Geosynthetics 2013

We are pleased to present the electronic proceedings of Geosynthetics 2013.

The Geosynthetics 2013 plenary and technical programs included more than 140 papers assigned to 26 sessions over the three-day conference period.

Geosynthetics 2013 also featured a sold out trade show and impressive participation from our very generous sponsors. We wish to thank them for their generous financial contributions that helped make this show possible. Please be sure to visit their websites by clicking on the logos to the left.

Disclaimer: The opinions expressed and the data provided during Geosynthetics 2013 and the published Proceedings are those of the author(s) and/or presenter(s) and do not necessarily represent the opinions of the Industrial Fabrics Association International (IFAI) or any of its subsidiaries or divisions. Papers contained in these proceedings are the original work of each author. For permission to reprint any paper or presentation materials in these proceedings, please contact the authors directly or the IFAI Bookstore Manager, 1801 County Road B West, Roseville, MN 55113-4061 USA.

GRI - 25

Geosynthetics 2013 is the site for the 25th edition of the [Geosynthetic Research Institute](#) (GSI) conference, GRI-25.

The theme for this year's conference is "25-Year Retrospective on the Geosynthetics Industry and Glimpses into the Future."

[GRI-25 Foreword and Table of Contents](#)

April 1

Geosynthetic Materials and Properties

[Innovation in Polyolefin Resins Used in Geosynthetics Over the Past 25 Years](#)

Grace Hsuan, Drexel University

[Antioxidants for Geosynthetic Resins and Applications](#)

Joseph J. Fay, BASF Corp.

[Overview of Geomembrane Manufacturing Methods](#)

Fred Struve, Consultant

[Opportunities and Solutions, Developments and Growth of the Geomembrane Industry](#)

Gary Kolbasuk, Raven Industries

[Thermal Seaming of Polyethylene Geomembranes](#)

Mark Sieracke, Weaver Boos Consultants Inc. and Ian Peggs, I-CORP Intl.

[The Language of an Industry: Geosynthetics Testing and Measurement](#)

Sam Allen, TRI/Environmental Inc.

[Background and Development of GRI's Geosynthetics Specifications](#)

George Koerner and Robert Koerner, Geosynthetic Institute

[Geotextile Filters...25+ Years of Research and Experience](#)

Robert D. Holtz, University of Washington and Barry Christopher, Christopher Consultants

[A Brief History of Geosynthetic Drainage Media: From Rocks to SIM Tested, Patented, Strand Geometries](#)

Boyd Ramsey, GSE Lining Technology LLC

[Engineering Characteristics of Geosynthetic Clay Liners: Questions Asked and Answered Over Time](#)

Dave Daniel, University of Texas - Dallas

[Geofoam: History of the Lightweight Contender](#)

Jamie R. Koerner

FOREWORD TO THE GRI-24 CONFERENCE

This conference focuses on the first 25 years of the geosynthetics industry insofar as its materials, properties, systems and infrastructure is concerned. Prior to that, there appeared very few extremely disconnected segments of the emerging technology at least from the perspective of written articles and papers. The earliest of these segments are the following:

- The first “pond liners” were used for reservoirs and canals in 1946
- “Net-like” drainage structures were developed and patented in 1960
- The first fabrics for soil subgrade stabilization, aka “road rugs”, were used in the late 1970’s
- “Filter fabric” applications were first reported in 1966
- “Grid-like” products were developed for soil reinforcement in the late 1970’s

Of course, the above “firsts” (with their eclectic names) have today been brought under the specific product terminology of geomembranes, geonets, geotextiles and geogrids. Together with the much more recently introduced products of geosynthetic clay liners, geofoam, geocells, and numerous geocomposites they form the technology we now know as “geosynthetics”.

This leaves the specific date of the beginning of *geosynthetics* very subjective. The earliest of conferences was in Paris in 1977, however, it focused entirely on geotextiles. This was followed by conferences in Las Vegas in 1982 and in Vienna in 1986, both predominately on geotextiles and then one in 1984 in Denver on geomembranes. The earliest books; on pond liners in 1977 and construction fabrics in 1980, were published by J. Wiley and Sons in a practical construction guide series. ASTM had its first impromptu meeting in New York City in 1977 and was focused mainly on “textiles in the ground”. The point we make is that none of these events can be considered as the beginning of the holistic technology of geosynthetics.

“Geosynthetics” as a unified and coalesced technology in its own right can arguably be dated by a series of closely dated events. They are the formation of the International Geosynthetics Society (IGS) in 1983, the publication of the magazine, GFR, also in 1983, the coalescence of the American Society of Testing Materials (ASTM) into a Geosynthetics Committee in 1985 and the formation of the Geosynthetic Research Institute (GRI) in 1986.

Thus, the beginnings of geosynthetics, per se, appears to the editors of these proceedings to be in the time frame of 1983-1986. Dating from this general time frame, we are now at the twenty-fifth of our GRI conferences and it appears to be a fitting time to reflect on the now unified technology of geosynthetics. In so doing, GRI-25 is presented as attempting to capture the past record of geosynthetics insofar as the materials involved, their myriad properties, how they are formed into systems for various major applications and the organizational infrastructure of the technology. We sincerely hope that the participants of the conference and readers of these proceedings find the efforts of the authors authoritative and reflective of the first quarter century of the technology.

ACKNOWLEDGMENTS

The Geosynthetic Institute (GSI) is an umbrella organization which encompasses all facets of geosynthetic materials. The five sub-institutes focus on research, education, information, accreditation and certification. A conference such as this one contains all of these activities. Clearly, research is being presented. Obviously, the effort is meant to be educational. Additionally, these proceedings form an information outlet which is available to all who are interested. Lastly, the important issues of accreditation and certification influence all of our undertakings.

The institute itself is open to all organizations involved or interested in geosynthetics. This includes government (federal, state and local) agencies, facility owners, designers, consultants, testing laboratories, quality assurance organizations, resin and additive suppliers, manufacturers, manufacturer's representatives, contractors, installers, and research institutes. Recent categories of Affiliated Organizations and Associate Members have been added to facilitate international outreach and to include state regulatory agencies, respectively. Information is available on our Home Page at <www.geosynthetic-institute.org> or from the editors of these proceedings. We wish to acknowledge and thank all of the GSI members and associate members for their support of our endeavors. The current organizations (in the order in which they joined the institute) and their representatives are as follows. Current Board of Director members are identified accordingly.

Full Members of the Geosynthetic Institute

GSE Lining Technology, Inc. - *Boyd Ramsey*
AECOM - *Kevin McKeon/Ken Bergschultz/John Trast*
U.S. Environmental Protection Agency - *David A. Carson*
E. I. DuPont de Nemours & Co., Inc. - *John L. Guglielmetti/David W. Timmons*
Federal Highway Administration - *Silas Nichols/Daniel Alzamora*
Golder Associates Inc. - *Mark E. Case/Tim Bauters*
Tensar International Corporation - *Mark H. Wayne [BoD]*
Colbond Geosynthetics - *Richard Goodrum*
Geosyntec Consultants - *Steve Poirier*
Syntec Corp. - *Aigen Zhao*
LyondellBasell Industries - *Fabio Ceccarani/Melissa Koryabina*

INNOVATION OF POLYOLEFIN RESINS USED IN GEOSYNTHETICS OVER THE PAST 25 YEARS

Y. G. Hsuan

Department of Civil, Architectural and Environmental Engineering, Drexel University, Philadelphia, PA USA

ABSTRACT

Polyolefin is the most widely used polymer for the manufacturing of geosynthetics and will be focused on in this paper. Over the past 25 years, the advance of polyolefin resins is significant and has contributed to the innovative development of new catalysts and modern design of the polymerization process. For example, polyethylene with bimodal molecular weight distributions can achieve an ultra-high stress crack resistance and impact resistance. For polypropylene, new copolymers produced by reactor granule technology can reach flexibility and impact resistance beyond some of the rubbery elastomers. This paper briefly summarizes the new catalysts and polymerization processes used to produce modern polyolefin resins.

INTRODUCTION

By definition, geosynthetics are defined as planar products manufactured from polymeric material used with soil, rock, earth or other geotechnical engineering related material as an integral part of a human-made project, structure, or system. Thus, polymers are the essential part (≈ 97 wt. %) of all geosynthetic products and their properties are related accordingly. The majority of geosynthetics (including polyolefins) are made from thermoplastic polymers which can be processed through an extruder into specifically designed products. Table 1 shows the polymers commonly used in geosynthetics. To varying degrees, polyethylene (PE) and polypropylene (PP) are the two dominant types of polymer for geomembranes (GM), geotextiles (GT), geonets (GN), geopipe (GP), geogrids (GG) and geocomposites (GC).

The four most widely used polymers: PE, PP, PET and PVC, are sometimes referred to as commodity plastics which are used in large volume in many commercial market. The basic polymerization processes of these types of polymers are relatively well defined but vary by the technologies patented by each chemical company. Galli and Vecellio (2004) summarized that PE and PP have growth steadily for the past 50 years. In 2003, 65 vol. % of the total plastics were PE and PP. They also emphasized that the growth of PE and PP was driven by the development of catalysts and polymerization technologies, as illustrated in Table 2. Polymers with high performance properties were produced stimulating new engineering products. Geosynthetic materials are one of the technologies that benefits from those new innovations and has evolved accordingly, for example, the development of HDPE geomembranes with high stress crack resistance and highly flexible PP geomembranes. In this paper, the innovative new developments in PE and PP resins used in geosynthetics over the past 25 years will be described.

Table 1 – Types of polymers used to manufacture geosynthetics, Koerner (2012)

Geosynthetic	Types of Polymers	Estimated Percentage in Usage
Geomembranes	Polyethylene (PE)	80%
	Polypropylene (PP)	10%
	Polyvinyl chloride (PVC)	10%
	Ethylene polyethylene diene terpolymer (EPDM)	3%
	Chlorosulfinated polyethylene (CSPE)	2%
Geotextiles	Polypropylene (PP)	90%
	Polyethylene (PE)	5%
	Polyethylene terephthalate (PET)	5%
Geogrids	Polyethylene terephthalate (PET)	50%
	Polypropylene (PP)	30%
	Polyethylene (PE)	20%

Table 2 – New Development in Catalysts and Polymerizations

Year	Catalysts	Year	Polymerization
1955	Ziegler-Natta	1977	Union Carbide LLDPE process
1968	High yield δ -MgCl ₂ supported catalysts for PE	1982	Spheriopol Process for PP
1975	High yield δ -MgCl ₂ supported catalysts for PP		

POLYETHYLENE

As seen in Table 1, polyethylene (PE) is perhaps the most widely used polymer in geosynthetics, as it is in many consumer products. PE is a unique polymer with a large range of densities, from 0.890 g/cc to 0.960 g/cc. There are two types of polymerization from which two different polyethylene molecular structures are created. The conventional process uses high pressure and relative high temperature to initiate free radical reactions, generating highly branched polyethylene chains; see Fig. 1(d). The density of this type of polyethylene is relative low and thus is categorized as Low Density Polyethylene (LDPE). The second process which became commercialized in the late 1960's utilizes catalytic polymerization at low pressure and temperature, generating linear polyethylene chains; see Fig. 1(a). Because of the linear

structure, this type of PE can achieve a very high density due to a high fraction of crystallized domains. However, the high crystallinity limits many potential applications for the polymer due to its relatively high brittleness, tendency to cracking, and generally low compliance. By introducing co-monomers to the polymerization process, the co-monomer can graft onto the linear polymer chains forming a short branches (Bobsein and Seeley, 1994). The branch length is governed by the co-monomer type which is an α -olefin, such as butene, hexene, octene, etc. On the other hand, the branching frequency directly influences the density of the PE with greater branch frequency leading to lower density; see Fig. 1. This results in a wide range PE resins with different densities. The linear PE is categorized into four groups based on the density range according to ASTM D883, as shown in Table 3.

