station, the dike axis is parallel to the coast line, so a discharge channel on one side of the dike near the coast is formed and is protected from the action of waves, while the other side of the dike fronts to the open sea. The water level, owing to the draining of heat water, in the discharge channel will be slightly higher than that of the open sea. The calculation profile of the heat-insulation liner within the dike is shown in Figure 1.

The dike is situated on the alluvial-slope from the land. The composite lining is placed below the base of the whole discharge channel, and extended within the

Figure 1. Computation section of dike and boundary conditions.

dike to the distance of 5 m perpendicular to the side-slope and the elevation of 7.5 m. Both sides of the impervious liner are filled with gravels 20~80 mm in granular diameter as a transition layer, the thickness being 1 m on both sides.

Eq. (1) is employed for calculating heat-insulating performance of the dike. For the inner thermal source of the discharge channel, it is prominent that heat transfer induced by joint seepage of the geomembrane composite will cause temperature rise of water, and the following can be written.

$$\frac{\partial \theta}{\partial \tau} = \frac{A}{\rho C_p} = QW \quad (2)$$

where,  $\theta$  denotes temperature rise of sea water;  $Q$ , thermal seepage discharge induced by the joints of the composite;  $W$ , temperature rise per unit volume of hot water in discharge channel.

Generally, there is a joint every 20 m of width for the geomembrane composite in engineering practice. Owing to the seepage discharge of heat water caused by the joint can maintain constant for a certain head difference, so the temperature rise due to heat transfer per unit volume caused by seepage discharge is also constant, for example, in the case calculation carried out by the authors, the constant value  $W = 10^\circ\text{C} / \text{m}^3$  have been obtained. Then the inner thermal source can be considered as a constant, thermal diffusivity of the geomembrane composite liner is assumed to be isotropic.

### 3.1 Boundary Conditions and Calculation Parameter

The region for heat-insulation calculation is 100 m long, and 110 m wide, from the foundation elevation of -8.0 m to the crest elevation of 12.0 m. There are 5 joints in the composite along the dike.

Temperature boundary: for the temperature of sea water, local annual average atmospheric temperature, i. e.  $21.3^\circ\text{C}$  is used; for water temperature in the discharge channel, because the temperature of water in discharge

channel is  $10^\circ\text{C}$  higher than that of the seaward side of the dike,  $31.3^\circ\text{C}$  is employed; for the temperature of the dike surface above the water surface of discharge channel,  $24^\circ\text{C}$  is used because there is a rise of the temperature of  $2.7^\circ\text{C}$  due to the solar radiation according to data of concrete gravity dam; the other boundaries are treated as adiabatic boundary ( $\partial T / \partial n = 0$ ) (see Figure 1).

The thermal diffusivities of various media for the heat-insulation calculation domain of the dike are shown in Table 2.

Table 2 Thermal diffusivities of various media

Materials	Thermal diffusivity ( $\text{m}^2 / \text{h}$ )
Cobble boulder	0.20
Medium coarse sand	0.01
Mild clay	0.002
Sea water	0.50
Composite No.6	0.00207
Concrete (No.10)	0.002995

### 3.2 Calculated Results and Their Analyses

The calculated results for heat-insulation calculation of the dike are shown in Figure 2 and indicate that

- (1) The heat-insulating effect of composite No.6 is fairly significant: a large quantity of heat conduction is insulated.
- (2) Owing to the temperature discontinuity between the water surface and the dike surface on the discharge channel side, there is a large temperature gradient at their interface.
- (3) The boundaries of the foundation and both sides of the dike in the heat-insulation calculation domain are treated as adiabatic boundaries, so the distribution of temperature rise contours is similar to the shape of the placement of the composite, and the temperature rise contours of other part present almost uniform perpendicular

Figure 2. Contours of temperature rise distribution for geomembrane composite liner.

distribution.

(4) Calculations for the dike with concrete heat-insulating wall are carried out, as shown in Figure 3. one can find that the temperature rise contours are obviously concentrated on the position of placement of concrete. It can be seen that the heat-insulating effect of concrete is also satisfactory.

(5) Comparing Figures 2~3, it can be seen that the distributions of temperature rise contours on the seaward side of the dike are almost identical; the reason is that seaward boundary of the calculation domain is treated as an adiabatic boundary. Therefore, the determination of the boundary conditions is the key to the analysis of the temperature field. The exact determination of dike surface temperature and seawater temperature, and the exact determination of boundary locations and conditions of the sea domain and discharge channel are still complex problems to be resolved. In this paper, the authors have to simplify these problems to show the heat-insulation effect of the composite.

#### 4 CONCLUSIONS

This paper has presented the preliminary study on the heat-insulating properties of the geomembrane composite, it can be seen that the geomembrane composite has both the properties of geomembrane and geotextile. Therefore, the geomembrane composite has good impermeous and heat-insulating property. The following conclusions can be obtained.

(1) The thermal diffusivity of geomembrane composite is usually small and is similar to that of concrete. It decreases with increase of the thickness (or mass per unit area) of the geotextile associated with the geomembrane.

(2) The heat-insulating effect of the geomembrane composite is remarkable, and it can prevent most of the heat conduction accross the geomembrane composite. For the calculation, the exact determination of boundary conditions is the key to the analysing the temperature fields. But the exact determination of boundary conditions

of the sea domain and discharge channel are still complex to be resolved, so the authors have to make some simplifications.

(3) The thermal diffusivity and heat insulating effect of geomembrane composite is about the same of concrete, however, the geomembrane composite is a soft material and can be suitable to the dynamic condition of engineering (as earthquake). Moreover, the geomembrane composite have other advantages: low cost, easy construction and maintenance. So that it is expected that the geomembrane composite will be used in place of concrete as heat-insulating material.

# Prediction of the UV Ageing of Polypropylene Geotextiles - Landfills case

O. Artières

Dr.-Ing., Bidim Geosynthetics S.A., Bezons, France

S. Gaumet

Dr., CNEP (Centre National d'Evaluation de Photoprotection), Université Blaise Pascal, Clermont-Ferrand, France

C. Bloquet

Dr., France Déchets, Gargenville, France

**ABSTRACT:** Geotextiles may be exposed to long weathering periods when used as a filter in drainage systems or geomembrane protection layer in specific applications such as landfills. There is therefore an urgent need to develop specific products able to offer the required durability of their functional characteristics for several months or years. The paper presents a methodology to assess the UV durability of polymers. This mechanistic approach firstly analyses the chemical degradation process of the polymer when exposed to natural weathering. Then it describes the rules able to control artificial accelerated ageing by keeping all the parameters into a representative range. The experimental investigation on polypropylene geotextiles in landfills is proposed as an example of this methodology.

**KEYWORDS:** Ageing, Geotextiles, Landfills, Ultraviolet Effects, Weathering Resistance

## 1 INTRODUCTION

Geotextiles are made of polymers, the most common being polypropylene, polyethylene and polyester. These pure polymers are sensitive to UV radiations which cause catalytic photo-oxidation reactions. These reactions in turn lead to breaks in the molecular chains, causing the degradation of the products. Polymer chemists have been aware of this phenomenon for a considerable number of years (but, we will see, the chemical mechanisms have only been discovered recently). They have found anti-UV and anti-oxidant stabilisers able to halt these reactions. These molecules are mixed with the polymer before it is melted.

In most earthwork applications, geotextiles are unwrapped and quickly covered in soil. Geotextile manufacturers have therefore adjusted the quantity of stabiliser into the polymer so that the products are not damaged after a few weeks' exposure. In such conditions, and in absence of any other chemical or mechanical erosion, geotextile will last for decades, as demonstrated in the sites built since the mid-sixties. Geotextile samples taken from a 25 years old earthdam have shown for example no significant damage (Delmas et al. 1994).

The damage becoming apparent on some geotextiles used in waste containment sites within periods ranging from 3 months to 2 years (Gisbert et al. 1997) stems from the disparity between these historical applications on one side, and the new constraints of landfill operation on the other side. In these applications, geotextiles are often installed on slopes as filter above a drainage layer or as geomembrane protection. They may be exposed for several months or years to weathering before being covered, instead of several weeks in current earthwork applications.

When geotextiles are exposed to sunlight for the whole period during which the site is in operation, special protection must be designed. One solution should be to

cover the geotextiles by a thin layer of soil. Another possibility is to impregnate them with a protective resin. One example of this technique is the Maraval's overflow-dike in southern France (Kern, 1977). The geotextile reinforced wall of the dike is exposed to permanent weathering. No deterioration has been observed on the site since it was built in 1976. A third possibility is to adjust the UV stabiliser content to the period of exposure.

In response to this specific requirement, a research program has been set up by Bidim Geosynthetics, producer, and France Déchets, landfill operator, to assess the effective lifetime of geotextiles laid in landfill, with the technical support of C.N.E.P. institute, from Clermont-Ferrand University, specialised in photodegradation of polymers. The paper focuses specially on the methodology used to assess the ageing of polymer products. Its principles are quite new in the area of geosynthetics even if it is used for several years in other industrial sectors (pipes, cars, fine arts, etc...). Some important results are given in the case of polypropylene geotextiles, but most of the principles apply to other types of geosynthetics.

## 2 AGEING METHODOLOGY

The methodology used in this study to predict geotextiles lifetime combines two complementary analyses on:

- Polymer durability through a mechanistic approach, as proposed by Blaise Pascal university (Lemaire 1996);
- Product lifetime through a functional approach.

### 2.1 Polymer Durability

#### 2.1.1 The conventional method : the simulation approach

A large part of the research and development on polymer

durability is based on an empirical approach developed in the early 1950s, with the expansion of polymeric materials. Laboratory testing was set up to reproduce the phenomena causing the degradation of the polymeric systems on a shorter time scale. Those systems were handled as macroscopic units characterised by their physical properties. The polymeric substrate was treated as a "black box" to which all the possible environmental physicochemical stresses—light, heat, mechanical, O<sub>2</sub>, liquid and gaseous water, O<sub>3</sub>, pollutants—were applied.

The devices designed for laboratory ageing experiments tried to simulate qualitative and quantitative environmental stresses as exactly as possible. For example, the choice of xenon light sources in simulation units (Weather-O-Meter, Xenotest) instead of medium-pressure mercury was justified on the fact that the spectral distribution of the light emitted as a semicontinuum was close to that of daylight (except in the range 240-300 nm which needs to be strictly filtered out). However, the fundamental concepts of photochemistry, especially the existence of vibrational relaxation of excited states in the condensed phase, would allow the relevant use of medium-pressure arcs.

But the stress simulation approach has some negative aspects:

- The control of the temperature of the exposed surfaces, which is an important parameter of photoageing, is not seriously considered.
- Water sprinkling designed to simulate rain could be questioned as well, because many of the effects of water are not produced in this manner. The first effect of water on a solid surface is to provoke the mechanical abrasion of the external oxidized layers and to wash out low molecular weight compounds that have migrated to the surface of samples.
- The degradation criteria are mainly based on the variations of the physical or mechanical properties. This "black box" approach connecting macroscopic and microscopic changes could not be rationalised, because many different chemical evolutions could have the same physical consequences.
- It is difficult to identify the actual origin of an observed degradation if many physical and chemical stresses are applied simultaneously.
- As there is no control of the real chemical reactions occurring inside the polymer, the environmental stresses should be applied at their exact level with a time scale as close as possible to the real time scale in outdoor conditions and without accelerated conditions to ensure relevancy.

Therefore, any relationship obtained with the simulation approach between, on one hand, lifetimes in natural weathering conditions, and on the other hand, lifetimes in artificial ageing, is nothing more than an experimental correlation whose variations cannot be explained.

Despite these difficulties, the simulation approach has been developed steadily since 1950. Most standards are based on such experiments, and in many cases, results are

consistent with the long-term behaviour of the polymer. Still many predictions have caused significant accidents, especially when the degradation criteria were based on laboratory results. The simulation approach had both succeeded and failed without being able to explain it.

### 2.1.2 The mechanistic approach

With this approach, the polymer durability is predicted from its chemical evolution which is observed when relevant physico-chemical stresses are applied. When a polymeric material is submitted to moderate environmental stresses, the degradation of most physical properties is attributable to chemical ageing: the polymer should be treated as a "photochemical" reactor in the presence of light and as a "thermal" reactor without light. Therefore, it should be possible to pinpoint the exact nature of the chemical events responsible for the physical detriment.

The mechanistic approach requires therefore to control both the analysis methods assessing the polymer chemical evolution and the laboratory accelerated conditions.

### 2.1.3 Analysis of the chemical evolution of the polymer

The analysis and follow-up of the chemical evolution of a polymeric material submitted to light, heat, O<sub>2</sub>, H<sub>2</sub>O, and other potentially degrading elements occurring in artificial conditions—as well as in natural weathering or real use conditions—have two advantages. Firstly, they allow the correlation to be relevant, based on the comparison of ongoing chemistry. Secondly, because the extent of the chemical evolution can be related to the exposure duration in either average (weathering) or well-defined (artificial ageing) conditions, the lifetime in-laboratory conditions can be converted into lifetime in-use conditions.

This analysis is complex for the following reasons:

- The analysis should be carried out in the solid state;
- The degradation products should be considered at very small concentrations;
- Chemical evolution includes many mechanisms.

But usually, the most important route involves a photo-oxidation or a thermo-oxidation mechanism whose products are formed in concentrations high enough to be observed in vibrational spectrophotometry. It allows identification of the main intermediate oxidation products (i.e., hydroperoxides, ketonic groups, and alcoholic groups), the main conversion route of those intermediate products, and the major final products that accumulate in the matrix (e.g., acidic, ester and lactonic groups).

### 2.1.4 The recommended accelerated testing

Acceleration is at the moment the recommended technique due to the impossibility of extrapolating data collected in nonaccelerated conditions. But the usual techniques of homogeneous kinetics cannot be applied to handle the chemical transformation of a polymer matrix through

ageing due to the complexities of the reactions that take place and because of the heterogeneity of a semicrystalline matrix which is oxidized in only a very small part of its amorphous zones.

CNEP and Blaise Pascal University formulated a set of principles that provoke accelerated chemical evolutions in solid polymers and that obey the same mechanisms as the nonaccelerated evolutions :

- For each polymer system, the ageing process should be controlled via chemical analysis so that both ageing processes have the same intermediate products, the same conversion pathway for each intermediate, and the same final products or functional groups accumulating in the matrix.
- Acceleration should be stopped when chemical distortions such as enhanced cross-linking resulting from biradical recombinations are observed.
- Photoageing acceleration should take place as a result of high light intensity and high temperatures. It should not result from shorter wavelengths of light. Temperature increase should be limited so that the photothermal transformation will exceed any pure thermal conversion.
- Mechanical stress does not generally influence chemical reaction rates, but it does modify the correlation between the chemical evolution and the variations of physical properties.

Accelerated testing is only valid when one unique dynamic process controls the ageing in natural and artificial conditions. In many outdoor uses of polymeric systems, photo-oxidation is the main detrimental mechanism. Thus, the artificial conditions must accelerate photo-oxidation without introducing some irrelevant control attributable to an oxygen starvation effect or to a stabilizer migration. In the first case, oxygen diffusion is a competitive dynamic process that does not exist in environmental conditions. In the second case, stabilizers are expected to migrate on the time scale of natural weathering, an equivalent migration should be introduced into the artificial conditions. Dark periods throughout exposure are sometimes required for that reason.

When low temperature thermo-oxidation is the controlling detrimental mechanism in weathering conditions, it is difficult to accelerate ageing simply by increasing temperatures. In that case, acceleration should be limited and analytically controlled.

## 2.2 Geosynthetic lifetime

Many of the studies undertaken on geosynthetic lifetime after weathering refer to the loss of mechanical characteristics of the product, specially the tensile resistance. If this approach is relevant for products for which tensile strength is a functional characteristic for the long term, such as geotextile or geogrid for reinforcement, in most of the other geosynthetic functions, tensile strength is mainly required during installation stage. This

characteristic must therefore keep the required value only for a short term period corresponding to several weeks, except for specific applications as discussed before such as landfills, where the product is not immediately covered.

On the contrary, functional characteristics must exceed the designed service values during the whole service life of the work. The lifetime of geosynthetics should be evaluated through the variation of these functional characteristics. Table 1 gives the corresponding functional characteristics in case of the geotextiles for filtration and geomembrane protection studied in this program (CFG 1995).

## 3 EXPERIMENTAL STUDY

The ageing methodology previously discussed was applied in the case UV ageing of polypropylene geotextiles in landfills.

### 3.1 Geotextiles

2 types of geotextiles representative of the products used in landfills for the filtration and for geomembrane protection functions were exposed to outdoor weathering and artificial ageing. Their characteristics are given in Table 1.

### 3.2 Natural Weathering

#### 3.2.1 Outdoor sites

Four European sites at different latitudes were chosen for their specific climatic conditions (Table 2). Geotextiles were installed in June 96. A weathering period of 1 year is already available.

Table 1. Characteristics of the analysed geotextiles (1)

Function	Filtration	Protection
Functional characteristic	Opening size (3): 110 $\mu\text{m} \pm 10 \mu\text{m}$ Permittivity (4): 2.8 $\text{s}^{-1} \pm 0.4 \text{s}^{-1}$	Protection efficiency of a geomembrane: 1.0 $\text{kN} \pm 0.2 \text{kN}$ (2) Thickness (5): 4.0 $\text{mm} \pm 0.2 \text{mm}$
Characteristic for installation	Elongation (6): 75 % $\pm 10$ % Dyn. perforation: 22 $\text{mm} \pm 2 \text{mm}$ (7)	Tensile strength (6): 35 $\text{kN/m} \pm 3 \text{kN/m}$ Dynamic perforation: 10 $\text{mm} \pm 2 \text{mm}$ (7)

### 3.2.2 Geotextile installation

The geotextiles were exposed in a Southwards direction and inclined on a 45° angle to meet extreme conditions. As described on figures 1, 2 and 3, the exposed area allows a sampling of strips at 4 ageing periods. The size of each strip is sufficient to carry out the tests listed in Table 1. Test specimen are localised in such a way that the effect of the product heterogeneity is low. The variations between the strips are mainly due to the action of weathering.

The geotextiles were fixed on a HDPE geomembrane to reproduce the current landfill situation, except in Clermont-Ferrand, where the smaller sized samples are exposed on a frame allowing air circulation on both sides.

### 3.3 Artificial ageing

In outdoor conditions, the most detrimental effect on polypropylene systems results from the photothermal oxidation due to the UV, heat and O<sub>2</sub> conjugated influences. Water has been shown not to be a major stress (see § 2.1.1). The lifetime prediction of PP systems is therefore based on the experimental results obtained in SEPAP 12.24, an unit in which the accelerated photoageing is attributable to the combined effect of light intensity and heat only. The acceleration factor is largely dependant on the nature of the polymer (Lemaire 1996).

This unit described by Tang et al. (1982) is built as a parallelepipedic chamber with medium-pressure mercury arcs lamps located at each of the 4 corners. They emit between 280 and 405 nm and a borosilicate double envelope filters out any low-intensity radiations with wave length < 290 nm. The emissions are delivered with a constant intensity and a spectral distribution over 4000 h. As long as the relative percentages of short and long wavelengths are considered, the medium-pressure mercury source emission is a closer approximation to daylight than xenon source emission.

24 samples fixed on a rotating support in the centre of the chamber receive a homogeneous distribution of

Figure 1. Panels for outdoor exposure (MD: Machine direction).

Figure 2. Positioning of the test specimen on a strip of geotextile for protection (2.5 m x 0.5 m).

Figure 3. Positioning of the test specimen on a strip of geotextile for filtration (2.5 m x 0.5 m).

radiation. The temperature of the exposed surface of a reference film is controlled and maintained constant between 50 and 80°C (±1°C). The reference film is chosen to have the same surface properties (same colour and processing) as the other 23 samples. This unit was used in our study with a temperature of 60°C.

## 4 POLYPROPYLENE (PP) PHOTOOXIDATION

As discussed before, the control of the accelerating factors applied during artificial ageing is based on the knowledge of the type and rate of the chemical reactions occurring in the polymer during outdoor exposure.

### 4.1 Chemical mechanism

The mechanism of PP photothermal oxidation has been thoroughly examined for many years by most groups working in polymer. The most recent and the most complete version of the photooxidation mechanism is presented on Figure 4 (Delprat et al. 1995; Vaillant et al. 1994). The proposed mechanism is based on :

Figure 4. The main photooxidation route of PP

- the identification of the various photoproducts formed on the macromolecular chains, observed through FTIR spectrophotometric and microspectrophotometric measurements, with or without derivatization reactions;
- the identification of the various low molecular weight products through mass spectrometry.

The complete picture could be useful when the main oxidation route is well identified among all the possible conversions of intermediate products. That main route is represented on Figure 4. Among the final photoproducts which accumulate in the matrix, the chain end acidic groups  $\text{CH}_3\text{—C—COOH}$  were selected as "critical photoproducts", i.e. products of which the concentration was found to be correlated with the variations of functional characteristics.

From direct comparison of the formation rate of the critical photoproducts between the accelerated conditions of a SEPAP 12.24 unit and the first phase of in-use weathering conditions, the lifetime of unstabilized PP materials could be predicted.

The lifetime of stabilized PP is predicted from the comparison of the loss rate of stabilizers between artificial accelerated conditions and natural weathering.

#### 4.2 Identification of the Polymer Ageing

Using the correlation between the variations of physical

Figure 5. FTIR spectrum of 2 filtration geotextiles samples after 6 months weathering. V: Villeparisis on geomembrane - C: Clermont-Ferrand without support.

properties and the variation of the critical product concentrations under accelerated conditions, we can determine the lifetime of the polymeric material in the artificial condition. This result is converted into an estimate of the lifetime in weathering conditions using a predetermined acceleration factor based on the corresponding chemistry.

The loss rate of stabilizers and the chemical evolution of the polymer is analysed using FTIR (Fourier Transform Infra Red) spectroscopy in photoacoustic mode (PAS). This technique allows the analysis of the first 15  $\mu\text{m}$  near the surface of non translucent samples without specific preparation of the samples.

The FTIR spectral evolutions and the observed stoichiometry events at the molecular scale are the same with artificial ageing and outdoor weathering. This proves that SEPAP 12.24 units at 60°C reproduce well the outdoor PP ageing. For example, the growth of the main critical photoproduct (acid) is followed at 1720  $\text{cm}^{-1}$ . A typical FTIR spectrum is given on Figure 5.

## 5 BENEFITS OF THE METHODOLOGY

When the main target of the experimental study was the definition of the type and content of the UV stabiliser to be used in the geotextiles produced by one of the authors, 2 general results of great significance must be pointed out.

### 5.1 Influence of the Support

Even with lower climatic conditions (Table 2), the photooxidation rate in Villeparisis was found to be much higher than in Clermont. Spectrophotometric analysis of the Villeparisis samples shows that the UV stabilisers totally disappeared and that the concentration of the main critical photoproduct is about 3 times higher than in Clermont (Figure 5). The explanation corresponds to a

problem of air circulation around the sample : when samples are laid on a geomembrane, air doesn't circulate and the geotextile's temperature increases. The geomembranes acts also as a dark body which accumulates the sun energy and maintains the surrounding temperature at an high level over a longer period. Therefore, the stabiliser loss rate, the oxidation kinetic and the correlation between accelerated ageing and outdoor exposure cannot be the same. In this case, as discussed in § 2.1.4, the acceleration procedure has firstly to take into account this migration of stabilisers by keeping dark periods, and secondly to adjust the temperature of the ageing chamber at least to the level measured on the site by controlling the stoichiometry of the reactions

This result points out 3 main conclusions. Firstly, the conventional approach would not be able to explain these differences of behaviour. Secondly, the stabilisation level of a geotextile laid on a geomembrane must be much higher than for a geotextile laid on a soil with the same weathering conditions and during the same period. Thirdly, each specific application need specific outdoor exposure. It is false to extrapolate existing data to another situation.

## 5.2 Geotextile Durability

In many studies, geosynthetic ageing is related to the loss of tensile strength, even if this is not an essential characteristics. Our investigation has shown that significant loss of tensile strength doesn't necessarily means that the fonctionnal characteristics decrease with the same ratio. Table 3 gives the changes of the functional characteristics of a filtration and of a protection geotextile having the same level of stabilisation after one year's exposure in Villeparisis. Even with a 55 % reduction of its tensile strength, the fonctionnal behaviour of the filtration geotextile is still correct.

For the geomembrane protection geotextile, the reduction of the protection efficiency is also lower than the loss of tensile strength. It is know that even if the initial tensile modulus of the geotextile is of great importance to

Table 3. Geotextile characteristics and their variations (in brackets) after 12 months weathering in Villeparisis compared to the initial values. (1)

Function	Filtration	Protection
Functional characteristic	Opening size : 120 µm (0%) Permittivity : 3.7 s <sup>-1</sup> (+32%)	Protection efficiency of a geomembrane: 0.7 kN (-20%) Thickness : 4.2 mm (0%)
Tensile strength loss	-55 %	-25 %
(as comparison)		

Notes : (1) The geotextiles have both the same level of stabilisation and are laid on a geomembrane. If the measured value is found inside the variation range of the characteristic, it is assumed that there is no significant change.

protect the geomembrane against high strain, the geotextile thickness is also a major factor to decrease the local stress (Wilson-Fahmy et al., 1996).

## 6 CONCLUSION

The geotextile lifetime exposed to a long period of weathering should be assessed by combining : (i) the evaluation of the polymer durability based on a mechanistic approach to be sure that the same chemical reactions occur between natural weathering and artificial ageing; (ii) the changes of the functional characteristics of the products, instead of the tensile strength when it is not justified.

This methodology applied in the case of geotextiles used in landfills shows the efficiency of these tools to explain the high level of ageing when they are laid on a geomembrane.

Finally, the designer should use the fonctionnal approach to specify minimum values for each of their essential characteristics that the geosynthetics have to keep before being covered.

# Geosynthetic Proficiency Testing

G. R. Koerner

Geosynthetic Institute, Drexel University, Philadelphia, PA USA

**ABSTRACT:** A major tasks of the Geosynthetic Accreditation Institute's Laboratory Accreditation Program (GAI-LAP) is monitoring and evaluating laboratory test data measurement reliability. The program has developed data bases for assessing measurement reliability among geosynthetic testing laboratories. This paper describes the data base development and how it is utilized as a benchmarks from which proficiency test results are evaluated. It is felt that this type of an accreditation program is more challenging in assessing a laboratory's capability of performing specific tests than are programs that only check the existence of a quality system. While a quality system is indeed important to a laboratory performing tests, it is the actual test-by-test capability that is ultimately important to the end user of geosynthetic test results. It is this type of capability that is monitored and evaluated by the program.

**KEY WORDS:** Geosynthetic, laboratory testing, proficiency testing, precision, bias.

## 1 BACKGROUND

Test data reliability and quality are indeed worldwide concerns. A laboratory is not only expected to work efficiently but also expected to provide quality results in accordance with a well conceived quality system.

Upon observing questionable laboratory results in the recent past and realizing that many geotechnical and materials testing laboratories were starting fledgling geosynthetics test laboratories, the Geosynthetic Accreditation Institute (GAI) under the umbrella of the Geosynthetic Institute (GSI), began Geosynthetic Accreditation Institute's Laboratory Accreditation Program (GAI-LAP) in 1995. The program is intended to assure that a laboratory is capable of properly providing advertised tests.

Program representatives audit laboratories based on two international quality standards. The labs are directed to use ISO Guide 25 as their model for conducting business and encouraged to draft their quality manual, as per ISO 9003. Although the program suggests the use of these standards, it does not profess to be affiliated with ISO. Rather, the program is a hybrid one which tailors the above two standards to serve the immediate needs of the geosynthetic testing community. Also it should be made clear that this program does not "certify" laboratories, per se, nor the results that come from them. The intent of the accreditation program is to provide credentials to a laboratory showing that it has met requirements in regards to equipment and documentation for specific standard test methods.

Figure 1 shows a flow chart which highlights the accreditation process. As can be seen in the flow chart, there is considerable exchange of information and documentation prior to an actual audit. When successfully fulfilled, an on-site audit is conducted. At the audit, documentation, procedures and general laboratory protocol are first verified. When completed the auditor proceeds to supply the laboratory technician(s) samples of geosynthetics for which a data base exists. The technician prepares test specimens, tests

them in accordance with the appropriate standard and is required to have results fall within  $\pm 2$  standard deviation of a data base average. After progressing through the laboratories repertoire of tests an audit report is prepared summarizing all general and specific deficiencies. At the closing meeting these deficiencies are brought to the attention of management. Upon closing these deficiencies, the laboratory's accreditation is granted and a fee is paid.

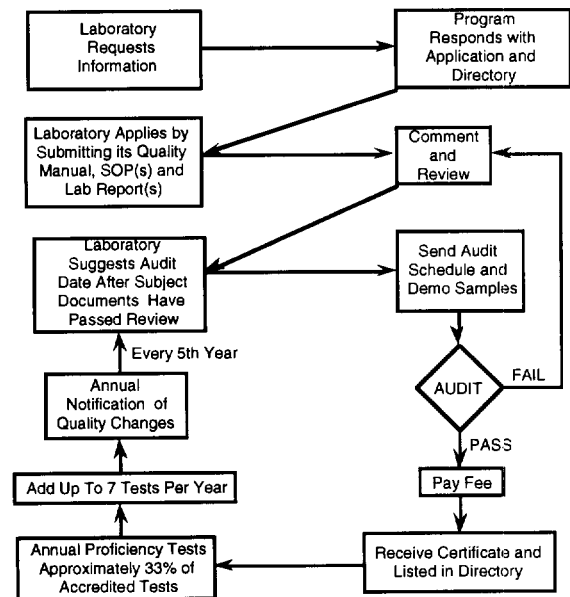

Figure 1. Program flow chart.

In subsequent years, the laboratory enters into a loop where off-site proficiency testing is required for approximately 20% of the laboratory's accredited tests. Every five years an on-site audit is conducted. In 1996 and 1997, proficiency testing was carried out among 19 laboratories. Using Geosynthetic Institute's laboratory as a reference, submitted results are compared with established data base averages.

At present, 80 data bases have been generated which involve 11 different rolls of "standard" geosynthetic materials. These materials are the following:

- HDPE smooth geomembrane
- HDPE textured geomembrane
- VFPE smooth geomembrane
- PVC geomembrane
- Scrim reinforced PP geomembrane
- Needle punched nonwoven geotextile
- Slit film woven geotextile
- GCL
- Geonet
- Stiff geogrid
- Flexible geogrid

One hundred test specimens are cut from samples of these rolls and are conditioned prior to testing. In order to obtain representative test specimens from the samples, no more than 10 specimens are cut from a particular roll width. In addition, no specimens are taken within 300 mm of the roll edge. All data base test specimens are evaluated on the same equipment, by the same technician. No more than 10 replicates of any given test are performed in a single day. The data base results are statistically analyzed by JMP® (1994). This computer program is a user friendly statistical software package. A histogram and control chart are generated for each data base. Values such as mean and standard deviation of each data set are determined.

Proficiency data bases are repeatability rather than reproducibility data bases. Repeatability testing is defined as "conducted in one laboratory by one technician on the same piece of equipment." Conversely, reproducibility testing is defined as "conducted at several laboratories by various technicians on different pieces of equipment." This has created some anxiety with participating laboratories because two standard deviations of a repeatability database is a smaller window of acceptability than that of a reproducibility data base. In addition, such a small window ( $\pm 2\sigma = 95\%$  confidence limit) is unprecedented in geotechnical testing industry to which geosynthetic testing is often compared. Many federal agencies such as AASHTO (1995) and ASTM (1993) use a 99% confidence limit ( $\pm 3\sigma$ ) as their grading requirement.

## 2 PROFICIENCY TEST RESULTS

Results of the 1996 and 1997 proficiency tests are presented in Tables 1 and 2 respectively. The tables are subdivided into two parts illustrating numeric results of the data bases and an analysis of the laboratory submittals with respect to them. Data bases are described by the average (Avg. 1), upper control limit (UCL) and lower control limit (LCL). In this regard, the UCL is defined as "plus two standard deviations of the data base average" where the LCL is defined as "minus two standard deviations of the data base average." In

contrast, laboratory submittals are illustrated by an average (Avg. 2), maximum (Max.) and minimum (Min.) of the results submitted that year. In addition, results are rated based on the following grading requirements which represents a 95% confidence limit of each data base in question.

5 = data within  $\pm 0.5$  standard deviation of average,  
4 = data within  $\pm 1.0$  standard deviation of average,  
3 = data within  $\pm 1.5$  standard deviation of average,  
2 = data within  $\pm 2.0$  standard deviation of average, and  
1 = data  $> 2.0$  standard deviation of data base average.

Finally, the above numeric ratings are averaged on an individual test basis, by way of a grade point average (GPA). This number can be thought of as a score for how well the submitted results match the data base in question. Five (5) indicates a good match where two (2) signifies a poor one. Note that a grade of one (1) is considered unacceptable and requires corrective action to be taken on the part of the submitting laboratory.

## 3 DISCUSSION

Depending on ones perspective the results presented in Tables 1 and 2 hold promise as well as disappointment. As can be seen in Table 1 the task of constructing a geosynthetic data base for a particular test and material is achievable. During the course of conducting this effort there have been many skeptics. Discussions about aging of the test material, damage during transit and vagueness of the test standards have been encountered. After 2 years of work, and 178 attempts at matching with 28 data bases, the merits of this exercise are apparent.

When the average GPA is calculated for both 1996 and 1997, a score of 3.5 is obtained. This quite respectable value highlights the success of this overall endeavor.

As far as test scores are concerned it is seen that three groupings can be considered.

Tests with statistical results between 5 and  $>4$ , e.g., Melt flow index (D 1238), Transmissivity (D 4716), Thickness (D 5199), Break Stress (D 638), Break Strain (D638), Density (D 1505), Mullen Burst (D 3786), Mass/Area (D 5261), Peak Friction Angle (D 5321), and 2% Secant Modulus (D 5323).

Tests with statistical results between  $<4$  and  $>3$ , e.g., Geomembrane Tear (D 1004), Permittivity (D 4491), 10% Modulus (D 882), Apparent Opening Size (AOS) (D4751), Puncture (D4833), Thickness (D5199), and Residual Friction Angle (D 5321).

Tests with statistical results between  $<3$  and  $>2$ , e.g., Specific Gravity (D 792), Grab Tensile (D 4632), Yield Stress (D 638), Yield Strain (D 638), Stiffness (D1388), Carbon Black Content (D 1603), Trap Tear ( D 4533), Wide Width Tensile (D4595).

<sup>a</sup>Avg. 1 = Average of data base<sup>b</sup>UCL = Upper control limit of data base<sup>c</sup>LCL = Lower control limit of data base<sup>d</sup>Avg. 2 = Average of laboratory submittals<sup>e</sup>MAX = Maximum laboratory submittal<sup>f</sup>MIN = Minimum laboratory submittal<sup>g</sup>GPA = Grade Point Average

The rating of one (1) for some of the tests performed by accredited labs gives rise to concern and deserves some discussion. It should be mentioned that not matching the data base is not always the fault of the submitting laboratory. If results are reproduced by the majority of laboratories but are rated as one (1), the database shall be brought into question. In addition, it should be noted that a 95% confidence level ( $\pm 2\sigma$ ) of a repeatability data base is a very small target and that there are several suspected reasons for low ratings. The most evident being existing confusion with respect to gray areas of some ASTM standards. Gray areas such as gripping, preloading, conditioning and strain rate still persist in standard which offer guidance instead of clearly defining test conditions. These gray areas are most notable with performance rather than index tests and are particularly evident for test methods not specific to geosynthetics.

From a review of Table 1 and 2, there does not appear to be a trend as far as category of test, i.e., physical, mechanical, hydraulic or chemical. It was surprising to find that physical and mechanical results were not easier to match than hydraulic or chemical tests. In addition, trends showing that force and pressure measurements were easier to match than deformation and strain measurement did not materialize.

It was surprising to note that the submitted performance test responses matched very well with their respective data bases. Namely, transmissivity (ASTM D4716) and direct shear (ASTM D5321) responses had a combined average GPA of 4.0. However, in all cases the cross sections examined were rather simple geosynthetic ones. For example, a geonet between two rigid platens for the transmissivity test and a geomembrane against a geonet for the direct shear test were used. The effect of adding soil to the respective cross section has yet to be evaluated.

It was interesting to note significant material variation on any given roll of geosynthetic. Such variation were more significant across the roll width and were particularly noticeable with needle punched nonwoven geotextiles. Such results corroborate current efforts in writing specifications around the minimum average roll value (MARV) for geotextiles as mentined by Koerner (1994).

Along with the positive correlations drawn from matching the lab submittals to the data base, there were several shortcomings. The first of which was the determination of stiffness via ASTM D1388. This relatively obscure test caused a great deal of difficulty for laboratories who have all passed an on-site audit. While determining the corrective actions for outliers, it was determined that unit conversion mistakes were the root cause of the two incorrect submittals. It appears that United States laboratories loose sensitivity for the order of magnitude of results when reporting results in metric units.

The second general test shortcoming was in regard to grip slippage or stress concentration imparted by testing grips. Ideally a grip should not initiate failure while it should allow a specimen to break within the gage length

as it prevents slippage. Grip problems were encountered with the tear test, ASTM D4533, and the puncture test, ASTM D4833. In cases where stress concentrations was encountered with the tear test, results were lower than anticipated. Such conservative results are a disservice to the material. Conversely, when slippage was encountered with the tear test, results were higher due to realignment of the specimen from a tearing mode to quasi tensile mode. In cases where slippage was encountered with the puncture test, results were lower due to a "yielding puncture" rather than a "crisp rupture" of the material. Due to these findings, it is felt that in general more attention should be placed on how geosynthetic specimens are gripped prior to testing.

A related area of concern is the preload or manner in which specimens are loaded into grips. This issue appears to have an effect on the failure strain and modulus results generated from data acquisition systems. Although not a major source of problems in either the 1996 or 1997 proficiency test results, it is envisioned that as the data base values become more refined, such subtleties shall become significant.

#### 4 SUMMARY AND CONCLUSIONS

It is felt that the work presented in this paper illustrates the merits of geosynthetic proficiency testing. The author believe that analyzing quantitative results (via proficiency testing) is a more viable means of assessing a laboratory's quality than merely discussing its attributes. By making proficiency testing the focus of an accreditation program, rather than a voluntary aside, one creates a better program. It has been shown that geosynthetics lend themselves well to proficiency testing and that results within the 95% confidence level are attainable using repeatability data bases.

#### ACKNOWLEDGMENTS

The author would like to take this opportunity to thank members of GSI for their insight and financial support in regard to this work. In addition, an acknowledgment of the geosynthetic testing laboratories who have participated in this program is expressed.

**ABSTRACT:** Liners below landfills may be constructed either over relatively permeable materials (sands and silty sands or a drainage layer) or over relatively low permeability formations (silts and clays). These conditions either allow full drainage and consolidation of the low-permeability liner component or allow only partial drainage and consolidation. These varying field conditions will have different impacts on mobilized liner interface strengths. The mobilized strengths influence factors such as construction sequencing, final height and slope of the landfill, and both static and seismic stability. This paper presents the results of interface strengths under various subgrade drainage conditions and presents their impacts on landfill stability and airspace by citing case histories.

**KEYWORDS:** Interface strength, Landfills, Liners, Stability.

## 1 INTRODUCTION

The importance of composite lining systems, which include both a geomembrane and low-permeability soil components, to reduce the potential for leakage has been recognized for years in the development of the modern sanitary landfill. The composite liner, however, has introduced variables that need to be considered in landfill design; among them the interface shear strength between the geomembrane and low-permeability soil. The importance of this parameter has been recognized for years, as evidenced in the literature references, with emphasis placed on laboratory shear strength testing, especially the direct-shear test described in American Society of Testing and Materials (ASTM) D 5321.

ASTM D 5321 is an important step in evaluating shear strengths, but leaves much to be determined by the design engineer "to simulate field conditions." While the authors acknowledge the importance of simulating field conditions, more information is required on how this is to be done. Two variables, drainage and consolidation, that ASTM D 5321 currently leaves unspecified, can impact tests. In an attempt to address these issues, we offer the following.

## 2 DRAINAGE AND CONSOLIDATION OF SOIL

### 2.1 Effects of Drainage and Consolidation on Shear Strengths of Low-Permeability Soil

The impacts of drainage and consolidation are described in any number of standard soil mechanics text books (Lambe and Whitman 1969; Terzaghi, Peck and Mesri 1996), but a short discussion is appropriate here as it directly affects the evaluation of interface strengths. Soils tested in the unconsolidated undrained (UU) condition usually represents short-term conditions. In laboratory testing, such as triaxial tests (ASTM D 2850), the soil is not permitted to drain either during the initial application of confining pressure nor during shearing. Pore pressures are not dissipated and shear strengths ( $S_u$ ) are constant (e.g., strengths do not increase with confining pressure) for saturated cohesive soils.

Triaxial testing (ASTM D 4767) that allows drainage during the initial application of confining pressure but does not permit drainage during shearing is referred to as consolidated undrained (CU). This represents soils that have consolidated under load, but are sheared quickly so that pore pressures generated during shearing are not dissipated.

Shear strengths under CU, for total stress conditions, are presented by the Mohr-Columb equation:

$$\tau = c + \sigma \tan \phi \quad (1)$$

where:  $\tau$  = shear stress;  $c$  = cohesion, which is the shear strength intercept when the normal stress is equal to zero;

$\sigma$  = total normal stress on the failure plane at failure; and,  
 $\phi$  = angle of internal friction.

Testing conducted at strain rates slow enough to allow drainage during shearing represent consolidated drained (CD) conditions. Consolidated drained conditions may also be estimated by measuring pore pressures during the CU triaxial test and accounting for them to determine effective stresses. These conditions typically reflect long-term conditions. Cohesion is usually low or negligible under drained conditions for normally consolidated or slightly over consolidated soils.

## 2.2 Effects of Drainage Conditions on Interface Shear Strengths

For typical design and testing purposes, the low-permeability soil is considered initially saturated. Compacted low-permeability soil liners are usually well compacted at moisture contents above optimum, which results in a soil placed near saturation. Initial moisture migration from compacted soil to the geomembrane/soil interface due to factors, such as, thermal gradient effects is enough to saturate the soil near the interface. Compression under load may also increase the degree of saturation. To model these field conditions, interface strength testing is conducted under submerged conditions and the top of the clay is sprayed with water prior to placement of geomembrane.

Two distinct models are generally considered for drainage conditions. Low-permeability soil constructed over a relatively permeable soil subgrade or a subdrain should consolidate quickly, less than one year, and consolidated shear strengths are considered (Figure 1a). Liners constructed over relatively low-permeability subgrades or a naturally occurring layer of low-permeability soil may not consolidate quickly (Figure 1b).

Figure 1. Field conditions representing relatively permeable and low permeability subgrades

In this case, unconsolidated strengths are typically considered, at least for short-term to intermediate conditions. It should be noted that textured HDPE geomembrane has been used and post-peak strengths have been considered in the analyses.

## 3 RELATIVELY PERMEABLE SUBGRADE

### 3.1 Consolidation

Low-permeability soil liners constructed over relatively permeable subgrades are likely to consolidate and increase in strength over time. Interface shear strengths between textured geomembrane and the soil should likewise increase in strength due to consolidation if the texturing is sufficient enough to push the failure plane into the upper surface of the soil as opposed to the geomembrane sliding above the surface. The time required to consolidate the soil near the interface is related to the soil characteristics, specifically the coefficient of consolidation, according to the following equation:

$$t = \frac{TH^2}{c_v} \quad (2)$$

where:  $t$  = the time for consolidation to occur,  $T$  = appropriate time factor for desired percent consolidation,  $H$  = length of the drainage path (thickness of the layer for single drainage), and  $c_v$  = coefficient of consolidation from consolidation test (ASTM D 2435).

For most practical purposes, 90 percent consolidation is probably sufficient to consider the soil consolidated and even 50 percent consolidation may be enough to result in measurable increases in strength. The above equation is applicable to relatively permeable subgrades such as a natural granular deposit, leachate detection, or subdrain layer beneath a primary clay liner. In such cases 90 percent consolidation is likely to occur within a year (e.g., assuming a 610 mm thick layer with  $c_v = 1 \times 10^{-4} \text{ cm}^2/\text{sec}$ ).