Table 3 – Polyethylene density classification according to ASTM D883

Category	Abbreviation	Density range (g/cc)
High Density Polyethylene	HDPE	>0.941
Medium Density Polyethylene	MDPE	0.926 – 0.940
Linear Low Density Polyethylene	LLDPE	0.919 – 0.925
Low Density Polymer	LDPE	0.910 – 0.925

Note: LDPE is the highly branched type of polyethylene

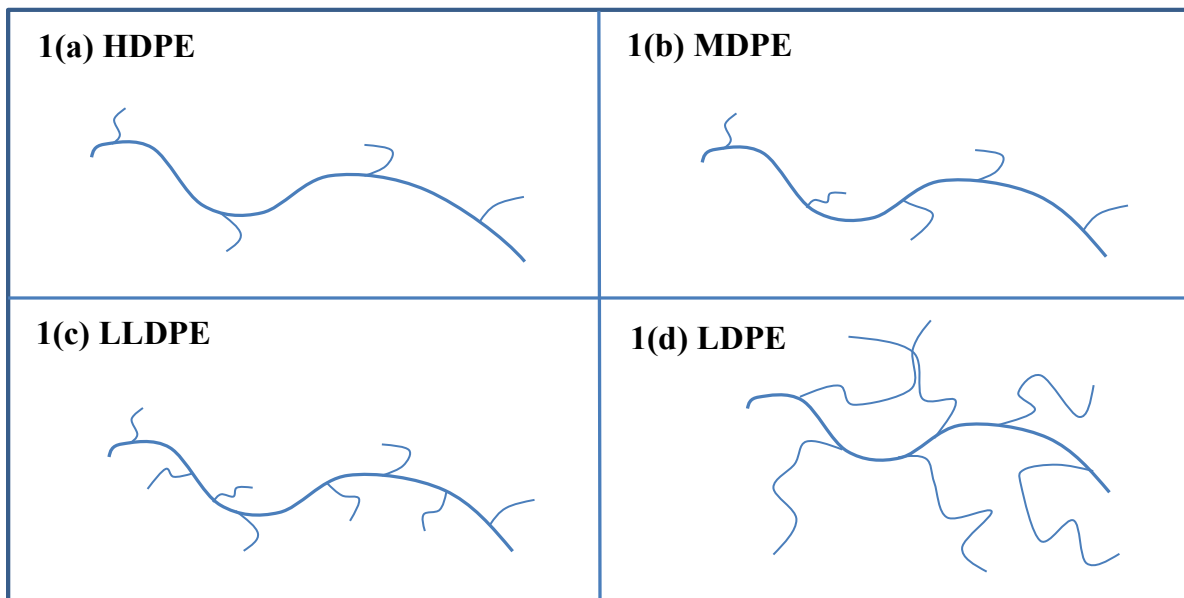

Figure 1 – Four types of polyethylene with respect to its branching length and frequency. (heavy line = carbon polymer chain, light lines = chain branches)

In the last 25 years, the advances in PE polymerization technology and catalysts have produced a series of polyethylenes with different molecular weight distributions yielding a variety of performance properties. There are three types of catalysts: Ziegler-Natta, supported metal oxides (Phillips type of catalysts), and metallocenes (Rodriguez, 1996).

- (i) Ziegler-Natta Catalysts and Phillips Type of Catalysts: These two types of catalysts have multiple reactive sites differing in reactivity. Polyethylene being generated from these catalysts consists of a broad molecular weight distribution and long polymer chains. Furthermore, the comonomer branches tend to concentrate in the short polymer chains reducing the lubricating effect during the product extrusion process.
- (ii) Metallocenes: These catalysts have a single active site, enabling them to generate polymers with narrow molecular weight distribution. Also the comonomer branches are uniformly distributed. With well controlled molecular weight and comonomer type, a PE with high crystallinity and high elastic property can be created.

The progression toward high performance PE resin is reflected in the advance of PE pressure pipes, particular in the enhancement of stress crack resistance and creep resistance. In the 1980's the highest pressure rated PE pipes were certified to sustain internal pressure of 80 MPa at 20°C for 50 years. They were designated as PE80. The PE80 resins are polymerized using either Ziegler-Natta catalysts or Phillips processes in a single reactor, as described above. The resin possesses a broad molecular weight distribution curve and the short chain branching tends to concentrate in the shorter polymer chains. In past ten years, a new type of high performance polyethylene resin, PE100, was developed and is currently being used in high pressure PE pipes. Pipes made from this resin can sustain 100 MPa at 20°C for 50 years which is 20 MPa higher internal pressure than the PE80. Such enhancement is contributed by the new bimodal PE resin. The uniqueness of PE100 bimodal resin is that the short chain branching is concentrated on the longest polymer chains and thus lowers the crystallinity and increases the probability of tie molecule formation. The stress cracking resistance of PE100 can well exceed 1000 hours using the PENT test (ASTM F1437) and similar improvement should also be expected in the notched constant tensile load (NCTL) test (ASTM D5397) as used in the geosynthetic industry. Furthermore, high creep rupture strength and rapid crack propagation are also afforded. Forcing the short chain grafting onto the longest polymer chains, the bimodal resin must be produced via the polymerization process in a reactor rather than melt blending in the extruder. This is because phase separation can take place during the melt mixing when blending two resins with large difference in molecular weight distributions (Moreno et al., 2012). There are two types of polymerization processes used to create bimodal PE resins with the desired short branching distribution:

- (i) Two stage polymerization runs a specific single catalyst through two sequential reactors (Alt, et al., 2001). This process has a much higher cost than the single reactor process that is used to polymerize PE80.
- (ii) Single stage polymerization uses a new catalyst. Currently it is possible to polymerize PE100 in a single reactor (DesLauriers et al., 2005).

In summary, there are three types of molecular weight distribution curves with different short chain branching distributions which vary between a broad molecular weight polymer and a bimodal molecular weight polymer. This can be seen in Figure 2.

Polyethylenes used for geosynthetics are made from the polymerization process yielding PE80 (Bobsein and Seeley, 1994). Each type of geosynthetics (such as GM, GG, or GN) uses

different PE resins with specific melting index and density to optimize the extrusion processing and to comply with performance requirements. For unique applications that require extremely high stress crack resistance and creep resistance, PE100 resin can be used to manufacture a geosynthetic product that meets extremely high engineering performance demands.

Figure 2 – Schematic diagrams to illustrate three types of molecular weight distribution curves and corresponding short chain branching distribution curves.

POLYPROPYLENE

Polypropylene (PP) is similar to polyethylene as a type of polyolefin which is composed of carbon and hydrogen atoms in the molecular structure. The difference, however, is that a pendant methyl (CH_3) group is attached to every other carbon atom along the polymer chain. The location of the methyl group with respect to the zigzag conformation of the polymer chain creates three types of PP: atactic, isotactic, syndiotactic. In an atactic, the methyl group is randomly distributed along the polymer chain. Isotactic PP has the methyl group positioning along one side of the polymer chain. A regular alternative arrangement of methyl groups characterizes the syndiotactic PP. The three types are shown in Figure 3. It is the regular structure of the isotactic type that allows PP to be crystalline.

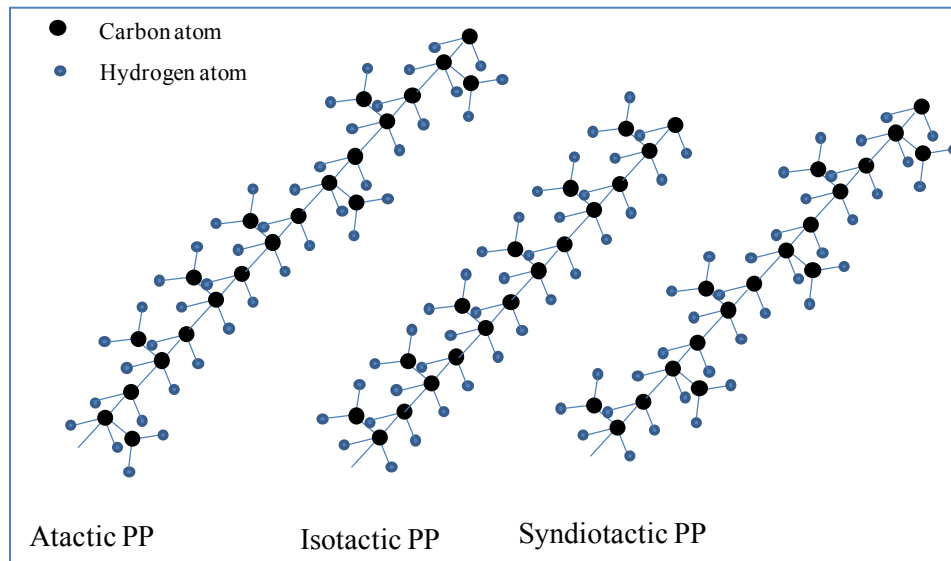

Figure 3 – Three types of tacticity of PP.

Prior to the invention of Ziegler-Natta catalytic polymerization, only amorphous atactic PP was produced which had very limited engineering applications. In 1954, Giulio Natta successfully created isotactic PP using Ziegler catalysts and recognized the significance of catalyst architecture, particularly surface chemistry. Goodall (1986) categorized the progress of PP into three generations based on the percentage of isotactic PP being generated. The first and second generations are based on TiCl_3 catalyst yielding 90-95 wt% to 96-97wt% of isotactic PP respectively. The third generation, which has been applied to produce commercial PP since 1980, utilizes MgCl_2 as the supporting catalyst. Although the percentage yield of isotactic PP is lower than the first generation, ranging from 90 to 95 wt%, the weight percentage of polymer generated increases almost 1000 fold for a unit gram of catalyst.

Isotactic PP is used in geosynthetics, including geotextiles, geogrids, and geocomposites as shown in Table 1. As a homopolymer, isotactic PP however possesses a relatively high glass transition temperature (100°C) and high rigidity, and thus it is not an ideal polymer for manufacturing flexible geomembranes. On the other hand, the propylene based copolymer synthesized using reactor granule technology (RGT) has created a new type of geomembrane classified as flexible polypropylene (or fPP) geomembranes. RGT was developed by Himont/Montecatini's during 1980s using the superactive MgCl_2 /Ziegler-Natta catalysts. The final polymer is spherical particles with interior morphology to be either "onion shaped" or porous (Galli, 1994). Such processes can eliminate the pelletization step of the resin. In the meantime, advanced polymerization processes make it possible to produce PP copolymer with a much higher impact resistance in an effective and economic way. The two internationally known processes are Spheripol and Catalloy, as shown in Figure 4. Spheripol processes use liquid monomers mixed with catalyst components in the loop reactor to create homopolymer which is then fed into a gas phase reactor to generate co-polymers. In the Catalloy process, different types of olefinic monomers are introduced during the polymerization of propylene, generating multiphase polymer alloys (Bigiavi, et al., 2005).

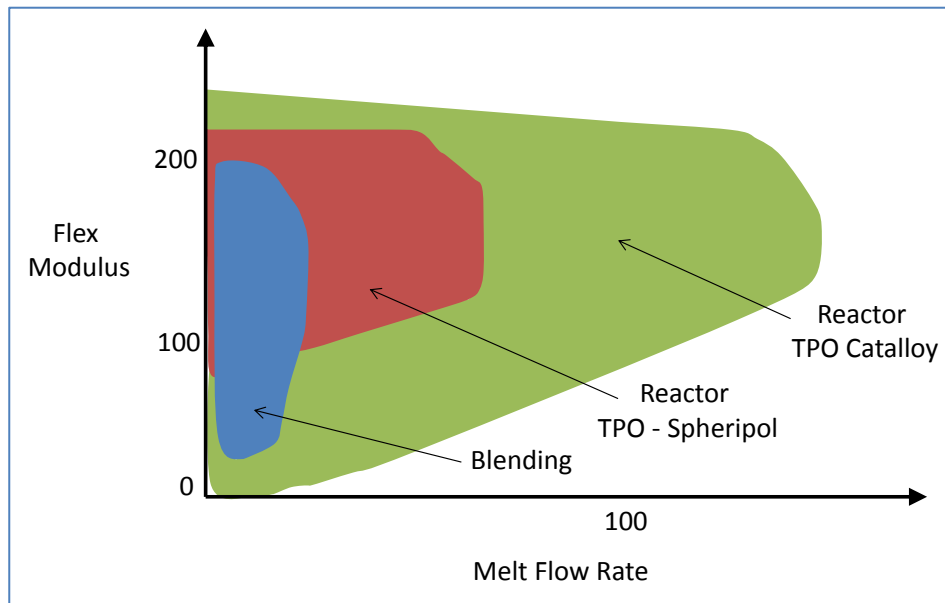

Figure 4 – Flexural Modulus of different thermoplastic olefins (TPO), (Galli, 1994).

CONCLUSION

Over the past 25 years, the innovation in polyolefin polymerization has greatly enhanced the performance of many geosynthetics. In particular, polyolefin geomembranes have benefited the most. HDPE geomembranes can possess enhanced properties although they require a delicate balance, such as crystallinity and stress cracking. The new bimodal PE100 resin can provide excellent stress crack resistance as well as high chemical resistance. For fPP geomembranes, a variety of polypropylene based copolymer resins can be used depending on the required engineering properties.

ANTIOXIDANTS FOR GEOSYNTHETIC RESINS AND APPLICATIONS

Joseph J. Fay and Roswell E. King III
BASF

ABSTRACT

Polyolefins are intrinsically susceptible to oxidative degradation. Depending upon the polymer type, processing conditions and end use requirements, a variety of antioxidants may be added to the polymer to provide stability and protection against oxidation. For geomembranes, geonets, geogrids and other geosynthetic materials, it is important to protect the polymer during manufacturing processes as well as during storage and installation to prevent degradation which could affect the durability of the final product. For materials designed for long term use, antioxidants are needed to provide stability and to prevent premature product failure. There are several types of antioxidants which can be employed to improve the stability of geosynthetics that may be subjected to thermally and/or photolytically initiated degradation. A brief review of antioxidant types, mechanisms and application test data relevant to geosynthetics is presented.

INTRODUCTION

Polyolefins are used in numerous applications due to the wide spectrum of properties that can be designed into the polymer through current polymerization technologies and the broad variety of manufacturing processes that can be used to convert these polymer resins into finished products. Polyolefins are produced on a huge scale. Worldwide polyethylene capacity exceeds 50 million tons and polypropylene capacity exceeds 20 million metric tons (Wigotsky, 1994) attesting to their prolific use. Additives, of one type or another, are incorporated into nearly every pound of polyethylene and polypropylene produced to improve the performance of these polymers.

Geosynthetics are but one of the many highly specialized applications in which polyolefins are used. Geosynthetics, which may be geotextiles, geomembranes, geogrids, etc., are also used in a wide array of applications. The application area spans a multitude of uses in environmental, transportation and geotechnical engineering. Typical functions include separation, reinforcement, filters, drains and barriers (Suits, 1994). Amongst the multitude of polyolefin products, polymer stabilization principles transcend product line boundaries and often play an integral role in the development and use of such products.

In geosynthetic applications, stabilizer additives (antioxidants) are incorporated (melt compounded) into the polymer during manufacture. Antioxidants (AO's) are used to protect the polymer during melt processing as well as to protect the finished product from the negative effects of oxidation (Klemchuck and Horng, 1984). Oxidation, which results from either thermally or photolytically initiated chemical reactions in the presence of oxygen, degrades the polymer and reduces physical properties, thereby altering the suitability of the material for the intended application. It is important to consider a broad range of properties when selecting a material to meet regulatory and design standards. These properties include tensile properties,

tear and puncture resistance, as well as numerous endurance properties such as chemical resistance, and creep and stress relaxation, in addition to others (Cadwalader, et al., 1992). Stabilizers, when used judiciously, can effectively counter the tendency of the polymer to oxidize and can significantly increase the service life of the material (Schmidt, et al., 1984).

ANTIOXIDANTS

In the absence of stabilizing additives, polyolefins are prone to degrade via oxidative mechanisms as depicted in the auto-oxidation cycle, Figure 1. Polymer degradation may be initiated by polymerization catalyst residues, heat or shear which initiate chain scission in the polymer, generating free radical species. Oxygen reacts readily with the unstable, reactive carbon centered radical to form a peroxy radical. This oxygen centered radical species then abstracts a hydrogen atom from the surrounding polymer to form a hydroperoxide and create yet another carbon centered radical species. The resultant hydro peroxide can be decomposed to yield two additional oxygen centered radical species. The polymer carbon centered radical can react with oxygen to continue the cycle. As this radical generation is geometric in nature, a significant radical flux can be generated which can severely transform and ultimately degrade the polymer. Even at ambient conditions, unstabilized polymers are found to degrade, as evidenced by changes in color, physical properties and melt flow properties during storage. Ultimately, without the interruption of the free radical auto-oxidative chemistry, the polymer is oxidized to the point of discoloration, brittleness, crazing, cracking or chalking and product failure.

Figure 1. Auto-oxidative cycle.

Similarly, hydroperoxides, which may be formed during processing or as a result of auto-oxidation, are unstable toward UV energy and can be photolytically cleaved, generating radical species much in the same way that they are generated by thermal processes. Photo-oxidative degradation is depicted in Figure 2.

Figure 2. Photo-oxidative degradation pathways.

Antioxidants that are useful in polymer applications are generally classified by the mechanism in which they act as stabilizers during degradation. Primary oxidants provide stabilization by trapping or deactivating free radical species after they are formed. Secondary antioxidants decompose hydroperoxides, which may otherwise be transformed into free radical species, into non-radical species thereby inhibiting the formation of radicals. For each of these two categories, there are a few major classes of chemistries which are commercially significant. Antioxidants referred to herein are listed in Table 1.

PRIMARY ANTIOXIDANTS

This general class of antioxidants is capable of interrupting free radical processes by donating labile hydrogen atoms to the free radicals. These hydrogen donating antioxidants slow down oxidation by sacrificially competing with the polymer for free radicals, thereby decreasing the extent to which the polymer is transformed or degraded. Of course, the antioxidant is preferentially oxidized and if sufficient radicals are being generated in the system, the antioxidant may be entirely consumed and eventually rendered ineffective.

Heat, shear and UV light can initiate the formation of radical species. However, certain antioxidants, by the nature of their molecular structure, are more or less capable of reacting with radical species depending upon the conditions during which the radicals were generated.

Hindered Phenolic Antioxidants

The chemistry of phenolic antioxidants has been extensively reviewed (Pospisil, 1991; Pospisil, 1988; Scott, 1993) and consequently, will not be discussed in detail here, other than to describe how they can be used in practice. Phenolic AO's are incorporated into the polymer to stop the chemistry associated with the free radicals by first donating hydrogen atoms to interrupt the auto-oxidation process. Phenolics typically react with oxygen centered free radicals, and consequently, can interrupt the auto-oxidation cycle depicted in Figure 3. The resulting phenoxy

radical is thermodynamically more stable than the oxygen centered free radical. This is due to the resonance delocalization of the radical around the phenyl group, Figure 4.

Table 1. Key to Referenced Stabilizers

Code		Commercial Example
AO-1		Irganox [®] 1076
AO-2		Irganox [®] 1010
P-1		Irgafos [®] 168
MD-1		Irganox [®] MD 1024
HALS-1		Tinuvin [®] 770
HALS-2		Tinuvin [®] 622
HALS-3		Chimassorb [®] 944
HALS-4		Chimassorb [®] 119

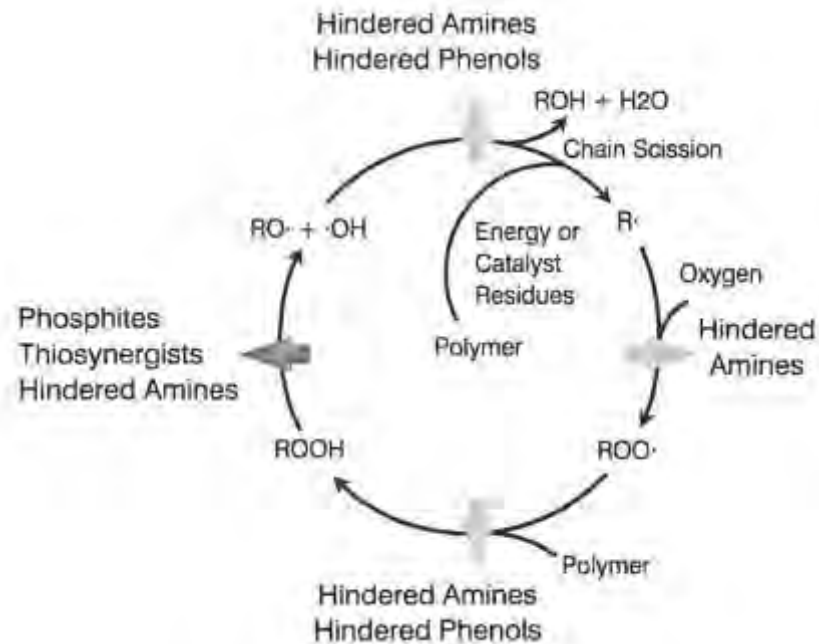

Figure 3. Autocatalytic thermo-oxidation cycle depicting points at which various stabilizers are effective.

Figure 4. Initial stabilization reactions of phenolic antioxidants and resonance stabilization of the free radical.

Phenolic AO's, depending upon the specific molecular structure, are capable of donating hydrogen atoms, undergoing rearrangement reactions, and further reacting with free radicals until they are no longer reactive towards radical species. This total consumption of the phenolic is typically undesirable due to the generation of color bodies, especially in unpigmented and lightly pigmented systems. Co-additives, such as trivalent phosphorous compounds and scavengers for acidic catalyst residues, are commonly used in combination with the phenolic to improve overall performance.

Figure 5 illustrates the significant improvements in long term heat aging (LTHA) that are obtained with the addition of AO-1 and AO-2 to polypropylene.

Figure 5. Phenolic antioxidants can significantly improve the oxidative stability over a broad temperature range in Polypropylene homopolymer containing 0.1% calcium stearate, 120 μm film.

Hindered Amines

This class of antioxidants is historically associated with light stability since they are extremely effective at protecting polyolefins from the damaging effects of ultraviolet radiation (Gugumus, 1990). However, hindered amines are also useful as primary antioxidants as they are also capable of scavenging free radicals, albeit at lower temperatures (less than 135°C). The most common hindered amine is based on the 2,2,6,6-tetramethylpiperidine functions group. The antioxidant behavior of hindered amines is illustrated in Figure 6. The hindered amines differ fundamentally from hindered phenols in that the hindered amine mechanism is a cyclical and regenerative (Klemchuk and Gande, 1989; Carlsson, et al., 1979; Denisov, 1989). Only when undesirable side reactions take place is the hindered amine rendered ineffective. It has also been proposed (Dulog and Bleher, 1986) that hindered amines are capable of decomposing hydroperoxides, further broadening the mechanisms for stabilization.

Figure 6. Stabilization mechanism for HALS depicting regenerative, cyclic process of radical scavenging.

Nevertheless, hindered amines efficiently interrupt the auto-oxidation chain reaction, Figure 3, via mechanisms which may involve reactions with carbon and oxygen centered radicals, as well as decomposing peracids or hydroperoxides (Gugumus, 1993). Regardless of the specific mechanisms involved, hindered amines provide excellent performance as stabilizers at lower temperatures as long term thermal stabilizers (Gijsman, 1994; Drake, et al., 1992) in addition to their recognized efficacy as light stabilizers (Gugumus, 1994). HALS-1, HALS-2 and HALS-3 are typical hindered amine light stabilizers which can be used to provide UV stability for geosynthetics during storage and installation, where UV exposure can potentially damage the product. Representative performance of HALS is illustrated in Figure 7.