In cases where consolidation of the soil liner can be substantiated, testing should be conducted to reflect consolidated conditions. For the interface shear strength testing, we have applied the full overburden load test load for about 16 hours and allowed the sample to consolidate under this load prior to shearing. Generally, clay samples 25-mm-thick used in the interface shear strength test should consolidate (80 to 90 percent) within 12 hours. The test apparatus should allow for drainage beneath the soil sample. In such situations, shear rates of 1 mm per minute would most closely represent consolidated undrained conditions. This CU strength is appropriate for modeling

seismic conditions and is an appropriate value for long-term static conditions.

### 3.2 Soil Testing

One of the short comings of the direct-shear testing (ASTM D 5321) is that drainage conditions are not easily controlled. When simulating consolidated conditions, the impact of consolidation during shearing is probably not significant compared to initial consolidation prior to shearing. The dissipation of pore pressure during shearing, however, does have an impact of whether the test can be considered drained or undrained. While attempting a CU test, true undrained conditions can not be achieved since some dissipation of pore pressure is allowed during shearing. True CD conditions may be approached if shear rates are low enough to prevent pore pressures from accumulating. Shear rates slower than 0.1 mm per minute are usually required which results in shearing times in excess of one day.

In an attempt to overcome these short comings, the authors typically conduct shear strength testing on the soils alone using triaxial testing where drainage conditions can be controlled. Unconsolidated undrained triaxial shear testing for saturated samples is conducted to represent short-term strengths. This strength should represent worst-case conditions and be lower than the consolidated interface shear strengths under typical refuse loading (greater than 240 kPa). UU strengths may be used to analyze interim refuse slopes where consolidation of the soil liner may not yet be appreciable.

Consolidated undrained triaxial shear strengths should represent the upper limit of strength. This testing is important, however, in that it reflects the effects of consolidation on soils and is conducted under known drainage conditions. In addition to triaxial shear testing, consolidation tests may also be conducted to determine coefficients of consolidation under various load increments. This is important, along with fill sequencing, in determining how much consolidation may be achieved.

### 3.3 Case Histories

#### 3.3.1 Compacted clay/HDPE liner system

Consolidated shear strengths were used in the design of a municipal solid waste landfill along the California Central Coast (Site A). Low-permeable soils were available for soil liner construction from a nearby borrow source, while subgrade soils were generally sands that allowed for consolidation. Groundwater was more than one meter below the liner.

At 93 percent relative compaction (ASTM D 1557), the UU shear strength of the soil met the required 38 kPa short-term strength. The CU triaxial compression strength

(total stress) was a friction angle of 13.5 degrees with a cohesion of 53 kPa. The CU interface shear strength (post-peak) with textured HDPE geomembrane was represented in a two-part curve to model non-linear behavior; a friction angle of 10.5 degrees under loads less than 190 kPa and 4 degrees with a cohesion of 21 kPa at higher loads. The peak interface strength of 11 degrees with a cohesion of 39 kPa is roughly 80 percent of the CU clay strength. As shown in Figure 2, under high loads the interface strength falls between UU and CU triaxial soil strengths. Note the significant drop in post peak interface shear strengths from peak strengths that has been associated with plastic clays. (Sharma, et al. 1997). Consolidation tests resulted in a coefficient of consolidation around  $1 \times 10^{-3} \text{ cm}^2/\text{sec}$  which allows for significant consolidation of the clay within months. The landfill was designed using CU post-peak interface strengths. The stability of interim refuse slopes was also checked using the UU triaxial soil strength.

(a) Shear stress-displacement relationship

(b) Shear strength envelopes

Figure 2. Interface strength for consolidated conditions (Site A: permeable subgrade)

### 3.3.2 Admix soil/HDPE liner system

Another MSW site in the Southern California area (Site B), where the excavated subgrade materials are predominately coarse-grained sandstone, required either imported low-permeability clay or screening site material and admixing with 7 percent high-swelling sodium bentonite. To achieve static stability (factor of safety = 1.5) and seismic deformation (average 6 inches) requirements, an admixed low-permeability material was specified. A field test pad fill confirmed that the admixed material could meet the field permeability requirement of  $1 \times 10^{-7}$  cm/s.

A saturated, UU triaxial compression strength of 76.8 kPa and CU triaxial compression strength (total stress) of a friction angle of 19.5 degrees with a cohesion of 23.8 kPa were achieved on the selected admix soil design with specimens remolded at 92 percent of the maximum dry density (ASTM D 1557) at 5 percent above optimum moisture content.

Two series of saturated direct shear interface tests (ASTM D 5321) between the selected admix soil and the 1.5 mm thick textured high-density polyethylene (HDPE) geomembrane were performed (Figure 3). The first series of tests were performed under partially consolidated conditions where the soil was submerged for at least 16 hours under a 6 kPa overburden pressure, the load ramped to the selected normal overburden pressure, and then sheared at 1 mm per minute. The second series of tests were performed under similar consolidated conditions described for the first series testing, the load ramped to the selected normal load, and the soil was allowed to consolidate under the full load for 1 to 4 hours (80 to 90 percent consolidated) prior to shearing.

Figure 3. Interface strengths for relatively permeable subgrade, Site B

The static stability analyses for fill sequencing were performed using the saturated, interface shear strength envelope for partially consolidated soil conditions. The seismic stability analyses were performed using the saturated, interface shear strength envelope for the consolidated site conditions. The basis for using the higher strength envelope to assess seismic and long-term static conditions is due to the following:

- The coefficient of consolidation from a laboratory test performed on an admix specimen ranged from  $1 \times 10^{-3}$  to  $2 \times 10^{-3}$  cm<sup>2</sup>/s.
- A low-permeability admix material will be underlain by predominately coarse-grained materials which will provide a drainage path.
- The thickness of the low-permeability admix material is limited to 0.6 m, therefore, about 90 percent of field consolidation should occur within 30 days.
- The probability of the design earthquake occurring before completion of 90 percent of consolidation is very small.

## 4 LOW-PERMEABILITY SUBGRADE

### 4.1 Testing

Low-permeability subgrades are slow to drain and do not permit rapid consolidation of the soil liner. With a constant unsaturated vadose zone beneath the liner, consolidation of the soil liner is probably inevitable (on a long-term basis), but should not be counted on for near term conditions (during landfill operations).

Direct-shear interface strength testing in these cases should be conducted to simulate UU conditions as closely as possible. As noted earlier, however, consolidation and drainage during shearing (ASTM D 5321) do not allow testing under true UU conditions. To approximate this state, the soil sample is placed under a setting load (6 to 24 kPa) and submerged overnight. The full load is placed immediately before shear (immediately in this case means applying the load quickly in stages of about 50 kPa per minute). The amount of the setting load may have minimal impact at high overburdens, but should be considered carefully especially for testing under low overburdens (50 kPa or less).

Triaxial testing under saturated UU conditions should also be performed to develop soil strength data under controlled drainage conditions. Slope stability analyses should be performed for both direct-shear interface and triaxial strengths. Although interface strengths should be no greater than the internal soil strengths, consolidation during testing may have increased the interface strengths resulting in a higher interface strength than soil strength.

Testing under CU conditions is not required for this scenario since consolidation is not expected under this field condition.

## 4.2 Case Histories

### 4.2.1 Compacted high plasticity clay/HDPE over shale subgrade

A site in the San Francisco Bay Area is being developed as an MSW landfill over a foundation consisting largely of shale (Site C). Excavated weathered shale is recompacted as a 610 mm-thick soil layer over the shale. A dendritic patterned subdrain system is being installed to collect isolated subgrade seeps, but the spacing of the drainage trenches is thought to be too large to dissipate pore pressures in the soil layer in the near term.

Testing under UU conditions has resulted in an interface shear strength friction angle of 7.5 degrees under normal stresses less than 290 kPa with a slightly lower friction angle under higher stresses (Figure 4). The friction angle for lower stresses under CU conditions is about 10 degrees. The soil itself has an undrained shear strength of 34 kPa. These relatively low strengths have a significant impact on allowable refuse slopes and landfill capacity. The interface shear strengths have limited landfill refuse heights to 100 feet to maintain a minimum static factor of safety of 1.5 with a maximum allowable seismic displacement of 1 foot.

Figure 4. Interface strengths for low-permeability subgrades, Site C

To avoid staging over long periods and to potentially increase refuse slopes, we are currently evaluating enhancing the subdrain system and improving the clay strengths. Remembering that the relatively low post-peak strengths are associated with plastic clays, we have initiated testing a blended soil consisting of 75 percent clay (site shale) and 25 percent on-site silty sand. The blended soil has a lower plasticity index and a CU interface strength approximated with a friction angle of 16 degrees. Together with the enhanced subdrain, the higher strengths may permit a substantial vertical expansion. Testing under UU conditions is underway to determine if adequate strengths can be achieved without enhancing the subdrain system.

### 4.2.2 Compacted high plasticity clay/HDPE over claystone subgrade

A similar situation occurs in a Colorado landfill (Site D) where the landfill is constructed largely on claystone. Interface shear strength (between clay and HDPE) testing for the first composite-lined cell for this landfill resulted in an adhesion of 19 kPa and friction angle of 9° for CL type soil and adhesion of 9.5 kPa and friction angle of 5° for CH type soil (normal load range from 100 to 500 kPa) under undrained conditions (Figure 5). On-site clays with lower plasticities (CL soil with PI equal to about 20 to 22) have higher strengths, but were difficult to identify in the field, and selectively excavate in sufficient quantities to construct the low-permeability soil layer.

Figure 5. Interface shear strengths for low-permeability subgrade, Site D

The low interface shear strengths, barely sufficient for originally permitted refuse slopes, have impacted vertical expansion plans. Current permitted capacity is 19 million m<sup>3</sup> but expansion plans were to increase the capacity to 37 million m<sup>3</sup>. The initial thought was to provide a subdrain to allow the clay to consolidate, but initial interface testing under CU conditions at 290 kPa normal load showed minimal increase in strength over UU conditions (a shear strength of 56 kPa compared to 53 kPa). The current plan is to admix bentonite with on site-silty sands (similar to Site B) or blend the plastic clays with sand (similar to Site C) to achieve a shear strength with an internal friction of 16 degrees.

## 5 CONCLUSIONS AND RECOMMENDATIONS

Based on the results of laboratory tests, analyses, and case histories cited in this paper, the following conclusions and recommendations can be made:

- Subgrade drainage conditions should be considered in the soil and interface strength testing program and eventual landfill liner design.
- For relatively permeable subgrade conditions, CU triaxial and interface tests (with normal loads allowed to consolidate) should be performed. For low-permeability subgrade conditions, UU triaxial and interface tests (where shearing occurs immediately upon application of the full normal load) should be performed.
- The application of UU or CU interface shear conditions for fill sequencing analyses depends on project-specific soil characteristics, fill sequencing, and drainage conditions.
- Differences in UU and CU strengths vary ranging from negligible difference (Site D) to differences only at large normal loads (Site B) to about 20 percent increase in CU strength over UU strengths (Site C).
- For compacted soil liners consisting of highly plastic clays (CH), exhibiting low undrained interface strength, blending the clay with sandy material should increase interface shear strengths while maintaining low permeability. This approach can provide additional airspace for landfills with slope stability constraints.

**ABSTRACT:** Geosynthetic clay liners (GCLs) are often used as one layer of a composite landfill liner, with a geomembrane forming the other layer. GCLs offer significant advantages over compacted clay liners in terms of their ease of installation. Some recent experience with the testing and use of a variety of GCL products is presented particularly with respect to complex liner systems on steep slopes in Hong Kong, which require careful consideration to determine appropriate internal and interface shear strengths to be used in design.

**KEY WORDS:** Geosynthetic Clay Liners, Geomembranes, Protection, Interface and Internal Shear, Slopes.

## 1. INTRODUCTION

Geosynthetic clay liners (GCLs) have been rapidly adopted as an alternative for compacted clay liners in many landfills around the world, and they have been widely used in composite liners for landfills in Hong Kong.

Hong Kong has a mountainous terrain, with many steep sided valleys, or canyons, which have 25° to 40° natural side slopes rising from near sea-level to a height of a few hundred metres. Three new landfills are being constructed and operated in these valleys, and the liner systems are being placed on some very steep and high slopes. With building development at the toe of these landfills, stability is an important issue.

Multilayer lining systems using geomembranes and GCL's can have relatively low internal and interface shear strengths, so they have the potential to act as a slip planes, and often form the weakest link in stability considerations. The naturally low shear strength of the bentonite component of GCL's has required careful measurements of their strength, with due consideration to the use of these measurements in design.

## 2. TYPICAL COMPOSITE LINER

A typical Hong Kong landfill liner comprises a geomembrane overlying a geosynthetic clay liner. A groundwater drainage layer is usually placed below the liner, and a leachate drainage layer is placed above the liner.

Depending on various design and availability considerations, these drainage layers may comprise crushed granitic rocks (with a geotextile cushion to protect the liner) or geonets. A typical arrangement is shown in Figure 1.

Figure 1. Typical Hong Kong Composite Lining System

The geomembrane is usually a 2mm thick sheet of high density polyethylene (HDPE), with either textured or smooth surfaces. The GCLs are usually needlepunched with woven or non-woven geotextiles on each side of the bentonite, which may be in powder or granular form. Whilst powdered bentonite can be more effective in terms of distribution and hydration performance, it can be more difficult to retain within the GCL during transportation and placement.

GCLs based on woven geotextiles offer the capacity for better tensile strength at less elongation, compared to non-woven geotextiles. However, the non-woven geotextiles are more effective at retaining the bentonite gel, although there may still be enough weeping to reduce the interface shear strength. The tendency for bentonite to weep through woven geotextiles allows these materials to have better self-sealing properties at the overlap joints. Products using non-wovens require additional bentonite at the seams, which some manufacturers introduce at the roll edge during manufacture.

Some GCLs have a woven geotextile on one side and a non-woven on the other side, and some have a composite geotextile with a woven material within the non-woven base.

### 3. DESIGN ISSUES TO BE CONSIDERED

#### 3.1 Maximum and Minimum Induced Stresses

The maximum depth of waste planned for Hong Kong's landfills is currently around 150 metres. With a possible unit weight of 1.4 tonnes/cubic metre (Cowland et al, 1993), this depth of waste could impose a stress of around 2000 kPa on the GCL. At the other extreme, the depth of soil overlying a GCL in a landfill cap may be less than one metre, giving rise to an induced stress as low as 10kPa. In addition, the stresses on a GCL on a side slope will vary from the top to the bottom of the slope. So the normal stresses to be considered in the GCL shear strength testing programme may need to range from 10 to 2000 kPa.

Although high ultimate loadings may be expected, it is still possible for a slip failure to occur at low normal loads during construction of the liner, caused by the downdrag of an overlying granular leachate drainage or protection layer.

#### 3.2 Degree of Hydration

The internal and interface shear strength of a GCL usually decreases as it becomes wet. Although the overlying geomembrane will help to keep it dry, with the typical lining system there is a groundwater drain immediately below the GCL. Experience has shown that with its high affinity for water, the bentonite component of a GCL will soon start to become hydrated even when only a small amount of moisture is present in the underlying drainage medium.

Some designers try to keep the GCL dry by encasing it between two geomembranes. However, the long term effectiveness of this measure, given the possibility of minor leaks or other damage or deterioration of the geomembrane, is unknown.

Examination of two liner systems, where it was known that heavy rainfall had penetrated through the geomembrane, and remedial action was required, has shown a surprising extent of lateral moisture travel along the GCL/geomembrane interface. It was observed that water easily travels through compressed wrinkles in the geomembrane to wet a large surface area of the underlying GCL.

#### 3.3 Relevant Shear Surface

The bentonite layer within a GCL can have a low shear strength, especially when hydrated, resulting in a low internal shear strength through the mid-plane of the GCL. In addition, the bentonite can be squeezed through the openings of the geotextiles, producing a low friction surface at the interface between the GCL and the adjacent material.

Exhumation after a construction failure has shown that slip surfaces can pass through the mid-plane of the GCL, and also along interfaces between the GCL and adjacent layers. Thus, the testing should be arranged to examine both these potential failure modes.

### 4. GCL SHEAR TESTING CONSIDERATIONS

Shear strength parameters of GCLs for both internal and interface shear are determined following the form of the standard American Society for Testing and Materials (ASTM) test method D 5321-92 for geosynthetics (ASTM, 1992). However, when this test method was first developed for geomembranes and geotextiles, GCLs were not considered and there is on-going work to further develop this ASTM test method for GCLs.

It is generally considered that the shear box should be at least 300 mm square, as smaller boxes will introduce excessive edge effects and give distorted results, particularly if granular materials are involved. Figure 2 illustrates schematically a large scale shear box. A constant normal compressive stress is applied to the apparatus and one section of the box moves in relation to the other. The shear force and corresponding displacement is recorded and shear stress is plotted against normal compressive stress.

Although ASTM D 5321-92 provides guidance for shear displacement rates, with emphasis on the need for slow rates to dissipate pore water pressures, a lot of testing has been carried out using a default shear displacement rate of 60 mm/hr.

The GCL is usually hydrated in the shear box, under the design normal load, for 24 hours just prior to shear. However, more information is needed on the impact of different hydration times and boundary materials.

Figure 2. Typical Interface Shear Test Device

## 5. A SITE SPECIFIC TEST PROGRAMME

During a recent project, the deformation and shear strength of the interface between a smooth HDPE geomembrane and a needle-punched GCL, resting on coarse granular material, was examined. The main issues were the deformation imposed on the geomembrane by the interaction of the various granular surfaces and protective layers of geotextile, and the shearing capacity of the various interfaces in the liner system.

### 5.1 Deformation Testing

The deformation testing was carried out in a large scale geostatic test apparatus as shown in Figure 3, and as described by Frobel & Winneke (1993). Various combinations of geosynthetics and granular layers were under consideration for different stages in the design development.

The geostatic test is a relatively new performance test intended to provide a view of behaviour under field loading conditions. The layers of geosynthetic and granular materials are placed into a cylindrical vessel, where they are subjected to appropriate loadings, with submergence to achieve hydration as required.

Deformation is measured by the use of a highly deformable thin zinc plate which is placed under the geomembrane and which retains the deformed shape on disassembly. As yet, there is no standard test method for this new test.

Testing of protection layer materials for this project included both 1050 and 1200 gram/m<sup>2</sup> needlepunched non-woven geotextiles. The results indicated that the deformation performance of these very heavy products was influenced more by the tightness of the needed mat than by small variations in unit weight.

### 5.2 Degree of Hydration

Two series of hydration tests under load were carried out for this project. In the first, a number of GCL samples were hydrated for 24 hours under a constant confining stress of either 175, 350, 700 or 1000 kPa. The moisture content in the samples under 175 kPa confining stress was found to be in the range of 75 to 90% after 24 hours. Samples hydrated under larger stresses were found to have lower moisture contents, with values of 40 to 50% being measured after 24 hours under a load of 1000 kPa.

In the second series, specimens of a GCL were hydrated for different times under a stress of 10 kPa or a stress of 700 kPa. Initial hydration occurred more quickly under the lower stress, however, in neither case was hydration complete after 24 hours. These results are shown in Figure 4, and can be compared with Stark (1996) who found that a GCL under a load of 40 kPa was still hydrating after 250 hours.

It is strongly recommended that the degree of hydration (i.e. moisture content of the GCL) must be reported with the shear strength results.

### 5.3 Interface Direct Shear Testing

The interface direct shear testing for this project was carried out in a 300 x 400 mm direct shear box, using the various combinations of geosynthetics and granular layers that were under consideration in the design.

It was found that 10 - 20 mm angular drainage gravel under a GCL significantly deformed the interface between the GCL and an overlying geomembrane, which increased the interface friction angle by about 2 - 3°, but it had a detrimental effect on the integrity of the geotextile components of the GCL which allowed the bentonite gel to weep.

Non-woven geotextiles appeared to more successfully contain the bentonite gel than woven geotextiles.

## 6. SHEAR BOX TEST METHODOLOGY

Some of the many apparatus set up questions for GCL shear testing that are not answered by ASTM D 5321-92 include hydration method, loading period, displacement rates and fixing methods. The following discussion is based on direct experience.

### 6.1 Gripping Methodology

It is important that the gripping methodology for testing the internal shear strength of GCLs be carefully considered.

One system is to use sharp, one-way serrated steel surfaces that grip into the surface of the geotextile on either side of the GCL to uniformly force the shear plane into the hydrated bentonite/fiber structure. In addition, extensions of the GCL fabric are wrapped around the top and bottom plates to effect a positive tensile strain across the full width of the GCL fabric. Bolting of end sections is not recommended, due to tearing at bolt holes and disturbance of the specimen.

### 6.2 Hydration

After hydration under load, the normal stress applied should not be relieved before shearing. Thus, the sample should be hydrated in the shear box, unless a method can be found to maintain the normal stress during specimen transfer to the shear box. In view of the need to hydrate for some time, and the scarcity of large shear boxes, this issue requires further development.

### 6.3 Displacement Rate

Significant pore pressures are generated within the bentonite clay component of a GCL, and thus displacement rates reflecting consolidated-drained (CD) conditions should be considered.

The ASTM test method D 3080-90 (ASTM, 1990), gives a method for calculating the time to failure to achieve CD conditions. By using the time to failure from consolidation tests, and a required total displacement during shear (20 to 30 mm for reinforced GCLs), the displacement rate can be calculated. These displacement rates should be in the range of 1 to 10 mm/hr in order to reflect CD conditions.

For instance, it was found in one programme of GCL interface shear testing that the friction angles measured at a displacement rate of 2.4 mm/hr were 1 - 2° lower than at a displacement rate of 60 mm/hr. Faster displacement rates will result in indications of higher internal shear strength and should be avoided for design test purposes.

## 6.4 Area Corrections

In a square shear box, the contact or stressed area of a GCL decreases with increased displacement. Consequently, the compressive stress decreases, resulting in an increase in shear stress. So, it is important to apply an area correction, especially for larger displacements for GCL tests run under CD conditions. Alternatively, a shear box which has one half of the box longer than the other can be used to keep the shear area constant.

## 7. USE OF SHEAR STRENGTH DATA IN DESIGN

Having obtained strength data from careful testing, the designer needs to consider various aspects in the use of this data in design.

### 7.1 Peak or Residual Strength

With increasing strain, needlepunched GCLs typically exhibit shear strengths that rise to a peak and then fall to a residual value.

The difference between peak strength and residual can be relatively small for interfaces but can be quite large for internal shear. With needlepunched GCLs the peak shear strength is based on mechanical rather than friction bonds and is usually achieved after 20 - 30 mm of displacement, and thus the question of whether to use peak or residual strength is very significant.

Based on limited knowledge of landfill failures it would be unwise for the designer to rely on peak strength throughout the lining system. From a finite element back analysis of the Kettleman Hills Landfill failure, Byrne (1994) found that the onset of progressive failure mobilises residual strengths on the side slopes, although the peak strength may still be relied upon for a proportion of the base.

As noted by Koerner (1994), the analysis of side slope liner stability is complicated for a multi-layered liner and leachate collection system. The unit load of the waste gravitationally induces shear stress through the leachate collection system onto the liner and then onto the groundwater collection system. Depending on the frictional characteristics of the surfaces involved, it is possible that only a portion of the induced shear stress is transmitted to the layer below.

It is possible therefore, when a low friction slip surface is built into the upper part of the system, that some interfaces may not progress past their peak strength. However, extensive laboratory and field measurements, and a thorough finite element or finite difference analysis of the stresses and strains in the system would seem to be needed to determine whether individual interfaces should be designed using the measured peak or residual strengths.

## 7.2 Deformation of the Shear Surface

With a coarse granular leachate drainage layer above the lining system, and high normal loads, it is likely that the shear surface will become deformed. This deformation may result in an increase of the interface friction angle. However, in order to utilise this increased friction angle, the designer needs to be confident that the same deformation will occur in the laboratory and the field. The gravel used in laboratory tests needs to be truly representative of the gravel used in the landfill. Also, the normal loads in the laboratory tests should be varied to ensure the deformation would still exist with lower than expected normal loads in the field.

## 7.3 Landfill Loading Sequence

Load should be placed above the GCL as soon as possible after installation, in order that it does not get the chance to go into free swell and weaken, due to any moisture that may be available.

With a low strength lining material being placed on steep slopes, it would appear that there is a high chance of a slip occurring. However, Giroud and Beech (1989) have demonstrated that many of the stability problems associated with these materials can be avoided by utilising an incremental balanced method of placing the overlying load, using toe buttresses, and these methods have been used successfully in Hong Kong.

## 8. CONCLUSIONS

The GCLs currently being used in landfill liners and caps have the potential to act as slip planes, as the bentonite they contain has a low shear strength, especially when wet. For the designer, it is important to incorporate shear strengths obtained from relevant and independent testing into the design of the landfill. The designer needs to consider the complete range of loads that may be exerted on the GCL, the possible degree of hydration, and all possible shear surfaces. For drained shear strength parameters, it is important to maintain a low rate of strain during the test.

The determination of GCL shear strength needs to be both material specific and project specific. With the rapid development of GCLs incorporating different geotextiles and methods of bonding them together, it is not possible to rely on previous test results. The designer needs to know the shear strength characteristics of the individual product to be used in his landfill.

Obtaining reliable GCL interface and internal strength parameters is difficult and not recommended for laboratories with minimal GCL experience. Conformance test procedures must be described in detail and should

model the existing or design site conditions using the actual site soil materials and geosynthetics specified in the design.

It is not adequate to simply state the required GCL friction angle in the specifications for a project. Designers must specify in detail the test parameters required to generate design oriented values.

Research Associate, Institute for Foundation Engineering, Technical University of Munich, Germany

**ABSTRACT:** When calculating the slope stability of geomembrane-lined slopes in waste disposal applications, the shear behavior between the lining components have to be evaluated. The paper discusses the shear strength of compacted clay liners (CCLs), CCL/geomembrane and geomembrane/geotextile interfaces. The dependence between matric suction of the CCL and shear strength is shown. Shear tests between compacted clay liners and geomembranes demonstrate the influence of several test conditions (e. g. duration of consolidation, shear speed, normal stress and water content of the CCL). In addition, 1000 hours creep tests between geomembranes and geotextiles were conducted to evaluate the long term shear strength behavior.

**KEYWORDS:** Shear strength, Testing, Friction, Geomembranes, Compacted Clay Liner

## 1 INTRODUCTION

According to the relevant regulations, composite sealing layers - consisting of a mineral seal (compacted clay liner, CCL) a geomembrane (GM) and a geotextile protection layer (GT) - are current state of the art in Germany. Prior to installation, it needs to be proven that shear forces are transferred into the subsoil from the top of the cross section downward. The starting point of such slope stability proofs are shear box tests which determine the maximum transmittable shear forces within the sealing system. As the test conditions under which such shear box tests have to run are not yet clearly defined, the Arbeitskreis Grundwasserschutz AK-GWS (Working Group 'Groundwater Protection') initiated a research project to investigate the influence of various test conditions on the shear strength of the sealing system. Triaxial tests with CCLs under saturated and partly saturated conditions were carried out to show the influence between matric suction and shear strength. Direct shear tests between CCLs and GMs demonstrate the influence of drainage conditions, texturing of the GM and matric suction in dependent on the normal stress. Further tests were carried out on the long term effects of the shear properties between GTs and the GMs. The results of the research project which were carried out at the Institute for Foundation Engineering at the Technical University of Munich are given below in an abridged format.

## 2 CHARACTERISTIC DATA OF THE MATERIAL

Tests with one smooth GM and three textured GMs were carried out. All four GMs were manufactured of HDPE having a thickness of 2.5 mm. Furthermore, two highly plastic clays (a clay called 11A and a kaolinite clay) and a mixed grained soil (mixture of a coarse grained soil and

the kaolinite clay) were used for the investigation. Table 1 illustrates the characteristics of these three clays.

Table 1. Characteristic magnitudes of the testing soils

	Clay 11A	Kaolinite clay	Mixed grained material
$w_L$ (%)	58,8	73,6	
$w_p$ (%)	21,9	29,8	
$\rho_{Pr}$ (t/m <sup>3</sup> )	1,63	1,43	1,95
$w_{Pr}$ (%)	20,2	27,1	11,0

The clay used for the investigation were placed near optimum moisture content and compacted with standard proctor-energy. As a protection layer a mechanically bonded PP-nonwoven was used in these tests. The nonwoven had a mass per unit area of  $m_A > 1200$  g/m<sup>2</sup> (DIN EN 965) at a thickness of  $d = 8$  mm (DIN EN 964 TI-2).

## 3 SHEAR STRENGTH OF PARTLY SATURATED COMPACTED CLAY LINERS

CCLs are generally installed partly saturated in the field. The degree of saturation decisively influences the shear strength of the CCL and also the interface CCL/GM, as shown below.

### 3.1 Theory

Because of capillary and adsorptive forces partly saturated soils tend to absorb water. A negative pore water pressure incurs (suction), which is dependent on the grain size and pore size distribution of the soil. The discrepancy between

pore water pressure  $u_w$  and the pore air pressure  $u_a$  within the sample is described as matric suction. Referring to Bishop (1955) the matric suction increases the intergranular pressure  $\sigma'$  (1). The parameter  $\chi$  depends on the degree of saturation  $S_r$  of the soil. For saturated soils it can be stated that  $\chi = 1$  and for "dry" soils  $\chi = 0$ . The effectiveness of the matric suction can be described as a pre-stressing of the soil.

$$\sigma' = \sigma - u_a + \chi(u_a - u_w) \quad (1)$$

According to Coulomb the shear strength  $\tau_f$  of saturated soils is expressed by the effective cohesion  $c'$  and the effective angle of the internal friction  $\phi'$ .

$$\tau_f = c' + \sigma' \tan \phi' \quad (2)$$

Fredlund et al. (1978) define the matrix friction angle  $\phi^b$  (3). They assume that the parameter  $\chi$  is constant when the soil is compacted to the same water content and density. This results in the shear strength of partly saturated soils (4).

$$\tan \phi^b = \chi \tan \phi' \quad (3)$$

$$\tau_f = c' + (\sigma' - u_a) \tan \phi' + (u_a - u_w) \tan \phi^b \quad (4)$$

The shear parameters  $c'$  and  $\phi'$  are independent of the matric suction and can be determined under saturated conditions.

### 3.2 Test Description and Test Results

Within the framework of the research project the shear parameter  $c'$ ,  $\phi'$  and  $\phi^b$  of the clay 11A were determined at saturated and partly saturated conditions (D-Tests) using the triaxial apparatus. The "saturated" tests were carried out according to DIN 18137-2 at a back pressure of  $u_w = 5$  bar. The "partly saturated" tests were carried out at a constant water content and a pore pressure of  $u_a = 4$  bar. The change of the matric suction in the "partly saturated" tests was measured with a tensiometer located on the top pressure plate. Table 2 shows the average results of 9 tests at  $w_a = 23\%$ .

Table 2. Results of the triaxial test with clay 11A

$w_a$ (%)	$c'$ (kN/m <sup>2</sup> )	$\phi'$ (°)	$\phi^b$ (°)	$R^2$ (-)	$\chi$ (-)
23	30.6	14.6	12.8	0.92	0.87

The high regression coefficient  $R^2$  shows that the shear strength of the partly saturated soil can be represented well by means of the equation of Fredlund et al. (1978).

Figure 1 shows the result on a stress diagramm. The increase of the shear strength as a result of capillary forces at lower normal stresses can clearly be recognized. At the same time it is noticed that while the mean stress increases, the matric suction decreases. When the values reach 800 kN/m<sup>2</sup>, the sample's stresses are so high that the formerly partly saturated samples have changed into saturated samples by way of consolidation.

Figure 1. Partly saturated and saturated tests (Clay 11A,  $w_a = 23\%$ )

According to the test results, it can be summarized that even in high saturated conditions the increase of the shear strength of compacted clays is considerably high under low confining stresses because of the matric suction. This matric suction also influences decisively the shear behavior of the CCL / GM interface as shown in the next chapter.

## 4 SHEAR STRENGTH AT THE COMPACTED CLAY LINER / GEOMEMBRANE- INTERFACE

### 4.1 Test Description

The following describes the influence of different test parameters which influence the shear test results between the CCL and the GM. As this is the shear strength between two different material types the shear parameters are renamed. Adhesion  $a$  and interface friction angle  $\delta$  take the place of cohesion  $c$  and the angle of internal friction  $\phi$ . The corresponding critical condition between two materials according to Coulomb is as follows:

$$\tau_f = a + \sigma \tan \delta \quad (5)$$

Both a 30 cm x 30 cm (30x30-SG) and a 10 cm x 10 cm (10x10-SG) direct shear apparatus were used for this investigation. Within the framework of the research project the basic comparability of both shear apparatus' regarding the maximum shear stress could be proven (Fillibeck and Heyer, 1995). Since the matric suction cannot be measured at the interface, the evaluation of the test results is shown in a  $\sigma/\tau_f$ -diagramm whereas  $\sigma$  is the acting total normal stress differentiated from the confining stress. Figure 2 shows a schematical test setup of the direct shear apparatus 30x30-SG. It is important that the compaction of the soil sample is not carried out on top of the GM and that the soil

sample has a constant thickness so that the normal stress can be transferred evenly.

Figure 2. Schematic cross section of the 30x30-SG

The shear force was applied by means of a plate with webs (Figure 3) in order to achieve a fairly constant distribution of the shear stress across the interface.

Figure 3. The direct shear apparatus 30x30-SG as a detail

As the top part of the shear box cannot be displaced in the vertical direction, the normal stress transfer must be possible without significant loss of stresses due to side wall friction between the soil sample and the upper shear box. Measurements show a reduction of the normal stress of up to 20% due to this effect. To avoid this, two layers of teflon foil were installed between the soil sample and the wall of the shear box (figure 3). In addition the smallest possible thickness of the clay layer was chosen.

In the case of the shear tests carried out in the direct shear apparatus 10x10-SG the geomembrane was also placed in the lower shear box and the compacted soil in the upper shear box.

#### 4.2 Drained Shear Tests with Partly Saturated CCLs

Figure 4 shows drained shear tests (shear speed after consolidation  $v = 0.3$  mm/h) between three GMs and the kaolinite clay ( $w_a = 30\%$ ). Comparatively the shear strength of the kaolinite clay alone is shown by a dotted line.

Figure 4. D-tests between kaolinite clay and 3 GMs

The  $\sigma/\tau$ -behavior can be shown with two straight lines which are valid for two different normal stress ranges (high and low). Shear parameters can thus be assigned to each normal stress range. Under very low normal stresses the high internal shear strength of the CCL cannot be transmitted to the GM, as there occurs no intimate contact between the GM and the CCL. The shear behavior corresponds to the shear behavior of a coarse grained soil with high friction angle and only little or no adhesion. The intimate contact improves with increasing normal stresses. The shear properties of the test soil under higher normal stresses develops progressively. In the high normal stress range the best possible intimate contact is achieved.

As expected, the shear behavior between the GM and the CCL is clearly influenced by the texturing of the GM. Under high normal stresses, some textured GM/CCL interfaces can almost reach the shear strength of the respective CCL alone.

#### 4.3 Comparison between UU-Tests and D-Tests

As known in soil mechanics, the difference in shear strength between UU-tests (unconsolidated, undrained tests) and D-tests (drained tests) of a fine grained soil because of existing pore water pressure is well known. The following considers whether pore water pressure or pore air pressure influences the shear strength of the interface between GM and partly saturated CCL.

UU-tests were carried out with a shearing speed of  $v = 10$  mm/h. Such tests were compared with results from D-tests performed with a shearing speed of  $v = 0.3$  mm/h (after the primary consolidation). It was assumed that possibly existing pore water and excess air could not decrease at fast shearing rates. Figure 5 shows representative results of tests carried out with a textured GM and clay 11 A ( $w_a = 23\%$ ).

Figure 5. Comparison between UU and D-tests

In the lower normal stress range (at  $\sigma < 200 \text{ kN/m}^2$ ) decreasing pore water pressures and trapped pore air pressures do not develop within the shear plane between the CCL and the GM due to the high stiffness of the CCL. At this stage, intimate contact between the CCL and GM has not yet developed. Only if high normal stresses are achieved, pore water and trapped pore air pressures do develop within the clay directly after applying the load. These pore water and trapped pore air pressures also influence the shear strength within the interface. These can decrease during the D-Test whereas the shear strength increases compared to the UU-Test. In the case of an increase of the normal stress to  $\sigma > 800 \text{ kN/m}^2$  the additional normal stresses are only absorbed by means of trapped pore water pressures. Consequently, the shear strength which is achieved in the UU-Test does not further increase, as evidenced by the asymptotic nature of the  $\sigma/\tau$ -curve in figure 5.

The question needs to be asked at which normal stresses does differing results between drained and undrained tests occur. The answer certainly depends on the water content of the soil and on the compacting process used to prepare the soil specimen. In general when CCL's are compacted on the wet side of proctor-optimum it can be assumed, that the shear speed and duration of consolidation under low normal stresses only slightly influence the shear behavior. Note that this condition is typical for CCL's.

#### 4.4 Comparison between Tests with Partly Saturated and with Saturated CCLs

On several occasions it is assumed that the capillary and adsorptive forces, which are responsible for the high shear strength between CCLs and GMs, can at least partly get lost in excessive situations. This can be the case if - for example - perspiration occurs on the bottom side of the GM as a result of temperature differences or if rainwater is collected under the geomembrane during installation. In order to consider this condition, tests with saturated CCLs were carried out according to Bembem & Schulze (1995). For these tests the soil samples were installed into the shear box partly saturated and subsequently consolidated in a water bath so that the negative pore water pressure approached zero.

Figure 6 shows the results of tests which are carried out with partly saturated and saturated samples (D-Tests) between the smooth geomembrane and the clay 11A.

Figure 6. D-Tests with partly saturated and saturated CCLs

The shape of the  $\sigma/\tau$ -curve of the series of tests carried out with the saturated CCL proceeds fairly linearly in the whole range of the normal stress. Under low normal stresses, the water content of the soil sample increases during consolidation (up to 7%). Thus its strength decreases significantly. The result of this is - in contrast to the tests carried out with the partly saturated samples - that already under low normal stresses a good contact between the soil sample and the geomembrane is achieved. Under very low and under very high normal stresses the shear strength of the tests carried out with partly saturated samples and those carried out with saturated samples are comparable. Under very low normal stresses still no extensive contact is achieved between the partly saturated CCL and the GM. Under high normal stresses ( $\sigma \geq 800 \text{ kN/m}^2$ ) the partly saturated CCL is so excessively compressed that saturation appears after the consolidation.

In the middle range of the normal stress, the shear strength of the partly saturated tests is considerably higher than the shear strength of the saturated tests.

#### 4.5 Test Procedures for the Practical Application

Referring to the test results above, the following test procedures can be proposed:

For stability calculations under low normal stresses (e. g.  $\sigma \leq 50 \text{ kN/m}^2$ ) during construction, usually partly saturated tests have to be carried out. It is recommended to choose a water content for the shear test which is slightly higher than the installation moisture content. To prevent the increase of the water content of the CCL after installation, constructive measures have to be taken, by means of covering the CCL directly after its placement with a GM and a drainage layer and installation of drainage trenches to collect the rain water. Thus shear tests can be run at a high speed (e. g.  $v = 10 \text{ mm/h}$ ) with a reduced consolidation time.

For stability calculations under low normal stresses for the post-installation condition (e. g. landfill cap) partly saturated, drained shear tests can be used. However only if it is ensured that the water content of the CCL cannot increase. Field investigations have shown that this is normally the case for landfill caps. It is recommended to choose a water content slightly higher than the installation water content. Water saturated tests show a comparable worst case condition.

For stability calculations under high normal stresses (e. g. base sealing of landfills) drained tests should be carried out (shear speed  $v = 0.3 \text{ mm/h}$ ) because it is often the case that the normal stress does not increase in such a way that pore pressures occur. As long as the CCL can adsorb water due to capillarity from the ground water, saturated tests should be carried out.

Because of the nonlinear dependence between the normal stress and the shear stress, normal stresses have to be used for the shear tests which are close to the normal stress occurring on site. The shear parameters which are calculated

by linear regression from the test results are only valid for the range of the chosen normal stresses. If shear tests were carried out under higher normal stresses, an appropriate friction angle can be used which is calculated by linear regression through the origin of the coordinates.

## 5 SHEAR STRENGTH AT THE GEOMEMBRANE / GEOTEXTILE INTERFACE

Usually shear tests between geotextiles and geomembranes are determined by constant shear speed. However, in practice the interface is mostly developed at a constant shear stress which is better simulated by a stress controlled test. Because of the creep behavior of geosynthetics, it has been investigated in the research project, if the results of strain controlled tests compare to those of stress controlled tests and which displacements appear close to the peak value as a function of the time.

### 5.1 Comparison of Stress and Strain Controlled Shear Tests

Tests were carried out in the 10x10-SG and 30x30-SG shear boxes. In both cases the geotextile was placed in the upper shear box.

At stress controlled shear tests the failure in the interface is induced by increasing the shear stress step by step. In contrast to strain controlled tests, the shear rate is not constant. After increasing the shear stress the shear rate  $dx/dt$  is measured as a function of the time. The shear force is increased once the shear rate drops below 0.05 mm/min. In each case 4 shear tests were carried out at normal stresses of 50, 100 and 300 kN/m<sup>2</sup>.

For the strain controlled shear tests a shear rate of 10 mm/h was chosen. 10x10-SG tests were carried out at a normal stress of 10, 20, 50, 100, 200, 400 and 800 kN/m<sup>2</sup> and under a normal stress of 10, 20, 50, 100, 200 and 300 kN/m<sup>2</sup> in 30x30-SG. In Table 3 the friction angles of the shear tests between the geotextile and two different geomembranes are given.

Table 3. Stress and strain controlled shear tests

Shear test	10x10-SG	10x10-SG	30x30-SG
	stress contr.	strain contr.	strain contr.
	$\delta$ (°)		
KDB I	28.3	29.6	28.3
KDB II	15.7	16.5	15.9

It is obvious from these results that the stress controlled shear tests correspond very well to the strain controlled shear tests. Thus the strain controlled shear test which can be carried out easier can be regarded more suitable for the determination of the shear parameters. Also it can be noted

that there exists a good conformity between the 30-30-SG and the 10x10-SG results.

### 5.2 Creep Test

The stress controlled creep tests were carried out in the 10x10-SG. The shear stress was kept constant for about 1000 hours. During this time the shear speed was monitored. The creep shear stress was determined by the chosen stress intensity  $D$  which is defined as the ratio between the creep shear stress and the maximum shear stress gained from the strain controlled shear test. To analyse the creep tests the potential equation (6) was used to describe the shear speed  $dx/dt$  in dependence of the time  $t$ .

$$\frac{dx}{dt} = A_1 \times t^{-m} \quad (6)$$

In a double logarithmic scale the potential function is a straight line with the inclination  $-m$ . The smaller the constant  $m$  the more it creeps (higher creep potential). The constant  $A_1$  is the shear speed at the time  $t = 1$ . The shear displacement  $x$  can be calculated by integration of the potential equation (7).

$$x = \int \frac{dx}{dt} dt = \frac{A_1}{1-m} t^{(1-m)} + x_G \quad m \neq 1 \quad (7)$$

For  $t \rightarrow \infty$ , and  $m > 1$  the shear displacement  $x$  is close to the constant  $x_G$ . The  $t/x$ -curve approaches a horizontal asymptote which meets the displacement axis at  $x_G$ . For  $m < 1$  there is no horizontal asymptote ( $x \rightarrow \infty$ ). In Figure 7 the creep curve of a test with a textured GM under  $\sigma = 300$  kN/m<sup>2</sup> and a stress intensity  $D = 95\%$  is shown. Table 4 shows some test results for a textured GM.

Figure 7. Creep test between the textured GM and the geotextile ( $D = 95\%$ ,  $\sigma = 300$  kN/m<sup>2</sup>)

Table 4. Results of creep tests

$\sigma$	D	creep function $x = A_1 / (1 - m) t^{(1-m)} + x_G$	$x_G$
[kN/m <sup>2</sup> ]	[%]	[1/100 mm]	[mm]
50	90	$-250,1 t^{-0,24} + 274,6$	2,7
	95	$-394,7 t^{-0,21} + 361,0$	3,6
300	90	$-193,0 t^{-0,12} + 185,9$	1,9
	95	$-382,3 t^{-0,13} + 280,3$	2,8

The constant  $m$  was in all the tests higher than 1 even with the stress intensity  $D = 95\%$ . This means that the shear speed decreased in such a way that the shear displacement approached  $x_G$  for  $t \rightarrow \infty$  (Table 4). The value  $x_G$  approximately corresponds to the shear displacement of the stress controlled shear test. Therefore no large creep displacements are expected which is very important for landfill applications.

After testing the creep behavior for 1000 hours the shear stress was increased until failure. The maximum shear stresses rose from 10% to 40% when comparing with the short term tests. This can be explained by the reduction of the stress peaks during the creep test (redistribution of the stress). If the shear stress is increased quickly, e. g. in the stress or strain controlled shear test, the interface between geotextile and GM is stressed irregularly and a progressive failure is the consequence. If the shear stress is kept constant prior to failure (e. g. in the creep test), the highly stressed areas of the interface can be reduced (relaxation). As a consequence, no progressive failures occur and the maximum shear stress after this relaxation is higher than the one in the stress controlled test. For practical applications it is important to know, that the shear parameters from stress or strain controlled short term tests are safe and reliable.

## 6 SUMMARY

This paper treats the shear strength of composite sealing layers consisting of a compacted clay liner (CCL), a geomembrane (GM) and a geotextile protection layer (GT). The influence of selected test conditions on shear test results is shown.

The comparison of triaxial shear tests with saturated and partly saturated CCLs show the dependence of capillary and adsorptive forces (matric suction) on the shear strength. It proved that under small normal stress the shear stress of partly saturated soils increases quite visibly due to matric suction. Matric suction diminishes with increasing normal stress and the shear stress response approaches that of the saturated soils.

The matric suction also influences the shear strength of the CCL / GM-interface. Shear tests showed a bilinear dependence between normal stress and shear stress.

Therefore the shear strength of this interface can be described quite well by 2 pairs of shear parameters for an upper and a lower range of normal stress. Under low normal stress, the influence of the shear speed and consolidation time upon the shear strength with partly saturated CCLs is negligible but increases with higher normal stress. Compared to tests with saturated CCLs the shear strength with partly saturated CCLs is - normal stress dependent - recognizable higher.

At the interface between the GT and the GM the long term shear behavior was investigated under constant shear stress. The results of the creep tests (duration 1000 h) showed that even under a high stress intensity the occurring deformations decreased quite quickly. The calculated displacements are almost equivalent to the measured displacements of shear tests under constant shear speed. After the creep tests the maximum shear forces increased compared to the maximal shear stress measured in tests under constant shear speeds. Therefore shear tests with constant shear speeds (e. g. 10 mm/h) are conservative and reliable.

The published test results of the investigated shear interfaces show that with suitable materials slope inclinations of 2.5 : 1 to 3 : 1 (H:V), safe designs utilizing composite lining systems can be achieved.

## ACKNOWLEDGMENTS

# Issues in Clay / Textured Geomembrane Interface Testing

Paul J. Sabatini, Gary R. Schmertmann, and Robert H. Swan Jr.  
GeoSyntec Consultants, Atlanta, Georgia, USA

**ABSTRACT:** This paper presents the results and interpretation of interface direct shear testing using varying shear displacement rates and normal stresses on compacted clay / textured geomembrane interfaces. The testing included eight clay soils from project sites throughout the United States and two HDPE textured geomembranes. Seventeen pairs of interface direct shear tests were performed where one test was run at a relatively rapid shear displacement rate (fast test) and another test was run at a slower rate (slow test). Shear displacement rates varied from 1 to 5 mm/min for the fast tests and from 0.01 to 0.1 mm/min for the slow tests. Testing normal stresses ranged from 10 to 960 kPa. The test results reveal that larger shear strengths are sometimes measured in the slow test and sometimes in the fast test.

**KEYWORDS:** shear strength, laboratory tests, soils, geomembranes, interface testing, direct shear testing

## 1 INTRODUCTION

Liner and cover systems for modern landfills often contain layers of soil and geosynthetic materials. The shear strength of the weakest interface within these systems, under both long-term and short-term loading conditions, is often required for slope stability analyses. These shear strengths are commonly evaluated using the results of laboratory interface direct shear tests.

The weakest interface within liner and cover systems is often that between a compacted clay soil layer and a geomembrane. In conducting direct shear tests on this interface, pore pressures in the clay are not commonly measured. Without knowledge of pore pressures near the interface, it is not known whether the measured interface shear strength is appropriate for short-term or long-term loading conditions. This issue has been discussed by previous investigators (e.g., Fishman and Pal, 1994).

Common practice in the United States is to perform laboratory interface direct shear testing in accordance with the American Society for Testing and Materials (ASTM) D 5321 test standard. The test standard includes a default shear displacement rate of 1 mm/min for testing soil/geosynthetic interfaces. This displacement rate is appropriate for evaluating short-term strengths of clay/geomembrane interfaces as it typically results in peak strengths being achieved after a shearing duration of 5 to 50 minutes. This displacement rate may be too rapid, however, to evaluate the long-term strength of clay/geomembrane interfaces, particularly when the compacted clay is at or near saturation. Many engineers may assume that shear strengths measured using the default shear displacement rate are conservative for both short-term and long-term conditions.

This paper presents the results of laboratory interface direct shear testing using varying shear displacement rates and normal stresses on clay / textured geomembrane interfaces from project sites throughout the United States. Seventeen pairs of comparative results were obtained by

performing a test using a relatively rapid shear displacement rate (fast test) and another using a relatively slow rate (slow test). Differences in measured shear strengths from the fast and slow tests are discussed. The test results were accumulated from project-specific testing performed by the authors' firm between 1993 and 1995. Although not part of a systematic testing program designed specifically to evaluate the effect of shear displacement rate, the results provide a set of data believed to be valuable to practicing engineers.

## 2 INTERFACE DIRECT SHEAR TESTS

### 2.1 Test Device and Procedures

The interface direct shear tests were conducted in accordance with ASTM D 5321 using a direct shear device that consists of an upper shear box and a lower shear box. The upper box measures 300 mm by 300 mm (plan) by 75 mm (high). The lower box measures 300 mm by 360 mm (plan) by 75 mm (high).

Each test specimen included a compacted clay / textured geomembrane interface. Although other soil and geosynthetic materials were included in some of the test specimens, the reported test results all involve shearing on the compacted clay / textured geomembrane interface. The steps used to set up each test are described below.

- A lower bedding layer was compacted into the lower shear box. The bedding layer consisted of either a concrete sand or a site-specific soil.
- The geomembrane was placed on top of the lower bedding layer and attached to the lower shear box. The direction of shear was the same as the machine direction of the geomembrane. For some tests, the geomembrane was wetted with a fine mist of water.
- The clay soil was compacted away from the geomembrane in the upper shear box to specified

moisture and compaction conditions to a thickness of 25 to 50 mm and then placed on the geomembrane.

- A normal stress was applied to the complete test specimen and the test specimen was then soaked (submerged in water) or consolidated (no submergence) for a period of time prior to shearing.

After the soaking or consolidation period was complete, the test specimen was sheared at a constant rate of deformation. Shearing was conducted until a peak shear strength was measured and then continued until a stable, large-displacement shear strength was achieved.

## 2.2 Soil Properties and Geomembrane Materials

Index properties, including percent passing the US Standard No. 200 sieve (%P200), Atterberg limits (LL, PI), and compaction results (optimum water content,  $w_{opt}$ , and maximum dry unit weight,  $\gamma_{D(max)}$ ), for the eight clayey soils used are provided in Table 1. The soils used are typical for compacted clay components of liner and cover systems and range from sandy and clayey silts to sandy clays and silty clays of medium to high plasticity.

Textured HDPE geomembranes from two different manufacturers were used in the testing. The geomembranes ranged in thickness from 1.5 to 2.0 mm.

Table 1. Properties of Clay Soils.

Clay Soil No.	%P200 (%)	LL	PI	$w_{opt}^{(1)}$ (%)	$\gamma_{D(max)}^{(1)}$ (kN/m <sup>3</sup> )
1	93	77	48	27.2 <sup>(2)</sup>	14.5 <sup>(2)</sup>
2	-	-	-	14	18.5
3	-	-	-	15	17.4

7	70	-	-	17.2 <sup>(2)</sup>	17.6 <sup>(2)</sup>
8	81	35	18	12.1	19.4

Notes: (1) Modified Proctor compaction test (ASTM D 1557) unless otherwise noted.

(2) Standard Proctor compaction test (ASTM D 698).

## 2.3 Test Conditions

The compaction conditions, soaking and consolidation times, normal stresses, and shear displacement rates for each test specimen are reported in Table 2. For the comparative test pairs, both tests were performed with the same soil and geomembrane materials, target clay compaction conditions, and test specimen configuration. Other features of the testing were as follows:

- Target clay compaction conditions for all the tests reflect typical values specified for landfill liner and cover system construction, with the target water content being above the optimum water content.

- Shear displacement rate for the slow test of each pair was ten to one hundred times slower than the fast test.
- Wetting, soaking, and consolidation conditions were not always the same for both tests in each comparative test pair. These conditions reflected anticipated project-specific field conditions and loadings.

## 3 INTERFACE DIRECT SHEAR TEST RESULTS

### 3.1 Overview

Test results including change in water content and peak and large-displacement shear strength are summarized in Table 2. The ratios of both peak and large-displacement shear strength measured during fast tests to those measured during slow tests vary from 0.7 to 1.4. These results are discussed subsequently.

### 3.2 Influence of Normal Stress Levels on Shear Strength

Previous investigators have indicated that differences in interface shear strength from fast and slow tests can be attributed, in part, to the existence of drained versus undrained conditions during shear (Bemben, 1993; Fishman and Pal, 1994; Takasumi et al., 1991). Fishman and Pal (1994) also suggested that these differences may be affected by pore pressure generation during undrained shear. If a saturated clay tends to dilate during shear, as for a heavily overconsolidated material, negative pore pressures may develop in fast tests. Conversely, if a saturated clay tends to compress during shear, as for a normally consolidated material, positive pore pressures may develop in fast tests. Pore pressure development will affect the shear strengths measured in fast tests. These characteristics may be relevant in evaluating shear strengths from fast and slow tests.

Compaction of a clay soil induces an apparent preconsolidation pressure,  $p_c'$ . For compacted clays tested at normal stresses lower than  $p_c'$ , the clay will be more likely to behave as an overconsolidated material and may develop negative pore pressures in fast tests. These negative pressures would result in larger shear strengths than in slow tests. For compacted clays tested at normal stresses higher than  $p_c'$ , the clay will be more likely to behave as a normally consolidated material and may develop positive pore pressures in fast tests. These positive pressures would result in smaller shear strengths than in slow tests. Although the value of  $p_c'$  was not evaluated for the compacted clays used in the testing, the influence of the testing normal stress was considered.

To evaluate the influence of testing normal stress, the ratios of peak shear strength measured during fast and slow tests were plotted as shown in Figures 1 and 2. Figure 1 shows the results for tests performed at relatively

low normal stresses (i.e.,  $\sigma_n < 40$  kPa), and Figure 2 shows the results for tests performed at higher normal stresses (i.e.,  $\sigma_n > 40$  kPa). For landfills, low normal stresses are generally present in cover systems and high normal stresses are generally present in liner systems.

Figure 1. Peak Strength Ratios at Low Normal Stresses.

Figure 2. Peak Strength Ratios at High Normal Stresses.

Five of the seven comparative test results shown in Figure 1 indicate that, at low normal stresses, fast shear tests result in greater shear strengths than slow tests (i.e., peak strength ratio  $> 1$ ). Eight of the ten comparative test results shown in Figure 2 indicate that, at high normal stresses, fast shear tests result in lower shear strengths than slow tests (i.e., peak strength ratio  $< 1$ ). These results are generally consistent with the possible influence of normal stress previously described. Similar trends are apparent for the large displacement strength data.

### 3.3 Limitations

In addition to shear rate and normal stress, other testing factors may affect pore pressure conditions during shear and measured interface shear strength. Some of these

factors include initial saturation of the clay soil and changes in saturation during consolidation and shear. Saturation conditions during shearing could not be assessed as sufficient water content and volume change measurements are not available. The type and quality of geomembrane texturing was not considered, but it also effects measured strength. Although all tests were conducted by the same laboratory, unknown testing variability exists. Based on these uncertainties, the trends illustrated in Figures 1 and 2 are considered preliminary.

## 4 CONCLUSIONS

The results of 17 pairs of comparative direct shear tests on compacted clay/textured geomembrane interfaces were evaluated. Each comparative test pair included one test at a relatively fast shear rate and one test at a relatively slow shear rate, and used the same clay soil, textured geomembrane, compaction conditions, and test specimen configuration. Interpretation of the comparative test results is considered preliminary due to unknown testing variability, differences in clay moisture conditions, and the limited number of comparative tests.

The test results are generally consistent with the hypothesis that at low normal stresses the compacted clay/textured geomembrane interface may behave as an overconsolidated material, and at high normal stresses the interface may behave as a normally consolidated material. The results suggest that the interface strength measured in laboratory direct shear tests, using a shear rate such as 1 mm/min, may be unconservative for use in long-term stability analyses of cover systems and other soil/geosynthetic systems subjected to low normal stresses. The results imply that it is prudent to establish project-specific shear displacement rates, moisture conditions, and loading conditions when evaluating the shear strength of compacted clay/textured geomembrane interfaces.

**ABSTRACT:** Geosynthetic Clay Liners (GCLs) are increasingly popular as a barrier material in waste containment. While GCLs have many desirable engineering properties, long-term performance issues are not documented. This information is critical for designers and regulators to prudently implement GCLs in waste containment. With the cooperation and assistance of GCL manufacturers and consultants, US EPA initiated a field study to examine the performance of GCLs on slopes. The project purpose is to assess field performance and to verify design parameters associated with the application of GCLs in waste containment applications. The two slope angles, 2H:1V and 3H:1V, were selected to model GCL performance in a challenging situation. The experiment aims to reveal the internal shear properties of the GCLs by forcing the internal bentonitic clay to provide stability for the entire cross section. The experiment is designed to force the shear plane inside the clay of the GCL. The experimental design includes cross sections with varying GCL product and varying drainage materials.; These 13 field plots are monitored for displacement and moisture content. The slope experiment has been underway since the Spring of 1995, and this paper summarizes the experimental design, monitoring techniques, and interim results.

**KEYWORDS:** Geosynthetic clay liner (GCL), Landfill cover, Solid waste containment, Shear strength

## 1 INTRODUCTION

Geosynthetic Clay Liners (GCLs) are often considered in modern landfill cover design. GCLs have consistent and desirable hydraulic properties, and may be easier to reliably construct in cover applications than a compacted clay liner (CCL). GCLs provide a reasonable alternative to CCLs in composite waste containment cover applications. This research effort was initiated with the assistance of GCL manufacturers to gain greater understanding of the shear and slope stability characteristics of GCLs.

Technical documentation covers GCL development from their introduction as an engineering material through to their field performance (Daniel and Estornell, 1991, Daniel and Boardman, 1993, Daniel and Scranton, 1996, Koerner, Gartung and Zanzinger, editors, 1995). Technical comparisons between GCLs and CCLs when used in waste containment applications have been made between GCLs and CCLs and are detailed in Daniel and Boardman (1993). Like any engineering material, GCLs must be chosen for use based on site-specific characteristics, and specifiers must understand the impacts of changing engineering properties over time.

One property that remains unproven in the long-term is internal shear strength which relates directly to geotechnical slope stability. The curiosity about this property emerges from our understanding of the technical properties of

bentonitic clay, commonly used in GCLs. Bentonitic clay has undesirable engineering properties when hydrated, such as low shear properties under low overburden pressures. Relatively low overburden pressures are present in most landfill cover applications.

Modern landfill covers contain many natural and geosynthetic components, presenting the designer with multiple stability design issues. A multilayer system contains multiple interface friction conditions. Some materials, like GCLs, present an internal friction situation with potential to change with varying moisture conditions. Landfill covers containing geosynthetics and/or natural barrier materials will remain stable only if the interface and internal shear properties remains stable over time. Landfill covers are a common application for GCLs.

Some GCLs are specifically designed to serve in slope applications. These materials are made with particular attention paid to the stabilization of internal shear properties. This can be accomplished by joining the top and bottom textiles with one or a combination of techniques. The techniques utilized for the GCLs involved in this research include stitching, needle-punching, and heat burnishing. All intend to feed fibers through the GCL clay material and join the two textiles. This project focuses on only one property, the internal shear characteristics of GCLs. Other interfaces and shear properties were selected to be satisfactory for the

purposes of this experiment.

## 2 MATERIALS AND METHODS

Utilizing GCLs being manufactured at the time of project initiation, the project was constructed at full scale beginning in November, 1994. Thirteen (13) test plots were constructed and instrumented for physical displacement, and for soil and GCL clay moisture conditions, the primary indicators of slope stability and long-term performance.

Drainage materials were of two types, drainage sand, and a geosynthetic drainage composite consisting of a drainage net thermally bonded to nonwoven geotextiles on both surfaces.

Cover soils were consistent on the slopes at approximately 1 m thickness.

## 3 EXPERIMENTAL DESIGN

Slopes of 3H:1V (18.4 degrees) and 2H:1V (26.6 degrees) were selected to represent two conditions. The slopes were intended to represent typical landfill cover applications, and a more aggressive slope nearer the minimum factor of design safety (for this particular experiment), respectively. Each plot consists of two roll widths, to include a field constructed seam running vertically along the length of the slope. Slope lengths were to accommodate a 9.2 m vertical elevation change. This resulted in GCL panel lengths of 29 m for the 3H:1V slopes, and of 20 m for the 2H:1V slopes. Each plot is separated by a drainage area in approximately 3 m widths to accommodate monitoring, plot isolation and drainage.

### 3.1 GCLs Involved in Study

Five products from all four GCL manufacturers (at the time of project initiation) were included in the study. The GCLs included in this study are described in Table 1.

Table 1. GCLs involved in study.

Figure 1. Cross section of 3H:1V test plot. (Scranton, 1996)

Product	Substrate GT as Field Placed	Superstrate GT as Field Placed	Top/bottom Joining Technique	Roll Width
				m
Bentofix NS	NP-NW	NP-NW	heat burnished	4.7
Bentofix NW	W-SF	NP-NW	heat burnished	4.7
Bentomat ST	NP-NW	W-SF	needle punched	4.6
Claymax SP500	W-SF	W-SF	stitched, 100 mm spacing	4.2
Gundseal	HDPE-T GM or none	none or HDPE-T GM	adhesive bonded	5.3

Key: GT = geotextile  
 NP-NW = needle punched nonwoven geotextile  
 W-SF = woven slit film geotextile  
 HDPE-T GM = high density polyethylene, textured both sides, (GM orientation varied per plot)

Table 2 describes the configuration of the test plots and the identifying letter. The cross section of a typical plot is presented in Figure 1 (for 3H:1V slopes).

Recall that all plots have geosynthetic erosion control products applied to rapidly establish vegetation, except plot M, which is an experimental control. Project plots are similar in construction except for these details:

- 1) Some cross sections contained composite barriers consisting of a GCL overlain by a geomembrane, and some had only a GCL used without a geomembrane, and
- 2) Some cross sections contained geosynthetic drainage composites, and others had GCL overlain by sand and a geotextile to form a drainage layer.

Table 2. Description of plot cross sections.

Plot	GCL	Cross Sections (described from top to bottom)

 GCL = geosynthetic clay liner  
 GT = geotextile  
 NW GT = nonwoven geotextile  
 † = replaced plots G and H, lost prior to testing  
 \* = units: degrees

### 3.2 Instrumentation

Two key parameters that would indicate the performance of the plots are moisture properties, to determine hydration of subgrade and GCL, and movement of the GCL panels down slope. To monitor this behavior, three instruments were utilized.

#### 3.2.1 Moisture Sensor in Soil Subgrade

Subgrade soil is monitored by the use of dielectric resistance moisture probes calibrated to the subgrade soils. Probes are positioned beneath each plot. To monitor subgrade moisture, gypsum blocks were employed were placed at evenly spaced intervals in a column at three positions along the slope length. Each probe has electrical leads that extend beyond the boundary of each panel to accommodate measurement. The location of the sensors is shown in Figure 2.

#### 3.2.2 Moisture Sensor in or near Bentonitic Clay

Sensors at the GCL/subbase interface are similar in function to the gypsum blocks used for soil subgrade, but consist of fiberglass wafers. These probes were inserted into the interface between GCL and soil subbase. On occasion, probes are inserted into the clay portion of a GCL blanket. Sensors are calibrated to function in site soils. The GCL bentonite probes were placed in a similar grid as the soil subgrade sensors, with electrical leads that also extended beyond the boundary of each panel.

#### 3.2.3 GCL Deformation - Translational Movement

Motion is monitored by a series of steel wires designed to detect motion in the textiles that form the top and bottom of each GCL individually. The sensors are comprised of braided stainless steel wire encased in plastic sleeve tubing to allow movement of the wire inside the sleeve. The wires were connected to the GCL in a 5 row by 2 column grid along the vertical centerline of each GCL panel. The wire displacement sensors are attached to both the top and bottom textile of each

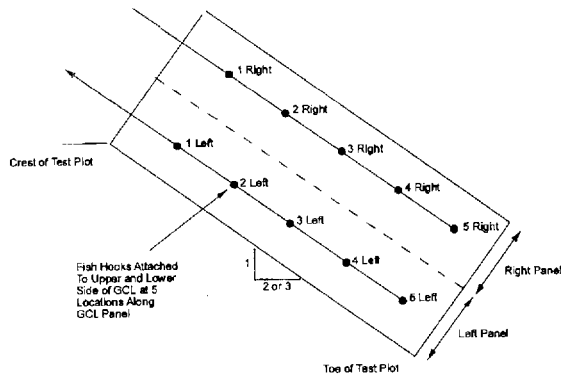

Figure 2. Location of Moisture Sensors, typical. (Scranton, 1996)

GCL panel. This monitoring configuration would allow the detection of translation movement and therefore, internal shear motion. The design was slightly modified for Gundseal, a GCL which is comprised of granulated bentonite adhered to a geomembrane overlain by an extremely lightweight geotextile web (or in most cases, no geotextile at all). Monitoring displacement data for Gundseal products is difficult in this experiment due to the inability to monitor both surfaces effectively. The steel wires are brought to the surface monitoring area at the crest of each slope (in two locations per plot, one for each panel) and the wires are exposed on tables with motion indicators attached.

**Figure 3.** Plan view of arrangement of displacement gauges.

**Figure 4.** Cross-section of displacement gauge location.

## 4 CONSTRUCTION SEQUENCE

Construction of each plot followed the following chronological sequence:

- Subgrade preparation (wet conditions prevailed)
- GCL deployment
- Geomembrane deployment and seaming (where required)
- Drainage layer installation (either geocomposite or GCL/sand/geotextile)
- Cover soil emplacement
- Removal of bottom buttress
- Installation of erosion control geosynthetics
- Hydro seeding of slope surface

### 4.1 EXPERIMENTAL COMMENCEMENT

Near the end of construction, the largest supportive force, the soil toe buttress (necessary for construction) was removed, and the overlying geosynthetics were then severed, marking the beginning of the experiment.

## 5 RESULTS AND DISCUSSION

**Figure 5.** Severing of overlying geosynthetics.

Results are being collected as the project progresses. This paper provides a brief overview and discussion of data collected up to the point of writing. Below is a discussion of events that have occurred.

### 5.1 Field Performance - Short Term

Shortly after construction, two interface shear slides occurred. Two slopes (former plots G and H) were lost in translational slides at 20 and 50 days after construction, respectively. In each case, the underlying GCL (in these cases, a woven slit-film material interfaced with textured geomembrane), which remained intact. The two plots were later replaced with another plot P. These slides revealed no useful information regarding internal shear properties.

All other plots remained stable throughout the construction process, showing minimal motion.

### 5.2 Field Performance - Long-Term

Experiments formally began with the severing of overlying geosynthetics. This was done so that the geosynthetics could not contribute to slope stability in a tensile fashion. Textiles and/or geomembranes were carefully severed at each layer. For GCLs other than Gundseal, only the bottom geotextile remained intact. For Gundseal, only the geomembrane remained intact (for bentonite up applications). After severing, it is primarily the clay that resides within any individual GCL that resists movement on each plot.

#### 5.2.1 Interface Slides

Plot F experienced an interface slide between the underlying GCL and the overlying geomembrane at approximately 10 months into the experiment. As with the post-construction slides discussed earlier, the GCL remained on the slope, while overlying materials slid. Panel F was constructed such that the clay of the GCL was positioned between two geomembranes, and this arrangement should prevent massive hydration of bentonitic clay within this cross section. Yet wetting of the GCL progressed quickly, indicating a malfunction in slope construction or site management.

### 5.2.2 Subbase Failure

In May of 1997, approximately 700 days into the experiment, Plot I experienced a subbase failure in the soil beneath the plot. Subbase soils were found to contain a pocket of highly plastic clays, and over time, the slope became unstable and a soil slide occurred. The GCL was performing satisfactorily until this event occurred.

### 5.2.3 Investigative Disassembly

In June of 1997, approximately 730 days into the experiment, Plot K was experiencing significant tensile stretching (little evidence of any internal shear), on the order of 900 mm of stretching over a length of 16.5 m. This plot was disassembled in an attempt to learn from the plot before any slide occurred. Disassembly allowed access to the GCL, which was observed to be intact.

### 5.3 Data Summary

Data is summarized in Table 3. The table shows indications of deformation and hydration status at the time of writing. As can be seen from this data, some motion is detected on 2H:1V plots at the time of writing.

## 6 PROJECT STATUS

This effort will continue as long as possible. Monitoring continues on a monthly basis. Final technical project reports will be forthcoming from the authors and US EPA in 1997 and upon project conclusion.

Plot	Maximum Total Deformation (mm)	Maximum Differential Deformation (mm)	Hydration Status	
			GCL/ Subgrade	Subgrade
A	30	10	low	moderate
B	30	25	low	moderate
C	30	10	wet	wet
D	35	15	wet	wet
E	30	10	moderate	wet
F	Slid		wet	wet
I	Slid		wet	wet
J	900	30	moderate	wet
K	Disassembled	75	moderate	moderate

## ACKNOWLEDGMENTS

This project is funded by US EPA via cooperative agreement CR-821448 with David Carson as technical project officer. The grantees and key members associated with the project (in addition to the authors) are: George Koerner - Geosynthetic Research Institute at Drexel University, John Bowders, Jr., and Heather Scranton - The University of Texas at Austin, Majdi Othman - GeoSyntec Consultants Inc., Robert Landreth (retired), Mike Davis, Taras Bryndzia, Lynnann Hitchens, Donna Fisher, Jim Horton, and Scott Ebert - US EPA National Risk Management Research Laboratory, Remediation and Containment Branch. Further, this project is supported in kind by the GCL manufacturers who were represented at the time of project initiation by Robert Trauger - CETCO, John Fuller and Richard Carriker - Claymax (now CETCO), Richard Erickson, Fred Struve, Jim Anderson, Mark Cadwallader - Gundle Lining Systems (now GSE), Larry Lydick and Ted Dzierzbicki of National Seal Corporation, who also provided construction services and related geosynthetics. This project is also supported with in kind contributions from Waste Management Inc., Cincinnati, Ohio, managed by David Bower and formerly by John Stark. This project received geosynthetic materials for erosion control from many suppliers as a subset study. Many participants have moved to other positions after the time of project initiation. Their commitment and support of this project is greatly appreciated.

**ABSTRACT:** This paper summarizes the results of a study which uses the recently developed Optical Profile Microscopy technique (Dove and Frost, 1996) as the basis for investigating the role of geomembrane surface roughness on the shear strength of geomembrane/geotextile interfaces. The results show that interface friction can be quantitatively related to the surface roughness of the geomembrane. The peak and residual interface strengths increase dramatically through the use of textured geomembranes as opposed to smooth geomembranes. For the textured geomembranes, the peak interface strength is mainly mobilized through the micro-texture of the geomembrane, however, the residual interface strength is primarily attributed to macro-scale surface roughness which pulls out and breaks the filaments from the geotextile. The results of this study can be used to provide a quantitative framework that can lead to a significantly improved basis for the selection and design of geotextiles and geomembranes in direct contact.

**KEYWORDS:** Geomembranes, Geotextiles, Surface roughness, Interface strength

## 1 INTRODUCTION

Geomembranes are commonly designed to be in contact with soils or other geosynthetics. A textured geomembrane with roughened top and/or bottom surfaces is used to increase the shear resistance mobilized with soils or other geosynthetics as compared to the shear resistance mobilized along smooth geomembrane interfaces. The recently developed Optical Profile Microscopy (OPM) technique (Dove and Frost, 1996) can be used to provide a quantitative measure of surface roughness for geomembranes and enable the role of geomembrane surface roughness on the shear strength of geomembrane/geotextile interfaces to be investigated.

It has been observed that geomembrane surface topography affects not only the shear resistance but also the shear mechanisms operating at the interface. Stark et al. (1996) investigated the interface shear strength between geomembranes and geotextiles using a torsional ring shear device. They reported that the textured geomembranes yielded a substantial increase in interface shear strength over smooth geomembranes (Figure 1).

Based on a quantitative measure of surface roughness, the relationship between surface roughness and geomembrane/geotextile interface shear strength is evaluated in this paper. More importantly, the role of

geomembrane surface roughness on the shear mechanisms of geomembrane/geotextile interfaces is investigated.

Figure 1. Comparison of failure envelopes for smooth and textured geomembrane/geotextile interfaces (after Stark et al. 1996).

## 2 EXPERIMENTAL STUDY

### 2.1 Surface Roughness Parameter

The surface roughness of geomembranes can be characterized by the recently developed Optical Profile Microscopy (OPM) technique (Dove and Frost, 1996). The OPM technique uses digital image analysis to quantify the profile roughness on three cross-sections of a geomembrane oriented at 120 degrees to each other.

Theoretically, the two-dimensional profile roughness parameter,  $R_L$ , is defined as the ratio of the actual length of the profile to the projected length of the profile. Similarly, the three-dimensional surface roughness parameter,  $R_S$ , is defined as the ratio of the actual area of the surface to the projected area of the surface. Values of  $R_S$  can vary from 1.0 for perfectly oriented surfaces to infinity, theoretically, although the resulting surface roughness parameter ranges, in practice, from about 1.05 for "smooth" geomembranes to greater than 1.70 for "heavily textured" geomembranes.

Since the measurement of real area of geomembrane surface is not an easy task, the surface roughness parameter,  $R_S$ , can be derived, in practice, from the stereology-based relationship (Gokhale and Drury, 1990). More details of this procedure is provided by Dove and Frost (1996).

## 2.2 Surface Roughness Characterization

Three coupons oriented at 120 degrees to each other and approximately 50mm in length are taken from the geomembrane samples. The three sections are placed vertically into a mold filled with a plaster of Paris mixture. After the mixture hardens, the polished surfaces are captured with a CCD camera and evaluated using an image analysis system (Dove and Frost, 1996).

## 2.3 Geosynthetics Used in the Interface Shear Tests

One smooth and three textured HDPE geomembranes which are considered to be representative of the range of textures and texture patterns presently available to designers were utilized in this study. In addition, four different geotextiles were used.

- Dura Seal HD and Friction Seal HD geomembranes manufactured by National Seal Co.
- GSE Friction Flex geomembrane manufactured by GSE Lining Technology, Inc.
- Poly-Flex textured HDPE geomembrane manufactured by Poly-Flex, Inc.
- Trevira Spunbond 110/550 geotextile : Continuous filament polyester nonwoven needle punched fabric manufactured by Hoechst-Celanese with a mass per unit area of 16 oz/yd<sup>2</sup>.
- Amoco #4506, #4510, and #4516 geotextiles : Staple filament polypropylene nonwoven needle punched

fabric manufactured by Amoco with a mass per unit area of 6, 10, and 16 oz/yd<sup>2</sup>, respectively.

## 2.4 Geomembrane Specimen Preparation

The geomembrane specimens were glued to the underside of a 1/4 inch thick 4 inch square aluminum plate using a spray epoxy. The geomembranes were oriented so that the machine direction of the roll was parallel to the shear direction of the plate. The adhesive was allowed to cure for 24 hours under a normal stress of approximately 10 kPa. The geomembrane was then trimmed flush with the rear and side edges of the aluminum plate, leaving excess geomembrane extending from the leading edge. The excess geomembrane was then wrapped completely around the leading edge of the plate, cemented, clamped and allowed to cure overnight. The geomembrane - aluminum plate combination was then bolted to the underside of a 4 inch square aluminum block (Figure 2). This configuration prohibits relative displacement between the geomembrane and the aluminum plate. It also provides a smooth leading edge, allowing the geomembrane to be sheared against the geotextile without peeling back and folding under.

## 2.5 Geotextile Specimen Preparation

The geotextile specimens, approximately 6 inches wide by 10 inches long, were glued to a flexible geomembrane backing using a spray epoxy. After curing overnight, the geotextile - geomembrane combination was placed on the testing platform of the direct shear apparatus, with the machine direction of the geotextile parallel to the shear direction (Figure 2). The geotextile was secured by fastening a 1 inch wide metal bracket along the rear and two side edges of the specimen. The geomembrane backing was used to give the underside of the geotextile added rigidity. The backing in combination with the metal brackets eliminated the relative displacement that would take

Figure 2. Schematic geomembrane/geotextile interface shear test configuration.

place if the geotextile was fastened directly to the metal testing platform of the direct shear apparatus.

## 2.6 Interface Shear Tests

A modified large displacement direct shear test apparatus was used to measure the shear strength of the geomembrane / geotextile interfaces. This device was used to permit large displacements and hence residual conditions to be achieved in the tests. The tests were conducted at normal stresses of 50, 100, and 150 kPa. The geomembrane was placed on top of the geotextile, after which the normal stress was applied via a metal cross arm and series of dead weights (Figure 2). The geomembrane-aluminum block was then fastened to the direct shear arm and sheared at a constant rate of 0.08 in/min. A load cell and LVDT mounted on the apparatus were used to measure the shear force and displacement, respectively. The test data was collected and displayed on a computer via a LabView data acquisition system.

## 3 RESULTS

### 3.1 Geomembrane Roughness Determinations

The average values of  $R_s$  determined for each geomembrane sample along with the standard deviation are shown in Table 1.  $R_s$  values measured in this study agreed well with those from the previous study reported by Dove et al. (1997).

### 3.2 Effect of Geomembrane Surface Roughness on Interface Shear Strength

Figure 3 shows typical plots of the shear stress - horizontal displacement relationship for geomembrane/ nonwoven geotextile interfaces. As expected, the tests performed using the more textured geomembranes result in a higher peak strength. It is also shown that as the surface roughness of the geomembrane increases, the displacements required to achieve peak and residual strength increase. One interesting aspect of the plot is the relative shape of the different curves. The stress-displacement curve corresponding to the smooth geomembrane results in an initial rise in strength which remains constant once the peak strength is mobilized. The stress - displacement curves for the more textured geomembranes, however, exhibit an initial rise and well defined peak, followed by a decrease to a residual state. This trend is consistent throughout the various textured geomembrane / nonwoven geotextile combinations tested. This is principally attributed to the fact that sliding of the geotextile is the

Table 1. Results of surface roughness determinations.

Figure 3. Typical stress-displacement curves : geomembranes/Amoco #4510 geotextile.

Figure 4. The impact of reusing geomembrane.

main mechanism for smooth geomembrane interfaces, however the pulling out and tearing of the filaments from the geotextile and the breaking of micro-textured asperities from the geomembrane are key mechanisms for textured geomembrane interfaces. This phenomenon is well defined by investigating the impact of reusing geomembranes.

Figure 4 illustrates the impact of reusing a geomembrane specimen on the shear stress - horizontal displacement relationship for Poly-Flex textured geomembrane / nonwoven geotextile interface. This plot shows the results of a series of four tests, the first of which involved using both a virgin geomembrane specimen and a virgin geotextile specimen. In the other three tests, the original geomembrane specimen was reused and sheared against a new geotextile specimen in each test. In addition to reducing the magnitude of the peak interface strength, reusing the geomembrane specimen also effects the shape of the shear stress - horizontal displacement curve. The test performed using virgin textured geomembrane specimens results in a stress - displacement curve exhibiting a sharp rise, peak and decrease in shear strength. The subsequent tests do not exhibit the same trend. Instead, the shear stress - horizontal displacement curve more closely resembles that of a smooth geomembrane, in which the shear strength rises to a peak value with little or no subsequent reduction in strength.

The data presented in this figure suggests micro-texture on virgin geomembrane specimens contributes significantly towards the peak strength of a textured geomembrane / nonwoven geotextile interface. More importantly, the micro-texture can be removed by a relatively small amount of displacement, resulting in a substantial loss of strength. For the textured geomembranes, the peak strength is induced by the tearing of micro-texture geomembrane asperities. After all the micro-texture is removed by the geotextile filaments, the strength reduces to a residual state where the pulling out and the tearing of the filaments in the geotextile occurs. Thus, the residual state is primarily controlled by the macro-scale surface roughness.

Figure 5(a) shows the peak interface friction angle as a function of the surface roughness,  $R_s$  at a normal stress of 100 kPa. All interface friction angles presented herein are secant values computed for an adhesion intercept of zero. It is observed that the peak interface friction angle increases rapidly with small changes in roughness up to a certain  $R_s$  value, above this roughness, the rate of increase of peak interface friction angle with the change in roughness decreases. As hypothesized, the peak strength is mainly mobilized by the geomembrane micro-texture and not the global roughness which includes both macro-scale roughness and micro-scale roughness. For the moderately and

heavily textured geomembrane, even though the  $R_s$  value which is much more affected by the macro-scale roughness, changes in a broad range, the micro-texture does not follow the trend of  $R_s$  values at the same rate. This make the rate of increase of peak interface friction

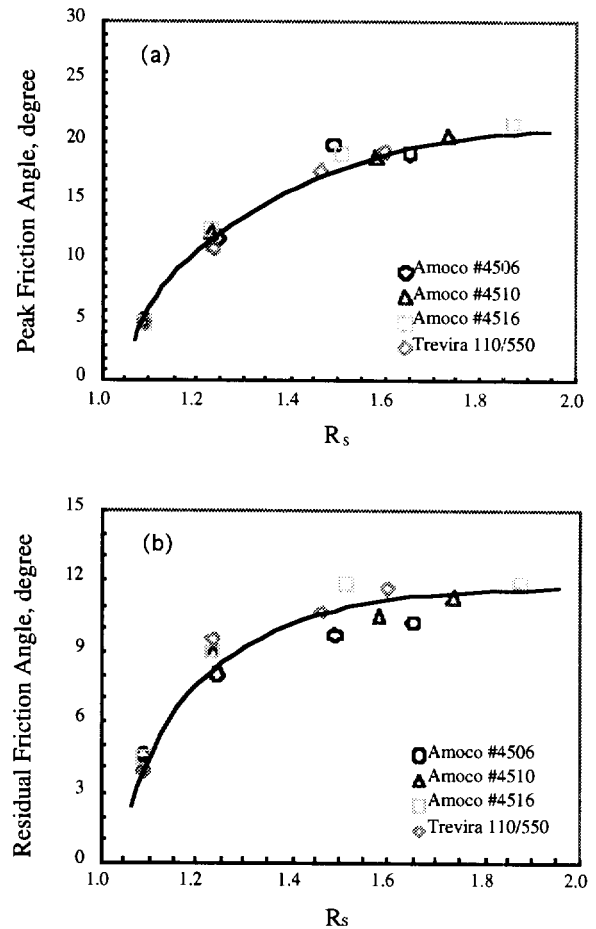

Figure 5. Peak and residual interface friction angles.

Table 2. Results of roughness decrease by reusing of geomembrane.

Geomem-brane	No. of Tests	Virgin $R_s$	Reused $R_s$	% Decrease

	7	1.587	1.492	6.0

angle decrease with the change in roughness,  $R_s$  for moderately and heavily textured geomembranes.

Figure 5(b) shows residual interface friction angle as a function of  $R_s$  for a normal stress of 100 kPa for different geotextiles. As with the peak interface friction angle, it is noted that the residual interface friction angle also increases rapidly with small changes in roughness up to a certain  $R_s$  value, after which, the rate of increase of residual interface friction angle with the change in roughness decreases. Even though the trend is the same as for the peak interface friction angle, the mechanism for the residual interface friction angle is somewhat different. The residual strength is primarily a function of macro-scale surface roughness, since almost all the micro-texture is removed at displacements near the peak stress. This means that beyond a certain value of surface roughness, the residual strength is mainly attributed to the pulling out and tearing of the filaments from the geotextile, and consequently the real strength is influenced by the more pronounced geomembrane asperities, and is a function of strength of the geotextile itself.

Table 2 shows the amount of decrease in surface roughness resulting from the reuse of textured geomembranes. The decrease in surface roughness increases dramatically when the same geomembrane is used multiple times. Single reuse of the geomembrane where the micro-texture influences the peak strength shows that the surface roughness,  $R_s$ , decreases by about 0.4%, 1.1%, and 1.0% for slightly, moderately, and moderate/heavily textured geomembranes, respectively. However, multiple reuse of a geomembrane induces large decreases in surface roughness, where, as described, the shear strength may come from the geotextile itself.

### 3.3 Effect of Geotextile on Interface Shear Strength

Figure 6 presents the effect of geotextile mass per unit area on textured geomembrane/geotextile interface strength at 100 kPa normal stress. The curve shows the results from the same textured geomembrane sheared against the same type of geotextile, with the only difference being the mass per unit area. The trend is for the geotextile with the higher mass per unit area to peak at both a higher stress and a higher degree of displacement at normal stresses less than 100 kPa. This can be explained by the difference in geotextile thickness. Geotextiles with more mass per unit area are thicker. As the geomembrane is sheared against the geotextile, the top of the geotextile is displaced while the bottom is fixed to the geomembrane backing. Displacement rearranges the geotextile fabric, stretching the fibers between the moving geomembrane and the stationary base. The fibers of the thicker fabric can

stretch over a longer distance, resulting in a higher horizontal displacement. The higher strength comes from the increase in fibers per unit area.

Figure 6. Effect of geotextile mass per unit area.

Figure 7. Peak failure envelope for geomembrane/geotextile interface.

### 3.4 Failure Envelope

Figures 7 and 8 present the peak and residual failure envelopes for the geomembrane/geotextile interfaces, respectively. It can be seen that the failure envelopes are approximately linear within the normal stress range tested, although the failure envelope clearly has some degree of curvature. It is also noted that the peak and residual interface strengths are increased dramatically by the use of textured geomembranes instead of smooth geomembranes. However, the post peak strength loss is

substantially greater with a textured geomembrane as shown in Figure 9 where the sensitivity is plotted as a function of roughness.

Figure 8. Residual failure envelope for geomembrane/geotextile interface.

Figure 9. Interface strength sensitivity.

#### 4 CONCLUSIONS

This paper has quantitatively illustrated the influence of geomembrane surface roughness on geomembrane/geotextile interface strength. The results show that surface roughness has a first-order effect on the strength of geomembrane/geotextile interfaces. The following conclusions are based on the data and interpretation presented in this paper:

1. Textured geomembranes mobilize higher peak and residual shear strengths than smooth geomembranes.

2. The sliding of the geotextile is the main mechanism for the smooth geomembrane surfaces, however pulling out and tearing of the filaments from the geotextile and the tearing of micro-texture at asperities from geomembrane are key mechanisms for textured geomembrane surfaces.
3. For the textured geomembrane, the peak interface strength is mainly mobilized by the micro-texture of geomembrane asperities.
4. For the textured geomembrane, the residual interface strength is primarily attributed to the pulling out and tearing of the filaments from the geotextile, and consequently is attributed to the characteristics of the geotextile (e.g., filament entanglement, filament strength, filament length/diameter) and how it interacts with the geomembrane macrotopography.
5. The geotextiles with the higher mass per unit area induce the higher strength and the higher degree of horizontal displacement at peak stress at normal stresses less than 100 kPa.
6. The interface sensitivity can also be quantitatively related to the geomembrane roughness.