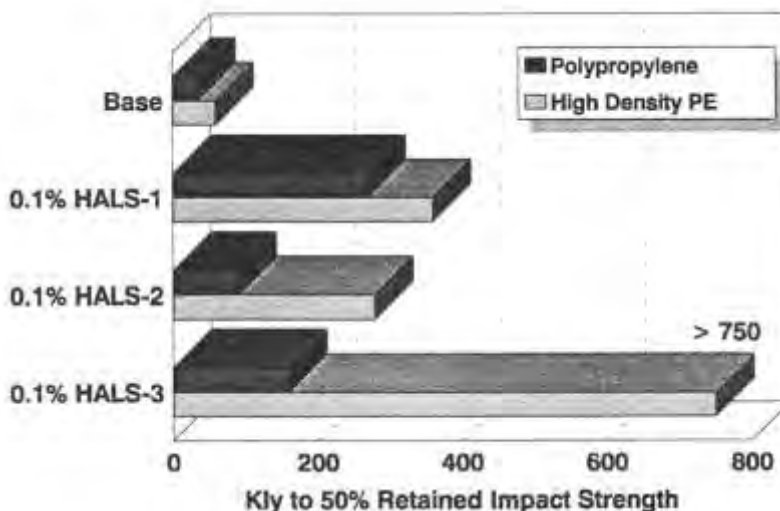

Figure 7. Light stability of PP and HPE, PP contains 0.05% AO-2/0.05% P-1 and 0.1% Ca stearate; Ziegler HDPE contains 0.025% AO-1, 0.5% TiO₂ and 0.1% Ca stearate. 2 mm plaques, Florida 45 degree south exposure.

As mentioned above, it should be clearly stated that the antioxidant capability of hindered amines proceeds most efficiently at temperature below 135°C, but preferably below 120°C where performance is much more effective, Figure 8. Consequently, hindered amines should not be considered as melt processing stabilizers. In practice, after melt compounding most polymers are not typically exposed to such high temperatures during end use applications. For those that are exposed to high temperatures, other combinations of antioxidants can be used, such as those based upon phenolic and thiosynergists which are discussed below.

Figure 8. HALS provide thermal stability at temperatures below 135°C in polypropylene homopolymer containing 0.10% P-1/0.05% AO-1 and 0.05% calcium stearate; oven aging of 40 mil plaques.

SECONDARY ANTIOXIDANTS

One of the most damaging species in the auto-oxidation process is the hydroperoxide moiety, ROOH as illustrated in Figures 1 and 2. Under elevated temperatures, hydroperoxides decompose via a hemolytic cleavage to yield two free radicals. This step is representative of the catalytic nature of auto-oxidation. The destruction of the hydroperoxides which continually build up in the polymer, is essential in protecting the polymer. Most commercially available peroxide decomposers are based on trivalent phosphorus compounds and divalent sulfur compounds.

Phosphites: Trivalent Phosphorus Compounds

The chemistry of phosphites and phosphonites has been reviewed (Pobedimskii, et al., 1980; Schwetlick et al., 1987). In essence, a P(III) compound reacts stoichiometrically with hydroperoxide, ROOH, to produce an alcohol, ROH, with the simultaneous oxidation of P(III) to P(V), as shown in Equation 1.

This reaction occurs during melt compounding and extrusion of the polymer. However, at ambient temperatures, the reaction is very slow. This increases the importance of the hindered amines mentioned above, which are capable of decomposing hydroperoxides at temperatures below 120°C to 135°C.

Phosphorus (III) compounds may also react with free radicals (Schwetlick, 1987). However, the contribution of this chemistry is secondary in comparison to hydroperoxide decomposition.

Thiosynergists: Divalent Sulfur Compounds

Dialkyl thiodipropionate esters, such as distearyl thiodipropionate (DSTDP) and dilauryl thiodipropionate (DLTDP), are more commonly referred to as thiosynergists. The chemistry of S(II) compounds has also been reviewed (Kulich and Shelton, 1991; Armstrong, et al. 1979; Armstrong, et al., 1975). Thiosynergists react similarly to phosphorus compounds in that hydroperoxides are transformed into alcohols, with concomitant oxidation of S(II) to S(IV) as shown below.

The chemistry does not stop with the formation of the sulfone (Equation 2) or sulfoxide (Equation 3). Elimination reactions result in the formation of sulfonic and sulfonic acids, which can further decompose to sulfur dioxide and sulfur trioxide. Fortunately, these sulfur transformation products are also very effective at decomposing hydroperoxides and contribute to polymer stabilization. As a result of these additional reactions, thiosynergists can react with more than one equivalent of hydroperoxide species. However, these decomposition products can have a negative effect on the ability of hindered amines to function as antioxidants or light stabilizers, which is discussed below.

METAL DEACTIVATORS

Polymers that come into contact with metals of low oxidation potential, such as copper or iron, are susceptible to oxidation from the metal catalyzed decomposition of hydroperoxides, as shown in Equations 4 and 5.

One way to avoid the negative influence copper on autooxidation is to use metal deactivators (Muller, 1990). Metal deactivators are typically designed to contain hydrazide or amine functional groups that can complex with the metal, providing stabilization. Metal deactivators, such as MD-1, also include a phenolic antioxidant as part of the molecular structure to provide antioxidant performance as well.

EFFECT OF TEMPERATURE

Figure 9 summarizes the temperature ranges over which the major classes of antioxidants are effective. Phenolic antioxidants have the broadest applicability as they function over the broadest range of temperatures. Note that thiosynergists, in combination with a phenolic antioxidant, are effective at providing thermal stability at elevated temperatures, but that they do not provide stabilization during melt processing. On the other hand, phosphites only provide melt processing stability and are not effective antioxidants at lower temperatures. Hindered amines, as mentioned above, are most effective at temperatures below 135°C. For many applications, it is necessary to use a combination of two or more antioxidants to provide the needed stabilization.

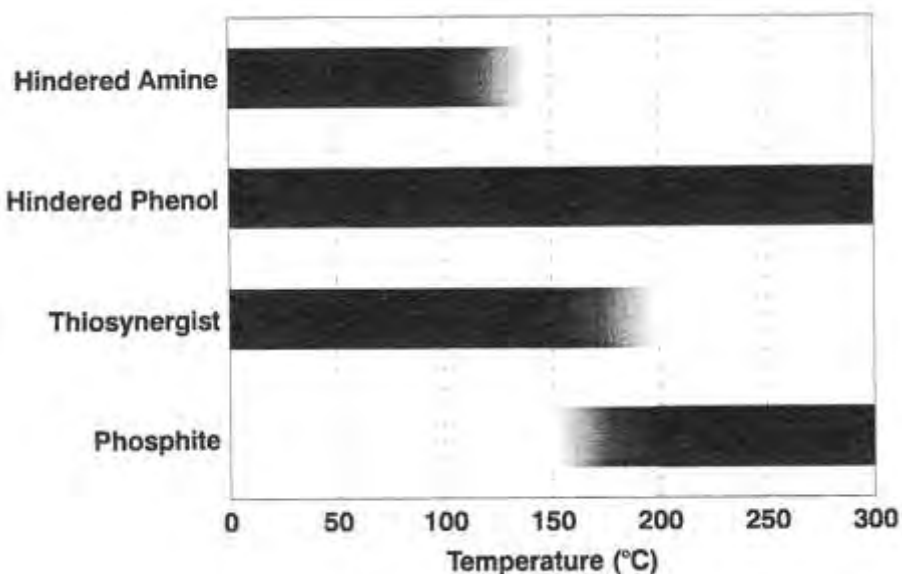

Figure 9. Effective temperatures for stabilizers.

SYNERGISTIC MIXTURES OF ANTIOXIDANTS

When used alone, neither phosphites nor thiosynergists are capable of providing complete melt processing and thermal stability of the polymer. However, in combination with a phenolic antioxidant, the performance of these binary systems is typically better than the sum of the performance levels of each additive. This is known as synergism.

For example, blends of a phenolic antioxidant and a phosphite are very useful for melt compounding of polyolefins (Zinke, et al., 1980) and engineering polymers (Muller and Schwarzenbach, 1982). When both additive classes are used together, the combination of hydroperoxide scavenging (phosphite) and free radical scavenging (AO) probably results in more effective stabilization. As a result, a lower total radical flux occurs and there are fewer radicals to degrade the polymer and to deplete the additives. However, if the phosphate is entirely consumed at the end of the polymer processing, it has done its share of work. Also, consumption of the phosphite also preserves more of the phenolic antioxidant for long term thermal stability.

In Figure 10, the combined use of P-1 and AO-2 results in an increased concentration of AO-2 in the polymer following multiple pass extruder compounding. For geosynthetic applications, preservation of the antioxidant, which provides long term thermal stability, is very important.

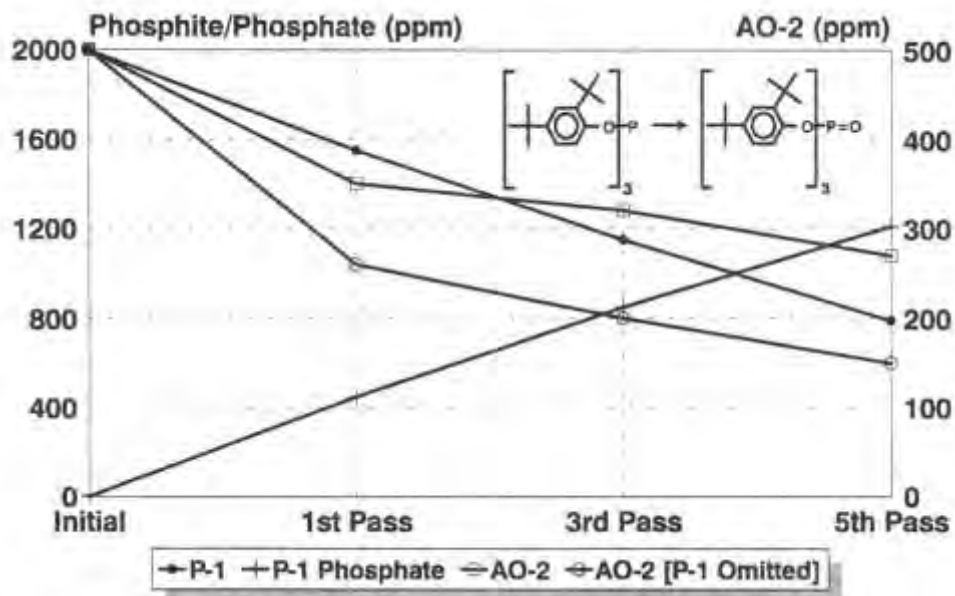

Figure 10. Effect of using P-1 on AO-2 concentration. HDPE containing 0.05% AO-2 and 0.2% P-1; multiple extrusion at 260°C.

Similarly, blends of phenolic antioxidants with thiosynergists provide exceptional long term thermal stability to polyolefins. Although thiosynergists provide no activity during melt processing, they do provide excellent performance as a hydroperoxide decomposer during long term thermal aging. Combined with the free radical scavenging capability of the phenolic AO's, superior formulations can be established.

ANTAGONISTIC MIXTURES OF ANTIOXIDANTS

While mixtures of antioxidants can be synergistic, they may also be antagonistic. For instance, if one wanted to ensure long term thermal stability and light stability, one might use a combination of phenolic antioxidant and thiosynergist for thermal stability and a hindered amine for light stability. Unfortunately, the oxidation products of the sulfur compound can be quite acidic. The acidic species from the sulfur transformation chemistry can react with the hindered amine (which is basic) to form a salt. This salt formation prevents the hindered amine from entering into the free radical scavenging cycle (Kikkawa, et al., 1987). Figures 11 and 12 document the negative effects of polypropylene and polyethylene UV stability that may be obtained when combinations of thiosynergists and hindered amines are used together. While significant reductions in UV stability and thermal stability may be observed, additional research has shown that the extent of antagonism is both variable and unpredictable. By varying both the total concentration of the additives and their ratio, it is possible to devise a formation in which the antagonistic effects are minimized.