**ABSTRACT:** The interface shear strength between various components of liner and cover systems is an important parameter in evaluating the stability of these systems. Typical stability analyses for liner and cover systems do not explicitly consider the potential variability of the interface shear strength. This paper presents the results of several interface shear conformance tests performed as part of the construction quality assurance program for two composite liner system projects. Interfaces tested include geonet/smooth geomembrane, hydrated geosynthetic clay liner/textured geomembrane, and compacted clay liner/textured geomembrane. The test data provides insight on the statistical distribution of interface shear test results. The data provided are expected to be useful in: (i) evaluating the reliability of interface shear strengths established during the design phase; (ii) performing probability-based stability analyses for liner and cover systems; and (iii) evaluating construction quality assurance interface shear conformance test results.

## 1 INTRODUCTION

Slope stability is an important design consideration for waste containment systems employing geosynthetic layers. These geosynthetic layers have the potential for creating interfaces with low shear strengths when combined with other geosynthetic layers or weak soil layers. The presence of these low shear strength interfaces has been an important factor in slope stability failures (Mitchell et al. 1990). As a result, the evaluation of these interface shear strengths has received significant attention. In the current state-of-the-practice, slope stability analyses are performed using interface shear strengths based on prior experience, published data, and/or limited site-specific testing. In addition, these slope stability analyses do not consider the variability of interface shear strengths. These variabilities can result from geosynthetic material manufacturing processes such as geomembrane texturing (Dove et al., 1997), from errors inherent in the testing procedure (Criley and Saint John, 1997), or from variations inherent within natural soil materials. The variability in geosynthetic material manufacturing can be manifested from roll to roll or within individual rolls. Understanding the variabilities of these interface shear strengths can provide useful insight into interpreting slope stability results and can form the basis for performing probabilistic slope stability analyses.

This paper presents the results of interface shear conformance testing performed as part of the construction quality assurance program for two composite liner system

projects in California. The interfaces tested include a geonet/smooth high-density polyethylene (HDPE) geomembrane, hydrated geosynthetic clay liner (GCL)/textured HDPE geomembrane, and compacted clay liner/textured HDPE geomembrane. The statistical distributions of the test results presented and are characterized. The statistical nature of the test results forms the basis for evaluating the confidence level for the specified minimum shear strength.

For both case histories presented, the cover material stability on the slopes was obtained by progressively placing the cover materials in a wedge configuration as the waste disposal operations proceeded up the slope.

## 2 GENERAL TESTING PROCEDURE

The interface shear testing presented herein was performed in general accordance with the American Society for Testing and Materials (ASTM) D 5321 standard test procedure. The shear box apparatus measured 300 mm by 300 mm. The tests were performed at a displacement rate of 1.02 mm/min. Post-peak shear strengths were measured at displacements varying from 43 to 58 mm. The ASTM D 5321 standard test procedure does provide some flexibility in the selection of test parameters which can significantly affect the interface shear strength test results (Sharma et al., 1997). As a result, the project specific details of the interface shear testing procedures are presented in the following section. All tests were

performed at the same laboratory using procedures standardized within the laboratory and consistent with ASTM D 5321.

### 3 PROJECT DESCRIPTIONS

#### 3.1 Shafter-Wasco Landfill Module 2

The Shafter-Wasco Landfill is located about 4.4 km west of the City of Shafter, California. The landfill is an "area-fill" operation with 3 horizontal:1vertical (3H:1V) side slopes about 6-m high. Module 2 was completed in June 1995 and included about 96,000 square meters of lined surface area. Construction of Module 2 included an alternative to the regulatory prescriptive composite liner system comprised of (top to bottom): (1) 340 g/m<sup>2</sup> nonwoven geotextile; (2) additional 205 g/m<sup>2</sup> nonwoven geotextile on the side slopes; (3) geonet; (4) 1.5-mm thick smooth on top textured on bottom HDPE geomembrane; (5) GCL; and (6) 0.45-m thick select subgrade layer with a maximum saturated hydraulic conductivity of  $1 \times 10^{-7}$  m/s. The GCL included a 270 g/m<sup>2</sup> needlepunched nonwoven geotextile and a 110 g/m<sup>2</sup> woven geotextile. The two geotextiles were needlepunched together with a layer of bentonite between them. The interface shear strength for the liner system was specified to have a minimum friction angle value of 7 degrees.

Twenty-five interface shear conformance test series were performed as part of the construction quality assurance program. In this paper, the results of 21 test series performed in two groups will be discussed. The two groups of tests complied with the intent of the specifications. Each test series consisted of three tests (i.e., total of 63 tests) performed at different confining pressures. The first group consisted of twelve (12) test series with the select subgrade, GCL, and HDPE geomembrane components prepared as a sandwich. The HDPE geomembrane was attached to the shear box while the GCL was not attached. For these tests, peak strength displacements occurred at the select subgrade/GCL interface (Group 1a) and post-peak strength displacements occurred at the GCL/textured HDPE geomembrane interface (Group 1b). The second group (Group 2) consisted of nine (9) test series with all the liner system components prepared as a sandwich. The geosynthetics for these tests were not attached to the shear box and were overlain by a second layer of compacted soil. For these test series peak and post-peak strength displacements occurred at the geonet/smooth HDPE geomembrane interface. For each of the Group 1 and 2 test series, geosynthetics were obtained from different rolls on-site and a single bulk sample of select subgrade soil was used for all tests.

For each test the select subgrade material was placed at about 4 percent wet of the optimum moisture content and compacted to 90 percent of the maximum dry density, obtained in accordance with the ASTM D 1557 standard test method. The GCL was hydrated for 24 hours under a confining pressure of 14.4 kPa. The materials were then sheared at normal stresses of 36, 72, and 144 kPa.

#### 3.2 Bena Landfill Network 4

The Bena Landfill is located 27 km east of Bakersfield, California. The landfill is operated as a canyon fill. Network 4 of the Phase 1 development has 3H:1V side slopes up to 25.3m high. Construction of Network 4 was completed in 1995 and included about 111,540 square meters of lined surface area. Network 4 included an alternative to the regulatory prescriptive composite liner system comprised of (top to bottom): (1) geocomposite drainage layer (i.e., geonet sandwiched between two nonwoven 205 g/m<sup>2</sup> geotextiles); (2) 2-mm thick textured on both sides HDPE geomembrane; and (3) 0.6-m thick compacted clay liner with a maximum saturated hydraulic conductivity of  $1 \times 10^{-8}$  m/s. The interface shear strength of the liner system was specified to have a minimum friction angle value of 11 degrees.

Eighteen interface shear conformance test series were performed as part of the construction quality assurance program. Each test series consisted of three tests (i.e., total of 54 tests) performed at different confining pressures. The tests were performed with the compacted clay, HDPE geomembrane, and geocomposite prepared as a sandwich. The geomembrane was not attached to the shear box while the geocomposite was. For 46 tests the peak (Group 3a) and post-peak (Group 3b) strength displacements occurred at the compacted clay liner/textured HDPE geomembrane interface. For the remaining eight (8) tests, peak and post-peak strength displacements occurred at the geocomposite/textured HDPE geomembrane interface. The test series were performed using samples of the geosynthetic materials obtained from different rolls on-site and a single bulk sample of the clay material.

For each test the clay was compacted to about 4 percent wet of the optimum moisture content and to 90 percent of the maximum dry density, obtained in accordance with ASTM D 1557. The clay was subsequently hydrated for 24 hours under a confining pressure of 14.4 kPa. The materials were sheared at normal stresses of 108, 216, and 432 kPa.

### 4 TEST RESULTS

In evaluating the variability of interface shear test results, an important consideration is what form of the test data

should be used. For interface shear testing this leads to a consideration of: (1) the form of the reported test results; (2) the form of the specified minimum value; and (3) the shape of the statistical distribution.

In accordance with ASTM D 5321, the following interface shear test results are typically reported: (1) shear stress plotted against shear displacement; and (2) shear stress plotted against normal stress. In addition, a best fit line is used to define an angle of friction (i.e., slope) and an apparent adhesion (i.e., y-intercept) on the shear stress versus normal stress plot for each series of three tests. The apparent adhesion value obtained from this best fit line can be an important factor in stability analyses where low confining loads are dominant (e.g., veneer stability). However, the reliability of the apparent adhesion value obtained from a best fit straight line is questionable when the true nonlinear nature of the shear stress versus normal stress plot (Sharma et al., 1997) is considered. At low normal stresses, the best fit line may overestimate the apparent adhesion value. Giroud et al. (1990) suggested the use of an apparent friction angle for veneer stability problems. This apparent friction value combines both friction and adhesion into one parameter and is represented by a best fit line passing through the zero value of the y-intercept. The use of an apparent friction angle or slope value, without a separate apparent adhesion value, to represent the interface shear strength is consistent with the current practice of specifying a minimum interface friction angle for material conformance.

To evaluate the apparent friction angle, or slope value, the interface shear strength values obtained for the Group 1a, 1b, 2, 3a and 3b tests were normalized with respect to normal stress. This normalization allows the normalized interface shear strength for each test result to be grouped with test results obtained at other normal stresses. In addition, a singular normalized interface shear strength value simplifies statistical characterizations and allows each test result to be verified for compliance with the specified minimum friction angle value. However, normalization does not explicitly account for the apparent adhesion value or the nonlinear nature of the shear stress versus normal stress plot. The apparent adhesion is implicitly represented in the statistical distribution of the normalized test data while the nonlinear behavior may influence the statistical variations in the data.

Histograms of the normalized test data for Groups 1a and 1b are presented on Figure 1. A histogram of the normalized test data for Group 2 is presented on Figure 2. It should be noted that the peak and post-peak values were identical for all Group 2 tests, which is typical of geonet/smooth geomembrane interfaces. A histogram of the normalized test data for Groups 3a and 3b are presented on Figure 3. Data where displacements occurred at the geocomposite/textured HDPE geomembrane were not included in Figure 3.

Assuming a normal distribution, the sample arithmetic mean and standard deviation for each group of test data are presented in Table 1. Assuming a normal distribution, Table 1 also presents a lower estimate of the true

Figure 1. Histogram of Group 1 interface shear data.

Figure 2. Histogram of Group 2 interface shear data.

Figure 3. Histogram of Group 3 interface shear test data.

population mean corresponding to a 2.5 percent probability of the true mean being less than the lower estimate using the Student-t distribution. The standard deviations given in Table 1 for Groups 1a and 3,

Table 1. Summary of interface shear statistical parameters.

Statistical Parameters	Test Group				
	1a	1b	2	3a	3b
Sample Mean	0.400	0.287	0.215	0.381	0.370
Lower True Mean Estimate	0.380	0.276	0.206	0.363	0.352
Sample Standard Deviation	0.060	0.032	0.024	0.062	0.062

soil/geosynthetic interfaces, are significantly less than the standard deviations presented by Criley and Saint John (1997) also for soil/geosynthetic interfaces. It is not clear why the variations observed in this testing program are less than those observed by Criley and Saint John. However, variability between different laboratories may explain some of the differences observed.

Using the lower (i.e., 5 percent) estimate of the population mean and a 95 percent confidence interval, the test data also indicate that:

- the lower confidence limit for the Group 1a (i.e., GCL/select subgrade) results is 0.281;
- the lower confidence limit for the Group 1b (i.e., GCL/textured geomembrane) results is 0.224;
- the lower confidence limit for the Group 2 (i.e., geonet/textured geomembrane) results is 0.167;
- the lower confidence limit for the Group 3a (i.e., compacted clay/textured geomembrane) results is 0.261; and
- the lower confidence limit for the Group 3b (i.e., compacted clay/textured geomembrane) results is 0.25.

## 5 CONCLUSIONS

The variability of interface shear strength described herein can be considered significant by geotechnical standards. The variability occurred even with the use of a single laboratory, standardized test procedures, and a single soil sample (where applicable). It is believed that the observed variability in the test results can be primarily attributed to the geosynthetic materials. The variability of the geosynthetic materials typically results from roll to roll variations in characteristics. However, variations across rolls may also be a contributing factor.

Based on the data presented herein, the statistical significance of a non-conforming (i.e., a test result less than the minimum specified value) test result can be evaluated. This can be observed in the Group 3 test results

where 10 normalized residual interface shear strength results were less than the specified minimum value, yet 75 percent of the results were greater than the specified minimum value. This supported the acceptance of the non-conforming interface shear strength results for this project. In addition, the data presented herein can be used to perform probabilistic slope stability analyses where the statistical distribution of the interface shear test results can be used to optimize liner and cover designs.

The standard deviations presented herein can also be used to predict and/or optimize the required number of conformance samples on projects with similar interfaces based on a Student-t distribution analysis.

Professor, Department of Civil Engineering, Rensselaer Polytechnic Institute, Troy, New York, U.S.A.

**ABSTRACT:** In this paper the frictional characteristics of geotextile / geonet and geomembrane / geonet interfaces are discussed. The shear strength properties of such interfaces demonstrate some interesting characteristics. The possible effects of parameters such as specimen size, orientation of geonet, normal stress, number of cycles and shearing rate were investigated under monotonic (commonly known as static) and cyclic loading conditions. It has been observed that the interface friction angle is largely dependent on the direction and orientation of the strands forming the net, with respect to the direction of shearing motion.

**Keywords:** Landfill liner, Landfill cover, Geonets, Interface friction, Direct Shear tests

## 1. INTRODUCTION

The stability of multi-layer liner systems is of great concern in the design of modern landfills with relatively steep side slopes. The different components of such liners include interfaces that have been known to possess low friction properties. The interface shear strength at such interfaces, therefore, play a major role in the stability of landfill slopes.

Geonets are commonly used in landfill liner systems to function as drainage layers. They are usually placed in contact with other geosynthetic surfaces, such as geotextiles or geomembranes. In order to perform appropriate design procedures, it is important to understand the various factors that influence the frictional properties at such interfaces.

## 2. EXPERIMENTAL APPROACH

This paper presents results from a research project in which the interfacial friction properties of different common geosynthetics used as landfill liner components were

studied. In this study twelve different geosynthetic interfaces were studied. The details of the project are published in De (1996). In this paper the important features regarding the frictional behavior of geonet/geotextile and geonet/smooth geomembrane interfaces are presented.

The geonet used in the tests was a medium density polyethylene and had a thickness of 5.2 mm (205 mils). The geotextile used in the tests was a continuous filament, non-woven needle punched fabric made of polypropylene material with mass per unit area of  $270 \text{ g/m}^2$  (8 oz/yd<sup>2</sup>). The geomembrane (smooth) was a high density polyethylene having a thickness of 1.5 mm (60 mils).

### 2.1 Orientation of Geonet

The geonet was tested at different angles of orientation between the major direction of the strands forming the interface and the direction of sliding motion. It is believed that the amount of shearing resistance offered by a geonet during sliding is influenced by its orientation with respect to the direction of sliding. This is best explained with the help of the schematic shown in Figure 1.

Figure 1. Orientation of geonet mesh

The orientation in which one of the strands is along the direction of the force is termed aligned. The case where the strands are at 60° with the direction of the force is termed transverse. When the strands are at 30° to the force direction, the orientation is termed longitudinal. The three orientations were treated as three different surfaces and tested accordingly.

The influence of orientation of geonet on its frictional properties has also been observed by other researchers, viz. Geotek (1987) and Mitchell et al. (1990).

The frictional behavior of these interfaces were studied under both monotonic and cyclic loading conditions.

## 2.2 Apparatus

The monotonic and cyclic tests reported here were performed using a direct shear device that tested specimens 900 cm<sup>2</sup> (144 in<sup>2</sup>) in area. The shear force was controlled by means of servo-hydraulic actuators. The normal force was produced by means of a pneumatic control system.

## 3. EXPERIMENTAL RESULTS

### 3.1 Monotonic Tests

The test results are classified as geonet / geotextile, and geonet / smooth geomembrane. The tests were performed in a direct shear apparatus using a stroke-controlled mode at a displacement rate of 1.27 mm/min. Four direct shear tests were conducted for each interface at different normal stress levels between 21 and 43 kPa (3 to 6 psi). Each piece of geonet specimen was used for two consecutive tests and the orientation and the side of the geonet was altered after one test, so that transverse and longitudinal tests were performed alternately. The geotextile specimens were reused in three to four consecutive tests. A fresh geomembrane specimen was used in every test. The details can be found in De (1996).

#### 3.1.1. Geonet/geotextile interfaces

The results from the monotonic direct shear tests on geotextile/geonet tests are presented in Figure 2. Plots of shear stress versus displacement for all three orientations, tested under the same normal stress, are presented for comparison.

The plots in Figure 2 exhibit significant differences in the behavior of the three orientations when subjected to shear stress. For the transverse orientation, the shear stress continues to increase after the peak. In the case of the longitudinal orientation, the stress continues to remain at about the level where the peak occurs. Finally, in the case where the strands are aligned in the direction of the force, there is a slight reduction in the shear stress.

Figure 2. Shear stress versus displacement results from direct shear tests: geotextile over geonet (transverse, longitudinal and aligned)

The cause for this orientation dependent behavior of the geonet strands is not completely understood. It appears that an arrangement of the strands along or almost along the direction of the force leads to an elasto-plastic type behavior, whereas an arrangement where the strands face sideways to the direction of loading leads to a strain hardening effect.

The results of peak shear stress versus the normal stress for four tests on each geotextile/geonet interface are shown in Figure 3. It can be seen from the figure that the shear stress versus normal stress behavior in the case of the transverse and longitudinal orientations is not linear, and dependent on normal stress. In the case of the aligned orientation the relationship appears to be linear. The cause for this behavior is not known; however it may be caused by deformation of the geotextile under high stress. Unfortunately, these interfaces could not be tested at a wider range of normal stresses to confirm this theory, because of limitations in the testing apparatus.

Because of the stress dependent nature of the friction angles for the transverse and longitudinal orientations, it was deemed appropriate to report the static friction angle values as ranges, instead of single values, as was done for the other interfaces.

For the transverse orientation, the calculated peak friction angles ranged from 14.5° to 22°, with the smallest value associated with the highest normal stress (41.4 kPa) and the largest value associated with the lowest normal stress (20.7 kPa) used in these tests. In the case of the longitudinal orientation, the value of residual friction angle was between 14° (for 41.4 kPa normal stress) and 17° (corresponding to 20.7 kPa stress). The behavior of the aligned orientation appears to be more linear, and the peak friction angle is about 10.5°.

Figure 3. Peak shear stress versus normal stress from direct shear tests: geotextile over geonet (transverse, longitudinal and aligned)

From a practical standpoint, geonet orientation could play a significant role in liner interface behavior after sliding is initiated in the field. For the case of sliding along a geonet oriented transversely to the direction of movement, the amount of slip occurring after the shear strength of the interface is exceeded will be relatively small. However, where sliding occurs in a direction parallel to the direction of the strands, larger displacements can result following slippage, due to the relatively low value of residual shear strength.

### 3.1.2. Geonet/geomembrane interfaces

Experiments similar to the ones described in the last section were performed on geonet/smooth geomembrane interfaces. For a detailed account the reader is referred to De (1996).

Figure 4 shows the plots of shear stress at peak versus normal stress for interfaces between smooth geomembrane and geonet in three orientations. In this case the residual friction angle appears to be less dependent on the orientation of the geonet, than in the case of the interfaces involving geotextile. The minimum value of friction angle of  $8^\circ$  corresponds to the aligned orientation and the maximum value is about  $11^\circ$  for both the transverse and the longitudinal orientations.

Figure 4. Peak shear stress versus normal stress from direct shear tests: smooth geomembrane over geonet (transverse, longitudinal and aligned)

## 3.2 Cyclic Tests

Sinusoidal displacement-controlled excitation was applied to the geosynthetic interfaces in the cyclic direct shear tests. The peak dynamic friction angle at the end of each cycle was calculated on the basis of the peak shear stress and the normal stress.

### 3.2.1. Geonet/geotextile interfaces

In the case of the geonet/geotextile interfaces, the dynamic friction angle was found to be dependent on normal stress and no variation was observed due to the number of cycles of loading.

### 3.2.2. Geonet/geomembrane interfaces

The dynamic shear stress behavior of geonet/ smooth geomembrane interfaces appeared to depend both on the normal stress and the number of cycles of loading. Figures 5, 6 and 7 show plots from tests performed on geonet/geomembrane (smooth) interfaces with the geonet oriented in the transverse, longitudinal and aligned orientations, respectively.

It can be seen from Figure 5 that the dynamic friction angle varies quite substantially with the number of cycles of loading. For the first cycle the dynamic friction angle is approximately  $11^\circ$ , for all normal stress levels. Then there is a very rapid increase in the value of dynamic

friction angle for about the next five to ten cycles. After that the increase is at a much slower pace, and the rate of increase is related to normal stress, with the lowest normal stress showing the most rapid increase.

Figure 5. Variation of friction angle with number of cycles from tests using the direct shear device: Smooth geomembrane over geonet (transverse)

Figure 6. Variation of friction angle with number of cycles from tests using the direct shear device: Smooth geomembrane over geonet (longitudinal)

Plots of dynamic friction angle with number of cycles of loading for longitudinal and aligned orientations of the geonet are shown in Figures 6 and 7. The basic nature of the curves are similar to those in Figure 5. However, the dependence on normal stress is not as prominent in Figure 6, and absent in Figure 7.

Figure 7. Variation of friction angle with number of cycles from tests using the direct shear device: Smooth geomembrane over geonet (aligned)

#### 4. CONCLUSIONS

From the experimental results it may be concluded that the following parameters have an influence on the monotonic and cyclic shear behavior of geonet interfaces:

- a) orientation of the geonet strands;
- b) normal stress (for transverse and longitudinal);
- c) number of cycles of shear loading.

The dynamic friction angle obtained at the end of the first cycle of a cyclic direct shear test is close to the value obtained from a monotonic shear test.

# Geosynthetic Interface Friction Testing in Germany

## - Effect of Test Setups -

W. Blümel

Professor, Institute of Soil Mechanics and Foundation Engineering, University of Hannover, Germany

C. Stoewahse

Research Engineer, Institute of Soil Mechanics and Foundation Engineering, University of Hannover, Germany

**ABSTRACT:** An interlaboratory friction test program, initiated by the German Society of Geotechnical Engineering (DGGT), was organized and evaluated by the authors. As a main part of this program friction tests between a geotextile and a rough geomembrane as well as between a Standard Sand and a geotextile were performed by several German testing institutions. Some selected results of this interlaboratory test program are presented with special reference to effects induced by different test setups. Results of additional investigations performed by the authors with a modified testing device, where the vertical resultant force in the friction plane can be controlled during testing, help to explain the high scattering of data obtained by the interlaboratory tests. Mainly based on the results of the program a working group of DGGT has proposed preliminary recommendations for investigation of friction between different geosynthetics and between soils and geosynthetics. Some main proposals are presented in the conclusions as a basis for further discussion.

**KEYWORDS:** Interface Friction, Geotextiles, Laboratory Tests, Landfills, Direct Shear Testing

### 1 INTRODUCTION

Landfill sealing systems usually consist of different materials like compacted clay, granular soils, geomembranes and geotextiles. For stability calculations the parameters of friction between the components of the sealing systems have to be determined experimentally.

Friction tests for geosynthetic-geosynthetic or soil-geosynthetic interfaces are mainly performed in devices which are comparable with direct shear equipment commonly used in soil mechanics. Data obtained from such friction tests with geosynthetics performed by different institutions often do not correspond to each other. This leads to complex discussions and problems in defining friction parameters for design work. Different testing devices, setups, procedures etc. seem to be the cause for this situation.

The determination of reliable friction parameters for the components of liner systems is of central importance for stable and economical constructions. This includes the choice of partial safety factors in relation to the scattering of test data. Slope failures may occur, if friction available under in situ conditions is overestimated by friction tests performed with boundary conditions, that are not covering all critical stages during building and life of a landfill structure or any other geotechnical construction with inclined layers of geosynthetics and soils.

Caused by the problems explained above a working group of the German Society of Geotechnical Engineering (DGGT) has performed interlaboratory tests, which were organised by the authors at the Institute for Soil Mechanics and Foundation Engineering (IGBE) of the University of Hannover. These arrangements also included basic work for evaluating and summarising test results. The main aim

of the activities of the working group are preliminary recommendations for the investigation of friction between different geosynthetics and between soils and geosynthetics.

### 2 INTERLABORATORY TESTING PROGRAM

As a main part of the interlaboratory test program friction between the following materials was investigated:

- nonwoven PP-geotextile, 1200 g/m<sup>2</sup>, vs. rough textured geomembrane
- sand according to the European Standard EN 196-1 vs. nonwoven HDPE-geotextile, 300 g/m<sup>2</sup>.

The grading of the Standard Sand is given in Table 1.

Sieve Size mm	Cumulative Sieve Residue %
2.00	0
1.60	7 ± 5
1.00	33 ± 5
0.50	67 ± 5
0.16	87 ± 5
0.08	99 ± 1

Table 1. Grading of Standard Sand

The first test series was performed with only few instructions given by the organizers. The participants were allowed to choose several boundary conditions like the type

of test setup, fixation of geosynthetics etc. with their own engineering sense and experience. But it has to be pointed out that the participants received more instructions concerning the test conditions than normally given by construction companies, consultants, etc. for project tests.

The results of the first test series show significant variations in the characteristics of friction stress vs. displacement curves as well as in magnitudes of the peak friction stress values. Some results of the first test series are published by Blümel et al. (1996 a, b). Further details about the scattering of test data are given by Blümel et al. (1997).

Generally it can be stated that the scattering of data was unsatisfactorily high in all investigated cases. Therefore, it was decided to perform a second test series where all participants received more detailed instructions concerning the boundary conditions and testing procedure. The testing procedures recommended in this second test series were developed by the working group of DGGT after a discussion with the participants of the first interlaboratory test series.

About twenty institutions participated in each interlaboratory test series. All devices used for the tests had friction interfaces of at least 30 cm square. For all tests a constant rate of displacement of 10 mm/h was proposed. The vertical load was applied to the samples one hour before starting the displacement. Tests had to be performed with four different loads to meet the following values of average vertical stresses in the friction interface: 20/50/100/200 kN/m<sup>2</sup>. The tests were run without submerging the samples.

### 3 SELECTED RESULTS

#### 3.1 Friction Between a Geotextile and a Geomembrane

Test instructions defined two different test setups to conduct these friction tests.

Figure 1. Test setup for geotextile-geomembrane interface friction

The first type of test setup for determination of geotextile-geomembrane interface friction is shown in Figure 1. The geotextile is clamped to the upper box of the shear device. The upper box is partly filled with Standard Sand. The geomembrane is fixed to a rigid support in the lower box.

This type of test setup also opens possibilities to investigate friction with those soils that will be placed above the geotextile in the liner system. It has to be taken into consideration that granular soils neighbouring the geosynthetics can affect the interface friction behaviour.

Typical friction stress vs. displacement curves for a vertical stress of 100 kN/m<sup>2</sup> obtained with the first type of test setup are shown in Figure 2. Nearly all data generated by the different institutions fits together quite well. This is true for the characteristics of the curves as well as for the peak friction stresses.

Figure 2. Friction stress vs. displacement measured with test setups according to Figure 1

A second test setup as shown in Figure 3 could also be used for investigating friction between two geosynthetics. The geotextile is fixed to a rigid block placed inside the upper box. The geomembrane is fixed to a rigid support in the lower box in the same way as described above.

Figure 3. Modified test setup for geotextile-geomembrane interface friction

The coefficients of variation of peak and residual friction stresses are in the same magnitude for both test setups. For a small vertical stress of 20 kN/m<sup>2</sup> the coefficient of variation of the peak friction stress reaches about 30 % but decreases with increasing vertical stresses. For 200 kN/m<sup>2</sup> the coefficient of variation is about 13 %. Interlaboratory direct shear tests in soil mechanics led to coefficients of variation of the same magnitude.

The friction stress vs. displacement curves obtained with the two test setups displayed in Figure 2 and 4 show only little differences concerning the form of the curves which doesn't seem to be significant. Relative friction stress maxima before reaching the absolute peak values measured with the second type of test setup may be caused by tilting of the rigid block placed in the upper box.

Figure 4. Friction stress vs. displacement measured with test setups according to Figure 3

### 3.2 Friction Between Standard Sand and a Geotextile

Friction stress vs. displacement curves obtained at a vertical stress of 100 kN/m<sup>2</sup> for the interface between Standard Sand and a geotextile, 300 g/m<sup>2</sup>, are shown in Figure 5. The geotextile is fixed uniformly to a rigid support in the lower box and additionally is clamped on one side. Standard Sand as defined in EN 196-1, was placed in a dry state in the upper box with a density of 1.8 g/cm<sup>3</sup>. Sketches of the setups used by the participating institutions are shown in Figure 6 and Figure 8.

As in the case discussed in chapter 3.1 the participants were supplied with detailed information concerning the boundary conditions of the tests. Nevertheless, the data generated by the institutions for friction between sand and geotextile scatter within a wide range. This is true for peak and residual friction stress values. The coefficients of variation calculated from the friction stresses at a displacement of 30 mm are between 40 % for a vertical stress of 20 kN/m<sup>2</sup> and 23 % for a vertical stress of 200 kN/m<sup>2</sup>. In addition, friction stress vs. displacement curves

differ in shape. Some curves do not show any significant peak friction value at all. Others were obviously faulty due to insufficient test setups and were omitted from the evaluation.

Figure 5. Friction stress vs. displacement for sand-geotextile interface obtained with two different setups according to Figure 6 and 8

Additional tests were performed by the authors in order to identify specific factors which may affect the friction in the sand-geotextile interface, e. g. the method of fixation of the geotextile to the support or the rate of displacement. It was found that the rate of displacement is not a significant factor. But the method of fixation of the geotextile to the rigid support is likely to have an effect. Insufficient fixation can lead to friction stress vs. displacement curves without any friction peak value. Other possible reasons for the scattering of data caused by the test setup like the height of the sand filled into the upper box or the use of smooth or ribbed loading plates could not be identified from the interlaboratory test data.

Devices of different manufacturers were used by the participants. Seven participants used an equal type of testing device but the scattering of data delivered by this subgroup was found to be in the same range as for the whole group.

Figure 6. Test setup with horizontally supported upper box for soil-geosynthetic interface friction

In general, devices with a movable lower box were used for the tests, some with a completely fixed upper box (with vertical and horizontal support) and others with an only horizontally supported upper box. For the latter type of test setup we have to recognize that effects as explained in Figure 7 may occur during testing.

Figure 7. Interaction forces, stresses and deformations occurring in a test setup according to Figure 6 (Wernick 1979)

For the test setup with completely fixed upper box vertical friction stresses can occur at the inner walls of the upper box which will lead to a reduction of the average vertical stress in the friction interface (Figure 9).

These effects are well known in soil mechanical direct shear testing (Kast 1986; Jewell 1989). Especially for test devices of the type discussed in this paper with larger dimensions than commonly used for soil testing we have to take these effects into our considerations concerning the evaluation and interpretation of test data.

The type of test setup shown in Figure 6 has an upper box, which is only horizontally supported at one point. The type with a completely fixed upper box is displayed in Figure 8. The upper box is fixed vertically and horizontally and therefore no displacement or rotation of the box is possible, but the loading plate can rotate within a small range.

The friction stresses measured in tests with a fixed upper box are in most tests higher than those obtained from tests in the device with an only horizontally supported upper box. But we have to regard that the number of data obtained with the latter type of construction is very small. Furthermore, the results of the friction tests for the geotextile-geomembrane interface show nearly no differences for test setups with fixed and horizontally supported upper box.

Figure 9. Interaction forces, stresses and deformations occurring in a test setup according to Figure 8

#### 4 ADDITIONAL INVESTIGATIONS

Depending on the test device the vertical load is applied to the top of the sample with weights, hydraulic jacks or hydraulic or pneumatic bellows. A stiff plate is often used for load distribution over the test area. The distribution and magnitude of the normal stress acting in the friction interface during testing is unknown.

The assumption that a constant vertical stress derived from the load applied to the top of the sample is acting in the friction interface is most probably valid for testing devices with a point supported upper box (Figure 6) before starting horizontal displacement. This assumption is questionable for devices with a fixed upper box as effects like friction between test material and internal walls of the upper box can occur.

Figure 8. Test setup with completely fixed upper box for soil-geosynthetic interface friction

To investigate such effects, the testing equipment used by the authors was modified. To determine the average vertical stress acting in the friction interface during horizontal displacement the vertical forces at the corners of the fixed upper box were measured. A sketch of the device is shown in Figure 10. The equipment was manufactured by Wille-Geotechnik GmbH, Göttingen/Germany.

By summarizing the values of the vertical support forces the resulting vertical force acting in the friction interface can be obtained. The air pressure in the bellow is regulated during horizontal displacement of the lower box in order to keep the resulting vertical force and average vertical stress acting in the friction interface at a constant value. Information about the vertical stress distribution in the interface can also be obtained with this setup.

Figure 10. Modified test setup with measuring devices to keep a constant vertical stress in the friction interface

Friction tests for the interface between Standard Sand and a nonwoven geotextile of 300 g/m<sup>2</sup> and direct shear tests for Standard Sand were performed. One series of tests was carried out with a constant load applied to the top of the sample and the other with a constant vertical force in the friction interface. The tests were performed under conditions of repetition. The boundary conditions were the same than those chosen for the interlaboratory testing program described above. Several tests were done for both series to meet the following values of vertical stresses: 20/50/100 kN/m<sup>2</sup>.

Figure 11 shows the friction stress vs. displacement curves obtained from tests with a fixed upper box with the two different methods of controlling the vertical stress. The scattering of test data for the case with a constant pressure applied to the top the sample is smaller than in the interlaboratory test program. The coefficient of variation derived from the measured peak friction stresses in these tests under conditions of repetition is only about 5 %. The shape of the friction stress vs. displacement curves is similar, but certain variations in the curves are found for greater values of displacement after passing the peak friction value. All data obtained from the tests with a constant vertical force in the interface show very good conformity.

Figure 11. Friction stress vs. displacement for sand-geotextile interface with two different procedures of vertical stress control during testing

The peak friction stresses obtained from the tests with vertical stress controlled by measurement during horizontal displacement are significantly smaller than those found for tests with constant pressure on top of the sample. In the latter case the average normal stress in the shear plane increased to about 130 kN/m<sup>2</sup> at a normal stress of 100 kN/m<sup>2</sup> applied to the top of the sample. In the tests with a constant normal stress in the shear plane of 100 kN/m<sup>2</sup> the air pressure in the loading equipment decreased to about 75 kN/m<sup>2</sup>. These effects are most probably caused by interaction and compulsory forces between soil and box during shear. Shibuya et al. (1997) obtained comparable results in direct shear tests on sand with a fixed upper box device and constant load on top of the sample.

Figure 12. Normalized friction stress vs. displacement for sand-geotextile interface with two different procedures of vertical stress control during test

For further evaluation the friction stress data was divided by the vertical stress. In Figure 12 these

normalized friction stresses vs. the displacement are plotted. It can be seen from this plot that the deviations are decreasing with increasing vertical stress.

## 5 CONCLUSIONS

The determination of friction properties between different geosynthetics and between soil and geosynthetic in direct shear devices is complicated due to high scattering of data. Test equipment, boundary conditions, test procedures and the mechanical properties of soil affect the characteristics of the friction stress vs. displacement curves and the magnitude of the peak friction stresses. Therefore, the experimental investigations, test setups and boundary conditions should be in accordance with the expected situations at the site as well as possible.

The institutions which are performing the friction tests, have to be provided with detailed information about the type of construction and about the construction materials. The properties of the tested soils have to be considered.

The German preliminary recommendations on friction testing with geosynthetics prescribes standard test setups and boundary conditions of testing in order to minimize effects resulting from different setups and procedures. The method of load application and its effect have to be regarded and reported together with the results of the friction tests and other boundary conditions.

To cover data scattering observed under conditions of comparison it is recommended to carry out a sufficient number of tests by two different institutions for each project. Friction tests have to be performed with at least three different normal stresses. The vertical stress that is relevant for the project and the stability calculations, must be within this range. The test with this vertical stress must be carried out three times. The determination of test conditions, data evaluation and derivation of friction parameters for design calculations has to be done in close cooperation with the engineers responsible for design and stability calculations.

Based on further evaluations of friction tests with other geosynthetics and soils, which are not presented in this paper, it is recommended that adhesion derived from friction test results should be introduced into stability calculations only in special cases, e.g. for interfaces between cohesive soils and geomembranes. Considering all possible site conditions during building and during life of the structure the engineers responsible for the project must agree that adhesion will act continuously. Safety factors for the design value of the adhesion have to cover scattering of test data especially at low normal stresses.

## ACKNOWLEDGMENTS

The authors thank all colleagues and institutions for their contributions to the interlaboratory testing program.

# The Influence Of Equipment Style And Setup Dimensions On Sand/Geomembrane Direct Shear Test Measurements

S.M Bemben

Geotechnical Engineering Consultant, 147 Victoria Road, New Britain, Connecticut, USA.

D.A . Schulze

Senior Vice President, Laboratory Services, GZA Geoenvironmental, Inc., Newton Upper Falls, Massachusetts, USA.

**ABSTRACT:** The results of a testing program employing two sands and two geomembranes with a commercial direct shear device are presented. Two avenues of direct shear device modifications were utilized. The first avenue was to employ new upper shear boxes having 7.5 x 7.5 and 15 x 15 cm areas, as well as the original 30.5 x 30.5 cm area upper box, all upon longer length lower boxes so as to maintain a constant area of shear (termed new style). The second avenue was to employ each of the three sizes of upper boxes over identically sized lower boxes so as to create a constantly decreasing area of shear (termed old style). The paper compares the effects of size of shearing area, new and old style shearing boxes, size of the fixed gap between upper box and top of geomembrane, and thickness of sand layers on peak and residual stress ratios.

**KEYWORDS:** Friction, Geomembranes, Laboratory tests, Shear strength, Sand

## 1 INTRODUCTION

Every direct shear test requires selection of materials to be tested, test equipment, setup criteria, and rate of shearing movement. The purpose of this study is to determine the effects of size of shearing area, new and old style shearing boxes, size of the fixed gap between upper box and top of geomembrane and thickness of sand layers on peak and residual stress ratios for combinations of two sands and two geomembranes.

The most extensive guideline for sand/geomembrane testing is ASTM (1992). It will frequently be referenced.

## 2 EQUIPMENT, MATERIALS AND SETUP PROCEDURES

### 2.1 Direct Shear Device

The shear device employed was the same basic unit with improvement modifications previously described by Bemben and Schulze (1995). It is a commercial unit manufactured by Boart Longyear Company. Two new avenues of modifications were designed, fabricated and utilized by the writers. The first avenue was to employ upper shear boxes having 7.5 x 7.5 and 15 x 15 cm areas, as well as the original 30.5 x 30.5 cm area upper box, all upon longer length lower boxes (termed new style herein). The second avenue was to employ each of the three sizes of upper boxes over identically sized lower boxes topped by geomembranes having top surfaces flush with the top of the box (termed old style herein). The various shear box areas employed for both the new style and old style tests are presented in Table 1.

Table 1. Sand/geomembrane setup sizes.

Setup size	Top box sand area (cm x cm)	Geomembrane area (cm x cm)
SM1	30.5 x 30.5	35.5 x 43.2
SM2	30.5 x 30.5	30.5 x 30.5
SM3	15.2 x 15.2	30.5 x 38.1
SM4	15.2 x 15.2	15.2 x 15.2
SM5	7.6 x 7.6	30.5 x 38.1
SM6	7.6 x 7.6	7.6 x 7.6

As shearing movements occur, the upper box is fixed and the lower box displaces laterally. The rate of displacement was 0.1 cm/min. This is in accord with ASTM (1992) for dry and nearly dry sands. Shear force corrections for friction losses associated with movements of the traveling container were made in accord with ASTM (1992).

### 2.2 Geomembranes

Two geomembranes were employed. Geomembrane 1 was a textured high density polyethylene liner manufactured by GSE Lining Technology, Inc. and having their HDT designation. Geomembrane 2 was a smooth high density polyethylene liner manufactured by GSE Lining Technology, Inc. and having their HD Designation.

For new style tests the geomembranes were clamped to the leading edge of the lower traveling box. For old style tests the geomembranes were fastened to plywood support blocking by finishing nails. For textured membrane tests, the direction of travel during shearing was in the direction of roll production. Textured geomembranes were generally used for two tests and smooth geomembranes

were always used once. Textured geomembranes were from two rolls of different thicknesses and smooth were from one roll.

### 2.3 Sands

Two sands were employed. Sand 1 was a medium sand having subangular particles which is commercially available under the name Flint Sand. Sand 2 was fine to coarse sand having angular particles and was from a glacial deposit. Grain size distributions are presented in Table 2. The two sands are classified SP and SW-SM, respectively, by the Unified Sand Classification System.

### 2.4 Setup Criteria

#### 2.4.1 Fabrication of Sand Layers

For tests with Sand 1, the sand was compacted air dry to a unit weight of 17.66 kN per cubic meter. For tests with Sand 2, the sand was compacted to a dry unit weight of 17.59 kN per cubic meter with a water content of 3%. The sands were maintained with the same water contents during shearing as those during fabrication.

The total height of sand is called the sand layer thickness. When the sand layer thickness was 2.5 cm or less, the sand layer thickness was fabricated by one compacted lift; when the sand layer thickness was greater than 2.5 cm, it was fabricated by employing the minimum number of multiple compacted sand lifts of equal thickness not exceeding 2.5 cm. (For example, a 5.7 cm thickness is composed of three 1.9 cm lifts). Sand was compacted in lifts, first by direct hand tamping with a 2.5 kg weight having a 5 cm diameter and then by hand tamping with the same weight onto a steel plate. Six measurements with calipers were made to control the thickness of each compacted lift.

#### 2.4.2 Gap Setting and Load Transfer Plates

The gap is the space between the bottom of the top box and the top of the geomembrane. The gap is set and remains constant during sand fabrication and shearing movements.

Table 2. Grain size distributions.

Sieve number	Opening (mm)	Percent passing	
		Sand 1	Sand 2
4	4.76	100	100
10	2.00	100	91
20	0.840	100	77
40	0.420	28	48
60	0.250	2	31
100	0.149	0	18
200	0.074	0	11

Load transfer plates were provided at the top of the sand layer in accordance with ASTM (1992). The plates were unbonded pieces of Geomembrane 1 which were cut slightly less in area than the area of the box.

## 3 PRESENTATION OF DATA

Data pertaining to 48 direct shear tests are presented in Tables 3 through 5. Data are also presented by Figures 1 through 5. The definitions of peak and residual stress ratios are shown by Figure 5.

Figure 5. Comparison of stress ratio and change in height – shear movement curves for Sand 1/ Geomembrane 1, Sand 2, Sand 2/Geomembrane 1, and Sand 2/Geomembrane 2 tests.

## 4.1 Residual Stress Ratios

### 4.1.1 Effect of Sand Layer Dimensions

Residual stress ratios versus sand layer thickness are shown by Figures 1 and 4. Bands of data comprising the writers' appraisal of acceptable ranges for residual ratios are indicated for each combination of materials. (It will be shown that the development of acceptable residual stress ratio values requires the selection of proper sand layer thickness and gap size dimensions). For Sand 1/Geomembrane 1, the range is 0.45 to 0.49; for Sand 2/Geomembrane 1, the range is 0.61 to 0.69, and for Sand 2/Geomembrane 2, the range is 0.31 to 0.34.

The range of sand layer thickness values for which the bands of each combination of materials apply is seen to be from the smallest thickness up to at least 2.5 cm providing the acceptable range of gap values also exists.

Relatively thick layers are unacceptable for shear box testing. The residual stress ratios are typically too low when too thick layers are involved. This is largely due to vertically directed shear stresses arising between the inside walls of the upper shear box and the sand within as the sand tries to move upward and downward. Such movements are shown by Figures 5. As the sand dilates during early shear, the shear stresses arising at the walls of the upper box produce an increased downward force on the failure surface resulting in a too large peak shear stress. As shear movement continues and the sand contracts, the shear stresses at the wall surfaces are reversed. If the reversal is not completed when shearing movement is stopped, either a residual shear stress state will not be reached, or it will be incorrect. ASTM (1992) provides that the "stationary" upper box "should be adjustable" to compensate for deformations of the sand. No definition is given for "adjustable".

A different problem exists for the smallest sand layer thickness for the Sand 2/Geomembrane 1 case shown by Figure 4. The layer thickness to maximum particle size is (1.8cm/0.48cm) or 3.75. ASTM (1992) requires the ratio to be 6 or larger. It is surmised that this requirement allows sufficient ease for the larger particles to move about as shearing is ongoing. Thus, the measured residual stress ratios for the locked in grains of the too thin layer are higher than the acceptable range even though the gap is acceptable.

### 4.1.2 Effects of Gaps and Area Sizes

The size of the gap affects the measured residual stress ratio. If the gap is too small, the measured residual stress ratio will be too large or may be cyclic in nature. For Sand 1, Figure 1 shows that the gap must be greater than 0.38 cm; for Sand 2, Figure 4 shows that a gap of 0.53 cm is large enough; this is also about 0.3 cm larger than  $D_{85}$ . This conflicts with ASTM (1992) which allows the gap to

be as small as  $D_{85}$  of the sand. The sounds of grinding sand particles during shearing were emitted when the gaps were too small. All gaps larger than the minimum sizes were acceptable.

Figures 1 and 4 show that the setup size has no effect on the acceptable residual stress ratio providing the proper sand layer dimensions and gap sizes exist. The possibility of using a shear box of lesser area than the 30.5 x 30.5 cm standard size is provided by ASTM (1992).

## 4.2 Peak Stress Ratios

### 4.2.1 Effect of Sand Layer Dimensions

Peak stress ratios versus sand layer thickness are shown by Figures 1 and 4. Bands of data showing the ranges in the peak stress ratios at each value of sand layer thickness can be envisioned. They have much larger spread than the bands of acceptable range for residual stress ratios. The discussion will be limited to the range of acceptable sand layer thickness associated with acceptable residual stress ratio behavior, namely, up to 2.5 cm.

The bands of the sand/textured geomembrane combinations are sloping. The peak values increase with increasing sand layer thickness. This behavior is surmised to be due to the volume change behavior during shear previously described. With increasing sand layer thickness, the wall area providing downward stresses during early shear movements increases and, hence, the excess normal stress on the failure plane increases. Because the excess normal stress increases with increasing sand layer thickness, the peak shear stress does likewise.

Figure 4 shows the peak shear stress ratio does not increase with sand layer thickness for the sand/smooth geomembrane case. Figure 5 shows the sand layer thickness does not experience dilatancy during shear, hence the vertical wall shear stresses are very small. The failure mechanism is deduced to be sliding of the intact sand layer over the smooth geomembrane. The creation of the peak stress ratio is attributed to the angular sand particles biting into the geomembrane. The smooth geomembranes had readily visible scratches in the direction of travel.

### 4.2.2 Effects of Gaps and Areas

At any one sand layer thickness, the effect of gap size on measured peak stress ratios is usually about 0.1 in magnitude. Usually, the case is that the smallest gap employed presented the highest peak stress ratio and the largest gap presented the lowest.

Figures 1 and 4 show that the setup size has no effect on the band of peak shear stress ratios providing that proper sand layer dimensions and gap sizes are in effect.

### 4.3 A Precarious Failure Envelope Situation

Two failure envelopes developed from Sand 1/Geomembrane 1 tests are shown by Figure 2. The failure envelope using the SM3 setups involves Tests 1.5, 1.12 and 1.13. These test setups meet the previously presented sand layer dimensions, gap sizes and other setup criteria. As expected, the residual failure envelope is within the acceptable range. Figure 2 also shows for the SM3 setup tests, that residual stress ratios are independent of the normal stress and peak stress ratios are dependent on the normal stress.

The failure envelope using the SM1 setups involves Tests 1.25, 1.26, and 1.27. The sand layer thickness is greater than 2.5 cm; hence, poor test results are anticipated. The residual stress ratio for the 96 kPa normal stress is too low. Not shown are the results for six other tests at 24 kPa, 48 kPa and 96 kPa normal stress with gaps of 0.20 and 0.76 cm. The stress ratios for the set at 48 kPa are shown on Figure 1. These six tests concluded with the stress ratio decreasing without ever experiencing a true residual case. Only by a fortuitous chance setup combination of the too small 0.37 cm gap with the too thick sand layer dimensions involved did the SM1 setups produce the precarious envelope.

## 5 DISCUSSION OF OLD STYLE SETUP DATA

Stress ratio-shear movement curves for Sand 1/Geomembrane 1, and Sand 2/Geomembrane 2 are presented by Figures 1 and 3. The stress ratios have not been corrected for changes in the area of the failure plane. This is acceptable ASTM (1992).

With the exception of Test 1.16 (the small SM 6 setup), the peak stress ratios are in fairly good agreement with those for new style setups having the same sand layer thickness.

It is very difficult to ascertain the residual stress ratios. The stress ratio-shear movement curves usually have decreasing ratios from the peak to the end of the test. The writers feel old style setups are usually inferior to new style setups for ascertaining residual stress ratios. But, the junior writer's laboratory has produced some stress ratio-shear movement curves (with other sands) from which residual stress ratios were reasonably discerned.

## 6 CONCLUSIONS

The following conclusions derive from the described direct shear testing program using the cited equipment, normal stresses, materials and setup dimensions and procedures. Extensions to other situations should only be made with appropriate considerations.

1. New style setups are superior to old style setups for

testing of sand/geomembrane combinations.

2. For new style setups, the residual stress ratio for each sand/geomembrane combination is a unique value if proper sand layer thickness and gap size dimensions are used.
3. For new style setups, the peak stress ratio for each sand/geomembrane combination is not a unique value. The value depends on sand layer thickness, gap size, and normal stress level but not on size of area.
4. ASTM (1992) promulgates the use of too small gap sizes. This setup criterion results in too large peak and residual stress ratio measurements.
5. For each sand/geomembrane combination setup, the improper selection of layer thickness and gap size dimensions can lead to widely varying improper test data.
6. The minimum acceptable thickness of a sand layer is governed by the size of the largest sand particle. The maximum acceptable thickness is governed by the combination of the roughness of the inside walls of the upper box and the volume change during shear behavior of the sand.
7. The use of 15.2 x 15.2 cm top box sand areas on lieu of conventional 30.5 x 30.5 cm areas does not create any loss of test data accuracy.

## ACKNOWLEDGMENTS

The laboratory testing and publication costs were funded by GZA Geoenvironmental, Inc. as in-house research. The writers express their gratitude to Matt Trettel, the laboratory technician who performed all the tests. Gratitude is also extended to GSE Lining Technology, Inc. who provided funding to the senior writer for project expenses.

# Evaluation of Soil-Geosynthetics Interaction for Some Landfills in Algiers

A. Bouazza

Senior Lecturer, Department of Civil Engineering, Monash University, Melbourne, Victoria, Australia

**ABSTRACT:** The paper presents the results of a study concerning the potential use of geosynthetics in some MSW landfills in the Algiers (Algeria) area. The study focussed on the evaluation of interface shear strength between the different components of the proposed liner. Sand/woven geotextile, sand/non woven geotextile, sand/textured PVC geomembrane (locally made), and clay/PVC (smooth and textured) geomembrane systems have been investigated. It was found that efficiency on friction varied from 0.82 to 0.97 for sand/geotextiles and geomembranes systems and from 0.16 to 1.22 for the clay/geomembranes and geotextiles systems. Locally made textured geomembranes showed good promise in terms of efficiency and can contribute to a safe disposal of domestic waste. More importantly, the results showed that a minimum composite liner can be constructed taking into account the availability of some local materials. Thus avoiding the common practice of dumping the waste in a big open hole without a minimal protection.

**KEYWORDS:** Geotextiles, Geomembranes, Landfills, Liners, Interface friction

## 1 INTRODUCTION

The economic boom that most of the industrialised countries of the world have experienced in the past has brought both increased industrial and urban waste disposal problems. Industrial treatment sludges, along with an array of other industrial, hazardous and domestic waste, have been indiscriminately dumped into either disused rock quarries and sand pits, or in areas previously considered to be undesirable. Only minimal attention has been given to the control of leachate to prevent spread of contaminants in surface water and ground water. As a result, the total environmental and societal costs of landfilling have for a long time not realistically been considered. Programs for cleaning up many old sites, such as those identified by the Superfund program in the United States and in the contaminated land inventories in the European Community, have mainly started over the last decade.

Over the last decade considerable attention has been focused on environmental issues. Indeed, ground and groundwater protection and restoration of contaminated soils and waters are issues that have come under increased public scrutiny. It has become necessary to design and construct safe waste disposal facilities which employ the best of the available technologies. Nowadays, landfill waste containment systems often are comprised of several layers of geosynthetics and natural soils. Typically, the soil layers are predominantly fine grained and consists of large amounts of clay. Soils and geosynthetics are used in a liner system to serve as drainage and collection layers as well as hydraulic barriers. In most systems, the clay layer and a geomembrane are placed in direct contact to form a composite barrier and to increase the total effectiveness of the hydraulic barrier to contaminant migration out of the landfill. Multiple barrier and collection layers are often combined to provide redundancy to the design. However, in developing countries the above concept of

design is still in its infancy due mainly to the lack of guidelines, regulations, expertise, or funding. It is worth noting that funding when available is in competition with more basic needs such as those for housing, education or adequate nutrition.

The main problem which prompted the present study was linked to the state of the main refuse landfill situate at Oued-Smar 15 kms east of Algiers, Algeria (Figure 1).

Figure. 1 Site location

This landfill receives approximately 580000 t/year of wastes of all sorts. The typical refuse in the Oued-Smar landfill consists of 72% food (including, fibres, shells, etc.), 9% papers, 8% plastics, 4% textiles, 1% glass, and 5 % of other materials (Bouazza, 1993). Twenty years after its opening, it shows the signs of a poorly designed landfill. Unpleasant and unhealthy odours are emerging from the site, repulsive aspects which play a negative role on the neatness and the protection of the site.

Furthermore, the poor level of leachate migration control added to the fact that it is inadequately lined resulted in soil and groundwater pollution. There was a strong need to replace the existing landfill by a new landfill with a composite liner.

The work presented in this paper was part of a study of lining systems for some potential landfills to be constructed around the Algiers area (Algeria). This study has been carried out in the prospect of possibly usage of, locally (Algerian) made PVC geomembranes, local soils and imported geotextiles in the new composite liner.

## 2 MATERIALS

The geosynthetics used in the present study consisted of woven geotextile (GTw), non-woven geotextile (GTnw), textured PVC (GM), and smooth PVC (GM). The PVC geomembranes were selected because of their availability locally. The clay used was from the El-Harrach area where the main Algiers landfill is sited. All samples were taken at a depth of about 4-5 m. The physical properties from laboratory tests, conducted according to AFNOR standards methods, are: unit weight =  $17.10 \text{ kN/m}^3$ , natural moisture content = 12%, optimum moisture content (omc) = 14.5%, liquid limit = 38%, plasticity index = 17%. The mineralogical analysis of the sample showed that the clay was of a kaolin type. The sand was a medium clean uniform sand. It had the following properties: maximum porosity  $n_{\text{max}} = 48\%$ , minimum porosity  $n_{\text{min}} = 28\%$ , specific gravity  $G_s = 2.65$ , uniformity coefficient  $C_u = 1.9$ , shape = subrounded

## 3 TESTING PROCEDURE

A 100 mm x 100 mm shear box was used to determine the interface shear strength of the soil/geosynthetics systems in a non saturated state (dry condition). Conventional shear box tests were initially conducted to ascertain the internal angle of friction of the clay and the sand. Further shear box tests were then conducted but with clay or sand in the upper half of the box only, with the geosynthetic element material in the lower half. The lower half of the box was occupied by a hardwood block and the geosynthetic material was glued firmly to the surface of the block. The geosynthetic was aligned so that shearing occurred in a direction parallel to the longitudinal axis, along shearing direction. The block was adjusted so that the surface of the geosynthetic was flush with the top edge of the bottom half of the box, in order to ensure shearing could only occur at the interface. The clay was compacted in the standard proctor mold and then specimens were trimmed and placed into the upper split box. Sand samples were prepared by pluviating sand directly into the upper box to achieve a relative density

( $I_p$ ) of 65%. A normal pressure varying from 100 to 400 kPa was applied. The shearing rate was 0.1 mm/min. Once, the samples have been prepared and the desired normal stress applied, the sample was left for about thirty minutes to come to equilibrium and then sheared to failure.

## 4 RESULTS AND DISCUSSION

The interface shearing resistance between geosynthetic and soil is generally expressed by two parameters:

- 1) angle of friction ( $\phi_{\text{GT} \text{ or } \text{GM}}$ ) due to the friction between the soil particles and the geosynthetic surface;
- 2) adhesion ( $C_i$ ) due to the interface force holding soil particles at the geosynthetic surface, obviously in a cohesionless soil  $C_i = 0$ .

The contact efficiency, or efficiency on friction, (E) is then defined as the ratio of the tangent of the friction angle ( $\phi_{\text{GT} \text{ or } \text{GM}}$ ) for the soil-geosynthetic interface, to the tangent of the friction angle ( $\phi$ ) for the soil alone.

The data reported in this paper were obtained for normal pressures ranging from 100 kPa to 400 kPa. The results obtained with sand are presented in Table 1 while the results obtained with clay are presented in Table 2.

It is obvious to see that the friction angle ( $\phi_{\text{GT} \text{ or } \text{GM}}$ ) between geosynthetics and soils are smaller than the internal angle of friction ( $\phi$ ) of soil alone, except for the GTnw/clay system. In the latter, the shear tests have generated an efficiency value well above 1.00, indicating a perfect contact. This is probably due to the good interlocking between the clay particles and the geotextile fibres. This is further enhanced by the roughness and the random orientation of the fibres in the nonwoven geotextile. A similar behaviour has been noticed when testing nonwoven geotextile/peat interface strength (Bouazza & Djafer-Khodja, 1994). The interface friction angle of non-woven geotextiles (GTnw) and woven geotextiles (GTw) in contact with sand is  $32^\circ$  and  $34^\circ$  respectively mobilising 89 % and 96 % of sand's friction angle. The interface friction angle of textured PVC (GM) in contact with sand is  $30^\circ$  and mobilised 82 % of the sand friction angle. The above results indicate that the interface friction angles of geotextiles and textured PVC (GM) with sand are close to those obtained for sand alone. The friction angle between clay and textured PVC (GM) is  $22^\circ$  which mobilised 73 % of the clay friction angle. Whereas the smooth PVC geomembrane was found to have an efficiency of approximately 17 %. The low interface friction angle value and efficiency attained in the present case with the smooth PVC (GM) represent a high risk potential of failure due to slippage (Bouazza, 1996).

Table1. Peak interface friction results for geosynthetics/sand system.

Figure 2 shows typical direct shear data for the interface between the compacted clay and the different types of PVC (GM). The shear stress is plotted as a function of the horizontal displacement for a normal stress,  $\sigma_n = 200$  kPa. The measurements indicate that the roughness of the textured PVC (GM) contributes to the increase in the amount of the shear resistance at the clay/PVC (GM) interface. Apparently the rough surface of the textured PVC (GM) creates better interlocking with the clay material than the smooth surface of the second PVC (GM). One can also notice that the sample with a textured surface shows a peaking of shear strength at small displacements of less than 0.8 mm. Whereas the sample with smooth surface shows a flatter shear displacement curve. Another feature is also depicted in Figure.2. Indeed, one can also notice that the residual strength of the soil/smooth PVC (GM) system is almost identical to its peak value. Whereas in the soil/textured PVC (GM) system the drop from peak to residual strength value is more significant.

Composite liners, consisting of compacted clay and geosynthetic materials, are generally used in MSW landfills as they have proved to be an effective barrier against contamination of soils and groundwaters. However, the use of a composite liner requires that greater attention be paid to the stability of the landfill. The failure of a liner system can be catastrophic in terms of the harm it can do to the environment and the monetary cost to the community. The investigation of the sudden slope failure of the Kettleman Hills waste landfill in California, USA (Mitchell et al. 1990, Seed et al., 1990, Byrne et al., 1992) indicated clearly that failure occurred by sliding along one or more interfaces within the landfill liner system. The results of the geosynthetics interface shear test reported by Mitchell et al. (1990) in connection with the Kettleman Hills failure investigation as well as the results reported by Martin

Figure 2: Shear displacement relationship for smooth and textured PVC (GM) at  $\sigma_n = 200$  kPa.

et al (1984), Williams and Houlihan (1986), Negussey et al. (1989), Pasqualini et al. (1993) and Stark et al. (1996) are particularly instructive examples of the values and variabilities of interface shear resistances. However, published values of interface friction cannot be used for design of a specific project, without at least careful review of test materials, test conditions and test methods. For design purposes, an interface friction should be determined on a site specific basis. The present results provide some data for the local engineers, obviously more work needs to be carried out to optimise any solution to the safe disposal of wastes.

Perhaps more importantly, Giroud et al. (1995) queried whether a developing country should adopt or adapt landfill regulations and designs from countries with stringent environmental regulations. Their answer was that waiting to construct a landfill with a state of the art system in a developing country is likely to result, over time, in more pollution of the environment than accepting lower standards and immediately constructing a landfill with a liner built using local materials. The present results show indeed that local materials such as PVC (GM) and clay or sand can achieve an acceptable performance and present a viable economic alternative. However, extreme precautions should be taken when using PVC geomembranes. Indeed, Masada et al. (1994) stressed the fact that PVC geomembranes show rapid aging upon prolonged exposure to leachate and also that clay/PVC interface shear strength is susceptible to undergo a large reduction when exposed to leachate.

In the present specific case, it appears that the use of textured locally made PVC (GM) can alleviate certain environmental issues and contribute to the "safe" disposal of domestic waste. Economically, this is also a viable alternative for local authorities since the cost of having a composite liner is reduced. However, one should stress that this is not the panacea to all waste disposal problems in Algeria. Proper regulation should be put forward. More testing encompassing all aspects linked to landfill design are needed in order to optimise the locally made material.

**ABSTRACT:** A case history on the use of geosynthetic reinforcement for remedial action of a Southern California hazardous waste site is presented. The site consists of twelve pits containing highly acidic organic compounds and oil-based drilling muds. The organic compounds in the pits originated from oil and petroleum sludges, which have high percentages of sulfuric acid. The selected remedy for the site was to provide long-term isolation of the waste using a geosynthetic cover system and a soil-bentonite vertical barrier. Selection of the cover system components required consideration of the chemical compatibility between the waste and the geosynthetics and the ability of the cover to withstand differential settlement of the underlying wastes. The paper discusses the chemical compatibility test program, design and construction of the reinforced cover system used for this project and lessons learned during construction.

**KEYWORDS:** Reinforcement, Differential Settlement, Geogrid, Geocell, Chemical Compatibility.

## 1 INTRODUCTION

This paper presents a case history of the design and construction of a reinforced geosynthetic cover system at a Southern California hazardous waste site. The paper presents: (i) background information of the site; (ii) design considerations for the remedial action; (iii) the chemical compatibility testing program used to evaluate the long-term durability of the components of the cover system; and (iv) issues which arose during construction.

## 2 BACKGROUND

Twelve pits containing petroleum sludges and oil-based drilling muds exist at the site. The sludges were generated by the production of high-octane aviation fuel and were placed in the pits between 1942 and 1946. Between 1952 and 1964, the site was used for disposal of oil-based drilling muds. These wastes and their reaction products and byproducts are found as liquid, gas and solid phases within the pits. At the time of deposition, essentially all of the waste materials were mobile. Over time, much of the waste has hardened. Since deposition, the wastes have been present at the site without an engineered containment system. During the post-deposition period, occasional tar seeps and malodorous gaseous emissions emanated from the pits.

The solid and semi-solid material present in the pits consist of a thin layer of surface soil having a thickness between 0.8 and 1.7m, soil mixed with waste, drilling muds and soft flowable tar varying in thickness between 0.3 and 2.6m, and solidified waste having a measured thickness

from 0.6 to 7.8m. These materials are neither present in equal proportions or are they distributed evenly within the pits.

The drilling muds are a thixotropic semi-solid sludge, which can behave as a very viscous fluid. The tar portion of the waste is a black, moist, viscous material with the potential for mobility. Flowable tarry waste had seeped through the overburden soil cover to the surface at approximately fifty locations within nine of the twelve pits. Figure 1 shows one of the waste seeps observed at the site. The tar emerged to the surface in a viscous state but solidified following exposure to the atmosphere into a glassy substance that exhibited a tendency to fracture. The solidified waste, the predominant content of the pits, is a hard, friable immobile material that is the end product of a series of chemical reactions that have occurred among the various materials within the pits.

Beneath the pits are native soils consisting of thin beds of intermixed sands, silts and clays. There is no engineered lining system beneath the pits. However, the solidified waste is anticipated to act in a manner similar to an asphalt liner. The regional groundwater table is located 43 to 73m beneath the pits. There are isolated, transient lenses of perched water around the site at elevations higher than the regional groundwater table. The source of the perched water is likely infiltration and leaking drainage culverts. The highest transient lens of perched water is 3m below the bottom of the deepest pit.

Key considerations of the selected source remedy for the site were to: (i) provide a cover system that includes a barrier layer and a gas collection and treatment system over the pits to minimize infiltration of water and release of

Figure 1- Flowable waste seep through existing soil cover.

hazardous or malodorous gas emissions; (ii) provide a subsurface vertical barrier around the pits to minimize outward lateral migration of mobile waste or waste by-products and inward lateral migration of subsurface liquid; and (iii) provide slope stability improvements for unstable slopes at the site. As the focus of this paper is on the reinforcement requirements of the cover system, discussion of the subsurface vertical barrier will not be presented.

### 3 DESIGN CONSIDERATIONS

In addition to encapsulating the waste, the design of the cover system also considered long term use of the facility. Several slopes at the site required reconfiguration to resist seismic events deemed probable in the area. By designing geogrid-reinforced walls at the toe of these slopes, the grades of the slopes could be flattened sufficiently to achieve acceptable performance during the design seismic event. Other improvements included extending an adjacent golf course over the more stable pits, creating three holes and a water hazard. The other portions of the site were to be landscaped to a park-like setting.

The design of the cover system was complicated by the inhomogeneity of the material in the pits. Slight to moderate subsidence was observed in various areas over the pits. Considering this observation, there was a concern that additional overburden from the landscaping could aggravate any differential settlement of the cover system. Furthermore, the drilling muds of variable thickness were considered likely to generate significant differential settlement. To minimize stresses on the barrier layer of the cover system (a geomembrane) due to differential settlement, it was concluded that reinforcement was needed beneath the cover system. Two types of reinforcement were used based on the varying overburden stresses proposed. Over the pits containing high percentages of drilling muds, the cover system stress on these materials was limited in the design to minimize long-term settlement.

In these areas, a cellular confinement system (geocell) was used because the stiffness of the three-dimensional geocell is greater than that of two dimensional sheet reinforcement (i.e., geogrid) and does not require initial deformation to support the design loads. Over the pits that did not contain drilling mud, the design allowed placement of 4.6m of fill for the golf course. In these areas, geogrid reinforcement was used.

Further complicating the design was the highly acidic nature of the waste, derived from sulfuric-based petroleum sludges. As many materials typically used for cover systems perform poorly in a highly acidic environment, material selection was based on a chemical compatibility testing program.

### 4 CHEMICAL COMPATIBILITY

Due to the nature of the wastes and the extent of reactions and transformations occurring in the pits, many constituents of the waste exist at varying concentrations in different phases. Of particular importance to the constituent interactions are the sulfur compounds found in the liquid phase of the waste. These sulfur compounds are the result of catalyst-based reactions involving various organics, acidic clays, and the sulfate anion. The origin of the sulfur within the pits is the petroleum sludges. Typical acid concentration for these sludges was 90 percent sulfuric acid when initially placed in the pits, but is believed to be less now since reactions with organics and infiltrating precipitation have been occurring over time. The pH of the waste averaged 3.5, and ranged from 1 to 8.1, depending on the composition of the waste at the sampling location.

Selection of the materials to be used in the chemical compatibility program was based on a literature search on chemical resistance of polymeric materials. Based on the very low pH of the waste, polyethylene materials were selected. However, the literature review indicated that the organic compounds in the waste could be soluble in polyethylene, leading to a decrease in strength and an increase in ductility. Furthermore, the polyethylene could oxidize in the presence of the waste, leading to possible environmental stress cracking. Accordingly, both chemical exposure and environmental stress cracking tests were conducted on the polyethylene materials proposed for use in the cover system.

Due to the unsaturated conditions in the waste, it was not possible to obtain enough liquid from within the pits to perform laboratory analysis. However, a waste-derived liquid was prepared from samples of the waste for use in the chemical compatibility program. This waste-derived liquid (WDL) had a pH of less than one. Samples of the polyethylene geomembrane and geocell proposed for use were placed in exposure tanks containing both the waste-derived liquid and flowable tar. Polyethylene geogrid samples were not tested as the proposed material had a

higher density than the geomembrane and geocell materials, and hence was considered to be more resistant. However, it was agreed that any strength reduction noticed in the geomembrane and geocell samples would be applied equally in the design of the geogrid.

Figure 2 shows the influence of both waste-derived liquid and tar exposure on the geomembrane.

Figure 2. Chemical compatibility test results from geomembrane exposure tests in waste-derived liquid (WDL) and tar. While the data lacks a time dependent trend, softening of the polyethylene was observed upon initial contact with the waste.

The results of the exposure testing suggested that the polyethylene materials softened upon initial contact with both the tar and waste-derived liquid. Related properties such as puncture resistance and trapezoidal tear strength were similarly effected. Chemical concentration and elevated temperature appeared to influence the results of some of the exposure testing. However, the data lacked a time dependent trend, as shown in Figure 2 for the geomembrane testing.

To evaluate the effect of exposure on surface oxidation and related stress crack resistance, notched constant tensile load tests were performed. Samples of the geomembrane and geocell were retrieved from the waste exposure vessels after the samples were exposed to the waste-derived liquid for periods up to 120 days. The samples were then notched and placed in a surfactant bath. The samples were then loaded at a constant tension equal to 30 percent of the

materials yield strength. After 400 hours of exposure, the tests were terminated. No samples had tensile breaks prior to the 400 hour testing duration, suggesting that the stress crack resistance of the materials was still adequate following waste exposure.

Based on the results of the chemical compatibility program, reduction factors were included in the design of the reinforcement materials. Where waste exposure was considered to be possible, reduction factors of up to fifty percent were used in relevant design properties such as tensile strength and puncture resistance. In the reinforced earth structures, waste exposure was not anticipated, as these structures were placed above the barrier layer and/or outside the limits of the cover system. Accordingly, the chemical degradation reduction factors used in the design were typical values for conventional structures.

## 5 CONSTRUCTION

Extensive coordination was required during construction of the remedial action due to the complexity of the site and the schedule constraints of the project. In order to meet the project schedule, portions of the cover system had to be completed in phases, which caused some minor problems, as discussed below.

The geogrid reinforcement for the cover system over the more stable pits was constructed with two layers of uniaxial reinforcement placed orthogonal to one another. Connections at the end of each geogrid roll were provided by Bodkin joints. Adjacent geogrid panels did not have any permanent mechanical connections. This was found to be somewhat problematic, as additional care was required during placement of the overlying gas collection sand to minimize geogrid separation. After the connections were made, the geogrid was covered with sand and then pull taut using a backhoe to pull on the free end of the geogrid as shown in Figure 3.

Figure 3- Each geogrid panel was pulled taut by anchoring one end in soil and pulling on the free end with a backhoe.

A geocell reinforcement layer was constructed over the pits containing high percentages of drilling muds. While the construction of this reinforcement layer proceeded at a slower pace than the geogrid reinforcement, it did provide an immediate platform to support load. As the bearing capacity of the underlying drilling mud was quite low, the geocell provided load distribution, increasing the overall bearing capacity of the cover system.

A total of three reinforced earth structures were constructed at the site. One of the structures was necessary to provide a working pad for construction of the subsurface vertical barrier. This reinforced earth structure had to support the excavator with a gross operating weight of 1,100 kN that was used to dig the soil-bentonite cutoff wall. Another reinforced earth structure at the site had to span a portion of completed cutoff wall. Due to concerns that the

stress of the reinforced earth structure on the underlying soil-bentonite cutoff wall would lead to excessive deformation of the wall due to consolidation of the cutoff wall backfill, a flexible wall fascia was selected. As shown on Figure 4, the fascia consisted of galvanized wire baskets used to form a geogrid wrap-back. Each reinforced earth structure on the site used this type of facing. In one instance during construction, the wrap-back was not sufficiently tensioned, which led to deformation of the wall fascia during compaction of the wall backfill. Although the deformation was unsightly, the integrity of this wall was not compromised.

Figure 4- One of the reinforced earth structures completed during construction. Galvanized wire baskets were used to form the geogrid wrap-back earth structures.

## 6 SUMMARY

The chemical compatibility testing program performed during the design phase for this hazardous waste site remedial action provided several lessons. Although the literature can provide insight on many polymer degradation mechanisms, actual testing of the materials is required for competent design. The exposure testing performed to assess chemical compatibility allowed rational formulation of degradation reduction factors for use during the design, thereby limiting the use of conservative assumptions.

Construction observations also provided lessons. The techniques used to tighten the geogrid were successful in that the geogrid was not damaged during installation. Geocell was found to be an acceptable reinforcement over very soft materials. It became clear during construction of the reinforced earth structures that specifications need to clearly describe the tensioning of the wrap-back portion of the geogrid for acceptable construction of the wall fascia.

# Evaluation of a Geogrid-Reinforced Slope Subjected to Differential Settlements

**ABSTRACT:** A geogrid-reinforced toe buttress was constructed in 1987 under the direction of the Environmental Protection Agency (EPA) in order to enhance the stability of the southeastern slopes of the Operating Industries, Inc. (OII) Landfill Superfund site. The landfill is located approximately 16 km east of downtown Los Angeles, in an area of high seismicity. The front of the approximately 4.6 m high, 460 m long toe buttress was founded on concrete piers. However, as the back of the reinforced slope was founded on waste, the structure has been subjected to more than 0.6 m of differential settlements since its construction. Finite element analyses were performed to evaluate the long-term integrity of the geogrid reinforcements under the loads induced by 30 years of additional differential settlements followed by the design earthquake. The calculated maximum strains in the geogrid reinforcements after the long-term static and design seismic loadings are well below the allowable strain, indicating that the integrity of the toe buttress should be maintained even when subjected to large differential settlements and severe earthquake loads.

**KEYWORDS:** Finite Element Analysis, Landfills, Reinforcement, Seismic Loads, Settlement Analysis.

## 1 INTRODUCTION

A geogrid-reinforced toe buttress was constructed in 1987 under the direction of the Environmental Protection Agency (EPA) in order to enhance the stability of the southeastern slopes of the Operating Industries, Inc. (OII) Landfill Superfund site. The toe buttress is immediately adjacent to a residential development. The waste slopes behind the toe buttress are up to 37 m high, with intermediate slopes between benches up to 18 m high and as steep as 1.3H:1V. The approximately 460 m long, 4.6 m high toe buttress was founded on concrete piers at the front of the buttress and reinforced using HDPE geogrids. However, as the back of the reinforced buttress was founded on waste, the toe buttress has been subjected to significant differential settlements since its construction.

A thorough evaluation was undertaken to assess the long-term integrity of the reinforced toe buttress and, consequently, the stability of the southeastern landfill slopes behind the toe buttress. Analyses calibrated on the previous performance of the toe buttress were used to predict its future performance considering 30 years of additional settlement followed by the design (maximum credible) earthquake. The analyses of the toe buttress included three distinct components: (i) interpretation of monitoring data to evaluate the history of differential settlements in the toe buttress area and to project the future differential settlements to which the structure will be subjected over the next 30 years, (ii) analysis of the

global stability of the southeastern slopes of the landfill, assuming that the internal integrity of the toe buttress is maintained; and (iii) evaluation of the internal integrity of the geogrid-reinforced toe buttress, subjected to the predicted long-term differential settlements followed by the design earthquake, using nonlinear finite element analyses.

The scope of this paper is limited to some aspects of the element evaluation. Subsequent publications will present further aspects of the long-term and seismic evaluation of the geogrid-reinforced toe buttress. The finite element analyses presented herein were performed in three sequential phases: (i) toe buttress construction, modeled by sequentially activating soil and bar elements in the reinforced soil zone; (ii) development of differential settlements beneath the toe buttress, simulated by imposing incremental displacements at the base of the reinforced soil mass; and (iii) earthquake loading, modeled pseudo-statically by applying horizontal body forces, representing the maximum average acceleration estimated from a finite element site response analysis, to the reinforced soil mass.

## 2 BACKGROUND INFORMATION

Schematic profiles through the toe buttress and the waste slope along the southeastern perimeter of the OII Landfill are illustrated in Figure 1. Reinforced cast-in-place concrete piers were constructed along the roadway which

was located at the toe of the landfill, along the property line, in areas where the natural ground surface continued to slope downward beyond the property line (Figure 1a). Piers were not installed in areas where the ground surface was level beyond the toe of the waste slope (Figure 1b). A total of 201 piers, 0.9-m in diameter, were installed at 1.8-m center to center spacing along approximately 360 m of the 460 m long toe buttress.

An assessment of the available information on the geometry of the bottom of the waste beneath the toe buttress was undertaken to aid in the toe buttress global stability evaluation. The logs for the 201 concrete piers drilled along the toe buttress, along with historical aerial photos and limited data from borings through the waste, provided relevant information regarding the depth of the waste in the toe buttress area. This available information indicated that the bottom of the waste in the vicinity of the toe buttress area slopes down at an approximately 1H:1V inclination from the property line into the landfill.

Visual observations and survey data indicate that, since its construction in 1987, significant differential settlements have taken place over the width of the toe buttress along most of its alignment. The presence of the concrete piers under the front edge of the buttress and the increasing thickness of the waste towards the back of the buttress both contributed to the substantial differential settlements observed over the width of the toe buttress. Settlement profiles at eight stations along the toe buttress were measured in October 1992 and in April 1996. The results from the 1996 survey showed that, while the differential settlement rate at most of the stations along the toe buttress has decreased since 1992, significant differential movements were still occurring.

Because the settlement surveys were not tied to an external reference, it was assumed that the elevation of the toe buttress surface immediately above the drilled piers was fixed. The settlements monitored at the back of the toe buttress were projected forward in time to evaluate the potential for future settlements. Settlement was projected for each individual cross section as a straight line on a semi-logarithmic plot. The differential settlements projected 40 years beyond the end of construction (until year 2027) was less than 1.17 m for every cross section but one. For Cross Section 3 the projected differential settlement was 1.98 m. However, because of the inconsistency of the data for Cross Section 3, the projected differential settlement of 1.98 m for this section was considered to be an outlier. A differential settlement of 1.17 m was considered a conservative projection of the settlement at the back of the toe buttress over the next 30 years for the purpose of evaluation of the long-term integrity of the toe buttress. Nevertheless, in response to EPA comments, the performance of the toe buttress when subjected to a projected differential settlement of 1.98 m was also evaluated.

Figure 1: Typical profiles of the toe buttress at the OII Superfund Landfill.

### 3 MATERIAL PROPERTIES

The reinforcement elements used in the toe buttress were Tensar SR2 geogrids. Manufacturing of these reinforcement products had been discontinued by the time of this investigation. Consequently, the geogrid material properties needed for the analyses undertaken in this study were evaluated primarily on the basis of information available from the literature on this type of geogrid reinforcement. This literature information was supplemented with creep tests performed on archived geogrid samples provided by the geogrid manufacturer. A 10 percent limiting strain was established from the literature as a conservative estimate of the allowable geogrid strain for long-term static loading of this reinforcement (Bonaparte and Berg, 1987). A 20 percent limiting strain was established from the literature as the allowable geogrid strain for rapid earthquake loading (McGown et al., 1984). The laboratory testing program performed as part of this investigation included wide width tensile tests and creep tests followed by rapid loading to failure. The main objective of this testing program was to address concerns expressed by EPA that

sudden loading after an extended period of creep could reduce the allowable geogrid strain to a value less than that obtained from wide width testing. However, the test results verified that an allowable strain of 20 percent in the geogrid was applicable to the case of static creep followed by rapid seismic loading.

Construction records indicated that the toe buttress fill is a sandy gravel classified as GP using the Unified Soil Classification System. Specifications required a minimum relative compaction of 95 percent, based on modified Proctor compaction test, except within 0.61 m of the toe buttress face. The constitutive relationship used in the finite element analyses to model the backfill behavior is the hyperbolic model proposed by Duncan, et al. (1980). Hyperbolic model parameters for the backfill material were obtained from triaxial test results reported in the literature for a sandy gravel of similar grain size distribution and compaction characteristics (Zornberg and Mitchell, 1994). The parameters for the gravel constitutive model obtained from these triaxial test results are presented in Table 1.

As a component of the comprehensive investigation of the seismic performance of the OII landfill of which this investigation was part (GeoSyntec, 1996), a field sampling and laboratory testing program was undertaken to characterize the static and dynamic mechanical properties of the waste at the OII landfill. Direct shear test results were used to determine the shear strength properties of the waste material for the finite element analyses presented herein. Simple shear test results were used to define the hyperbolic stress-strain parameters required to characterize the behavior of the waste material in the finite element analyses. The hyperbolic parameters used in the finite element analyses to characterize the waste material are summarized in Table 1. Based upon data from the field investigation, a uniform unit weight of 15.7 kN/m<sup>3</sup> was used for the solid waste material in the analyses.

#### 4 FINITE ELEMENT EVALUATION OF THE TOE BUTTRESS

The integrity of the reinforced toe buttress subjected to the projected differential settlements followed by the design earthquake loading was evaluated via finite element analysis. The analysis was performed using the finite element code GeoFEAP developed at the University of California at Berkeley for analysis of geotechnical problems (Espinoza et al., 1995). Both material and geometric nonlinearity were considered in the analysis in order to account for the constitutive behavior of the materials and for the large displacements. The strains induced in the geogrid reinforcement were modeled using three sequential analyses: (i) construction

of the toe buttress, (ii) gradual increase of differential settlement, and (iii) earthquake loading.

The finite element mesh used in the analyses consisted of 1082 nodes, 1028 plane strain elements for representation of soil and waste, and 140 bar elements for simulation of the reinforcements. A relatively fine mesh discretization between reinforcement layers was found essential for the proper representation of the behavior of the soil layers.

Table 1. Hyperbolic soil parameters for the backfill and waste materials

Parameter	Parameter definition	Backfill	Waste
$K$	Young's modulus coefficient	913	212
$n$	Young's modulus exponent	0.6	0.61
$R_f$	Failure ratio	0.64	0.7
$c$ (kPa)	Cohesion	0.0	28.7
$\phi_0$ (°)	Friction angle at 1 atm.	46.1	31
$\Delta\phi$ (°)	Friction angle reduction parameters	5.3	0.0
$K_B$	Bulk modulus number	250	212
$m$	Bulk modulus exponent	0.8	0.61
$K_{ur}$	Unload-reload modulus coefficient	1485	428
$K_\theta$	At-rest lateral earth pressure coefficient	0.35	0.4

Construction of the toe buttress was modeled by sequentially activating soil and bar elements in the reinforced soil zone, as illustrated in Figure 2. Tensile strains were induced in the reinforcement during construction by the selfweight of the backfill material. The maximum reinforcement strain estimated in the construction analysis occurs in reinforcement level 7, located 2.7 m above the base of the 4.57 m high reinforced slope. The maximum strains that develop during construction in the geogrid reinforcements are very small, with a maximum strain of less than 0.4 percent. Figure 3 shows the strain distribution computed in reinforcement level 7 during the different stages of construction of the toe buttress. The different stages indicated in this figure correspond to the

placement of the soil layers during construction simulation.

The second phase in the finite element modeling of the toe buttress consisted of imposing differential settlement at the base of the reinforced soil mass, as illustrated in Figure 4. Strain and tension in the reinforcements were induced by progressively increasing the base settlements in a triangular pattern, with zero settlement at the front of the mesh and the maximum settlement at the back of the finite element mesh. A total of 2.0 m of differential settlement was imposed at the base of the finite element mesh to simulate the long-term differential settlement of 1.20 m projected for the surface of the toe buttress. The maximum geogrid strain computed after imposing this differential settlement occurs in reinforcement level 3, located 0.9 m above the base of the toe buttress. Figure 5 shows the strain distribution estimated in the reinforcement level 3 due to increasing differential settlements. The differential settlement was imposed considering ten intermediate stages.

Figure 2: Finite element simulation of the construction sequence of the toe buttress.

Figure 3. Estimated geogrid strains induced during construction.

Figure 4: Finite element simulation of the differential settlements in the toe buttress.

Figure 5. Estimated geogrid strains induced by increasing differential settlements.

The current (1996) average differential settlement at the back of the toe buttress is approximately 0.60 m. From the results shown in Figure 5, the maximum tensile strain in the geogrid reinforcements computed for the current condition is approximately 1.5 percent. Moreover, Figure 5 shows that the maximum tensile strain in the geogrid reinforcements computed for the long-term condition (i.e. after reaching 1.20 m of differential settlements on the surface of the toe buttress) is approximately 2.9 percent. Both the current and long-term geogrid strain levels predicted in the finite element analyses are well below the maximum static strain level of 10 percent established for the geogrid reinforcements. Extrapolation of the finite element results to larger strain levels indicates that it would require approximately 3.9 m of settlement between the crest of the toe buttress and the drainage ditch at the back of the structure to induce the

maximum allowable static strain of 10 percent in the geogrids. This exceeds by a factor of almost two the maximum long-term settlement of 1.98 m considered for Cross Section 3. As discussed previously, this magnitude of settlement was considered an outlier, but was addressed in response to EPA concerns.

To model the impact of seismic loading on the performance of the toe buttress, horizontal body forces corresponding to the maximum average acceleration estimated for the toe buttress area were applied to the active reinforced soil wedge, as shown in Figure 6. The design earthquake was a magnitude 6.9 earthquake on a blind thrust fault immediately below the site. A pseudo-static acceleration of 1.0 g, estimated in a finite element site response analysis as the maximum average acceleration of the toe buttress in the design earthquake, was used for the analyses presented herein. The earthquake-induced strains are most significant in the upper reinforcement layers of the toe buttress, in contrast to the results of the previous static phases of the analysis. Reinforcement level 9, located 3.66 m above the base of the 4.57 m high toe buttress, shows the maximum estimated tensile strain when the structure is subjected to the design pseudo-static seismic loading.

Figure 7 shows the strain distribution estimated in reinforcement layer 9 during application of the seismically-induced horizontal body forces. The strain distributions that correspond to the end of construction and to the long-term differential settlement are also shown in the figure (the 0.0 g cases). The final stage shown in the figure corresponds to the results obtained after applying the design earthquake loading (1.0 g). The magnitude of the maximum tensile strain in the reinforcement at this stage of the analysis is approximately 8.5 percent, considerably lower than the 20 percent allowable strain for combined static and dynamic loads. The 1.0 g pseudo-static seismic load induced a 6.7 percent strain increase in the reinforcement. Extrapolation of these results indicates that a seismic coefficient of more than 1.5 g would be required to induce an incremental strain of 10 percent in the geogrids (10 percent is the difference between the rapid and the creep limited allowable strains).

The numerical results obtained in the three phases of the finite element analyses show that the maximum geogrid strain estimated after each phase of the study does not occur at the same elevation. The maximum strain due to construction loading occurs at midheight of the reinforced toe buttress, while the maximum strain due to differential settlement occurs towards the base of the structure and the maximum strain due to earthquake loading occurs towards the top of the slope. The results of the finite element analysis presented herein show that the integrity of the toe buttress should be maintained even when the toe buttress is subjected to the projected long-term differential settlement followed by the design

earthquake loads. The predicted strain level in the geogrid reinforcement for the combined effect of these anticipated loadings is well below the allowable strains for combined long-term static and earthquake loading.