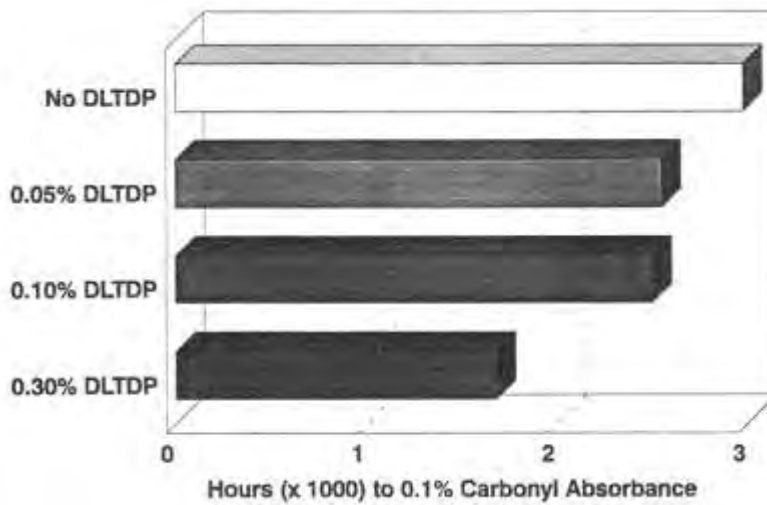

Figure 12. Effect of thiosynergists on UV Stabilized Ziegler high density polyethylene containing 0.15% HALS-1; Xenon Weather-O-Meter exposure.

CARBON BLACK

Carbon black is commonly compounded into polymers as both a pigment and a UV stabilizer (Mair, 1967; Walldner, et al., 1950). As UV stabilizer, carbon black can be quite effective, though at concentrations where UV protection is significant, processing can be adversely affected. The use of combinations of HALS and carbon black can be an effective way to reduce the amount of carbon black contained in the formulation which may improve processing and long term thermal stability, Figure 13. HALS-2 is generally preferred for carbon black applications. While carbon black is beneficial for UV stability, it may be detrimental with respect to thermal stability, as evidenced by the results of an oven aging test and measured embrittlement times, Figure 14. Again the use of HALS-2 or HALS-3 is an effective means of improving the thermal stability in carbon black pigmented applications. For geosynthetics that are carbon black pigmented, surface temperatures as high as 80°C (175°F) have been measured on exposed surfaces in the field (Cadwallader, 1988).

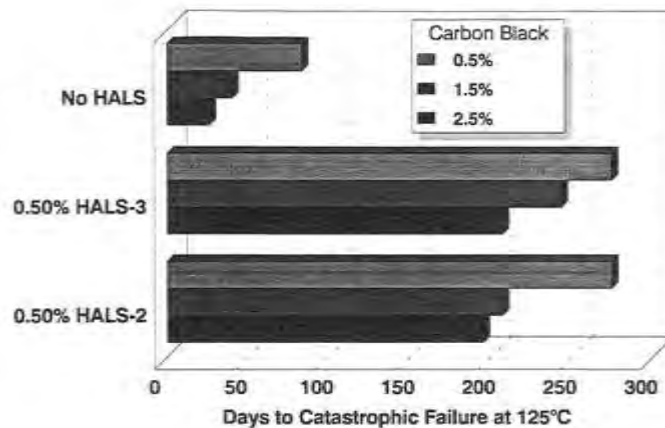

Figure 14. HALS effectiveness in PP homopolymer containing 0.1% P-1/0.1% AO-2 and 0.1% calcium stearate. Oven aging of 2 mm films; Vulcan 9 carbon black.

ACCELERATED AGING TESTS

In order to evaluate the thermal stability of polymeric materials, accelerated aging tests are often employed. This is necessary as the rate of oxidation at ambient temperatures for well stabilized polymers can be excruciatingly slow, especially with respect to the time frame for product development. As a result, testing at elevated temperatures is favored for it reduces the time needed for evaluation. Ideally, the accelerated test should be based upon correlations with actual performance. However, as suitable correlations may not always exist which account for all of the specific variables, one should proceed carefully with accelerated testing.

Oxidation induction times (OITs) and long term heat aging (LTHA) are common evaluation methods which are used to assess the thermal stability of polymers, and the effectiveness of antioxidant systems. OIT tests are typically done above the melting point of the polymer which does not reflect end use conditions, but testing can be completed in minutes or hours. Comparatively, LTHA tests are done below the melting point and are more relevant to end use conditions, but test times can be on the order of months or years.

In evaluating the performance of AO-1 and AO-2, the latter also in combination with P-1, by both OIT and LTHA, significant differences were noted between the two test results, Figure 15. Phosphites do not contribute to thermal stability, as the LTHA results show, except when the consumption of primary antioxidant during melt processing is decreased by the presence of P-1. However, significant increases in OIT were observed. To the casual observer the addition of P-1 would appear to provide a significant boost to LTHA. Most likely, the boost in OIT is due to the test being conducted in an oxygen rich environment where hydroperoxides are generated. Additionally, the high testing temperature allows the phosphite to contribute to the increased OIT values. Although this might seem like a good way to meet an OIT specification, in reality, the enhanced OIT results may be quite misleading as a predictor of actual performance. Similarly, in Figure 16, the correlation between OIT's and embrittlement times (from LTHA) is also poor when different pigments are evaluated. Several papers have recently addressed the topic of OIT testing (Cadwallader, 1988; Pauquet, et al., 1993; Todesco, 1992).

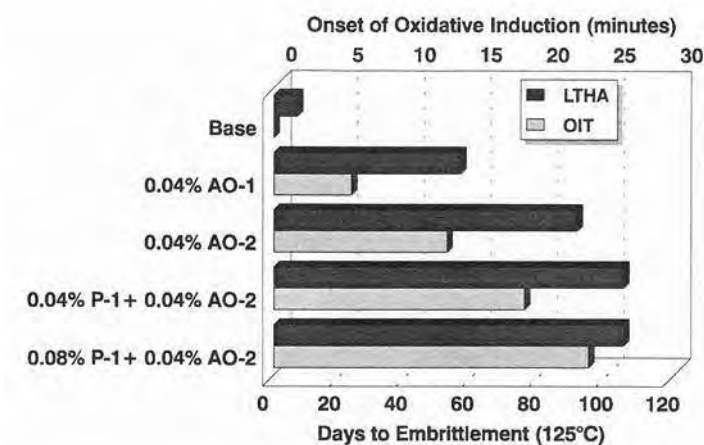

Figure 15. Comparison of LTHA and OIT data for a CRO₃/SiO₂ catalyzed high molecular weight high density polyethylene; oven aging on 125 mil plaques, OIT on 11 mil films at 200°C in O₂ on preoxidized AI pans.

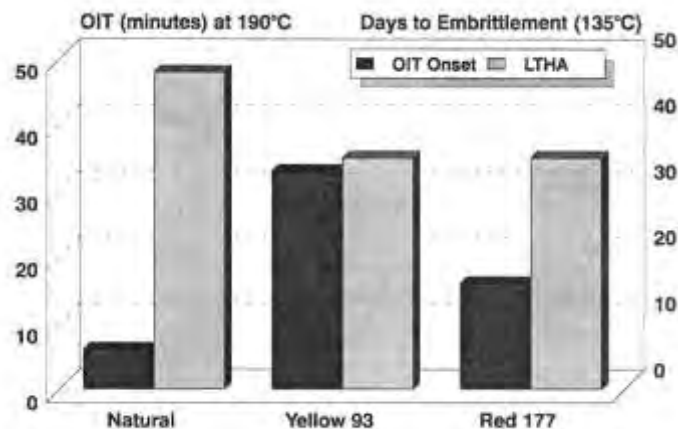

Figure 16. Lack of correlation between OIT and LTHA for polypropylene homopolymer containing 0.10% P-1/0.5% AO-2, 0.3% HALS-1, 0.05% calcium stearate and 0.5% pigment.

CONCLUSION

Antioxidants play an integral role in the development of polyolefin products. The inherent instability of polyolefins towards both thermal and photolytic degradation is such that without the incorporation of stabilizing additives, it is unlikely that polyolefin geosynthetic materials would be suitable for long term applications. Although antioxidants are very effective in most applications, certain combinations of additives have been found to have either synergistic or antagonistic effects on one another. Careful selection of appropriate additives and use levels that do not result in overstabilization and excessive cost need to be balanced with the need to manufacture and install materials which will withstand the environment to which they are subjected. The use of hindered amines as primary antioxidants offers a new choice in the selection of stabilizers to provide long term stability.

Continuous developments in polyolefin catalysis and the ever increasing demands that are required for both existing and new applications continue to push the limits of existing polymer stabilizers. However, polymer additives research and development has led to the recent development of enhanced systems and new products to meet the expanding needs of the geosynthetic industry as well as for others (Davis, 1994; Handreck, 1994; Horsey, et al., 1994; Drake and Cooper, 1993).

OVERVIEW OF GEOMEMBRANE MANUFACTURING METHODS

Fred Struve
Houston, TX

ABSTRACT

This paper describes the current manufacturing methods and equipment used for the most commonly installed geomembranes. They are the polyolefins, mainly high density polyethylene (HDPE), linear low density polyethylene (LLDPE), but also flexible polypropylene (fPP). The most significant differences between competing manufacturing methods are also presented.

1.0 POLYMER INTRODUCTION

Geomembranes, used for pollution control, water conservation, aquaculture, heap leach mining, etc., are a necessary and vital part of human endeavors to progress, conserve valuable resources and yet protect the environment.

While there are several methods used to manufacture geomembranes there are also certain applications which require very specific properties. For instance handling fluids at high temperature, or having resistance to particular chemically aggressive substances are common situations. However, the vast majority of applications are excellently served by the family of polyolefin based thermoplastic resins and copolymers.

The polyethylene resin family is made up, generally, of “commodity” resins with remarkably good resistance to an enormous range of common chemicals. The specific resins commonly used for geomembrane manufacture are selected with the major goal of optimizing longevity, chemical resistance; mechanical properties; environmental stress crack resistance; processability; availability; and price. The final selection is, understandably a compromise.

A few very general observations about the polyethylene polyolefin polymers are:

1. Higher density, improves chemical resistance, but reduces stress crack resistance.
2. Polyethylene copolymers of either hexene or butene are currently most commonly used.
3. Lower density improves flexibility and ability to deform when subjected to the deformation that subgrade settlement requires (for instance when used to cap landfills)
4. Relatively broad-molecular-weight distribution imparts improved melt strength which is important for product made from the circular die (aka blown-film) processes. The flat die extrusion processes is not as sensitive to the molecular weight distribution properties of polymers.
5. Relative ranking of prices of common copolymers are; butene-lowest, then hexene, and then octene.
6. The newer single-site-catalyst product costs and properties are not addressed in this document.

2.0 MANUFACTURING INTRODUCTION

Two manufacturing methods are in use for producing the wide width (typically 7.5 to 8.5 m wide), thick (typically 0.75 to 2.50mm thick) geomembranes in common usage

They are produced by extruding molten polymer through either circular dies or flat dies. The terms “round” for circular and “flat” will be used consistently throughout the balance of this paper.

Both methods have virtually identical requirements for “generic” items like:

- Raw material delivery, storage and handling equipment.
- Electricity and other utilities
- Extrusion equipment.
- Cooling capacity and heat exchangers.
- Material handling equipment ahead of the winder.
- Winding and finished roll handling equipment.
- Finished product storage and shipping facilities.

However they differ significantly in how the molten polymer, delivered by the extruder(s) is converted into a continuous web, and cooled, before ending up at the winder, to be wound into rolls, and stored/shipped.

The term “web” will be used consistently throughout the balance of this document instead of terms like geomembrane, sheet or flexible membrane liner.

Viewing typical facilities of both methods one would observe that:

3.0 DIE FLAT MANUFACTURING FACILITY

The flat production facility would have a typical industrial height building and a fairly long almost horizontal web path between the die area and the winder equipment (some 20 m). Such a facility is shown in the photographs of Figure 1.

(a) Control panel used in manufacturing

(b) Example of a large (8.0 in.) diameter extruder

Figure 1. Photographs of flat die web manufacturing.