## 5 SUMMARY AND CONCLUSIONS

A geogrid-reinforced toe buttress was constructed in 1987 under the direction of the EPA in order to enhance the stability of the southeastern slopes of the OII Landfill Superfund site. The toe buttress is immediately adjacent to a residential development. The waste slopes behind the toe buttress are up to 37 m high with intermediate slopes between benches up to 18 m high and as steep as 1.3H:1V. The landfill is located 16 km east of downtown Los Angeles, in an area of high seismicity.

The approximately 4.6 m high, 460 m long toe buttress was built using sandy gravel as backfill material.

The front of the structure was founded on concrete piers. However, as the back of the toe buttress was founded on waste, the structure has been subjected to more than 0.6 m of differential settlements since the end of its construction. In response to concerns regarding the internal stability of the reinforced soil structure, finite element analyses were performed to evaluate the long-term integrity of the geogrid reinforcements under static and seismic loads. The analyses considered 40 years of settlement followed by the design earthquake. The finite element modeling evaluated the strains induced in the geogrid reinforcement considering both material and geometric nonlinearity. The analyses were performed in three sequential phases: (i) toe buttress construction, modeled by sequentially activating soil and bar elements in the reinforced soil zone; (ii) gradual increase in differential settlements, simulated by imposing incremental displacements at the base of the reinforced soil mass; and (iii) earthquake loading, modeled by applying horizontal body forces representing the maximum average acceleration estimated in a finite element site response analysis.

A total of 2.0 m of differential settlement was imposed on the base of the finite element mesh to simulate long-term differential settlement. The maximum strain in the geogrid reinforcements calculated after this long-term static loading is less than 3.0 percent, well below the allowable static strain of 10 percent. The calculated maximum geogrid strain induced by construction, long-term differential settlement, and earthquake loading is approximately 8.5 percent, well below the allowable strain of 20 percent established for rapid loading. The results of this study indicate that the integrity of the geogrid-reinforced toe buttress should be maintained even when subjected to large differential settlements and severe earthquake loads.

#### ACKNOWLEDGMENTS

This study was part of the seismic investigation undertaken at the OII Landfill. The support of New Cure Inc. (NCI), in particular of Mr. Kenneth Hewlett and Dr. Lester LaFountain, is gratefully acknowledged. The review and suggestions provided by Dr. David Espinoza of GeoSyntec and the contributions of the members of the Seismic Working Group organized by NCI and the EPA Technical Review Panel are also greatly appreciated.

# High-Strength Aramid Geogrids to Prevent Sliding On Steep Landfill Basal Slopes

A. Plankel

Dipl.-Ing., Plankel, Pelzl & Partner, Lauterach, Austria

D. Alexiew

Dr.-Ing., HUESKER Synthetic GmbH & Co., Gescher, Germany

**ABSTRACT:** A landfill with steep basal slopes of 1V:2H is in the stage of filling. High-strength geogrids are required to ensure the sliding stability of the drainage gravel layers and parts of the waste. For some slopes aramid geogrids with 1200 kN/m and 550 kN/m ultimate tensile strength at less than 3 % ultimate strain have been selected. It is the first application of such geogrids as 'antisliding' reinforcement on landfill slopes. Formulation of the problem, general philosophy and considerations, and first measurement results are presented.

**KEYWORDS:** Geogrids, Landfills, Slope stabilization, Measurements, High-Strength

## 1 INTRODUCTION

For basal and capping systems of landfills multilayered structures consisting of soils and different geosynthetics are used. A world-wide overview of standardized solutions can be found, e.g. in Van Impe et al., 1996, the typical German solutions, which are similar to those in Austria, e.g. in Gartung, 1995, and alternative actual solutions e.g. in Alexiew et al., 1995, Alexiew and Sobolewski, 1997. All these 'sandwiched systems' have a common characteristic: they comprise some interfaces, in which the shear resistance could be lower than in the soils and geosynthetics themselves. The interface with the lowest resistance controls the sliding stability of multilayered slopes. If the shear resistance is not sufficient, the layers above this critical plane would slide downwards. In practice, a reliable solution is to lay an appropriate geogrid in the (soil)layers tending to slide on the critical plane. The geogrid has to be installed on the entire slope from the toe up to the crest, reinforcing throughout the layer, and anchored.

Recommendations are given e.g. in Alexiew, 1994, calculation procedures among many others in Koerner, 1994, Alexiew, 1994, and Alexiew and Sobolewski, 1997. The problem is shown in general in Figure 1, for a typical case.

## 2 GENERAL CONSIDERATIONS FOR REINFORCEMENT AGAINST SLIDING

### 2.1 Importance of Interaction ('Why a geogrid?')

A geogrid is recommended as reinforcement due to the high coefficient of interaction (bond coefficient) to the mineral layer to be reinforced and prevented from sliding.

The definition for geogrids (IGS, 1996) asks for mesh sizes larger than the constituents (bundles, strips, ribs etc.), which is the most important condition to ensure good interaction. Soil-grading related criteria are used also, e.g.  $B_{GG} \geq 3.5 \times d_{50}$  (Koerner, 1994, p. 338) or  $a \geq 1.67 \times d_{80}$  (DB AG-TL, 1997), where  $B_{GG}$  or  $a$  is the minimum mesh size

respectively;  $d_{50}$  and/or  $d_{80}$  is the grain size of soil for 50% and 80% passing, respectively. Contrarily to Koerner, 1994, p. 386 and Mannsbart, 1996, no geotextile or geocomposite without open aperture should be used because of the risk of insufficient bond, especially for saturated conditions accompanied by seepage pressure. For example, the use of woven geotextile as soil reinforcement in a multilayered system on a German landfill resulted in a general 'landslide' just around a month after installation. At the same time, geogrid reinforcements have been successfully used for both very long or very steep permanent slopes (Martin and Simac, 1995, Alexiew and Sobolewski, 1997).

### 2.2 Importance of Displacements and Strains

Simplified limit equilibrium analyses are mostly used for stability calculations, taking into consideration the driving and retaining forces along the entire slope, and resulting in one single scalar equation. The driving forces are generated by weight and seepage (and building machines in the construction stage), the retaining ones by friction, adhesion (which has to be assumed very carefully, if at all) and, if necessary for stability by the retaining force in the geogrid (Figure 1).

Despite some details, all calculation methods of this type usually have a common characteristic: all elements of the multilayered system are assumed to be absolutely stiff. Only force equilibrium is being analysed without taking into account displacements and strains.

Strictly speaking, such a concept is not fully correct (Long et al., 1994; Alexiew, 1994) Displacement compatibility (say limitation of sliding displacements in this case) is an important matter. Large displacements could result in reduction of interface shear resistance from 'peak' to 'residual' values, followed by loss of stability, or in tension stresses in the underlayered geomembrane, which is usually not allowed, etc.

Consequently, not only the strength, but the strain of a geogrid can control the design.

Figure 1. Geogrid reinforcement against sliding: typical case

From the theoretical point of view the ideal geogrid should mobilize the maximum tensile force at nearly zero strains, and should have zero additional long-term strain due to creep. Note, that the second condition (low creep) is more important (Alexiew, 1994), because the major part of short-term strains takes place usually during installation of the soil layer (Figure 1) by heavy equipment. During this process the layer tends to slide, and stresses the geogrid. In this way, until end of construction, the short-term strains are 'pre-consumed', tacitly compensated, and thus, of secondary importance. So, for a veneer slope, after completion only creep strain under the long-term constant load is of importance. Basal slopes are stepwise additionally loaded even after completion of drainage layer by the waste being filled, thus alternately short-term and creep strains can take place.

Geogrids, meeting perfectly all the 'ideal' conditions mentioned above, are not available yet. Nevertheless, a classification can be made in order of best-fitting the 'ideal geogrid':

- aramid (both short-term and long-term strains (creep) are extremely low);
- high-tenacity polyester (short-term strain is relatively low, long-term strain (creep) is very low);
- high-density polyethylene, drawn (short-term strain is low, long-term strain (creep) is relatively high).

### 2.3 Influence of Temperature

At the basal slopes of municipal waste disposals relatively high temperature can develop due to biological degradation of waste. Increasing temperature reduces the moduli and increases the creep tendency of geosynthetics, resulting in higher strains or creep rupture without increase of external load. Aramid and high-tenacity polyester are nearly insensitive to this phenomenon; for polyethylene and polypropylene the reduction of moduli and the increase of creep are noticeable.

## 2.4 Reliability of Design Calculations

As stated earlier, the most calculation procedures to determine the required force in the geogrid on a slope are based on simple equilibrium analyses. Advanced FEM-analyses are used by way of exception. Note, that the scatter of input parameters for design are of great importance for the results (e. g. required reinforcement force), and may have even a greater influence than the calculation method itself. In particular, a really exact stability calculation of a landfill basal slope seems very difficult because of feature of waste (scattering parameters, compaction, unsteady seepage etc.) Thus, assumptions and safety factors have to be set on the safer side (resulting in a stronger geogrid).

## 3. LANDFILL BÖSCHISTOBEL: STEEP MULTILAYERED BASAL SLOPES

### 3.1 Project Description

The landfill Böschistobel in the region Vorarlberg in Austria is located at the base of a steep mountain slope. This circumstance results in steep (1V:2H) and long (up to 160 m) slopes for nearly the half of the landfill area (Figure 2 and 3). The interface 'protective non-woven / HDPE liner' controls the sliding stability. The latter is insufficient not only due to slope steepness, but additionally due to horizontal base inclination required for drainage.

The slope multilayered system (Figure 4) is being constructed up from berm to berm depending on the filling of waste. More informations can be found in Fock and Plankel, 1996.

Figure 2. Situation of the Landfill

Figure 3. Multiple-Berms-Slope-Design, Cross Section

Figure 4. Monitoring Profile

Two groups of stability analyses have been performed. The first one comprises only the local sliding stability of the slope with the drainage gravel layer. The second one comprises the global stability of slope, base and waste fill for different stages. The analyses resulted for slope 'A' (Figure 4) in a geogrid with 1200 kN/m ultimate tensile strength (UTS), and for slope 'B' in a geogrid with 550 kN/m UTS.

### 3.2 Aramid Geogrids

For the entire slope 'A' (Figure 4 and position 3 in Figure 2) an aramid geogrid with 1200 kN/m UTS (Fortrac® 1200/50-10) was selected.

This geogrid had been primarily developed and applied to solve problems with overbridging sinkholes already in 1993 (Alexiew, 1997), being the first one in this class of strength. For slope 'B' an aramid geogrid with an UTS of 550 kN/m (Fortrac® 550/100-30) was chosen (position 2 in Figure 2), and a polyester geogrid with 550 kN/m UTS also on adjacent sections.

Both aramid geogrids are knitted (unfortunately, in Fock and Plankel, 1996, they are incidentally described as woven). Even the 1200-geogrid meets the criterion (IGS, 1996) for constituents to be thinner than the mesh size.

The exact stress-strain curves of the geogrids are shown in Figure 5.

Figure 5. Stress strain curves for the aramid geogrids 550 and 1200

Due to their mechanical behavior (very high tensile stiffness and very low creep strain) the aramid geogrids are close to the 'ideal' as mentioned in Section 2.2. Although the stability analysis applied does not take into consideration displacements and elongation, limitation of deformations to a possible minimum has been an important aim of design in this case according to the considerations in Section 2.2.

### 3.3 Measurement Program

At the slopes of the landfill Böschtobel a measurement program is being performed. The focal point in this paper is the behavior of the sections with the aramid geogrids: for the aramid geogrid 1200 the lower part (slope A) of the measurement profile MQ 1 on Figure 2, and for the aramid geogrid 550 the upper part (slope B) of MQ 2 in Figure 2.

The aims are:

- to register the strains of both aramid geogrids;
- to monitor the pressures in the gravel layer normal and parallel to the slope plane;
- to register the temperature in the geogrid-reinforced gravel layer (upper and lower side).

The data should clarify the real behavior of the aramid geogrids (e.g. are they really minimizing deformations on the slopes under increased temperature also), the correctness of design assumptions and simplified dimensioning procedures. The strains of the geogrids are measured by strain gauges fixed directly on them, with a measurement basis of 1000 mm and 0.01 mm sensitivity, which is important for high-modular geogrids. The pressures in the gravel layer are monitored by pneumatic cells both normal and tangential to the slope. The measurements were started in January 1996 parallel to waste filling. The gauges are depicted in Figure 4.

Because the filling of waste progresses slower than expected, a final data set is not available yet. Nevertheless, the

data are presented so far because of the lack of any information on the behavior of extremely high-strength geogrids under the conditions described.

### 3.4 Test Results and Preliminary Analysis

The bulk density of the waste was determined by a comparison of volume and registered weight. The waste volume in different stages of the filling was determined by geodetical survey. The average bulk density amounts to  $\gamma = 10 \text{ kN/m}^3$  and  $\gamma = 11 \text{ kN/m}^3$  for lower and larger fill heights, respectively. Thus, for the 'vertical load' lines in Figures 7 and 8  $\gamma = 10 \text{ kN/m}^3$  is set. Note, that for design calculations  $\gamma = 12 \text{ kN/m}^3$  has been assumed.

Filling of waste and temperature on top (T 1) and bottom (T 7) of the drainage layer is shown in Figure 6. After a rapid raise of temperature within the first two months the temperature stayed almost constant during a period of 1.5 years. The temperature sensor on the geogrid (i.e. bottom of the drainage layer) shows values from 30 to 36 °C, the sensor on top of the drainage layer shows temperatures from 32 to 39 °C.

Figure 6. Development of temperature and vertical load

The strains reached a maximum of  $\epsilon = 0,61 \%$  in the aramid geogrid 1200/50-10 on slope 'A' at a vertical load of approximately  $120 \text{ kN/m}^2$  (Figure 7). Although in winter 1996/97 the load was increased by 15 - 20  $\text{kN/m}^2$  (i.e. 15 - 20 %) the strain in the geogrid did not increase significantly. Under 'vertical load' the vertical load just over the points E 1 and E 5 respectively is mentioned.

In the aramid geogrid 550/100-30 (slope 'B') the strains reached a maximum of  $\epsilon = 0,32 \%$  at a vertical load of  $50 \text{ kN/m}^2$  (Figure 8).

At the beginning of the filling of waste strains increased rapidly up to 0,2 %. From July to December 1996 strains increased up to  $\epsilon = 0,28 \%$  without increasing of load.

Figure 7. Development of vertical load above E 1 and strain in geogrid 1200/50-10

After December 1996 the load was increased by approximately 12 kN/m<sup>2</sup> (i.e. ~ 20%), the strains in the geogrid increased only by 10 - 15 %.

It is known, that the aramid geogrids used are practically insensitive to the registered temperatures of about 30 °C to 35 °C and to creep/relaxation also for the period treated. Therefore, the short-term stress-strain relations may be used to determine the tensile forces in this case exactly enough for engineering purposes.

Accordingly, the tensile force is around 400 kN/m for slope A and around 45 kN/m for slope B. The corresponding stress ratio SR (=mobilized force/UTS) amounts to SR<sub>A</sub> = 30 % (geogrid 1200) and SR<sub>B</sub> = 8 % (geogrid 550). Thus, the relation of stress ratios is SR<sub>A</sub>/SR<sub>B</sub> = 30 %/8 % = 3.75.

On the other hand, the ratio of mobilized force vs. vertical load (say waste height above measurement point)  $\zeta$  is for slope A  $\zeta_A = 400/115 = 3.48$  and for slope B  $\zeta_B = 45/50 = 0.90$ , respectively (dimensions are intentionally ignored). Thus, the relation  $\zeta_A/\zeta_B$  amounts to  $3.48/0.90 = 3.87$ , which is nearly equal to 3.75 (=SR<sub>A</sub>/SR<sub>B</sub>, see above). Consequently, the registered response of both aramid geogrids is analogous, and data sets harmonize well.

For slope A the stress ratio of about 30 % is in acceptable agreement with the simplified calculation methods, parameter assumptions and (relatively conservative) factors of safety applied in design (Sections 2.4 and 3.1).

For slope B the registered stress ratio of around 8 % is surprisingly low to date, and the value of  $\zeta_B$  also. Underestimation of shear interface resistance on the textured HDPE-liner here, or overestimation of the load by waste could be the reasons. It is quite possible that the waste redistributes the load downslope, or that the geogrid needs more time for full response corresponding to 'delayed' waste self-compaction. The development of load by waste, geogrid strain

Figure 8. Development of vertical load above E 5 and strain in geogrid 550/100-30

and stresses in the gravel are shown in Figure 9 for the zone E 5 (Figure 4). The pressure cells indicate a 'delayed' increase of stresses without increase of waste height, in the same periods, which seems to be an indication of time-depending redistributions in the waste.

A vertical load (i.e. weight of waste) of 50 kN/m<sup>2</sup> should result in a pressure normal to the slope plane of  $\sigma_n = 50 \cos 26,5^\circ = 44,7$  kN/m<sup>2</sup> and pressure parallel to the slope plane of  $\sigma_t = 50 \sin 26,5^\circ = 24,4$  kN/m<sup>2</sup>. The measurements in June 1997 show values of  $\sigma_n = 55$  kN/m<sup>2</sup> and  $\sigma_t = 19$  kN/m<sup>2</sup>, indicating a good correspondence with theoretical values (with some delay).

Figure 9. Development of strain, tangential pressure, normal pressure and vertical load above E 5

#### 4. CONCLUSION

Aramid geogrids with 1200 kN/m and 550 kN/m UTS and ultimate strain of 2 % to 3 % have been used for the first time on steep landfill basal slopes.

The aim is to ensure local (gravel layer) and global (waste fill) stability against sliding at low displacements. Pressures, strains and temperature are being measured.

The following conclusions can be made to date:

- the geogrids used really ensure sufficient stability at very low displacements at increased temperatures
- the good agreement of geogrid strains in the drainage gravel layer and progress of waste falling on it indicates a perfect bond of the geogrids
- the stress ratio of the 1200-geogrid on a slope with smooth HDPE-liner corresponds well to the design assumptions; the simplified design calculations (equilibrium of forces only, displacement compatibility ignored) seem to be acceptable, at least for the extremely high-modulus reinforcement used
- the stress ratio of the 550 geogrid on a slope with textured HDPE-liner is lower than expected; high interface shear resistance and/or downslope waste load redistribution could be the reasons
- the measured pressures in the drainage layer correspond well with the calculated ones by simple equilibrium analyses.
- the temperatures in the drainage layer are relatively low for a municipal landfill base (convection on the slope)

The measurements are going on. Further long-terms data will be reported later.

# Landfill Closure Using Reinforced Soil Slopes

Kenneth W. Cargill

Associate, GeoSyntec Consultants, Atlanta, Georgia, USA

Kara L. Olen

Formerly of GeoSyntec Consultants, Atlanta, Georgia, USA

**ABSTRACT:** Through the innovative use of reinforced soil slopes and a shingled geomembrane liner, a steep-sided hazardous waste landfill was capped in an economical manner. This paper presents a case history describing the technical solution to the difficult task of construction of a capping system over a steep waste mound which was up to 42 m above the surrounding ground surface and where only limited regrading was possible. Stability issues associated with the design of reinforced soil slope modules and the arrangement of modules to achieve global stability are discussed.

**KEYWORDS:** Caps and closures, Case study, Geogrids, Reinforcement, Steep slope.

## 1 INTRODUCTION

The Town of Babylon Landfill is located in Suffolk County, Long Island, New York. The site, an inactive hazardous waste landfill, covers approximately 19 ha and has waste deposits down to 21 m below and up to 42 m above the surrounding ground surface. The steepness of existing waste slopes, some of which were up to 1 horizontal to 2 vertical (1H:2V) and which averaged steeper than 2H:1V, prevented capping using a conventionally designed final cover system due to restrictions on waste regrading. Regrading of the landfill to achieve slopes on which a conventional cover system could be constructed was not possible due to limits on the final landfill height and lack of alternate landfilling locations for the excavated waste.

In consultation with the New York State Department of Environmental Conservation (NYSDEC), an innovative system of reinforced soil slopes was selected from alternatives presented in a focused feasibility study (GeoSyntec, 1992). The Record of Decision described these slopes as, *"...a multiple-tiered reinforced soil wall bench system. Each bench will be covered with a final cover system..., using a geomembrane as the hydraulic barrier, with additional geomembrane sections incorporated within the reinforced soil walls to create a shingled hydraulic barrier over the covered slopes."*

The final closure system design for the steeper slope sections incorporated a shingled geomembrane within

geogrid-reinforced soil slope modules. The project included a total length of approximately 4,300 m of these modules which were up to 6.1 m high. In the most critical section, the reinforced soil slope modules were stacked to a total height of about 36 m. The design minimized infiltration of precipitation and release of landfill gas even though the geomembrane was not continuous throughout the cap. A discussion of the final closure system in conventionally capped areas and how the total system functioned to minimize infiltration, control landfill gas release, and manage surface-water runoff is presented elsewhere (Cargill and Olen, 1997). The area of final closure at the Town of Babylon Landfill is shown in Figure 1 where reinforced soil slopes are highlighted.

## 2 REINFORCED SLOPE MODULE DESIGN

While stability is the most important factor in the design of the reinforced soil slopes, other factors also played a role in the final selection of a slope cross section profile at the Town of Babylon Landfill. Minimization of excavation was required due to the classification of the landfill as a Class 2 inactive hazardous waste site. Minimization of waste excavation required consideration of additional fill requirements, landfill boundaries, and cost. These requirements were optimized in the final design by establishing and using a variety of soil slope standard sections, or modules, which could be stacked as required to closely match the existing slopes.

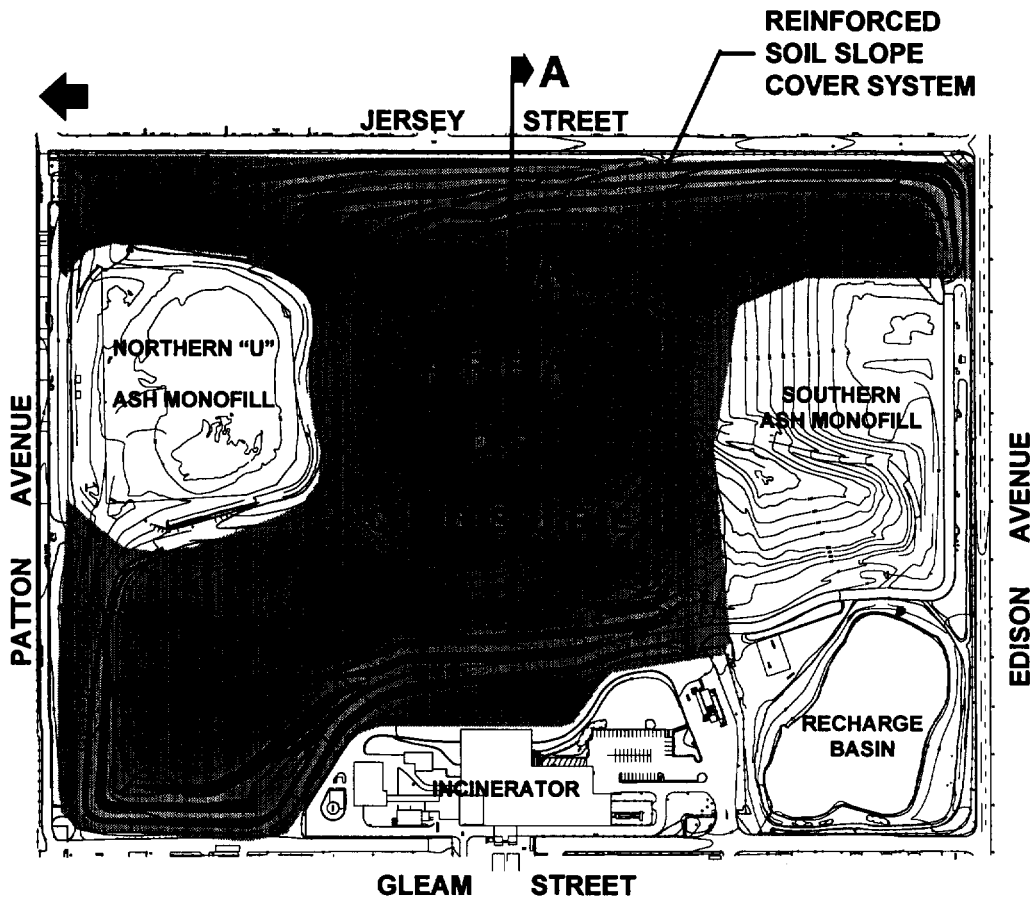

Figure 1. Town of Babylon Landfill area of closure and location of reinforced soil slopes.

These modules were first designed for individual stability and then assembled into stable configurations of multiple modules best fitting the existing landfill slope and also minimizing both required excavation and placement of additional fill behind the reinforced soil slopes. The face slope of the three basic modules used in the design are 1H:2V, 1H:1.5V, and 1H:1V. A standard maximum height of 6.1 m was chosen for the modules in order to comply with the state requirements (NYSDEC, 1988) that the vertical distance between drainage swales not exceed 6.1 m for slopes steeper than 3H:1V. A standard top bench width of 6.1 m was selected to provide space for a drainage swale between the slope shoulder and the toe of the next slope module. This width also provided space for equipment to maneuver

during slope construction and access for vehicles during post-closure maintenance.

The arrangement of the various slope modules was dependent on the geometry of existing landfill slopes on which they were built. Where possible, preference was given to building steeper modules at the lower elevations and less steep modules higher on the landfill in order to provide a more gradual tie-in to the flatter slopes at the top of the landfill. However, the specific geometry of the existing slopes often were better suited to a configuration of steeper slopes at the higher elevations. Thus, the final design contained both configurations.

The method of analysis used for design of reinforcement was a two-phase process. First, a preliminary reinforcement design based on the methodology presented in the Federal Highway

Administration (FHWA) Geotextile Engineering Workshop (1989) was performed. The FHWA method is based on design charts from which a horizontal tensile reinforcement force and length of reinforcement are calculated. Second, the preliminary design was analyzed in detail by the methodology incorporated in the computer slope stability program XSTABL (Sharma, 1992). The purpose of the detailed design was to minimize the module section, and thus minimize any required waste excavation, and to check the actual factor of safety based on selected reinforcement length and spacing. If the actual factor of safety did not meet the required minimum factor of safety, reinforcement spacing and lengths were adjusted and the second step repeated.

Material properties selected for the reinforced soil slope design were based on laboratory testing of locally available soils and typical geosynthetic reinforcement strengths. The laboratory testing of a bank-run, silty sand from a local pit indicated a minimum friction angle,  $\phi$ , of  $31^\circ$  and a cohesion intercept of  $184 \text{ kN/m}^2$ . For the slope design,  $\phi = 31^\circ$  and  $c = 0 \text{ kN/m}^2$  were used. The allowable geosynthetic tensile strength selected for design after reduction for creep and other typical factors of safety for construction and environmental factors was  $20.4 \text{ kN/m}$ . Based on a review of geosynthetic product literature, this value was considered reasonable and attainable. As a part of the contract specifications, the contractor was required to submit evidence that the geosynthetic reinforcement used met the minimum allowable strength. The contractor selected high-density polyethylene (HDPE) geogrids.

### 3 MODULE STABILITY

Each of the slope modules was initially designed for a minimum factor of safety of 1.25. This factor of safety was recommended in the focused feasibility study and approved by NYSDEC. It was considered adequate since the reinforced slopes were constructed on existing stable waste slopes and a detailed program of construction quality assurance was planned. The actual factor of safety was greater than the design value of 1.25 because of the actual number of geosynthetic reinforcement layers. The final factor of safety for each module was calculated based on the required tension forces indicated by the XSTABL analysis.

The preliminary maximum reinforcement spacing for each module was calculated using the FHWA method for a  $FS = 1.25$  and resulted in the following:

Module	Upper 2/3 of Slope	Lower 1/3 of Slope
1H:2V	1.36 m	0.82 m
1H:1.5V	1.84 m	1.10 m
1H:1V	2.83 m	1.70 m

In order to use the reinforcement efficiently, a secondary reinforcement was specified to wrap individual steps in the slope face and where primary reinforcement was not required. To maintain a uniform slope appearance and provide slope face stability and erosion resistance, a maximum secondary reinforcement spacing of 0.46 m was selected. The final spacing selected for primary reinforcement was:

Module	Upper 2/3 of Slope	Lower 1/3 of Slope
1H:2V	0.91 m	0.46 m
1H:1.5V	1.37 m	0.91 m
1H:1V	1.37 m	1.37 m

Using the above final primary reinforcement spacing and a reinforcement length of 3.96 m, the factors of safety for reinforcement and for block sliding of the slope modules was calculated by XSTABL. Results of the calculations are summarized below:

Module	Reinforcement Factor of Safety	Sliding Block Factor of Safety
1H:2V	2.6	2.5
1H:1.5V	2.0	1.8
1H:1V	2.0	1.3

### 4 MODULE CONSTRUCTION

Figure 2 shows the arrangement of the primary and secondary reinforcement in a slope module. The primary reinforcement consisted of a uniaxial HDPE geogrid and the secondary reinforcement was a biaxial HDPE geogrid. The shingled geomembrane hydraulic barrier, gas management components, and the drainage swale atop each module are also indicated in the figure.

Figure 2. Slope module geometry and reinforcement arrangement.

The secondary reinforcement was installed at each slope face setback and was used to wrap the slope face for erosion protection as shown in Figure 3. Figure 3 also shows how the secondary reinforcement was used to wrap the slope face and support a wedge of topsoil within a seeded erosion control mat until vegetation could be established.

Figure 3. Typical reinforced soil slope face wrap.

Slope face support during construction was provided by a welded wire fabric which was allowed to remain in place after construction. Figure 4 shows the wire mesh formwork and initial vegetation on the slope face.

Figure 4. Reinforced soil slope faces with secondary reinforcement wrap and wire mesh formwork.

A reinforced soil slope module under construction is shown in Figure 5. This module is located on the eastern side of the landfill. The level of primary and secondary reinforcement shown in the photograph is approximately 10 m above the street level shown on the right in the photograph and illustrates the proximity of the landfill to the public road. The reinforcement is in the second module going up the slope.

Figure 5. Module construction on eastern landfill slope looking north.

The system of reinforced soil slope modules under construction on the western slope is shown in Figure 6. The photograph illustrates the proximity of the landfill to the incinerator facility shown on the left in the photograph and the existing slope steepness.

Figure 6. Module system construction on western landfill slope looking north.

## 5 GLOBAL STABILITY

The final arrangement of the reinforced soil slope modules in plan view for the Town of Babylon Landfill is shown in Figure 1. Once the system of reinforced soil slope modules was assembled in the most efficient manner for cut and fill minimization, the global stability of the overall slope was also calculated using XSTABL. For this calculation, a waste strength of  $\phi = 28^\circ$  and  $c = 5 \text{ kN/m}^2$  was used. This waste strength was selected based on published values (Landva and Clark, 1990, Singh and Murphy, 1990) and a back analysis of several existing

slopes at the Town of Babylon Landfill. A critical cross section of the assembled reinforced slope modules on the eastern side of the landfill as indicated by Section AA in Figure 1 is shown in Figure 7 along with the trace of the potential failure surface. The calculated factor of safety for this surface was 1.3.

A photograph of the completed reinforced soil slopes on the eastern side of the landfill looking west is shown in Figure 8. Three soil slope modules are shown stacked in the photograph. A photograph of the completed reinforced soil slopes on the western side of the landfill looking north is shown in Figure 9. This is approximately the same area shown in Figure 6 during construction. Also seen in the photograph is the layout of drainage swales and downchutes for storm water management of the landfill final closure system.

## 6 CONCLUSIONS

This paper has presented a case study of how geosynthetic reinforced soil slopes were used as a component of a final closure system for a hazardous waste landfill. Through an arrangement of individually stable reinforced soil slope modules, excavation of waste was minimized and global slope stability was maintained. The reinforced soil slopes containing a shingled geomembrane functioned with conventionally capped waste areas to minimize landfill gas release and control surface water runoff. The design illustrates an innovative use of reinforced soil slopes which regulatory agencies and designers should consider for application at other sites with existing steep slopes and where excavation must be minimized.

## ACKNOWLEDGEMENTS

The support of GeoSyntec Consultants during the preparation of this paper is gratefully acknowledged. In addition, the authors wish to thank Ann Taylor for assistance in preparation of figures and Joyce Thomas for preparation of text.

**ABSTRACT:** Slope stability is an important concern in the design of waste containment facilities equipped with sophisticated lining and cover systems. An engineering solution consists of placing a high-strength geosynthetic reinforcement into the cover layer above the low friction angle interface. In order to simulate in situ conditions of geosynthetic lining systems (low confining stress, gravity load control), an experimental research was conducted on an inclined plane apparatus with a large size testing box (100 cm x 70 cm x 30 cm). A numerical simulation of the laboratory experiments with a 2D Finite Element model and a 1D Finite Difference model was also carried out in order to provide a fine interpretation of experimental data.

**KEYWORDS:** Geosynthetic Lining System, Inclined Plane, Geosynthetic reinforcement, Finite Element Method, Finite Difference Method.

## 1 INTRODUCTION

Recent landfills usually include composite systems - more or less complex - made of soil layers (vener, drainage) and geosynthetics (geomembrane, geonet, geotextile) in order to isolate waste from environment.

Low storage capacities or small available areas lead sometimes to the choice of high angles and lengths for the waste fill slopes. This results in a potential sliding failure due to an insufficient shear strength or in an excessive deformation of components which, with a short or long term evolution of geosynthetics and interfaces parameters, can be harmful to the protection function. To avoid stability problems, a solution consists in reinforcing the geosynthetic lining system with a geosynthetic such as a geotextile or a geogrid.

This paper deals with reinforcement by inclusion of a geosynthetic within the soil layer. This technique of reinforcement has been investigated by means of an inclined plane apparatus devised at the Lirigm, which reproduces the field working conditions : low confinement and gravity load control.

Concurrently, two numerical models have been developed in order to provide a fine interpretation of experimental data. Validity of interface characterization on inclined plane device and the fact of taking into consideration interface nonlinearity in the models are evaluated by comparison with experimental data.

## 2 THE LABORATORY MODEL

The diversity of geosynthetics and the versatility of their combinations may increase significantly the complexity of liner systems. Fortunately, it is possible to get an insight into the mechanism of reinforcement by means of a relatively simple scheme.

A schematic side view of the test apparatus is shown in Figure 1.

Figure 1. Schematic view of the inclined plane apparatus.

The reference case, ie unreinforced, includes a compacted soil layer filling an orthogonal rigid box (a), a geomembrane placed on a rigid horizontal PVC support and connected to an anchorage device (b). The PVC support is fixed on a tilting base plane (c). The box is supported on the base plane by means of metallic rollers on both sides.

In the present case, the reinforcement consists in placing a geosynthetic halfway up the thickness of the soil (d). The anchorage device allows a variation of the reinforcement vertical position.

The system is sollicitated by tilting progressively the plane at low constant vertical rate (0.5°/mn for an inclination of 30°) - which assures quasi-static conditions. The global state of the system can be described by the angle of plane inclination, the relative displacement of the box and the maximal axial force mobilized within the different geosynthetics. A continuous monitoring of these parameters is made through suitable data acquisition devices.

The main features of the laboratory model are the low confinement which has a great influence on the behaviour of the soil and interfaces, the control by gravity load, the maximal sollicitation of the reinforcement without toe buttress effect which has to be considered in field cases.

The inclined plane apparatus allows also a direct measure of the peak frictional resistance of geosynthetic interfaces under low confinement (2.5 and 5 kPa) and an indirect estimation of the residual friction by means of a compression load cell placed at the toe of the testing box.

### 3 TESTS RESULTS

All tests on reinforcement by geosynthetic inclusion were conducted with the standard sand EN 196-1, at a dense state ( $D_r \sim 80\%$ ). The water content is about 2%.

Three geosynthetics were used as reinforcements :

- a non-woven needle punched geotextile, in PP (Gt TGX),
- a biaxial woven geogrid, in PET (Gg TFM),
- an uniaxial stretched geogrid, in HDPE (Gg TFS).

With these materials, it was possible to investigate the influence of some important parameters as axial tensile stiffness, interaction with soil and bending rigidity (flexibility).

The main mechanical characteristics of the materials and interfaces are summarised in Table 1. Inclined plane apparatus was used for interface characterization (shear stiffness  $k_s$  and friction angles  $\Phi$ ). The two geogrids have comparable axial tensile stiffnesses ( $J$ ) but the Gg TFS is less flexible, due to its structure. Among the 3 geosynthetics, the Gt TGX is the more flexible and extensible material.

Table 1. Mechanical parameters of geosynthetics and interfaces.

Interface	$k_s$ (kN/m <sup>3</sup> )	$\Phi_{peak}$ (°)	$\Phi_{res}$ (°)
Geomembrane/PVC	$10^5$	20	16
Sand/Geomembrane	$10^5$	27	21
Sand/Gt TGX	$10^3$	45	32
Sand/Gg TFM	$10^3$	45	32
Sand/Gg TFS	$10^3$	17	-
<b>Geosynthetic</b>	<b>J (kN/m)</b>		
Geomembrane	125		
Gt TGX	15		
Gg TFM	650		
Gg TFS	650		
<b>Sand (50-150 kPa) <math>C_{peak}=2.5</math> kPa, <math>\Phi_{peak}=39^\circ</math>, <math>\Phi_{res}=32^\circ</math> (<math>\sigma=5</math> kPa : <math>\Phi_{peak} \sim 47^\circ</math> - value extrapolated)</b>			

Figure 2. Relative displacement of the testing box for an increasing inclination.

Figure 3. Evolution of the load within the geomembrane.

Figure 4. Evolution of the load within the reinforcement.

The test plane is progressively inclined until 40°, the end of the test. In these conditions, general sliding of the testing box was observed before a 40° inclination for the reference case (without reinforcement) and for the Gg TFS unlike the Gt TGX and Gg TFM cases (Figure 2).

The evolution of the relative displacement of the box and the loads developed within the geomembrane and the reinforcement are shown in figures 2-4. The laboratory model response shows an initial phase (low inclination value) with a very low axial force developed within the geosynthetics (Figure 3: geomembrane, Figure 4: reinforcement). The tensile solicitation of the geosynthetics begins for an inclination of about 20°, which corresponds to the Geomembrane/PVC interface peak frictional angle. The maximal tensile force developed within the geomembrane is obtained when the sliding between the sand and the geomembrane occurs (comparison between figures 2 and 3). After the initiation of the sliding process, a more effective solicitation of the geosynthetic reinforcement and a significant decrease of the geomembrane tensile force can be observed (figures 3 and 4).

- For an inclination less than 27° ( $\beta_c$ : limit of stability without reinforcement), it's worth noting that the tensile mobilization of the geomembrane is significantly mitigated by the existing reinforcement (Figure 3).

Efficiency depends mainly on the reinforcement axial stiffness, as shown clearly. The difference of behaviour between the Gg TFM and the Gg TFS demonstrates the influence of the material flexibility which tends to delay the axial tensile mobilization by an initial lack of reinforcement sheet flatness.

The Sand/Geomembrane sliding produces a threshold on the load carried by the reinforcement (Figure 4). This jump arises from the postpeak nonlinear behaviour of the Sand/Geomembrane interface, as observed with the inclined plane apparatus ( $\Phi_{peak} = 27^\circ - \Phi_{res} = 21^\circ$ ). Load transferred by friction to the geomembrane is partially reported towards the reinforcement. The same jump is also trapped on the evolution of the load carried by both geosynthetics because of the remanence of the viscoelastic geomembrane tensile force (Figure 5).

Figure 5. Evolution of the load carried by both geosynthetics.

- For an inclination more than  $\beta_c$ , a partial sliding may occur on the Sand/Geomembrane interface and the main purpose of the reinforcement is the stabilization of the soil layer. The Sand/Reinforcement friction becomes the main parameter as indirectly illustrated by the failure with the Gg TFS which has the lowest friction with the soil (Table 1).

## 4 NUMERICAL SIMULATIONS

Two numerical models of the reinforcement test were built as tools for the interpretation of the experimental data.

Given the smallness of strains observed within the soil and the low solicitation of the geosynthetics, a linear elastic behaviour was assumed for these materials.

To explain the evolution of the load within the components, nonlinear postpeak response of the interface (Dense Sand/Geosynthetic) was roughly idealized by an abrupt drop from peak to residual shear stress level.

### 4.1 The 2D - Finite Element model

The Finite Element mesh used is shown in Figure 6. The model combines continuum element for the soil, bar elements for geosynthetics and zero-thickness - type elements for the discretization of the interfaces.

An elastic perfectly plastic law describes the interface behaviour. The formulation adopted takes into account the postpeak response as indicated above. The improved linear interface element proposed by Kaliakin V.N. and Li J. (1995) is used for interface discretization. It allows, among other, to avoid stability problems with high shear stress gradient.

Figure 6. The Finite Element mesh used.

### 4.2 The 1D - Finite Difference model

The principle of reinforcement by inclusion consists in anchoring the soil layer by the reinforcement. The load transfer between the soil and the reinforcement depends on their relative displacement. If an homogeneous

displacement is assumed throughout the thickness of the soil, the reinforced system may be considered as layers connected with interface mechanisms (Figure 7). The Finite Differences method proposed by Gilbert R.B. et al (1993) can then be used for predicting axial load developed in the components.

Figure 7. Finite Difference discretization.

This model accommodates easily the interface postpeak behaviour by means of a simple nonlinear Shear Stress/Relative Displacement relation. Interface nonlinearity is integrated by an nonlinear elastic approach which assures displacement compatibility. Unlike the Finite Element model, the load path is not taken into account here.

#### 4.3 Comparison with experimental results

The geosynthetic axial modulus ( $J$ ) (Table 1) used for numerical simulations was obtained from secant modulus of Load-Strain index curve, within the range of solicitation observed with experimentations. The Young's modulus of the soil was extrapolated from triaxial tests in order to take into account the influence of the confinement ( $E = 10^3 \text{ kN/m}^2$ ,  $\nu = 0.3$ ,  $\gamma = 18 \text{ kN/m}^3$ ). The interface normal stiffness ( $kn$ ) was assigned a very high value ( $10^7 \text{ kN/m}^3$ ) to prevent incompatibility in the normal direction.

Globally, the responses of the two models are in agreement with the experimental results. According to the experimental results, the Finite Differences model behaves surprisingly better than the Finite Element model after the partial sliding of the Sand/Geomembrane interface. The difference between the two models is more evident with the Gt TGX in which case the observed sliding is more important (figures 8-9). Such difference informs about the influence of the partial sliding that tends to erase the memory of shear stress mobilization along the interface.

#### 5 CONCLUSION

Tests carried out with inclined plane apparatus showed the effectiveness of reinforcement by geosynthetic inclusion due to a significant increase in the stability angle or a decrease - in a factor down to 3.5 - of the geomembrane tensile force.

Optimal reinforcement working requires a great stiffness of the reinforcement sheet and a sufficient interaction with the soil, basal mechanics being the anchoring of the soil layer by the reinforcement sheet.

The idealization of the nonlinear interface behaviour considered here seems to be sufficient. Nevertheless, it requires accurate characterization of the maximal and residual frictions, which is possible using inclined plane apparatus. For such systems, numerical simulations must take into account the occurrence of partial interface sliding.

Figure 8. Comparison between the relative displacement measured and calculated (Gt TGX).

Figure 9. Comparison of the load measured and calculated within the reinforcement (Gt TGX).

**ABSTRACT:** The progression of analysis procedures, used in the United States, for internal design of geosynthetic reinforced soil retaining walls are summarized in this paper. Procedures are presented in chronological order over the past twenty-four years, to track changes in practice, from first use through current codes. Both the resistance and the load computations, and the combined effect of the two, are examined. It is concluded that large changes in design conservatism have not occurred since first use of geosynthetic reinforced soil walls; and that performance of existing structures is applicable to new design codes and guidelines. This documentation is directed towards researchers, practitioners, and regulators, and gives guidance for future research and development of codes for reinforced soil walls.