(c) Sheet existing the counter rotating rollers

(d) winder is part of a flat die production facility although it could just as well be used for round die production.

Figure 1 (cont.). Photographs of flat die web manufacturing.

4.0 ROUND DIE MANUFACTURING FACILITY

The round production facility would have a smaller footprint than the flat facility, but have a tower some 25m high directly over the die area. The web from a round die starts as a tube which is drawn up vertically into the high tower and then on its way down the tower it is slit and handled as web of width equal to the circumference of the originally extruded tube. This means that a round facility requires a “custom” high tower bay. Such a facility is shown in the photographs of Figure 2.

(a) Tower used in production

5.0 SPECIFIC FEATURES OF, AND DIFFERENCES BETWEEN, FLAT AND ROUND WEB PRODUCTION

This section addresses the design, features and detail differences between flat and round dies, as well as web handling and cooling directly after the polymer exits the die. This is the “heart” of the differences between the two methods.

The intention is to introduce only sufficient information to make sense of the limitations (advantages and disadvantages) of both technologies and to assist end-users when evaluating how well their end-product requirements would be met by one or the other. It is also to assist manufacturers in the process of selecting production equipment to meet their projected market requirements.

5.1 *Polymer Exit from the Die*

Flat: The molten polymer exits horizontally from a straight slit in a die.

Round: The polymer exits vertically upward from a circular slit in a die.

5.2 *Polymer Internal Flow Path in the Die*

Flat: The polymer passage in a flat die has complex profile to ensure that the pressure drop from the central polymer entrance to the center of the slit (some 450mm) is the same as that to each edge of the slit (some 3,500mm)

Round: The polymer is fed into the die centrally and has symmetrical and equal distribution to the die exit.

Discussion: For “normal” production of smooth sheet from polymers with rheology close to the design parameters of the extrusion die this difference is of little or no consequence

5.3 *Multilayer Coextrusion Capability*

Flat: Feed Block Coextrusion: A comparatively “simple” multilayer die block ahead of the flat die entrance can layer polymer from different extruders which then passes through the die as a “sandwich”; see Figure 3.

Manifold die coextrusion: In this case two or more completely separate dies are bolted together so that each has its own entrance and flow path, and they are configured to come together near the exit slit.

Figure 3. Die configuration for a three layer flat die web.

Round: Coextrusion is accomplished by “nesting” two or more dies together coaxially. This is comparatively straight forward as they are all concentric and symmetrical. Here too the different flows come together near the exit slit; see Figure 4.

Figure 4. Die configuration for a three layer round die web.

Discussion: For die block coextrusion, if the rheologies (viscosity) of the polymers in the different layers are not closely matched, the three layers will not distribute evenly across the width. The less viscous material will flow more easily towards the edges and the more viscous polymer will seek the “easiest” way out along the shorter pathway towards the center of the exit slit, resulting in a variable “sandwich” across the width of the web.

Manifold die coextrusion would eliminate this problem, however manifold dies are extremely costly, and I am unaware of any having been made anywhere near the width of interest for geomembrane webs.

Round coextrusion dies are also more expensive than monolayer dies as they are literally multiple dies nested together concentrically, however the machining of such dies is readily achieved on normal (but large) vertical lathes and milling machines. Many of these coextrusion dies of the sizes of interest have been made.

5.4 Thickness Control

Flat: Excellent thickness control by either manually or automatically adjusting bolts, which deflect the lip if the exit slit of the die, can be achieved (+/- 1%, or better). Changes of web thickness from say 2mm to 1.5mm are achievable. However, it requires stopping the line and adjusting the internal “choker bar” to suit the new requirement, see Figure 5.

Figure 5. Typical “flex-lip” flat die detail.

Round: Deforming the exit slit of a round die in the same way as done on flat dies is not possible. Various indirect methods of controlling thickness are used (adjusting cooling air flow and/or velocity) are used, but with limited success on dies of the sizes of interest, and web thicknesses of interest. New, clean, round dies can readily be expected to produce webs within +/-5% of nominal thickness. Changes of thickness from say 2mm to 1mm can be done “on the fly” with no downtime and only a few meters of transition “scrap”.

Discussion: Webs made from round dies will almost certainly require more raw material per unit area, than those made from flat dies in order to maintain a given thickness specification. A single anomalous “low” area of very limited width (die line) results in increasing the thickness of the entire web to bring that one line above the minimum specification.

5.5 Webs with Enhanced Friction Properties (“Textured” Product)

To achieve improved friction along the sloping sides of landfills impoundments and canals, the rather extreme “slipperiness” of the surface of polyethylene webs must be “roughened” in some way. Methods in use are listed as follows:

5.5.1 Embossing the surface. This method physically creates a surface pattern of some sort, by forcing the web between a set of rigid metal rolls which have had the desired pattern engraved on their surfaces. The web typically has to be quite soft (at high temperature) for this process to be successful. If not hot “enough” undesirable and unacceptable stresses are impressed into the web. If “too hot” the desired sharp definition of the pattern is lost as the polyethylene exhibits a memory of sorts and the pattern will “shrink” back and loose its definition. This is an “in-line” process. In addition it is extremely difficult/impossible to emboss web less than 1.5mm thick, see Figure 6.

Figure 6. Embossed web surface.

5.5.2 Spray-on. This is an additional “out of line” process in which a roll of smooth surfaced web is unwound and passed under a series of nozzles which spray droplets of very hot molten polymer onto the web. Being a secondary process, this is costly. It is also slow and “messy”. Providing droplets with sufficient heat content to melt into and bond with the web, as well as retain some desirable sharpness for enhanced friction is problematic, see Figure 7.

Figure 7. Spray-on web surface.

5.5.3 Injection of non polluting gas (typically nitrogen) into the surface layer(s) of a three layer coextruded web. On exiting the die, the gas expands. The polymer is too soft to allow bubbles to form and remain as discrete bubbles (as in foamed “clam shell” fast food take-out containers), instead the bubbles burst and smear on/in the surface layer(s) creating a distressed rough surface with enhanced friction properties. Gas injection into the melt for this process must be controlled accurately. Too much gas results in larger bubbles forming and intruding into the center (core) layer resulting ultimately in “pin holes” through the web, see Figure 8.

Figure 8. Injection-of-gas web surface.

5.5.4 Foaming and or nucleating agents in the surface layers of a web. These have been tried and found to make controllable “good looking” textured surfaces. This approach is unusable for two reasons: Firstly, all the added chemicals are not 100% activated so that when subsequently welding webs together, which requires heating of the surfaces in some manner, further activation occurs and results in defective welds; Secondly, in hazardous waste landfills, leachate is very carefully analyzed and the presence of “stray” chemicals can result in such a facility being shut down. As a result, there is no photograph of this type of surface pattern.

Flat: As previously noted, manifold dies have not been considered “reasonable” for the subject web widths and thicknesses. Further the widely differing path lengths from die entrance to slit exit in these dies results in different “bubble” formation from gas injection, resulting in a totally unsatisfactory overall web surface. To date gas injection is a non-starter.

Spray coating the smooth sheet is one option used by some.

Embossing is also used by some. The embossing rolls required are costly and will be discussed later in the section on web cooling and handling.

Round: The inherent symmetry of these dies is ideal for even distribution and control of multilayer structures. The vast majority of textured product is manufactured by round multilayer gas injection lines.

Commentary: The height of the friction enhancing protrusions above the base web (asperities) is specified, and checked, as an index test, during manufacturing. This “asperity height” specification is being raised and methods other than gas injection, are finding it increasingly difficult to meet the newer specifications.

5.6 Cooling the Web After it Exits the Die and Production Rate

Flat: When producing a smooth web, the molten polymer exiting the die slit is in close proximity to the nip of a set of cooling rolls, and the web is essentially deposited onto the lower roll. (Hence there is no need for high melt strength polymers). The thickness of the web is determined by the die. The web is just “kissed” (or “polished” in production terminology) in the nip of the two rolls. Undue pressure on the web at this stage results in differences in orientation and undesirable stress patterns frozen into the web. The web wraps around the middle roll and then around the top roll. These rolls are internally cooled and impressive examples of engineering design (and cost!), balancing strength (to minimize sagging over their considerable span) and maintaining an even temperature across the full width as well as good heat transfer performance (as this is where/how the web is cooled).

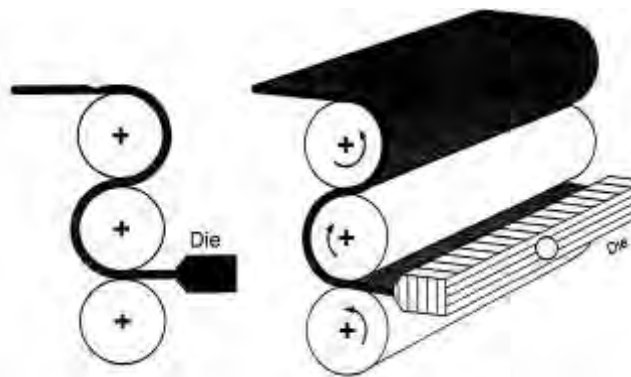

Figure 9. Manner of the web exiting the die.

Considering the span and mass of these rolls sagging/bending over their unsupported width is unavoidable. To compensate for this such rolls are sometimes “crowned”. However, irrespective of any and all schemes to cope with this issue it cannot be eliminated. This is the reason that there is a definite limit to how close to each other the rolls can be run (for thinner web production). A 1.0 mm web thickness is below or at the limit, and setting the roll clearances at this limit is, in fact, very risky, for if the rolls touch each other their plated and finely ground surfaces are marred, requiring difficult removal, re-machining, and re-plating.

To make a textured web by the embossing method requires at least the lower and middle rolls to have the required pattern engraved in them. Also changing from smooth to embossed production requires removal of one set of rolls and installation of the other; or separate dedicated production lines. The temperature control of the rolls is no trivial matter in all cases, but in the case of embossed web production, the production rate has to be decreased to achieve satisfactory product.

Round: As the web (in tubular form) is drawn vertically away from the die slit it is cooled by chilled air being blown against it from highly sophisticated and accurately machined air rings, both externally and internally. It is here that it becomes clear that broader molecular weight distribution polymers are necessary for the, as yet, “unfrozen” web to be strong enough to accept the machine direction pulling (tension) force as well as the impact of the cooling air.

Discussion: Since the web from a flat die is “dropped” onto the cooling surface, which cools the web by conduction (much more efficient than impingement and convection by air cooling), it is possible to operate extruders at higher temperature and high throughput rates, almost without regard to the lack of physical integrity of the “as extruded” web. Truly stellar production rates (~2,800 kg/hr) have been achieved on flat die extrusion lines.....Provided (there is always a caveat) the web is in the thickness range of 1.5mm to 2.0mm and smooth (not textured). Hypothetically if one had a huge and consistent need for product in this range, a flat die line would serve very well.

The most modern round die lines top out at rates of approximately 1,800kg/hr. They are very versatile with the ability to change thickness from less than 1mm to 2.5mm “on the fly” and to change to/from smooth to textured production “on the fly” also with very little transition scrap. Clearly they are best able to respond quickly to multiple differing customer needs.

5.7 Drawdown, Orientation and Dimensional Stability

Polymer exiting the die slit of both flat and round dies is thicker than the final web thickness. This is the result of shrinkage due to the phase change from the molten to the solid state, as well as shrinkage due to the coefficient of thermal expansion/contraction and reduction of temperature as the web cools from extrusion temperature to room temperature.

Further than the temperature effects, mechanical effects are in play. The web is drawn away from the die at a higher speed than that at which it exits the die....reducing its thickness and orienting it in the machine direction (MD) in both cases, see Figure 10.

Flat: As the web cools it is not restrained in any way (other than some minimal friction between it and the rolls) in the cross machine direction (XMD). Operators of flat die lines must control the line speed versus the die exit speed (extrusion rate) differential very carefully to avoid imparting an excessive amount of MD orientation to the web. This manifests itself later in the field when there is a tendency for the web to shrink in the MD when in the hot sun or when being welded. There are specifications and quality control tests to check the dimensional stability property of product.

Round: In addition to the MD drawdown, the extruded web-tube is inflated slightly by pressurized air to a diameter slightly larger than the actual die slit diameter which draws the web down in the XMD as well. (The ratio of the two diameters is known as the “Blow-up Ratio” or BUR). Webs made on round die lines generally exhibit evenly balanced MD and XMD orientation, comfortably within dimensional stability specification.

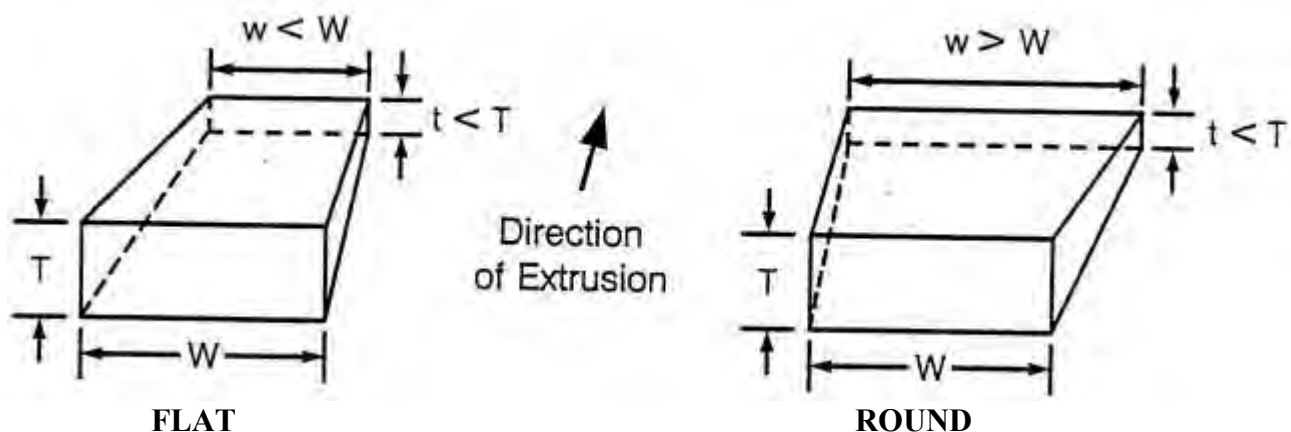

Figure 10. Depiction of the differences in web orientation flat vs. round.

6.0 SUMMARY AND CONCLUSIONS

The manufacturing methods described in this overview are, in principle, those that were in use in the general plastics industry 25 years ago. However their use to produce geomembranes was not common then. Stretching the time line from the 25 year central theme of this retrospective conference to 30/35 years, the following four developments highlight arguably the four most significant developments in the unique geomembrane-branch of the plastics manufacturing industry.

1. In the late 1970's Gundle Plastics, in South Africa demonstrated to the world that it was possible to make wide sheet up to 2.5mm thick from a large diameter round die. Before then, 0.5mm was generally considered the upper limit. This has become the most widely used manufacturing method.
2. During the 1980's bold geomembrane companies pushed machinery manufacturers of flat die equipment to make equipment that could produce the uncommonly wide thick sheet, suitable for geomembranes.
3. In the late 1980's the very important issue of Environmental Stress Cracking of geomembranes came under intense scrutiny driven by the EPA and GRI. The response, and developments made by the polymer industry, to improve this property were (and still are ongoing) extremely significant.
4. The development of geomembranes with enhanced surface friction characteristics, in the 1980's, and their subsequent acceptance by the design engineering community, was (is) also a significant event in the industry.
5. The innovative development of providing a smooth edge on textured sheet which greatly assisted the improvement of field welding quality.

Geomembrane manufacturers continue to develop new and better ways to make their products, many of them proprietary, but advancements to the basic "old" ways are continuously being made.

OPPORTUNITIES AND SOLUTIONS, DEVELOPMENT AND GROWTH OF THE GEOMEMBRANE INDUSTRY

Gary Kolbasuk
Raven Industries, Sioux Falls, SD, USA

ABSTRACT

Polymeric or synthetic hydraulic barriers (geomembranes) have been used in civil engineering applications for over 50 years. Spurred on first by the need to contain water for agricultural and potable water use and then by the need to protect water from pollutants, geomembranes went through an initially slow developmental and acceptance process. As environmental pollution pressures grew, interest and research in geomembranes as a solution accelerated. Eventually, action by regulatory agencies such as the US EPA, brought about rapid growth in geomembrane use and technology. This paper provides a short overview of this history.

INTRODUCTION

A relatively short paper such as this cannot do justice to the history of geomembrane development and use. As with geotextiles and some other geo-materials, there is enough information to write a book. What this paper attempts to do is to give the reader a flavor of what the industry was, how it grew and what it has become today. All materials and activities are not exhaustively covered. The focus is on the major products and activities in the industry.

Because of my background, this paper has a slightly different perspective than the other papers in this symposium in that I have spent most of my career working for manufacturers of geosynthetics and have never worked in academia. Wearing a manufacturing hat, I'm sure, has colored my view of the world and causes my priorities to be a little different than those of a professor, a regulator or a practicing engineer. Based on that perspective, this paper touches on not only the technical developments of geomembranes, but also the business climate, moods of the industry and some of the monetary motivations that caused the industry to change and grow. Also, while I have spent time working in the international market, the bulk of my experience is in the North American market and the information here reflects that bias.

Geomembranes came into use as a result of a growing world population putting increasing demands on our ever more precious water resources. Man's activities were polluting those resources at an alarming rate. Natural materials such as compacted clay and manmade inorganic materials such as concrete did not perform well enough and / or were too expensive to use in some applications.

ASTM's definition of a geomembrane is an essentially impermeable geosynthetic composed of one or more synthetic sheets. That bland description, while accurate, does not convey a picture of what a geomembrane is and does. In its simplest form, a geomembrane is a synthetic hydraulic barrier used to contain water and/or pollutants, keep water and/or pollutants out of a clean environment, act as a gas barrier or be a physical barrier in an aquatic environment.

Geomembranes have had a profound impact on the quality of life in developed countries and is improving the quality of life in developing countries. Society depends on geomembranes to contain hazardous waste byproducts in landfill, to control odors from industrial processing ponds, to collect gas generated in landfills, to preserve and convey potable water, to grow food in aquaculture applications, to waterproof dam faces, to control effluents in sewage treatment plants and to provide enjoyment from applications such as golf course ponds, decorative fish ponds and even the magic fountains at the Bellagio in Las Vegas.

PERIODS OR PHASES OF GEOMEMBRANE MARKET GROWTH

Cutting up the history of geomembranes into periods is somewhat artificial in that there are no real boundaries. The periods and dates I have selected are useful only in trying to organize a picture of the market and technology developments. Others, I'm sure, would divide up the history differently. But I think this is a useful exercise in setting the stage for the rest of the paper and organizing the information.

Phase I. Experimenting and Learning

The first phase of geomembrane history starts in the early 1950's as scientists and engineers started to explore the potential use of synthetic materials in civil engineering and agricultural applications. The research was basic in nature, finding out what these materials could do, how they could be used and how well they held up. Publications of this research made information available to a wider audience and supported acceptance and slow growth.

With some large chemical companies promoting the use of their materials and smaller fabricators, distributors and construction companies looking to make some money in a new field, a number of materials found progressive acceptance until in the late 1960's liner use became widespread. The growth in use, and lack of structure in the industry, brought about the need for standardization and specifications which opens the second period of geomembrane growth.

Phase II. Recognition and Growth

The second phase begins around 1970, plus or minus a couple years. Recognition began in the form of several standards being written for lining materials including three ASTM specifications, one each for polyvinyl chloride (PVC), polyethylene (PE) and butyl sheeting for pond, canal and reservoir lining. These standards were both material specifications as well as test procedures for some of the tests.

As the recognition phase continues, these materials began to find their way into environmental applications. State and federal regulations began to require flexible membrane liners (FML's) fueling an increase in liner use. Many new manufacturers and installers entered the market.

This period draws to a close as the geomembrane manufacturers, users and regulators gathered under the umbrella of the National Sanitation Foundation to provide a much needed consensus specification for a broad range of liners, bringing legitimacy to the industry, paving the way for the next phase of growth.

Phase III. Geo-Era, Technology and Prosperity

Of any of the dates for the beginning and ending of a phase of geomembrane history, for me, 1983 is the most solid. This is the start of the Geo-Era. 1983 is the year that Joe Fluet coined the term geosynthetics from which the rest of the geo-terms were created. Standard specifications and test methods were being written, technical publications were being born, industrial organizations being formed.

This phase was the most active of any stage, with the fastest growth in not only market size, but in new product development, testing technology, raw material technology and education. It was a fast paced fun time that slowly ended as the industry matured.

Phase IV. Mature Phase

This phase sort of sneaks up on the industry. It does not happen in a single year but is the slow maturing of the industry. Little business becomes big business. Small business, wild, shoot from the hip entrepreneurs that thrive in fast growing markets are replaced by more formal big business professionals (not always a different person, but certainly a major change in demeanor and focus). Broad scope, intensive research and learning is replaced by more limited focused areas of research and refinement of information. Innovation and high margins are replaced by commodity pricing and cost cutting. Custom job specifications are replaced with standard specifications (well, maybe someday). The excitement and enthusiasm of double-digit growth is replaced with running a day-to-day business with low single digit growth at best.

This does not mean that working in geomembranes is boring or that there is nothing left to learn or no new innovations to be made. Geomembranes are a very important product and the market place has enough stimulus to maintain interest. New products are being developed, but things are happening at a slower pace than before. The market place is not driving rapid change. For those who have been in the industry for 20 years, 30 years or more, some look back, sigh, and reflect on just how much fun they had back then and, by comparison, how life is now a little less exciting. Of course, I'm sure the changes in accepted business entertainment practices had nothing to do with that.

THE LIFE HISTORY OF SYNTHETIC GEOMEMBRANES

Trying to decide on how to organize the body of this paper caused me considerable consternation. There is an individual history to each of the materials as well as many other segments of industry history. There is enough information to write a long paper on each of the lining materials themselves. Rather than address each of their histories individually from start to end, I cover them in segments using the above four phases.

My apologies to the many people that have made extensive contributions to the geomembrane industry that I have neglected to mention in this paper. Since this is a paper and not a book, I have intentionally limited the details in order to provide an overview of the history of geomembranes.

PHASE I. EXPERIMENTING AND LEARNING

The early history of geomembranes no doubt has many starts in different places, but the best known is the early work of Mike Hickey at the Bureau of Reclamation and Dr. C. W. Lauritzen at Utah State University. Motivated by preserving valuable water resources in the western United States, they experimented with natural materials, concrete, flexible PVC, polyethylene, rubber sheeting, asphaltic products and other waterproofing sealants. Without the addition of a synthetic hydraulic barrier, many canals, ponds and reservoirs lost up to 50% of their water through seepage to the groundwater. This water was not necessarily lost from use, but was not available where needed and additional expense was needed to drill wells and recover the water.

Their experimentation resulted in a number of publications in the 1950's and 1960's that started the education process and began to make potential users aware of an alternative to natural materials and concrete. Some of the early titles of papers by Lauritzen et. al. are "Butyl Fabrics as Canal Lining Materials" (1953), "Ways to Control Losses from Seepage" (1955), "Plastic Film for Controlling Seepage Losses in Farm Reservoirs" (1956) and "Linings for Irrigation Canals" (1963). Some early papers by Hickey include "Evaluation of Plastic Films as Canal Lining Materials" (1957), "Report on Installation of Experimental Plastic Membrane Canal Lining Material" (1957) and "Plastic Film Cut Off and Canal Lining" (1959). The focus is clearly on water preservation and a basic understanding of how polymeric films and sheets could be used.

As this period progressed, on the business side of the equation, far away from the research, early manufacturing of plastic geomembranes was done or encouraged by large chemical companies that saw an opportunity to sell pounds. They were creating products and looking for a market for them. A chemical company or a manufacturer converting the raw materials into a liner sold to local distributors who they trained in solvent welding or taping who in turn trained the contractors. The distributors sold a variety of products and would sell whatever they could to whoever was willing to buy.