**KEYWORDS:** History, Reinforcement, Retaining walls, Safety factors, Reinforcement specifications & guidelines.

## 1 INTRODUCTION

Geosynthetic reinforced soil (GRS) retaining walls were first used in North America in 1974 for construction of geotextile reinforced walls supporting logging roads in northwestern United States. Use of GRS walls have grown steadily since this initial project. Significant increases in the use of GRS walls were realized with the introduction of geogrid soil reinforcement elements in 1982 and with the introduction of segmental retaining wall units in 1985. Today, GRS walls are routinely used on private land development projects and are becoming more commonplace in transportation works. It is anticipated that recent guidelines (Elias and Christopher 1997; FHWA 1997) and codes (AASHTO 1997) for highway works will spur use of GRS walls and that they will be routinely used throughout North American highways.

Growth in usage of GRS walls is partially attributable to the success of constructed works. Confidence in engineering of these walls today is based upon performance of GRS structures to date. To better understand this behavior, it is useful to the engineer to understand how design procedures have evolved over time. Were the successfully performing structures constructed to date designed with procedures more or less conservative than current guidelines and codes? This question is addressed within, specifically for the internal stability of GRS walls, by examining changes in the geosynthetic reinforcement design tensile strength and soil load determination procedures.

## 2 GEOSYNTHETIC TENSILE RESISTANCE

Internal stability analysis of a reinforced soil wall is performed to quantify required strength and vertical spacing of

the geosynthetic reinforcements. A safe, long-term allowable design strength (LTADS) of the geosynthetic reinforcement needs to be quantified for this analysis. Procedures for quantifying LTADS of geosynthetics have evolved over time, as summarized below. Note that connection strength limitations are not addressed, thereby, assuming that connection does not limit LTADS for purposes of comparisons within this paper. Common terminology is used within this paper to present the various procedures. In general, the basic form of the equation used to calculate the LTADS is:

$$LTADS = \frac{T_{ULT}}{RF \times FS} \quad (1)$$

where

$T_{ULT}$  = average value of ultimate wide width strength;

RF = product of reduction factors, or partial factors of safety, to account for creep, installation damage, chemical degradation and biological degradation; and

FS = overall factor of safety for other (e.g., material, geometric, loadings) uncertainties.

### 2.1 Forest Service Procedures

A 1977 U.S. Forest Service (USFS) manual (Steward et al. 1977) documents a design procedure for geotextile walls. The procedures in this manual were used for the design of a forest service wall constructed in 1974 (Bell et al. 1975), the first GRS wall built in North America. The LTADS is computed with Equation 2. The ultimate strength of the geotextile reinforcement (time frame is prior to introduction of geogrids) is measured with the Oregon State University (OSU) ring test. The OSU ring test ultimate tensile strength,

$T_{ult-OSU}$ , is approximately 80% of the wide width tensile strength (ASTM D4595 1986) for nonwoven needle-punched geotextiles. A FS of 1.5 to 1.75 is recommended, with the higher factor generally for use with heavy live loads (e.g., log haul trucks). Reduction factors, RFs, are not used for these temporary walls.

$$LTADS = \frac{T_{ult-OSU}}{FS} \quad (2)$$

## 2.2 Geogrid Procedure

An allowable strength procedure for geogrids was presented in a 1983 (Netlon) manual published in the United Kingdom. This procedure is presented in Equation 3. The creep limited strength,  $T_c$ , is the highest (tested) load level that precludes exceeding 10% strain or rupture, over the design life. An installation damage factor,  $RF_{ID}$ , is used to further reduce the creep-limited strength. This factor is quantified as the ratio of the ultimate strength of undamaged to damaged specimens. An overall factor of safety value of 1.35 is recommended.

$$LTADS = \frac{T_c}{RF_{ID} \times FS} \quad (3)$$

The approach in Equation 3 was modified for North American practice (Tensar 1986), for a particular product. The  $RF_{ID}$  was incorporated into the overall FS, as shown in Equation 4. An overall factor of safety value of 1.5 was recommended for use with Equation 4.

$$LTADS = \frac{T_c}{FS} \quad (4)$$

For the product addressed in the 1983 (Netlon) and 1986 (Tensar) manuals, the LTADS value calculated with Equation 3 is approximately equal to the value computed with Equation 4 for gravelly sand soils.

## 2.3 1987 Task Force 27 Procedure

The Task Force 27 (AASHTO 1990) procedure (implemented as early as 1987) for computing a LTADS uses a partial reduction factor approach (Bonaparte and Berg 1987). The LTADS is the lesser of the following two, limit state and serviceability state, equations.

$$LTADS \leq \frac{T_l}{RF_D \times RF_{ID} \times FS} \quad (5a)$$

$$LTADS \leq \frac{T_w}{RF_D \times RF_{ID}} \quad (5b)$$

Where

$T_l$  = highest tension level at which the creep strain-rate continues to decrease with log-time within the required design lifetime and which precludes brittle or ductile failure;

$T_w$  = tension level at which total strain is not expected to exceed 5% within the design lifetime; and

$RF_D$  = durability reduction factor, 1.10 minimum.

A minimum  $RF_{ID} = 1.25$  with Equation 5a is required if fill source is unknown at time of design. A 1.5 minimum FS is also required with Equation 5a. No minimum  $RF_{ID}$  is stated for Equation 5b.

## 2.4 1989 FHWA Report

The FHWA research report (Christopher et al. 1989) presented two procedures for quantifying LTADS of geosynthetics. The first procedure, stated as being complex and requiring extensive long-term strength testing, is the partial reduction factor approach presented by Bonaparte and Berg (1987). The second procedure, which can be used in absence of sufficient test data, is to calculate the LTADS with the following simplified equation:

$$LTADS = \frac{T_{ULT} \times CRF}{RF_{ID} \times RF_D \times FS} \leq T_s \quad (6)$$

where

$T_s$  = long-term tension capacity of the geosynthetic at a selected design strain (usually 5% or less); and

CRF = creep reduction factor (ratio of creep limit strength obtained from creep tests to ultimate strength).

$RF_D$  and  $RF_{ID}$  should be based upon product specific data, but not less than 1.1, each. A minimum FS value of 1.5 is recommended for permanent walls.

## 2.5 1991 AASHTO

The 1991 American Association of State Highway and Transportation Officials (AASHTO) Standard Specifications for Highway Bridges followed procedures for LTADS computation as presented in the Task Force 27 (AASHTO 1990) report (i.e., Equations 5a and 5b). However, a minimum  $RF_{ID}$  of 1.25 was stated.

## 2.6 1993 NCMA Procedure

Two optional methods for calculating LTADS are presented within the National Concrete Masonry Association (NCMA) design manual. Method A is a partial reduction factor

approach with a minimum  $RF_{ID}$  of 1.05, adapted from an FHWA publication (Berg 1993), as follows:

$$LTADS = \frac{T_{ULT-MARV}}{RF_{CR} \times RF_{ID} \times RF_{CD} \times RF_{BD} \times FS_{MU} \times FS_{to}} \quad (7a)$$

where

$T_{ULT-MARV}$  = minimum average roll value of ultimate tensile strength, which is typically 5 to 15% lower than  $T_{ULT}$ ;

$RF_{CR}$  = partial factor of creep deformation (ratio of  $T_{ULT}$  to creep limit strength), based upon not exceeding a 10% total strain;

$RF_{CD}$  = partial factor for chemical degradation;

$RF_{BD}$  = partial factor for biological degradation, with a minimum combined  $RF_{CD}$  and  $RF_{BD}$  of 1.1;

$RF_{MU}$  = partial factor for material uncertainty, 1.5 minimum; and

$FS_{to}$  = factor of safety against tensile overstress, 1.2 minimum.

Method B is similar to European practice and borrows heavily from the work of Jewell and Greenwood (1988). This method decouples the FS against overall uncertainties from the calculation of LTADS, and uses creep rupture to define CRF. The LTADS is calculated as:

$$LTADS = \frac{T_{ULT-MARV} \times CRF}{RF_{BD} \times RF_{CD} \times RF_{ID} \times RF_{CE} \times FS_{to}} \quad (7b)$$

where

$RF_{CE}$  = material factor for extrapolation of creep data, 1.3 to 1.5 typical for permanent walls.

## 2.7 1994 and 1996 AASHTO

The 1994 and 1996 AASHTO Standard Specifications for Highway Bridges followed equations (i.e., 5a and b) for LTADS computation as presented in the 1991 AASHTO manual. However, the overall factor of safety, FS, minimum was increased to 1.78. A minimum  $RF_{ID}$  and  $RF_D$  of 1.1 and 1.05, respectively, were stated in the commentary.

## 2.8 Current FHWA/AASHTO Guidelines

The current FHWA (Elias and Christopher 1997) and AASHTO (1997) guidelines present the following equations for quantifying LTADS.

$$LTADS = \frac{T_{ULT-MARV}}{RF \times FS} \quad (8)$$

Where

RF = product of applicable reduction factors (i.e.,  $RF = RF_{CR} \times RF_D \times RF_{ID}$ ), with a minimum value of 1.1 for both  $RF_D$  and  $RF_{ID}$ , and with  $RF_{CR}$  based upon creep rupture; and FS minimum of 1.5 is recommended.

An alternative procedure for LTADS is to use a default overall reduction value, RF, of 7, as shown in Equation 9. Application of this alternative is limited to conditions stated within the guidelines.

$$LTADS = \frac{T_{ULT-MARV}}{7 \times FS} \quad (9)$$

## 2.9 Current NCMA Guidelines

The current NCMA (1997) design manual uses the same equation (similar nomenclature) as the current FHWA/AASHTO (i.e., Eq. 8).

## 3 LOAD DETERMINATION

The lateral driving load to be resisted by the geosynthetic reinforcements is a function of the soil mass and surcharge loads, and, in some analyses, the overturning moment on the reinforced fill due to the retained backfill. The soil mass and surcharge loads are factored by a lateral earth pressure coefficient to compute reinforcement loadings. Design and analysis procedures over time have varied by the assumed lateral pressure coefficient and inclusion or not of the overturning moment effect. In general terminology, the tension in the  $i$ th layer of reinforcement, not including surcharge loads, is calculated as:

$$T_i = K \sigma_{vi} s_{vi} \quad (10)$$

where

$K$  = lateral pressure coefficient;

$\sigma_{vi}$  = vertical pressure at the depth of the  $i$ th layer; and

$s_{vi}$  = effective vertical spacing (i.e.,  $\frac{1}{2}$  distance to reinforcement above plus  $\frac{1}{2}$  distance to reinforcement below) of the  $i$ th layer of reinforcement. The procedures for determining the lateral load are summarized in Table 1 in terms of lateral pressure coefficient used and whether or not overturning (OT) effects are included in the computation of  $\sigma_{vi}$ .

The USFS manual (Steward et al. 1977) focused on the design of geotextile wrap-around walls for log-haul roads. These walls have a relatively short design life and are subject to large live loadings. The load is determined using the approach described by Bell et al. (1975). An at-rest lateral earth pressure coefficient (i.e.,  $1 - \sin \phi'$ ) is used. The normal pressure ( $\sigma_{vi}$ ) is the sum of the weight of the rein-

Table 1. Load computation procedures.

Procedure	K	$\sigma_{vi}$
1977 USFS	at-rest	w/o OT
Geogrid - 1983	active Rankine	w/ OT

1989 FHWA	1.0 to 1.5 active Rankine	w/o OT
1991, 1994 & 1996 AASHTO	active Rankine	w/ OT
1993 & 1997 NCMA	active Coulomb	w/o OT
1997 FHWA /AASHTO	active Rankine	w/o OT

OT — Overturning force from retained backfill.

forced fill (i.e., product of unit weight of soil,  $\gamma$ , and height of fill above  $i$ th layer of reinforcement,  $h_i$ ), uniformly distributed surcharge loads ( $w_s$ ), and other surcharge loads.

The 1983 (Netlon) geogrid wall design manual recommended use of active lateral earth pressure coefficient,  $K_a$ , with either the tie-back wedge or the coherent gravity analysis procedure. The tie-back wedge method with overturning effect was used extensively for design of geogrid walls in North America starting in 1983 (e.g., Berg et al. 1984; Tensar 1986; Berg et al. 1987). A Rankine active lateral earth pressure coefficient (i.e.,  $\tan^2(45 - \phi/2)$ ) is used with this procedure. The vertical pressure, assuming a Meyerhof-type of pressure distribution of the overturning force generated by the retained backfill, is shown in Equation 11, for level backfill conditions. The subscripts  $w$  and  $b$  refer to the reinforced wall fill and the retained backfill, respectively, and  $l$  is the length of reinforcement.

$$\sigma_{vi} = \gamma_w h_i + w_s K_{ab} \left( \gamma_b h - i + 3 w_s \right) \left( \frac{h_i}{l} \right)^2 \quad (11)$$

The overturning of component of  $\sigma_{vi}$  was deleted from the load computation (Simac 1990; Tensar 1990), at least in private practice, subsequent to and based upon discussions at the 1987 NATO Workshop on geosynthetic reinforced soil walls (Jarrett and McGown 1988). The method for calculating LTADS did not change, therefore, Equation 4 is applicable with this revised load determination procedure.

In the 1987 Task Force 27 (AASHTO 1990) procedure, the tie-back wedge method of analysis is recommended for analysis of geosynthetic reinforced retaining walls. The tension in the reinforcement is calculated as a function of the vertical stress induced by gravity, uniform normal surcharges

and active thrust from the retained fill (i.e., Eq. 11), multiplied by the Rankine active earth pressure coefficient.

FHWA research in the late 1980's (Christopher et al. 1989) led to a recommended stiffness approach for quantifying the lateral pressure coefficient. With this approach, a Rankine lateral earth pressure coefficient equal to  $K_a$  was recommended for geotextile reinforcements. A varying coefficient of  $1.5 K_a$  at the top of wall to  $1.0 K_a$  at a distance of 6 m below top of wall, and lower, was proposed for geogrid reinforcements.

The 1991, 1994, and 1996 AASHTO Standard Specifications for Highway Bridges followed procedures for load computation as presented in the Task Force 27 (AASHTO 1990) report.

Rankine theory was used for quantifying the  $K_a$  coefficient until the NCMA design procedure for segmental retaining walls (Simac et al. 1993) was published. A Coulomb theory is recommended in this manual, which allows for direct incorporation of the beneficial effects of wall face batter and interface friction between the fill soil and wall face. The NCMA procedure (Simac et al. 1993; NCMA 1997) for calculating the internal stability lateral load (without surcharge loads) is:

$$P_a = \frac{1}{2} \gamma_w K_{aC} H_e^2 \cos(\delta_i - \psi) \quad (12)$$

where

$P_a$  = active earth force acting over the effective height of the wall, per unit width of wall;

$\gamma_w$  = moist unit weight of wall infill soil;

$K_{aC}$  = Coulomb active earth pressure coefficient;

$H_e$  = effective height for battered walls;

$\delta_i$  = wall to soil friction angle; and

$\psi$  = total wall inclination from vertical.

The second edition of the NCMA design manual (1997) does not change the procedure for determining the soil load for internal stability analysis. The NCMA design procedure is one of the two procedures currently in widespread use in North America. The other procedure in widespread use was developed for the design of highway walls, with select granular fill, and is referred to as the simplified coherent gravity method.

The new FHWA manual (Elias and Christopher 1997) and the recent update to AASHTO bridge manual (1997) incorporated features of the stiffness, tie-back wedge, and coherent gravity approaches for analysis of walls — resulting in the simplified coherent gravity method. With this procedure an active Rankine lateral earth pressure, over the entire wall height, is recommended for computation of geosynthetic (both geotextiles and geogrids) reinforcement loads. Overturning effects are not included in the vertical pressure.

The changes in procedures to quantify the LTADS of geosynthetic reinforcement and the internal lateral load on GRS walls are quantified in Table 2. The values in Table 2 are based upon typical ranges of values for the partial factors used in practice, from the authors' experience. The resistance,  $R$ , is the LTADS in terms of percentage of ultimate wide width strength ( $\%T_{ULT}$ ). The load,  $L$ , is the total load on the wall, without surcharges, using the assumptions listed in Table 2, expressed as  $P/H^2$ , where  $P$  is the total force on the wall per unit length of wall. The  $R/L$  in Table 2 is a normalized ratio for comparing the various procedures, and not a design parameter. The lower the  $\%T_{ULT}$  used the more conservative the procedure. Also, with other factors remaining equal, the higher the assumed load the more conservative the method. Therefore, the lower the  $R/L$ , the more conservative the combination of resistance and load computations. The trend of  $R/L$  ratios over time and range of individual procedures are illustrated in Figure 1.

Table 2. Quantifying  $R/L$  ratios.

Procedure	Resistance ( $\%T_{ULT}$ )	Load ( $P/H^2$ )	$R/L$ Ratio
1977 USFS	~ 53	4.3	~ 12.3
Geogrid			
- '83	25 to 40	3.54	7.1 to 11.3
- post-87	25 to 40	2.77	9.0 to 14.4
1987 Task Force 27	20 to 28	3.54	5.7 to 8.0
'89 FHWA			
- Geogrid	20 to 27.5	3.2	6.3 to 8.6
- Geotextile	10 to 27.5	2.77	3.6 to 9.9
1991 AASHTO	20 to 27.5	3.54	5.8 to 7.8
1993 NCMA	16 to 28	2.3	7.0 to 11.7
1994 & 1996 AASHTO	18 to 24.3	3.54	5.1 to 6.9
'97 FHWA & AASHTO	14.6 to 26	2.77	5.3 to 9.4
- w/ Default	8.6	2.8	3.1
1997 NCMA	19 to 35	2.3	8.3 to 15.2

## Assumptions:

wall fill  $\phi = 34^\circ$   $\gamma = 19.6 \text{ kN/m}^3$   
retained backfill  $\phi = 30^\circ$   $\gamma = 18.8 \text{ kN/m}^3$   
 $H = 6 \text{ m}$  (1989 FHWA geogrid case)  $l/H = 0.7$   
batter =  $0^\circ$ ,  $\delta = \frac{3}{4}\phi$ , and  $FE = 1.3$  (NCMA cases)

Figure 1.  $R/L$  ratio trends and ranges.

## 5 CONCLUSIONS

The trend of change in the resistance to load relationship ( $R/L$  ratio) is illustrated in Figure 1. Observed trends are generalized and based upon assumptions previously stated. More precise results could be revealed by examining specific case histories over time. The following can be concluded from this plot.

1. Transportation specific procedures (i.e., FHWA, AASHTO) are more conservative than non-transportation specific procedures (i.e., geogrid, NCMA).
2. Transportation procedures have, generally, increased in conservatism throughout their development, primarily due to increases in resistance reduction factors. Calculated loads have decreased somewhat during this period.
3. The 1997 FHWA/AASHTO default value of 7 is more conservative than all of the procedures examined.
4. Large changes in conservatism with transportation procedures have not occurred since 1987.
5. Large changes in conservatism with non-transportation procedures have not occurred since first use in 1975.
6. Performance of existing structures is applicable to new design codes and guidelines.

# Aspects of Partial Factor Design of Reinforced Soil Walls

T. S. Ingold

Consulting Engineer and Honorary Professor of Geotechnical Engineering, The University of Birmingham, UK

**ABSTRACT:** In assessing margins of safety, geotechnical engineers have traditionally worked in terms of lumped factors of safety, often defined as the ratio of restoring force to disturbing force, that are calculated using soil parameters which are judged to be representative. This approach is lucid in so far as it deals with raw, unfactored, values of soil properties. In contrast, partial factor design deals with design disturbing forces, which are raw values artificially enhanced by partial factors, and design restoring forces which are raw values artificially depressed by partial factors. How these partial factors are applied has a major affect on the end result with this also being heavily influenced by the use of characteristic values of soil parameters. Certain approaches to partial factor design are more lucid than others and this is illustrated by making comparisons between some of the approaches prescribed in BS 8006 : 1995, "Strengthened/reinforced soils and other fills", and the pre-standard Eurocode ENV-1997-1 : 1994, "Geotechnical design - Part 1 : General rules".

**KEYWORDS:** Reinforced soil, Retaining walls, Design, Safety factors, Specifications

## 1 INTRODUCTION

Traditionally, geotechnical engineers factor design values of soil properties by judgment with this judgment, perhaps aided by regression analyses, accounting for a multitude of variables such as test method, validity of test results and variability of results. The resulting value is a raw, unfactored, value which is used for design.

In assessing soil induced forces involved in, say, base sliding of a retaining wall, of given geometry, then, for a cohesionless soil of given unit weight  $\gamma$ , these forces will be a function of  $\phi'$ , the effective stress internal angle of shearing resistance of the soil. The function maybe  $K_a$ , if considering a raw lateral disturbing force,  $D$ , or  $\tan\phi'$  if considering a raw horizontal restoring force,  $R$ . The lumped factor of safety against sliding may then be defined, traditionally, as  $F=R/D$ . Provided  $F$  equals, or exceeds, some prescribed value, typically 1.5 to 2.0, then there is deemed to be an adequate, definitive, margin of safety against forward sliding. Although definitive,  $F$  is a combined margin of undefined error and/or ignorance. Nonetheless, prescribed values have stood the test of time.

In contrast, non-geotechnical engineers often have the luxury of designing with well controlled materials, and loads, whose parameters are well documented. In this case it is possible to generate a general distribution of, say, material strengths and applied loads. Statistical analyses may be applied to these distributions to determine theoretical values of partial load and partial material factors which are then applied to statistically determined values of load and strength. The end result is that, when the partial factors are applied it, is possible to define the probability of the design load exceeding the design strength. So, for example, such an approach may define a probability of failure of 1 in 10,000. Clearly, this approach is totally different to the lumped factor of safety approach.

There has long been a move in Europe towards partial factor design and so the code of practice, BS 8006 : 1995,

"Strengthened/reinforced soils and other fills" was written in a partial factor format. The essence of this is that a partial load factor,  $f_t$ , is used to enhance a raw disturbing force,  $D$ , whilst a partial material factor,  $f_m$ , is used to depress a raw restoring force,  $R$ . An adequate margin of safety, against attaining an ultimate limit state, is deemed to operate when the identity  $f_t D \leq (R/f_m)$  is satisfied. A similar approach is proposed in the European pre-standard Eurocode 7, or just EC-7, which is formally entitled Eurocode ENV-1997-1 : 1994, "Geotechnical design - Part 1 : General rules".

## 2 BS 8006 AND EUROCODE 7

BS 8006 prescribes a variety of different partial material factors,  $f_m > 1$ , with different numerical values, to be applied to material strengths, such as those for soil or soil reinforcement, to define a design strength. It is important to note that soil unit weight,  $\gamma$ , and  $\tan\phi'$  are allotted a partial material factor of unity. So, in other words, these two parameters are not factored. Load factors,  $f_t > 1$ , with different numerical values, are applied to loads to determine design loads and these factors differ in magnitude from one prescribed loading condition to another. In addition, there is a further group of partial material factors, such as  $f_s > 1$ , which applies to specific failure modes such as bearing capacity, forward sliding or reinforcement pull-out. Table 1 presents some selected examples of partial load factors.

Table 1. Selected partial load factors from BS 8006

Load factor, $f_t$ , applied to	Loading case		
	A	B	C
Mass of the reinforced soil body	1.5	1.0	1.0
Earth pressure behind structure	1.5	1.5	1.0

Table 2. Selected partial factors from BS 8006

Soil material factor, $f_m$ , applied to $\tan\phi'$	1.00
Factor, $f_s$ , on sliding across reinforcement	1.30
Factor, $f_{ms}$ , on ultimate bearing capacity	1.35

BS 8006 considers two limit states; the ultimate limit state of collapse and a predefined serviceability limit state appropriate to the structure under consideration. In assessing the latter, all partial factors are set to unity per Case C in Table 1. In assessing the ultimate limit state of collapse, the code is formulated in such a way that partial factors with a value greater than unity are only applied to raw pressures or forces. So, taking the example of base sliding, stability is deemed satisfied if  $f_t D \leq (R/f_m)$ .

Since BS 8006 partial factors operate on what are effectively raw forces, the identity  $f_t D \leq (R/f_m)$  may also be expressed as  $R/D \geq f_t f_m$ . This formulation is identical to the traditional lumped factor of safety format in which  $R/D$  must equal or exceed a prescribed minimum value of  $F$ . For forward base sliding the prescribed value of  $F$  traditionally falls between 1.5 and 2.0. Loading case A of Table 1, a worse case for base sliding, implies a value of  $f_t$  of 1.5 and, for a perfectly rough basal reinforcement, Table 2 implies a material factor,  $f_s = f_m$ , with a value of 1.3. The product of these two factors is 1.95 which is essentially the value of the conventional lumped factor of safety  $F$ .

Indeed, the values of partial factors in BS 8006 were formulated such that  $f_t f_m = F$ . This formulation, with due regard for any interaction between various factors, was extensively calibrated against well established and proven design methods, as well as observed performance of existing structures, to render numerical values of partial factors which, with regard for commercialism, are consistent with adequate margins of safety. Perhaps more importantly, partial factors are applied in a lucid manner which has a linear effect on design loads and strengths.

Table 3. Selected partial factors from EC-7

Case	Favourable load	Unfavourable load	$\tan\phi'$
A	0.95	1.00	1.10
B	1.00	1.35	1.00
C	1.00	1.00	1.25

Eurocode 7 has a similar format to BS 8006 but has three loading cases pertaining to the ultimate limit state, per Table 3, as opposed to two cases, cases A and B of Table 1, in BS 8006. Like BS 8006, EC-7 sets all partial factors to unity when considering a serviceability limit state. EC-7 does not prescribe material factors which can be applied to assess internal stability nor partial factors which apply to specific failure modes such as base sliding.

For loading cases A and C, EC-7 prescribes the use of a materials factor,  $f_m > 1$ , on  $\tan\phi'$ . This gives a design value of friction angle  $\phi_d = \tan^{-1}([\tan\phi'] / f_m)$ . If, for example, lateral soil thrusts were being calculated to BS 8006 then  $\phi'$  is not factored and the resulting coefficient of earth pressure used in design is  $K_a$ , the conventional coefficient of active earth pressure. If  $\phi_d$  is used as the design value then the resulting earth pressure coefficient might be denoted as  $K_d$ . It is reasonable to assume that the  $f_m$  value defined in EC-7 is a component used with the objective of achieving a uniform, target, overall margin of safety, but, if the effects of  $f_m$  are assessed it transpires that resulting margins of safety are not uniform.

Figure 1 shows a plot of  $K_d/K_a$  against  $f_m$  for a range of unfactored values of  $\phi'$ . For soil with  $f_m = 1$ , per BS 8006, and  $\phi' = 20^\circ$  then  $\phi' = \phi_d = 20^\circ$  and the value of  $K_d/K_a$  is unity since  $K_d = K_a$ , but if  $f_m = 1.25$ , per EC-7, the value of  $K_d/K_a$  increases by 15 % so implying a concealed load factor component of 1.15. For  $\phi' = 50^\circ$  then, as before  $K_d = K_a$  per BS 8006, but according to EC-7,  $K_d/K_a$  increases by 38 % so implying a concealed load factor component of 1.38. So, the EC-7 approach introduces a non-linearity in margins of safety which penalise better quality soils and fills. This non-linearity varies according to which aspect of stability is being considered. If calculating tensile forces applied to reinforcement then  $K_a$  and a sine function is involved. If considering base sliding then both a sine and tangent function are involved.

Figure 1. Nonlinear effect of partial material factor on design value of lateral earth pressure coefficient

### 3 BASE SLIDING

Eurocode 7 does not give partial factors for internal stability so the following sections illustrate various aspects of the BS 8006 and EC-7 approaches by considering base sliding and bearing capacity in terms of  $\phi'$  and the ratio,  $\lambda$ , of wall base width,  $L$ , to wall height,  $H$ .

Conventional, lumped factor of safety, design defines the factor of safety against base sliding as :

$$(\gamma LH \tan\phi') / (\frac{1}{2}K_a \gamma H^2) = F \quad (1)$$

If  $F$  is some limiting target value to be achieved and  $L/H$  is written as  $\lambda$ , then Equation 2 can be rearranged as :

$$(2 \lambda \tan\phi') / (FK_a) = 1 \quad (2)$$

The corresponding EC-7 formulation is :

$$(2 f_w \lambda \tan\phi_d) / (f_t K_d) = 1 \quad (3)$$

where  $\phi_d = \tan^{-1}([\tan\phi'] / f_m)$  and  $f_w$  is a load factor on favourable dead load which may be less than unity. The corresponding BS 8006 Case B formulation is :

$$(2 \lambda \tan\phi') / (f_s f_t K_a) = 1 \quad (4)$$

For given raw values of  $\phi'$  values of  $\lambda$  can be determined for a given partial factor set.

Figure 2. Base width to height ratio -  $\lambda$  against  $\phi'$  values

Figure 3. Conventional lumped factor of safety against  $\phi'$

For each partial factor set and a given value of  $\phi'$ , Figure 2 presents the value of  $\lambda$  required by a given partial factor set to achieve an adequate margin of safety as defined by that partial factor set. As expected, values of  $\lambda$  for the conventional lumped factor of safety approach and BS 8006 Case B almost coincide. The EC-7 partial factor sets are closely grouped and, for a given value of  $\phi'$ , these generally indicate a requirement for a lower value of  $\lambda$  than BS 8006. To investigate the reasons for this, the  $\lambda$  values derived from each partial factor set were reanalysed to determine what conventional lumped factor of safety they would produce.

The results of these reanalyses are presented graphically in Figure 3 which is a plot of equivalent lumped factor of safety against unfactored  $\phi'$ . As expected conventional analysis produces a constant factor of safety, of 2.00, which is independent of  $\phi'$ . The same applies to BS 8006 Case B, with a constant value of 1.95, and to EC-7 Case B where the constant value is 1.35. Case A produces a variable factor of safety as does Case C which is the worst case for base sliding. The non-linearity effect of applying a material factor, greater than unity, to  $\tan\phi'$  is well illustrated by Case C where the equivalent factor of safety increases from 1.44 for  $\phi' = 20^\circ$  to 1.73 for  $\phi' = 50^\circ$ . It can be seen that in general EC-7 results in lower margins of safety against base sliding than BS 8006 and, in particular, it penalises better quality fills and soils which have higher  $\phi'$  values.

## 4 BEARING CAPACITY

To investigate the effects of different partial factor sets on margins of safety against bearing capacity failure, analyses have been carried out on a simple wall, with a constant value of  $\lambda$  of 0.7, founded at ground surface. The common theme of all partial factor sets is that the design ratio,  $\rho$ , of available design bearing capacity to applied design pressure should be equal to or greater than unity. The results of these analyses are presented in Figure 4 as plots of  $\rho$  against  $\phi'$ . For all partial factor sets a  $\rho$  value of unity or greater is obtained for  $\phi'$  greater than 30 to 33°. In particular the worst threshold case from BS 8006, Case B, is obtained at  $\phi' = 32^\circ$  whilst from EC-7 the worst case is Case C which is obtained at  $\phi' = 33^\circ$ . This indicates that, for the wall geometry analysed, BS 8006 and EC-7 render almost identical margins of safety against bearing capacity failure.

Figure 4. Variation of design ratio,  $\rho$ , with unfactored  $\phi'$

## 5 CHARACTERISTIC VALUES

The above analyses assume deterministic values of soil properties such as  $\phi'$  but BS 8006 and EC-7 imply the use of characteristic values. If statistical methods are used, the characteristic value should be derived such that the calculated probability of a worse value governing the occurrence of a limit state is not greater than 5%. Upper or lower values are used according to the problem.

Designing with characteristic values of  $\phi'$  for fills is not problematical since the designer can require a specified characteristic value. However, the effects of using characteristic values for insitu soils may be problematical.

Consider a wall imposing a pressure of 120 kN/m<sup>2</sup>. A designer might have 9 test results for the  $\phi'$  value of the foundation soil which are 32, 33, 34, 35, 36, 35, 37, 40 and 33°. The mean is 35° which leads to an ultimate bearing capacity of 670 kN/m<sup>2</sup> and lumped factor of safety of 5.6. The characteristic value is 31° which leads to a ultimate bearing capacity of 350 kN/m<sup>2</sup> and a lumped factor of safety of 2.9. If the designer had say only 3 results of 32, 35 and 38° the mean would still be 35° and the designer would calculate the same result as before. The characteristic value of this set is 30° for which the bearing capacity is 300 kN/m<sup>2</sup> with a notional factor of safety of 2.5. Hence, quality, quantity and distribution of test data may have as large an influence on margins of safety as the various partial factors which may be applied.

## 6 CONCLUSIONS

Traditionally geotechnical design employs lumped factors of safety and a key element in deriving these is the veracity of the soil parameters used. This is largely a matter of engineering judgment. In theory, if factors of safety are greater than unity, then there should be no failure. In fact failures do occur occasionally and these often call into question the judgment of the designer.

In Europe the move is away from lumped factor of safety design towards partial factor design. Since partial factors are applied to enhance raw loads, and to reduce raw strengths, the designer deals with design loads, and strengths, which are distorted from raw values. The aim of this distortion is to wean geotechnical design away from a deterministic approach to a probabilistic approach.

Some of the mathematical manipulations prescribed in partial factor design, such as factoring characteristic  $\phi'$  values, tend to produce distorted, nonlinear, design values. This tends to cloud the application of engineering judgment and it remains to be seen whether partial factor design introduces a real probability of failure which is lower or higher than that currently associated with traditional lumped factor of safety design.

# A Comparison of Design Approaches for Geosynthetic Reinforced Soil Structures In Europe

J. Penman and R.A. Austin

Tensar Division, Netlon Limited, New Wellington Street, Blackburn, UK

**ABSTRACT:** The use of geosynthetic materials to reinforce soil structures has become widespread in recent years. Traditional methods for the design of these structures using polymeric reinforcement are based on a limit equilibrium approach which can lead to a conflict in the design of different parts of the same structure. In a bridge for example, the deck itself is likely to be designed using a limit state approach while the supporting reinforced soil abutment could be designed using a limit equilibrium method.

For reinforced soil walls, the most popular design methods currently used in Europe are based on the tie-back wedge approach. For reinforced soil embankments the most common methods use modified forms of Bishop or Janbu equations for circular and non-circular slip surfaces respectively, the method outlined in the UK Department of Transport technical note HA 68/94 or chart based design methods. All these wall and embankment design methods are based on limit equilibrium principles.

The publication of the UK code of Practice for strengthened/reinforced soils and other fills, BS 8006 introduced alternative methods for the design of reinforced soil structures using limit state principles. The paper describes the advantages and limitations of both limit equilibrium and limit state approaches and outlines the economic implications of using the various methods in different conditions.

**KEYWORDS:** Design, Limit equilibrium, Limit state, BS 8006, Walls, Embankments

## 1 INTRODUCTION

When reinforced soil techniques were originally developed, only three or four methods were routinely used for the design of structures. With the wider acceptance of this developing technology, many countries now have at least one approved method for the design of walls and embankments and each is slightly different to the ones used elsewhere.

Since the introduction of modern soil reinforcement techniques by Vidal in the 1960's and the pioneering work for the design of reinforced soil embankments undertaken by Jewell in the 1970's, we have moved on to other more refined and flexible methods of analysis. However, the original coherent gravity method, Vidal (1966) and revised embankment design charts, Jewell (1990) are still very much in use today.

Whilst it is appreciated that many other design methods and Standards exist, this paper focuses on the methods most commonly used at present for the design of geosynthetic reinforced soil structures in Europe.

## 2 LIMIT EQUILIBRIUM METHODS

### 2.1 General

The limit equilibrium approach for the design of reinforced soil structures is based on the application of global factors of safety. Thus for external stability calculations, minimum target values are set which must not be exceeded in the design, while for internal stability calculations, a factor of

safety is applied to the reinforcement creep limited strength to determine the safe design strength.

Full details of the limit equilibrium design methods discussed in this paper can be found in Netlon Limited (1997).

### 2.2 Reinforced Soil Walls

#### 2.2.1 Tie-back Wedge Method

This method was one of the earliest developed for reinforced soil walls and is still very much in use today. Most of the more recent limit equilibrium design methods for geosynthetic reinforced soil walls could be regarded as variations of this traditional approach.

Figure 1. Main failure mechanisms for reinforced soil walls

The external stability of the structure is assessed based on the assumption that it behaves as a rigid body and the possible failure mechanisms are shown in Figure 1. Due to the large strains which develop in the soil, critical state soil parameters ( $\phi'_{cv}$ ,  $c'_{cv}$ ) are generally adopted in design.

Although overturning failure is usually included in external stability calculations, in the absence of any large horizontal loads (e.g. in bridge abutments), it is unlikely to be a problem. A target factor of safety of 2.0 is usually adopted for sliding while for bearing, the vertical pressure exerted by the reinforced soil block is normally calculated and compared with the allowable bearing pressure of the foundation soil. In the past, a trapezoidal pressure distribution was generally adopted for bearing capacity calculations, the vertical pressure being greater at the toe than at the back of the structure. This approach has now largely been replaced by a uniform Meyerhof pressure distribution which takes account of the eccentricity of the applied load at the back of the block in the calculation of the applied pressure.

In general, the base width of the reinforced soil block is chosen to satisfy external stability requirements with regard to sliding, overturning and bearing. A slope stability computer program is then used to check for potential slip failures at the back of the structure.

The internal stability of a reinforced soil wall is essentially concerned with the tension and pull-out failure mechanisms shown in Figure 2. For the purposes of the analysis, a uniform frictional fill is assumed and horizontal soil pressures are taken to be in the active condition throughout the structure; the at rest pressure which may develop during the construction phase will reduce to the active pressure when temporary supports are removed.

Figure 2. Tie-back wedge internal failure modes

In order to assess potential rupture, it is assumed that the reinforcement will carry tension as a result of the self-weight of the fill and the external loading. These tension components can be evaluated separately and combined to give the total tension to be carried by an individual layer of reinforcement. External vertical and horizontal line loads may also be included thus enabling forces from bridge abutments and parapets to be taken into account.

In order to investigate potential pull-out failure of the reinforcement, it is necessary to consider separately the possibility of inclined failure planes passing through the wall forming unstable wedges of soil bounded by the front face of the wall, the ground surface and the potential failure plane, Figure 3. For the purposes of the analysis, it is assumed that each wedge behaves as a rigid body and friction between the facing and the fill is ignored. A series of potential failure planes emanating at various heights behind the face of the wall are investigated and for each, a check is made to ensure that the total restoring force provided by all layers of reinforcement cut by the wedge exceeds the out of balance force, usually by a factor of two.

Figure 3. Tie-back wedge pull-out failure mechanism

## 2.2.2 The Deutsches Institut für Bautechnik Design Method

This design method, based on German DIN standards, has gained widespread acceptance in mainland Europe and is becoming increasingly popular in other parts of the world.

Although the method is based on the tie-back wedge approach, there are a number of important variations. For external stability calculations, these include a reduced target factor of safety of 1.5 for sliding and a specific method for the consideration of bearing failure which by modifying the Terzaghi bearing capacity equation, takes account of the inclination of the resultant force due to the active pressures at the back of the reinforced soil block. An additional check is included to ensure that the resultant force acts in the middle third of the base, this effectively replacing the overturning calculation in the traditional tie-back wedge method.

Internal stability calculations concentrate mainly on a consideration of reinforcement pull-out with the traditional single-part wedge being replaced by a two-part mechanism, the base of the upper wedge passing along the back of the reinforced soil block. An additional check is however required for structures with flexible faces; for each layer of reinforcement, it is necessary to ensure that the design strength (or the anchorage strength if a full-strength connection is not used) is not exceeded by the active pressure on the face.

Critical state soil parameters are used in the design and the reinforcement strengths adopted in the designs referred to in this paper are detailed along with the appropriate methodology in Deutsches Institut für Bautechnik Certificate No. Z-20.1-102 (1990).

### 2.3 Reinforced Soil Embankments

#### 2.3.1 Slip Circle Method

Until fairly recently, rigorous stability analyses of reinforced soil embankments generally took the form of a circular slip circle analysis using one of the methods of slices e.g. Bishop's method, Figure 4.

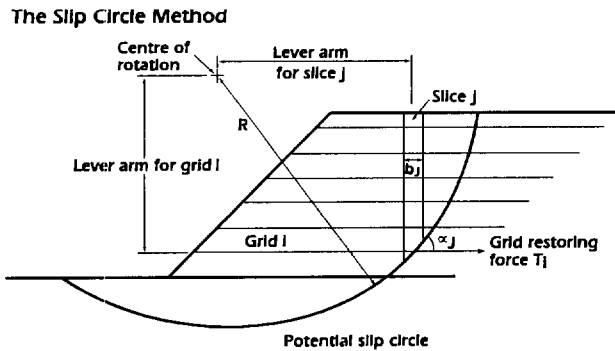

Figure 4. Bishop slip circle method

For each circle, the disturbing moment of the soil mass is compared with the restoring moment provided by the soil and the reinforcement and a factor of safety against failure calculated. If the minimum factor of safety is greater than the target value (usually around 1.3 for permanent structures), the design is deemed to be satisfactory in terms of stability.

Such an analysis is rapidly carried out using computer software developed by some individual manufacturers and the commercial software packages now available. It should be borne in mind however that the method of incorporating reinforcement into the design often varies between these software packages.

#### 2.3.2 The UK Department of Transport Design Method

The UK Department of Transport Advice Note HA 68/94 gives guidance on the design requirements for the use of reinforced soil and soil nailing techniques in embankments. A series of tables are provided in the document which are aimed at providing a simple method enabling engineers to produce independently replicable designs. However, in order to take full advantage of the economy in the design method outlined in HA 68/94, a computer program is necessary.

The HA 68/94 design method involves the consideration of two-part wedge failure mechanisms, Figure 5. Critical state soil parameters are used in the analysis but apart from

the normal factors applied to the strength of the reinforcement, no other factors of safety are present in the design. A general discussion of the principles involved in the HA 68/94 method and some of the potential difficulties with its application are discussed in Penman (1996 and 1996a).

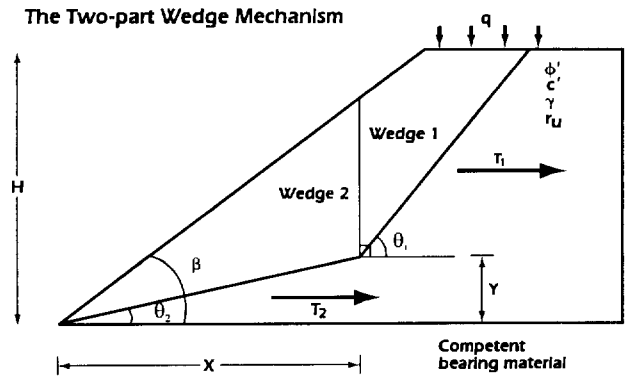

Figure 5. HA 68/94 two-part wedge failure mechanism

Although HA 68/94 is gaining widespread popularity, a number of implicit restrictions often require an alternative method to be used. These restrictions include the presence of a complicated embankment geometry, multiple fill types, the presence of horizontal loads and a less than fully competent foundation soil.

Comparisons using the modified design charts published by Jewell (referred to earlier) have not been included in the comparison exercise described below. However it is stated in Appendix A of HA 68/94 that the use of a  $\phi'_{12}/\phi'$  ratio of 0.5 for inter-wedge friction, yields similar reinforcement layouts to those achieved using the Jewell charts.

## 3 LIMIT STATE METHODS

### 3.1 General

The object of a limit state approach is to apply appropriate partial factors where they are required i.e. the greatest partial factors should be applied where there is the greatest uncertainty.

The publication of BS 8006 heralded a new approach to the design of reinforced soil structures. The Code of Practice adopts limit state principles for the design of walls and embankments whereby individual partial factors are applied to the various forces acting on the structure and the soil/reinforcement properties. It is questionable however whether BS 8006 has been successful in following the limit state objective of applying partial factors where they are required most; notwithstanding its endeavour to follow current practice, it is difficult to justify a partial factor of 1.5 for soil unit weight while a partial factor of unity is applied to the friction angle, there surely being greater uncertainty with the latter than the former.

It is stated in BS 8006 that provided a reinforced soil structure is unlikely to undergo excessive differential settlement, peak effective shear strength parameters can be used for design i.e.  $\phi'_p$ ,  $c'_p$ . It should be appreciated however that with the exception of some industrial fills (e.g. Pulverised Fuel Ash), an effective cohesion value of zero is normally adopted.