There was probably less concern than there should have been about whether the products were appropriate for some of the applications where they were used. Installers in the field typically were unaware of technical aspects of the products they were installing and just went out and "winged it" (in the words of an early installer). Installations were done on rocky subgrades and other horrible situations without giving it much thought. Stone backfill was frequently placed on the liners without cushion fabrics to prevent puncture. Many failures paved the way for the CQA companies that sprung up later. Engineering firms were involved, specifying materials, but much of the information they had to work with is what was supplied to them by the distributor representatives.

PVC

I do not know which material was used first for hydraulic containment so I will start with flexible PVC film and sheet since it grew to represent a large portion of the early geomembrane market. PVC is normally a rigid material, but when plasticizers are compounded into it, it becomes flexible and has improved low temperature properties. Flexible PVC's use in the

United States started in the 1930's and its first hydraulic containment application was swimming pools. In 1952, Union Carbide Corporation looked at the hydraulic containment market as a place with the potential to move some serious pounds of plastic.

The early PVC geomembranes had several attributes that made them very desirable and is what helped their use grow over other materials. They were very flexible which let them conform to irregular surfaces easily. They had a fairly low modulus, which let them stretch to conform to point stresses such as gravel. They had good puncture resistance and relatively good tear resistance for an unreinforced material. PVC sheet was easily fabricated into large sheets using chemical or heat welding. Also, important as its physical properties, PVC films and sheets were easily joined in the field with chemical methods such as solvent bonding or bodied solvent bonding.

As with all the materials, there were many failures that made learning possible. Animal activity, human activity and mother-nature in acts as violence such as debris carrying gulley washers down PVC lined canals challenged the liners. The early PVC films used by the Bureau of Reclamation were 0.2 mm (8 mils) thick. As the need for durability during installation and use became apparent, the thickness of the PVC liners continued to increase until 0.5 mm (20 mil) PVC was standard for more demanding applications and 0.75 mm (30 mil) was available for those wanting to be sure they were using a liner that would stand up to abuse.

Even though the market was growing, it was not growing fast enough to hold Union Carbide's interest and in 1962 they got out of the fabrication business. Charlie Staff, who had been working at Union Carbide on the PVC market, left the company and founded a company with his brother Ed that would eventually become Staff Industries. The Staff brothers were successful in their endeavor and helped shape the early PVC geomembrane manufacturing market.

Toward the end of the "experimenting and learning" phase, attention began shifting from pond, canal and reservoir linings to pollution concerns. Preventing pollution of ground water from brine ponds and other chemical storage ponds were becoming more of a concern. PVC was used to line new ponds, retrofitted into existing but cracked concrete storage facilities and being used in floating cover applications to protect potable water from bird droppings and other airborne contamination.

Polyethylene

In the 50's and 60's, polyethylene found limited use in hydraulic applications in the United States, primarily pond and canal linings. The polymer used in that period was conventional, high pressure, low density polyethylene (LDPE), suitable because of its flexibility. LDPE, not to be confused with linear low density polyethylene (LLDPE), has poor tear strength and did not fare well.

High density polyethylene (HDPE) geomembrane production and use originated in Germany in the late 1960's with Schlegel. Early high density polyethylene geomembranes consisted of narrow sheets of polyethylene laid down end to end on a hot roll, the roll indexing and then another layer being laid down on the hot roll, slightly overlapping the first sheet. In this way, a

long, wide sheet with cross direction fused overlaps was created. This type of geomembrane was successfully used, and continued to be used into this century. Since the sheet had irregular thickness due to the overlaps, an in between the sheets extrusion welding process was developed to join sheets of material on site.

Chlorosulfonated Polyethylene

Chlorosulfonated polyethylene (CSPE) was manufactured by DuPont and sold under the trade name of Hypalon. CSPE began being used in the mid-1960s in both unreinforced and reinforced forms. Reinforcement was typically a polyester scrim.

Black CSPE liners had an advantage over PVC in that CSPE had good UV resistance and was suitable for exposed applications. The reinforcement aided the material in holding up in high stress applications such as steep slopes and floating covers. CSPE saw limited use in this period but became a dominant lining material later.

Asphaltic Materials

Asphaltic or bituminous liners fall under the geosynthetic classification since they contain a synthetic reinforcement layer and many contain a polymeric film. Modern bituminous geomembranes look much more like geomembranes than did the first products in the market.

One of the very first synthetic liquid containment lining systems was an asphaltic product made by Gulf State Asphalt. They took the cutout tabs from making asphalt shingles, ran them through an extruder, reinforced them with fiber and made 4' by 12' planks. They were welded on site with hot asphalt. The finished liner was then frequently painted with a silver paint. The City of Phoenix used the product to line the inside of concrete water tanks.

W. R. Meadows, started in the 1950's. Meadow Mat was an 1/8" thick asphalt core board with a plastic 8 mil PVC film suspended between two layers of felt that had a weather coating on top of it. It was a seven element construction for pond linings and canals which sold until mid 70s. It was sold as 4' wide pieces 8' to 50' long. Joining was also with hot asphalt on overlapped pieces or they were butted against each other and gusset strips 6 to 8" wide covered the joints and were then hot moped in place.

These liners found use in military applications, potable water storage and brine storage ponds in the Houston chemicals industry. Because of the weight, it was expensive to ship, handle and install. But it was the only game in town until the more traditional geomembranes came along.

PHASE II. RECOGNITION AND GROWTH

Recognition and appreciation for the performance of flexible membrane liners is what spurred the growth during this period. Growth means business opportunities and more people and companies jumping on the wagon. Proliferation also means more choices as companies attempted to differentiate themselves based on product properties and / or cost. Those

attempting to use these materials felt the need for some organization and set about to write the first consensus standards for the products and their installation.

The American Society of Agricultural Engineers, after a number of years of work, wrote a specification on installation (AP340.1). In 1972 the American Society for Testing and Materials (ASTM) generated ASTM Standard D3083 for Flexible PVC Plastic Sheeting for Pond, Canal and Reservoir Lining; Standard D3020 for polyethylene and ethylene copolymer sheeting; and Standard D3254 for butyl rubber sheeting. These specifications provided an easy reference for the novice being introduced to these materials and helped add legitimacy to lining material use for water containment applications.

The Bureau of Reclamation was key in the development and acceptance of geomembranes. People like Bill Morrison and Ron Frobel continued the work of Lloyd Timblin at the Bureau and expanded the use in the western US for water containment.

But it was the United States Environmental Protections Agency (US EPA) that forced the technical growth of geomembranes that paved the way for the tremendous growth in the use of geomembranes in the third period of this history of geomembranes. Robert (Bob) Landreth was a significant force in the United States in this period and the next in providing not only Office of Research and Development (ORD) funding for a broad range of research projects, but also providing his leadership, ethics and insights across the many disciplines and interests that made up the industry.

Much of the increase in geomembrane use in the next phase came from environmental applications, fueled by the US EPA, which began supporting the use of geomembranes in the bottom of hazardous waste storage facilities. On July 6, 1982, the US EPA promulgated regulations that contained the following statement.

Prevention (via geomembranes), rather than minimization (via compacted clay liners), of leachate migration produces better environmental results in the case of landfills used to dispose of hazardous wastes. A liner that prevents rather than minimizes leachate migration provides added assurance that environmental contamination will not occur.

That statement highlights the recognition of value that geomembranes brought to environmental protection technology.

This activity was not limited to the United States nor was the United States working by itself. Klaus Stief was leading Germany along a similar direction that required the use of thick geomembranes in hazardous waste landfills. In fact, HDPE lining technology was developed in Germany and brought to the US.

Finally, I would be remiss if I failed to mention the mining industry in this paper. While mining does not hold the same interest for the public as pollution and the need for potable water, the use of geomembranes in mining applications certainly got the attention of mines, geomembrane manufacturers and engineers. Rising metal prices in the 1970's along with the abundance of low

grade ores, prompted the use of geomembranes in heap leach pads, solution ponds and evaporation ponds. And with the large size of many mining applications, mines came to represent a significant percentage of geomembrane use.

PVC

PVC's growth continued steadily during this period, being supported more and more by environmental needs. An example of PVC recognition by regulatory agencies is in 1977, prompted by an increase in drilling for oil in northern Michigan, the state of Michigan passed a requirement that reserve pits for the drilling mud be lined with 0.5 mm (20 mil) PVC. This and other regulatory activities brought new companies into the market. PVC found itself as the solution to many other environmental problems such as capping landfills, closing unlined facilities and in ponds at wastewater treatment plants.

As the market grew and there became more competition, quality improvements were made. Companies like Watersaver, Palco, EPI and Staff fabricated and installed PVC liners along with Hypalon and other lining materials. They were responsible for promoting the materials, improving factory seaming processes and improving overall product quality.

Even though PVC was not viewed as UV resistant or very chemical resistant, in most applications PVC performed very well and was relatively inexpensive. Toward the end of this period, PVC was king and life was good for those in the PVC liner business. By 1983, PVC had almost 50% of the geomembrane market (percent of area installed).

Polyethylene

As mentioned earlier, thick polyethylene geomembrane technology started in Germany with Schlegel. Heiner Hammer was a driving force responsible for many of the developments at Schlegel. With their new technology they tackled lining the Garling industrial waste site. From the experience at Garling, other landfills and ponds, Dr. Knipschild published the first product and installation specifications.

In South Africa around 1978, Clifford Gundle became aware of Schlegel, and was intrigued by the potential for large projects with polyethylene liners. Gundle was in the blown film and recycling business and was making construction and agricultural film up to 0.25 mm in thickness. Some of these were being used in what we would consider geomembrane applications, liners for irrigation ponds. They had been working with polyethylene since the 1960's, but not in geomembranes and they were interested in getting into the thicker liner market.

Gundle offered to supply Heiner Hammer (who was no longer with Schlegel) and his South African partner, to make a 1.5 mm HDPE liner for a large oil storage facility in South Africa. Gundle had an 1800 mm diameter die but had no idea how to make a 1.5 mm thick material. The HDPE they used at the time was a real HDPE with a density in the 0.960 range. To make it usable in geomembrane applications, they alloyed the HDPE with ethylene vinyl acetate (EVA). While they had a raw material with workable physical properties, they were not having any luck

making the heavy gauge material because the molten polymer was too weak to hold itself up during the extrusion process. Fred Struve came up with the idea of using an internal mandrel (cooling can) to hold the bubble up and stabilize the sheet. It worked and they were into the beginning of what I would consider to be main-stream polyethylene production.

Having made the sheet, the challenge of consistently making good welds was in front of them. Gundle was familiar with a variety of welding technologies but none worked as well as they would have liked. That is when Fred Struve invented his extrusion welder with the mixing tip that agitated the extrudate and surface of the sheet to make reliable welds. With that, they were in the business and ready to expand to the United States.

As a side note, today's standard width polyethylene geomembrane originated with that mandrel. They wanted to ship product by rail and two rolls 6.86 meter wide (22.5') would fit in a standard open top rail car. Once the mandrel was made, they had no options to make other sizes without making new mandrels. So they stuck with that size and brought it to the United States when they opened a plant in Houston.

Schlegel was first to enter the US HDPE geomembrane market. They started selling their liners out of a Houston facility in 1977 and started production there about 1979. Schlegel was the dominant player in the world thick (2.0 and 2.5 mm) HDPE liner market at the time.

Gundle started operations in the US in 1982, in part, because of the impending US regulations requiring the use of lining materials. They initially took the position of being a manufacturer only and relied on installation companies like Serrot to do the installations.

Schlegel and Gundle started the polyethylene geomembrane market in the United States and had the immense task of not only making and selling the materials, but educating the end users, installers and engineers on the material's properties and proper use. By comparison to even just a few years later, they were dealing with a very unsophisticated customer base, and were learning fast themselves

While Gundle and Schlegel started the HDPE geomembrane market, there were many other players that had a