BS 8006 clearly distinguishes two parts to the design process, the ultimate and serviceability limit states. As such it is the only document discussed in this paper which refers directly to the key issue of boundary deformation. Unfortunately, BS 8006 is vague in terms of how serviceability should be addressed and much is therefore left to the individual designer.

## 4 COMPARISON OF DESIGN METHODS

### 4.1 General

A number of designs have been undertaken for each of the various methods described above; the analyses were carried out using Netlon Limited's Winslope and Winwall computer programs for the design of reinforced soil structures, Figures 6 and 7. Each design was based on the use of the Tensar® range of HDPE geogrids and where possible, soil parameters were chosen such that the geogrid quantities were not governed by the normal maximum practical spacing criteria.

As the limit equilibrium and limit state methods use constant volume and peak shear strength properties respectively, clearly any comparison between methods adopting these two approaches is sensitive to the relationship assumed between the constant volume and peak values for a particular soil. For the purpose of this exercise, a  $\tan\phi'_p / \tan\phi'_{cv}$  ratio of 1.3 has been used throughout. For each design case, the most cost effective method was given a cost rating of 1.00, the relative cost

of using the other methods being based on typical current prices of the products used in the design.

### 4.2 Wall Design Methods

The results of the cost comparison exercise for walls are shown in Table 1. The most striking feature that comes out of the comparison exercise is the inefficiency of the traditional tie-back wedge approach for all but the smallest of structures. The main reason for this is the longer grid lengths required to satisfy the target factor of safety of 2.0 for sliding, although the method of dealing with the internal stability requirements is also slightly less efficient for the tie-back wedge than the Bautechnik and BS 8006 methods.

The Bautechnik method, in general uses shorter grid lengths than the BS 8006 method but the grid quantities required to satisfy internal stability criteria are significantly less in the BS 8006 method. Overall, for the examples considered in this paper, it would appear that for structures up to 3m high, the traditional tie-back wedge approach may be the most cost effective while for medium sized structures (3m to 8m high), the approach outlined in BS 8006 provides the most cost effective layouts. It should be appreciated however that for different soil and loading conditions, the 'switch in efficiency' between design methods will be at different heights of structure. Similarly, the relationship between the constant volume and peak strength properties for a particular soil will have a considerable effect on the relative performance of the limit equilibrium and limit state methods.

In addition to comparisons being made based on height of structure, the way the design methods deal with inclined faces and water pressure was also investigated. For inclined faces (Cases 7 and 8) the benefits gained by reducing the active earth pressures were equally well reflected in all three methods but when water pressure is present (Cases 9 and 10), it would seem that the BS 8006 method deals with these in a slightly more cost effective manner.

Figure 6. Winslope computer program

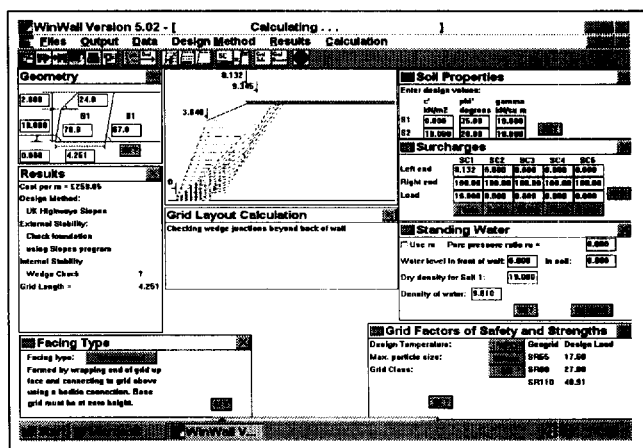

Figure 7. Winwall computer program

### 4.3 Embankment Design Methods

The results of the cost comparison exercise for embankments are shown in Table 2. It should be appreciated when examining the results that the actual reinforcement layout used to determine the cost ratio for a particular design method is based on both the minimum reinforcement requirement derived from the analysis and the maximum vertical spacing between reinforcement layers; for the latter this was 1.0m throughout. Although this undoubtedly has an effect on the overall costs used in the analysis, it is unlikely to affect the overall cost ranking of the design methods.

Possibly the most noticeable feature of the results for embankments is the significant economy attained by using a limit state approach rather than the traditional limit

equilibrium method for slip circle analyses. It would appear that the difference becomes greater for higher embankments and for shallower embankments constructed with comparatively weak fill (e.g. high plasticity clay).

The two types of HA 68/94 analysis carried out demonstrate the economy which can be attained by using a computerised approach to this method, with the inclusion of inter-wedge friction as opposed to the simplified method using the tables within HA 68/94. It should be appreciated however that in order to use a high value for inter-wedge friction (such as the value of 0.5 used in this exercise), it is necessary to check the stability of two-part wedges behind  $T_{max}$  (Love and Bond, 1996).

Table 1. Results of comparison exercise for walls

Case	Description	Bautechnik		Tie-back Wedge		BS 8006	
		Cost Ratio	Grid Length	Cost Ratio	Grid Length	Cost Ratio	Grid Length
1	3m high, 90° wall, $\phi'_{cv}=28^\circ$	1.08	2.00m	<b>1.00</b>	<b>2.60m</b>	1.10	3.00m

		Cost Ratio	Base Grid Length	Cost Ratio	Base Grid Length	Cost Ratio	Base Grid Length	Cost Ratio	Base Grid Length
1	4m high, 60° face, $\phi'_{cv} = 30^\circ$	1.23	2.80m	<b>1.00</b>	<b>2.00m</b>	1.33	2.00m	1.24	2.30m
2	8m high, 60° face, $\phi'_{cv} = 30^\circ$	1.37	5.30m	1.15	4.80m	1.08	5.25m	<b>1.00</b>	<b>4.75m</b>
3	12m high, 60° face, $\phi'_{cv} = 30^\circ$	1.66	8.00m	1.38	7.00m	1.12	8.00m	<b>1.00</b>	<b>8.00m</b>
4	4m high, 45° face, $\phi'_{cv} = 30^\circ$	1.34	3.40m	<b>1.00</b>	<b>2.40m</b>	1.43	3.40m	1.23	2.80m
5	8m high, 45° face, $\phi'_{cv} = 30^\circ$	1.50	6.00m	<b>1.00</b>	<b>4.60m</b>	1.47	6.75m	1.28	5.75m
6	12m high, 45° face, $\phi'_{cv} = 30^\circ$	1.66	8.00m	<b>1.00</b>	<b>7.00m</b>	1.29	10.0m	1.11	8.50m
7	4m high, 1 in 2 face, $\phi'_{cv} = 30^\circ$	1.72	4.80m	<b>1.00</b>	<b>3.80m</b>	1.87	7.30m	1.68	6.50m
8	8m high, 1 in 2 face, $\phi'_{cv} = 30^\circ$	1.56	10.50m	<b>1.00</b>	<b>7.00m</b>	2.03	14.5m	1.83	13.00m

n.b.  $\phi'_{12}$ =inter-wedge friction

Perhaps the most surprising feature of the results is the relative performances of the HA 68/94 and limit state slip circle methods. It would appear that despite the absence of a global factor of safety on soil strength for the HA method, with the exception of reasonably large embankments with steep faces (greater than or equal to 60°), there are considerable savings to be attained using the limit state slip circle approach.

## 5. CONCLUSIONS

The paper has reviewed the design methods most commonly used in Europe for the design of reinforced soil structures. It is clear that while there are many similarities between the methods used for the design of reinforced soil walls, several important differences exist which in some cases result in significant variation in the amount of reinforcement required to satisfy the various design criteria. Similar differences are observed in embankment design methods.

Overall it is not possible to indicate one particular design method for walls or embankments which consistently yields more cost effective reinforcement layouts. It would appear however that the limit state methods proposed in BS 8006 are economic in most cases.

There is the possibility that individual designers will select their own favourite methods for walls and embankments without being aware of the appropriateness of other approaches. However, when a particular method is chosen simply based on cost, it is important that the designer understands fully the design philosophy and reasons for the economy. In the case of HA 68/94 for example, the adoption of a high inter-wedge friction angle requires additional checks to be made to ensure a safe embankment design is achieved.

## ACKNOWLEDGEMENT

The writers would like to acknowledge the efforts of Mr. Paul McCombie in developing the design software used for the analyses referred to in this paper.

displacement field along the failure surface defined by a vertical top displacement  $y_1$  (see Figure 1), (ii) the anchored membrane concept (see Figure 2), and (iii) the geosynthetic extensibility. The local equilibrium of each sheet is considered, coupled with the tension constitutive model of the reinforcement and of that in friction of the soil-geosynthetic interface (elasto-perfectly plastic behavior). Faced with the problem of the determination of the soil stiffness modulus, a simplified mechanism of the membrane behavior has been considered by the authors: (a) The reinforcement tension is constant all along the membrane zone  $B_1B_2$  (see Figure 2) and is equal to the ones at  $B_1$  and  $B_2$ ; (b) This tension is either assumed to act in the horizontal direction or in the direction of the tangent to the failure surface (maximum inclination); And (c) the modeling of the geosynthetic behavior is considered either with a small or large displacements assumption. Note that the corresponding software "Cartage" is widely used in France for practical design work.

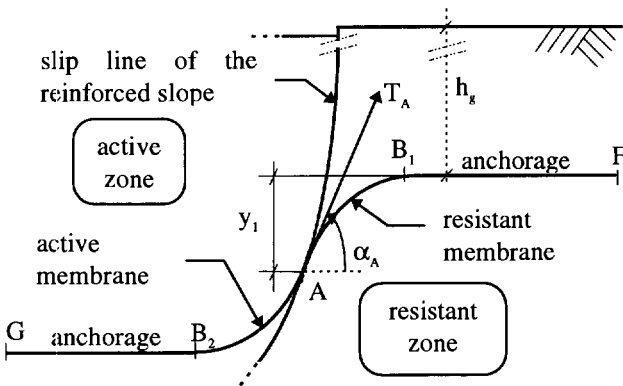

Figure 2: Anchored membrane concept.

## 2.2 Modified "Displacement Method"

This method considers a more rigorous mechanism (circular shape) of the membrane behavior. The determination of the reinforcement tension  $T_A$  (see Figure 2), which is also assumed to be constant all along the circular membrane zone, is based on the local equilibrium of this zone. Thus, the reinforcement tension and its inclination  $\alpha_A$  depend on the vertical top displacement  $y_1$  and the soil stiffness modulus. Note that the corresponding software "Membrane" is used essentially for research (Gotteland, 1991).

## 2.3 "Variational Displacement Method"

The problem has been split into two different parts:

- Global equilibrium of the sliding mass  
Applying the variational limit equilibrium method, elaborated by Baker and Garber (1977) in the case of unreinforced slopes, to the one of reinforced slopes, it

has been shown that (i) the trace of the critical failure surface is a log spiral (see Figure 1), and (ii) the only moment equilibrium equation of all forces acting on the sliding mass is enough for the determination of the safety factor  $FS$ , defined with respect to the shear strength parameters of the soil.

- Local equilibrium of the reinforcement sheets

In order to assess the reinforcement contribution to the stability, the variational calculus has been applied to the equilibrium of the membrane zone in the neighborhood of the failure surface, considering the principle of the "displacement method" (i.e.: the anchored membrane concept, see Figure 2). The variational approach allows the determination of the optimal shape (log spiral) as well as the optimal position of the sheet for which one obtains the extremal tension at the intersection with the failure surface. Thus, the tension is no longer assumed to be constant along the membrane zone. Furthermore, this method provides the tension distribution and the relative soil-geosynthetic displacements all along the sheets.

## 2.4 Comparison Of The Different Models

Table 1 shows the comparisons of some principles of the three above mentioned models, regarding (a) the global equilibrium of the sliding mass (columns 1 to 3) and (b) the local equilibrium of the reinforcements (columns 4 to 6). Note that the listed principles are those which differ from each other. It appears that the "Displacement Method" has gained in rigour in its two latter developments (i.e. less a priori assumptions). The improvement provided by the "Modified" model consists of a more rigorous determination of the reinforcement tensions. With the present model, it provides an improvement on the determination of both the safety factor (no a priori assumptions concerning the failure surface shape, nor the normal stress distribution along this surface), and the reinforcement tension (no a priori assumptions concerning the shape of the membrane zone, nor its critical position).

## 3 COMPARATIVE CASE STUDY

In order to show the developments of the "displacement method", the three above mentioned models have been applied to a 6m high wall reinforced with 11 geosynthetic layers. All other data required for the analysis are presented in Figure 3. For all three models, the safety factor  $FS$  of the soil in shear is set to 1.5. Note that all "Cartage" results correspond to the assumption of large displacements with a horizontal reinforcement tension (see §2.1).

Table 1. Comparison of some principles of the three models

Name	1. Limit equilibrium method	2. Failure surface shape	3. Search for critical failure surface	4. Critical position of the membrane zone (as rest)	5. Tension in B <sub>1</sub> B <sub>2</sub> (see Fig.2)	6. Inclination of tensions (null) or (maximum)
“Cartage”	“Perturbation”	any (circular more used)	manual	(as rest)	(constant)	(null) or (maximum)
“Membrane”	“Perturbation” Fellenius Bishop Jambu	(circular) (bilinear) (mixed)	manual	(fixed)	(constant)	(fixed)
Present model	Variational	Log-spiral*	automatic	result of minimisation process*	non constant*	result of minimisation process*

Notes: Terms in parentheses () refer to a priori assumptions, and the one followed by \* refers to analytical result.

### 3.1 Failure Surfaces

Concerning the two first models (i.e. “standard” and “modified”), and for each potential slip line (circular shape) considered, a critical vertical top displacement  $y_{ic}$  corresponding to  $FS=1.5$  is determined. The critical slip circle (represented in a dotted line in Figure 3), which is the same in both models, corresponds to the larger  $y_{ic}$  value considering six different potential slip circles (Gourc et al, 1989).

For the present model, the slip line shape is a log spiral and the critical position (represented in Figure 3) corresponds to the critical  $y_i$  value (called  $y_{ic}$ ) which provides a safety factor  $FS=1.5$  as its minimum value, considering 860 different log-spirals passing through the toe of the wall.

Note that these two lines are rather close to each other in the lower half part of the wall, then the log-spiral is placed further away from the facing than the circle. Nevertheless, regarding the difference in the determination of the critical position of the failure surface in each model, the scatter between these positions is small.

### 3.2 Critical Vertical Top Displacements

Concerning the critical vertical top displacements  $y_{ic}$ , the standard model gives 26mm, the modified one gives 50mm, and the present one gives 88mm (see Figure 3). Thus, it seems that there is a tendency in the development of the method for an increase of this key parameter.

### 3.3 Critical Tension Distributions

Figure 4 shows the distribution of the critical tensions and of their inclinations along the failure surfaces. It is interesting to note that the tension distribution of the present model is close to the one of “Cartage” in the

upper half part of the wall, and close to the one of “Membrane” in the lower half part. Plus, the present model gives the lowest maximal tension  $T_{max}$  (presented in Figure 4), which is reached in the lowest sheet in each model. Nevertheless, the scatter between these tension distributions is rather small.

Figure 3. Case study - Critical positions of the theoretical failure surfaces

### 3.4 Critical Tension Inclination Distributions

Concerning the tension inclinations, the distributions as given by “Membrane” and the present model (null for “Cartage”) are very different from each other. “Membrane” distribution decreases continuously with the depth, while the one of the present model passes through a minimum value at the second layer (see

Figure 4), then from the 8<sup>th</sup> layer and deeper it reaches the maximal inclination distribution, which corresponds to tensions tangent to the failure surface (the log-spiral of Figure 3).

Figure 4. Comparative study (case study of Figure 3)

### 3.5 Discussion

The present comparison study shows that (i) the critical failure surfaces obtained with the three models are close to each other (see Figure 3), (ii) the reinforcement tension distributions along the failure surface are similar (see Figure 4), but (iii) the obtained critical vertical top displacements  $y_w$  has been increased significantly from one model to its following development (92% between the two first, and 76% between the two last). However, the latter parameter is difficult to correlate to actual measurements, and further research should be performed on the validation of these models on real structures build and tested to failure.

## 4 CONCLUSION

This paper presents the recent developments of the "displacement method". This method, which is the standard in France for the design of geosynthetically reinforced earth structures, has since been improved at least twice. The first improvement concerns the determination of the reinforcement tensions, the second one also concerns the determination of the safety factor of the structure. Indeed, the originality of the latter is

the application of the variational calculus on both the equilibrium of the sliding mass and the one of the membrane zone in the vicinity of the failure surface. This analysis allows a significant decrease in the number of a priori assumptions considered in the previous models. A comparative study on a 6m high wall has shown that the rigour tends to increase the obtained critical top displacement.

# Locally Loaded Geosynthetic Reinforced Soil Structure: Calculation Method

E. Haza

Ph.D., Lirigm, Grenoble University, France

P. Gotteland

Assistant Lecture, Lirigm, Grenoble University, France

J.P. Gourc

Professor, Lirigm, Grenoble University, France

**ABSTRACT:** This article presents a proposed method for the preliminary design of geosynthetically reinforced soil structures, adapted to the case of localised surface loads. The first section describes two modifications made to the basic calculation method: firstly, to consider the deformable nature of geosynthetics and, secondly, to consider a local equilibrium calculation of each reinforcement. In the second section, an attempt is made to validate the proposed initial modifications on the basis of results obtained using an experimental structure locally loaded up to its failure point. The local approach seems satisfactory.

**KEYWORDS:** Retaining wall, Reinforcement calculation method, concentrated top load, Prediction, Experimentation.

## 1. INTRODUCTION

Geosynthetically reinforced soil embankments with flexible facings are commonly used in France for retaining purposes; their ability to bear is also currently being studied at the Grenoble Lirigm laboratory. This article will concentrate on this function for case where the head of the structure is locally loaded.

Little is known about structures with flexible reinforcement sheets which are locally loaded at the head. Observation of the way in which instrumented embankments fail (Matichard and al., 1992, Lensiewska and al., 1992) shows that the reinforcing sheets in the upper part of the embankment are placed under high stress by the slab which perforates the embankment, and that the tensile force and slope of the reinforcing sheets in the shear zone are greatly reduced towards the base of the embankment. This behaviour is the reverse of that of a structure with no localised overload or which is evenly overloaded, where the sheets at the base are under greatest tensile forces.

On a reference experimental structure (Gourc and al., 1995) (Photo 1), an attempt will be made to validate a preliminary design method for these structures which is quick and easy to use: the modified double-block method (shortened to DB), based on the limit equilibrium calculation principle. This method is sufficiently widely used to study the stability of structures which are either not overloaded or evenly overloaded.

Photo 1. The GARDEN experimentation

## 2. THE DOUBLE-BLOCK METHOD (DB)

With the DB method, the active part of the embankment is divided into two rigid blocks placed side by side and assumed to be slipping. The slip line is bilinear, with kinematic convexity condition.

The points where the slip line intersects the facing (point A) and the upper surface of the embankment (point C), as well as the positions of the slope break point and the inter-block line (point B) are selected by the user (Figure 1).

The limit equilibrium of the double block is calculated by applying a resultant horizontal thrust  $P$ , redistributed throughout the reinforcing sheets  $j$  (tensile forces  $T_j$ ) (Figure 1). The slip line is assimilated to the line along

which the maximum tensile forces are accommodated in the reinforcing sheets. The equality  $\Sigma T^j = P$  is checked.

Figure 1. Double-Block method principle.

Figure 2. Local equilibrium of a reinforcing sheet j.

The distribution used for the resultant vertical stress of the localised overload Q is almost vertical inside the embankment (angle of distribution  $\phi_{soil}/4$ ). The vertical stress at the reinforcing sheet j which is applicable in the distribution zone will be called  $\sigma_Q^j$ .

The safety coefficient F is applied to the mechanical properties of the earthfill. The theoretical failure of an embankment is thus obtained when  $F=1$ .

Two approaches are proposed for the preliminary design, one known as *overall* and the other *local*.

### 2.1 Overall Approach (OA)

Overall equilibrium of the unstable area is considered to be ( $\Sigma T^j = P$ ).

In a first option (OA1), the tensile forces  $T_{OA1}^j$ , mobilized in the reinforcement sheets, are fixed; the value of F is deduced.

A second option (OA2) consists in fixing F and then deducing a uniform tensile force distribution throughout

the reinforcement ( $T_{OA2}^j = T_{OA2}$ , except on case of anchorage problem). The critical slip line is obtained for the maximum value of  $T_{OA2}$ .

### 2.2 Local Approach (LOC)

Another approach consists in studying the local equilibrium of the complex [soil+reinforcing sheet] at the level of each reinforcing sheet for a predefined slip line (Figures 1 and 2).

The action of the localised head load Q is separated from the action of the deadweight of the soil. This means that a different distribution can be considered for each of these actions along the slip line.

The double-block equilibrium thrust  $P_Q$  is calculated for the double-block only subjected to Q, for a density of the soil body in the double-block assumed to be zero. In accordance with the observations already made, the distribution made is one whereby the upper reinforcing sheets which are under greater tensile forces. The distribution of  $P_Q$  is trapezoidal. The proposed hypothesis consists in assuming that the reinforcing sheets are under tensile forces only if their intersection with the slip line is included in the top load area of influence (Figures 1 and 2).

A thrust coefficient  $K_Q$  is calculated on the basis of  $P_Q$  to determine local tensile forces  $T_Q^j$  :

$$K_Q = \frac{P_Q}{\sum_j \sigma_Q^j \cdot \Delta H} \quad (1) \quad \text{and} \quad \begin{cases} T_Q^j = K_Q \cdot \sigma_Q^j \cdot \Delta H^j \\ \Sigma T_Q^j = P_Q \end{cases} \quad (2)$$

For the action of weight of the soil, the conventional triangular distribution hypothesis is considered. The thrust  $P_\gamma$  is calculated, equilibrium resultant of the double-block under its own weight, on the basis of which the thrust coefficient  $K_\gamma$  and the local tensile forces  $T_\gamma^j$  are deduced.

$$\begin{cases} T_\gamma^j = K_\gamma \cdot \gamma \cdot (H - Z^j) \cdot \Delta H^j \\ \Sigma T_\gamma^j = P_\gamma \end{cases} \quad (3)$$

The tensile force in the reinforcing sheet j is then obtained by (Figure 2):  $T_{Loc}^j = T_Q^j + T_\gamma^j$ .

Given the cases examined, where the overload Q is high compared with the soil weight, the tensile forces  $T_Q^j$  will be generally high compared to the tensile forces  $T_\gamma^j$ , and thus predominant in the design of the structure.

### 3. COMPARISON WITH EXPERIMENTAL RESULTS

#### 3.1 Experimental structures

The GARDEN programme ("Geotextile": Application in Reinforcement: Experimentation and Normalisation) consisted in loading to failure point two embankments with cellular facings (Löffel type), at an 80° slope (Photo 1).

These embankments have a total height  $H = 4.35$  m, and are reinforced by geosynthetics having a tensile strength ( $T_p$ ) and different stiffness moduli, with local head loading (Gourc and al., 1995). The loading system is presented on the Figure 3.

An exhaustive assessment of the behaviour of these two structures has been made (Haza, 1997). They were hardly instrumented (Figure 4).

One of these embankments is shortly presented here : the embankment reinforced by a non-woven polyester geosynthetic (NW embankment, Figure 5). The other embankment is reinforced by a woven polyester geosynthetic (W embankment, figure 6).

The mechanical properties of the earthfill are  $\phi = 36^\circ$ ,  $C = 4$  kPa and  $\gamma = 19$  kN/m<sup>3</sup>.

Figure 3. Loading system of both experimental embankments.

Figure 4. Instrumentation of the NW embankment.

Figure 5. NW embankment profile - slip lines retained for the reverse calculations.

Figure 6. W embankment profil - slip line retained for the reverse calculations.

### 3.2 Preliminary design stage

#### 3.2.1 Definition of profiles: overall approach (OA)

The preliminary design of these experimental structures was carried out using the overall approach (OA2): the safety coefficient was fixed ( $F = 1$ , theoretical failure reached), as was the maximum load considered at the conceptual design stage  $Q = 330$  kN/m.

The critical slip line was obtained (LG 1 in the NW embankment, Figure 7). The selected tensile strength of the geosynthetic used was equal to  $T_{OA2}$  ( $T_f = T_{OA2} = 25$  kN/m in the NW embankment).

Figure 7. Preliminary design stage - tensile force distribution (NW embankment).

However, since the anchoring strength of the two upper sheets is low ( $< T_f$ ), these sheets were made longer. Thus, the NW embankment is reinforced by eight 3 m long sheets and two 4 m long upper sheets and the W embankment is reinforced by three 3 m long sheets and two 4 m long upper sheets (Figures 5 and 6).

#### 3.2.2 Forecast failure load: local approach (LOC)

For  $Q = 330$  kN/m,  $F = 1$  and slip line LG 1 defined above, the tensile force distribution  $T_{LOC}^j$  gives values much higher than  $T_f (= 25$  kN/m) in the upper two thirds of the NW embankment (Figure 7).

A new loading condition  $Q$  was then calculated compatible with a maximum tensile force value  $T_{LOC}^j$  closer to  $T_f$ . A value of  $Q_{LOC}^F = 185$  kN/m was obtained for a maximum value of  $T_{LOC}^j = 25$  kN/m (Figure 7). The same value of  $Q_{LOC}^F$  was obtained for the W embankment, for a maximum value of  $T_{LOC}^j = 44$  kN/m ( $= T_f$ ).

### 3.3 Feedback from experimentation

At the end of the test, the maximum load applied on the two embankments was  $Q_{EXP} = 230$  kN/m.

By measuring the displacement of reinforcing sheet points at failure, the range of maximum reinforcement sheet strain zones can be obtained (Figures 3 and 4). The distribution of experimental tensile forces  $T_{EXP}$  can then be estimated (Figure 8, in the NW embankment). Observations of the two embankments confirmed that the upper sheets work much harder than the others, and tend to bend considerably (Gotteland and al., 1997).

The critical slip line selected for the preliminary design in the NW embankment (LG 1) was not exactly within the range of maximum tensile force values. In the following discussion, two other slip lines included within this range, LG 2 and LG 3, were considered in the NW embankment for carrying out the reverse calculation using the DB method. The slip line LG 4, included within the range of maximum tensile force values, was considered in the W embankment for the reverse calculation (Figures 5 and 6).

#### 3.3.1 Reverse calculation: overall approach (OA)

The forecast failure load in the overall approach (§ 3.2.1) was 330 kN/m, a value much higher than the load observed under experimental conditions ( $Q_{EXP} = 230$  kN/m).

The overall approach (OA1), with  $Q_{EXP} = 230$  kN/m and  $T_{OA1}^j = T_{EXP}^j$  applied along the line LG 2 and the deeper line LG 3, gives safety coefficient values of  $F = 0.66$  and  $F = 0.995$  respectively (Figure 8). Therefore,

with the overall approach, the safety coefficient  $F$  depends closely on the slip line chosen, although the two lines considered are relatively close. A satisfactory result is obtained for line LG 3 ( $F \approx 1$ ).

Figure 8. Experimental tensile force distribution in the NW embankment.

### 3.3.2 Overall approach: proposed development

In the shear zone, flexible reinforcing sheets become deformed. Therefore, the stress that builds up here does not remain horizontal.

A vertical component of the tensile forces along the shear line, taken into account in the active double-block equilibrium, was introduced into the calculation (Haza, 1997).

In the light of the observations, it is proposed to divide up the active zone of the embankment into two simplified zones :

- a "top" zone (above point B, Figure 1), where the tensile forces that build up in the reinforcements are all inclined at the same angle  $\beta$ ,
- a "bottom" zone (below point B, Figure 1), where the tensile forces remain horizontal.

As before, the option (OA1) is applied in the NW embankment with  $Q = Q_{EXP} = 230$  kN/m, by imposing  $T_{OA1}^j = T_{EXP}^j$  but inclining the "top" forces at  $\beta = 35^\circ$  (inclination of sheet n°10 measured when the structure was dismantled). To ensure that only the upper reinforcing sheets were inclined, line LG 2 is considered because point B is high up in the embankment.  $F = 0.705$  in place of 0.66 was obtained. By inclining these forces, a slight increase in the safety coefficient  $F$  was observed; it nevertheless remains less than 1.

### 3.3.3 Local Approach (LOC)

During the preliminary design, the foreseeable failure load obtained ( $F = 1$ ) is less than the failure load measured experimentally ( $Q_{LOC}^F (=185$  kN/m) <  $Q_{EXP} (=230$  kN/m)).

To compare the results of the local approach with the overall approach, the slip lines LG 2 and LG 3 are also used in the NW embankment (Figure 9), and the slip line LG 4 in the W embankment (Figure 10).

By applying  $F = 1$  and  $Q = Q_{EXP} = 230$  kN/m, the tensile forces distribution calculated along the slip line LG 2 is much higher than the distribution obtained experimentally, whereas along LG 3 it is closer. Thanks to the low position of point B on line LG 3, the deeper-lying reinforcement sheets in the embankment can also take part in the overload double-block equilibrium because they are directly involved in load distribution within the embankment (Figure 9). The thrust  $P_Q$  is thus distributed among a greater number of reinforcement sheets, thereby reducing the tensile forces  $T_{LOC}^j$ . Meanwhile, the tensile forces distribution calculated along the slip line LG 4 in the W embankment is not so close to the distribution obtained experimentally (Figure 10). The very large vertical space between the sheets at the middle level of the W embankment can be an explanation of this result.

Figure 9. Reverse calculation by the local approach (NW embankment)

As the point B (Figure 1) is near the bottom of the embankment, its exact position has little bearing on the values of  $T_{LOC}^j$ ; the same is true for the position of point A, as the level of participation of the lower sheets remains very low.

Figure 10. Reverse calculation by the local approach (W embankment).

This type of slip line, emerging at C, just upstream of the loading slab, with a high angular opening, would seem to match the local approach modelling system used here.

The same type of slip line could be used for the design of reinforced embankment whose geosynthetic is more or less stiff. Indeed, we observed, during the GARDEN experimentation, that the position of the experimental slip line is similar in both embankments (Figures 5 and 6). However, the stiffness moduli of the geosynthetics were different ( $J_{NW} = 95 \text{ kN/m}$ ,  $J_W = 340 \text{ kN/m}$ ).

#### 4. CONCLUSIONS

The operating and failure mechanisms of geosynthetically reinforced earth structures, with local head loading condition, are still relatively unknown. This paper proposes the outlines of a simple and fast calculation method for the preliminary design of such structures. Two modifications to the double-block method, the first to take into account the deformable nature of the reinforcing material (Overall Approach), and the other to take into

account a distribution of the tensile forces produced by Local Approach, are used to approximate the observed behaviour on experimental structures subjected to massive deformation.

The Local Approach proposed gives promising results and should become even more satisfactory with possible allowance being made for the angle of inclination of the tensile forces, i.e., consideration for the deformable nature of the reinforcing sheets.

We have suggested (Haza, 1997) a design method which needs now to be validated on several experimental results.

# Measuring geotextile strains with strain gages

Stanley R. Boyle  
 Engineer, Shannon & Wilson, Inc., Seattle, Washington, USA

Robert D. Holtz  
 Professor, Department of Civil Engineering, University of Washington, Seattle, Washington USA

**ABSTRACT:** Laboratory research was undertaken to evaluate the effectiveness of electrical resistance strain gages to measure geotextile strains. At low strains, typical of those observed in geosynthetic reinforced soil slopes and walls, the strain gages were found to underrecord total strain and incremental strain in both in-isolation and in-soil load-elongation tests on both polypropylene and polyester woven geotextiles. The degree of underrecording decreased with increasing geotextile strain. Strain gages were effective for measuring the strain distribution in geotextiles and for monitoring geotextile creep.

**KEYWORDS:** Geotextiles, reinforcement, strain gages, strain measurements, testing

## 1 INTRODUCTION

To evaluate the effectiveness of electrical resistance strain gages for measuring strains in reinforcement geotextiles, a series of load-elongation tests were performed on woven polypropylene and polyester geotextiles to which strain gages had been attached. Specimens 100 mm long by 200 mm wide were tested in isolation and confined in soil. Three polypropylene woven slit film geotextiles (PP1, PP2, and PP3) and two polyester woven multi-filament geotextiles (PET1 and PET2) were included in the test program, Table 1.

Table 1: Geotextiles tested.

Material	Material and Description	Strength <sup>1</sup>
PP1	Polypropylene, woven, slit-film	26 (15) <sup>2</sup>
PP2	Polypropylene, woven, slit-film, 2 layer stitch-bonded	49 (15) <sup>2</sup>
PP3	Polypropylene, woven, slit-film, 3 layer stitch-bonded	77 (15) <sup>2</sup>
PET1	Polyester, woven, multi-filament	215 (10) <sup>3</sup>
PET2	Polyester, woven, multi-filament	175 (10) <sup>2</sup>

<sup>1</sup> Wide width strength, kN/m, and associated (elongation, %), ASTM D 4595.

<sup>2</sup> Manufacture supplied data from Industrial Fabrics Association International (1990, 1992).

<sup>3</sup> Average value from Allen et al. (1992).

In-isolation wide width tests were performed using an MTS testing machine which had been fitted with hydraulically operated clamps, in accordance with ASTM D 4595. The geotextiles were loaded to failure at rates of 10%/min and 1%/min. In an attempt to eliminate end effects, overall elongation of the geotextiles was measured using a "scissors" type displacement measurement device,

Figure 1. The scissors were attached to the geotextiles by pushing needles, mounted at the end of each arm, through the geotextile. The distance between the needles at the beginning of each test, approximately 60 - 75 mm for 100 mm gage length specimens, was used as the initial gage length for calculating overall strains in the woven geotextiles. No measurable reduction in strength resulted from insertion of the needles.

Figure 1: In-isolation test device.

In-soil tests were conducted using a plane strain unit cell device (UCD), Figure 2. During UCD tests, horizontal deformation of the soil is resisted by an applied lateral confining pressure and by tensile loads induced in the reinforcement. Elongation and tension in the geosynthetic specimen are measured, respectively, by LVDT's and load cells connected to the clamps which grip the reinforcement at both ends. Stiff end plates, to which the clamps are mechanically linked, ensure the reinforcement and soil

Figure 2: Unit Cell Device (UCD).

displace equally in the lateral direction during loading and that the faces of the specimen remain orthogonal. Because the UCD is a load control device, with load applied vertically to the soil specimen, neither the vertical nor horizontal (reinforcement) strain rates could be controlled, but they could be measured.

Dimensions and yield strain of the high-elongation strain gages used in the testing program are presented in Table 2. A single gage was attached at the center of each in-isolation specimen. Two or three gages were used in the in-soil tests; they were positioned along the length of the geotextile specimen to permit measurement of the strain distribution. After preparing the surface with a primer, the Tokyo Sokki Kenkyujo, Co., Ltd. Model YL-series gages were attached to the polypropylene woven geotextiles using a cyanoacrylate type CN adhesive. The BLH, Inc. SR-4 type, model PA-series gages were attached to the polyester geotextiles using an SR-4 adhesive, without priming the surface. To protect the strain gages during soil compaction and load application in the in-soil tests, the strain gages and their lead wires were coated with type MB-4 rubber cement and then covered with a small piece of 0.3 mm thick latex rubber.

Table 2: Strain gages tested.

Gage Type	Gage Length and Width (mm)	Backing Length and Width (mm)	Yield Strain (%)
YFLA-2	2 x 1.8	7.5 x 4	10 - 15
YL-10	10 x 3	20 x 7	10 - 20
YL-20	20 x 3	30 x 7	10 - 20
PA-3	19 x 11	51 x 13	10
PA-7	6.4 x 7.5	29 x 9.5	8

Additional details on the in-isolation test procedure and results; UCD design, operation, test procedure and results; geotextile sample preparation; and strain gage tests are presented in Boyle (1995a, b), Gallagher (1995), and Boyle et al. (1996).

## 2 RESULTS

### 2.1 In-isolation Test Results

The YL-20 strain gages, attached to the woven polypropylene slit-film geotextiles, PP1, PP2, and PP3, appeared to work adequately until they reached the gage yield strain or the backing started to debond from the geotextile, conditions that typically occurred between 6% and 12% strain. In all cases the YL-20 strain gages reported less strain than was recorded for the overall specimen.

To facilitate evaluation of strain gage performance we looked at the ratio of strain gage strain to total strain (SR), defined as:

$$SR = \epsilon_{sg}(t) / \epsilon_{total}(t) \quad (1)$$

where:

$\epsilon_{sg}(t)$  = strain gage strain at time t

$\epsilon_{total}(t)$  = total overall strain at time t

The SR for a given strain gage-reinforcement combination changed throughout each test and differed from one test to another, Figure 3. After the first 1% strain the SR typically increased to a maximum that occurred between 3% and 8% overall strain.

Figure 3: SR versus overall specimen strain for in-isolation test on PP2 with YL gages.

To reduce the influence of initial strain readings on the analysis, an incremental strain ratio, ISR, was defined:

$$ISR = \frac{\epsilon_{sg}(t_2) - \epsilon_{sg}(t_1)}{\epsilon_{total}(t_2) - \epsilon_{total}(t_1)} \quad (2)$$

For the YL gages, as shown in Figure 4, the ISR results fell in a slightly narrower band than was exhibited by the SR. The pattern of ISR versus total strain for the three polypropylene geotextiles were similar. The ISR generally increased to a maximum between 3% and 8% total strain, and then decreased at larger strains (Gallagher, 1995; Boyle, 1995a). The decrease in ISR, and SR, after about 8% strain likely results from debonding of the strain gage from the geotextile or may be due to yielding of the strain gage. At small strains, i.e. 0.5%, ISR values were typically in the range 0.1 to 0.5. The ISR values for the YL-20 gages tested in isolation increased to a maximum at strains greater than 3%. These maximums were typically between 0.8 and 1.2, although values as high as 1.3 were found. Thus, at higher strains, the incremental strain measured by the strain gages was relatively accurately measured. However, strains of this magnitude have not been commonly reported for instrumented wall case histories (Allen et al., 1992; McGown et al., 1993).

Figure 4: ISR versus overall specimen strain for in-isolation test on PP2 with YL gages

Tests with PA-3 gages attached to polyester reinforcement PET2 met with only limited success. Only two of the in-isolation tests conducted with these strain gages produced reasonable results (Gallagher, 1995). For these two tests, the initial ISR values of 0.78 and 0.91 were higher than the initial values for the YL-20 gages attached to the polypropylene geotextiles. The maximum ISR values were approximately 1.1. ISR values on this order indicate the strain gages were not underrecording incremental strain substantially. However, the non-incremental strain ratio, SR, did underrecord strains, and was sensitive to the initial "zero" strain gage reading selected. Because the PA-3 gages tended to debond from the polyester geotextile at strains between 1% and 3%, evaluation of strain gage performance at higher strains was not possible on the woven polyester geotextiles.

## 2.2 In-Soil Test Results

The pattern of strain recorded by the YL strain gages when attached to the polypropylene geotextiles, including creep strain, was similar to the pattern for overall lateral (geotextile) strain in the majority of the UCD strain gage tests conducted, Figure 5. This similarity, plus the smooth, continuous nature of the data, was interpreted as evidence that the strain gages were behaving properly. As in the isolation tests, the gages underrecorded total strain, Figures 5, 6, and 7. For YL gages attached to polypropylene reinforcements PP1, PP2, and PP3, the SR ranged from 0.3 to 1.0. As occurred in the in-isolation tests, during the initial stages of each test SR increased with increasing strain, Figure 6. Since total strain was limited (by the UCD device) to less than 6% in the in-soil tests, debonding or yield of the strain gages did not occur.

Figure 5: Overall specimen strain and strain gage measured strain for in-soil test, PP2 with YL-10 gages.

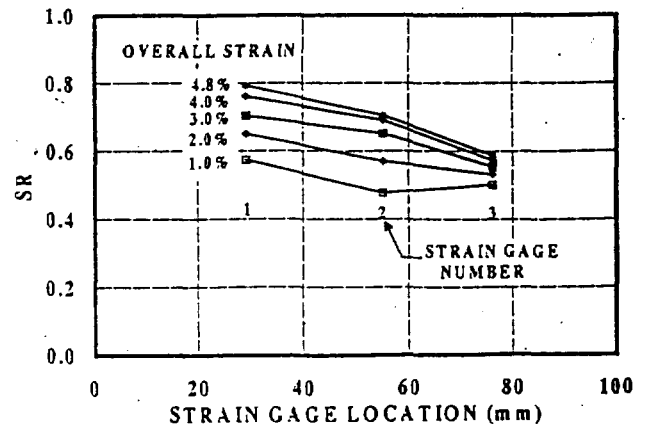

Figure 6: SR for gages at different locations along in-soil test specimen, PP2 with YL-10 gages.

Figure 7: ISR for gages at different locations along in-soil test specimen, PP2 with YL-10 gages.

There was less fluctuation in the ISR values for the YL strain gages in in-soil tests than was recorded in the in-isolation tests, Figure 7. The smoothing of the response may be due to the reduction of specimen flexibility by confinement in soil. As with the in-isolation tests, the ISR for in-soil tests tended to increase with increasing overall specimen strain. Initial ISR values (e.g., at 0.5% strain) for the three different length YL gages were between 0.20 and 0.80. At higher strains ISR generally fell in the range 0.3 to 1.10, although maximums as high as 1.32 were observed, see Table 3. While SR or ISR values near 1.0 would indicate relatively accurate measurement of geotextile strains, the SR and ISR did not approach or exceed 1.0 until strains greater than 3% were attained. This is three times the strain reported in geosynthetic reinforced walls (Allen et al., 1992; McGown et al., 1993).

Table 3: Range of SR and ISR values.

Strain	YL-series gages		PA-series gages	
	In-Isolation	In-Soil	In-Isolation	In-Soil
<b>SR</b>				
0.5%	----	0.3 - 0.8	----	0.3 - 0.7
4% - 6%*	0.5 - 1.0	0.4 - 1.0	----	0.3 - 0.7
<b>ISR</b>				
0.5%	0.2 - 0.7	0.2 - 0.8	0.8 - 1.0	0.4 - 0.7
4% - 6%*	0.8 - 1.3	0.3 - 1.3	0.7 - 1.1	0.1 - 0.9

\* Range at 1% to 2% used for PA gages.

Only two in-soil tests were conducted with PA-7 gages, both mounted on Reinforcement PET1. In these tests the ISR at 0.5% strain fell between 0.4 and 0.7, but ranged as wide as 0.1 to 0.9 at higher strains. These values are lower than was observed in the in-isolation tests for PA-3 gages attached to PET2. As with the in-isolation tests, the PA

gage responses were somewhat erratic and strains to only a few percent were recorded.

### 2.3 Discussion

The SR and ISR values for the YL gages in the in-soil tests were more uniform and less erratic than for the in-isolation tests. While the in-soil and in-isolation ISR values were similar, there was slightly less variation in the in-soil ISR values at each strain level, Table 3. From these tests, neither in-soil or in-isolation resulted in more accurate measurement of geotextile strains. At strains less than 2% the initial ISR for in-isolation tests were somewhat, though not significantly, lower than for in-soil tests. At strains from 4% to 6% in-isolation ISR values were slightly higher than in-soil values. Initial ISR values were also slightly lower for in-soil tests with YL-2 gages (7.6 mm length) than for the longer YL-10 (20.5 mm) and YL-20 (30.5 mm) gages. The PA gages did not behave better in-soil than in-isolation, and we experienced difficulties with their adhesion to the geotextiles under both test conditions. The in-isolation ISR values were closer to 1.0 than were the in-soil ISR values. This difference may be related to the different strain gage lengths; the longer PA-3 gage may be better at recording overall strain than the shorter PA-7 gage.

An insufficient number of tests were performed to conclude that the strain gages attached to geotextiles behaved better in in-soil tests than in in-isolation tests, or vice-versa, or that longer gages perform better than shorter ones. There is, however, sufficient data to conclude that strain gages of the type tested can be expected to underrecord both total and incremental strain when attached to woven polypropylene slit-film or woven polyester multi-filament geotextiles, especially at low strains. A number of factors may contribute to this phenomenon:
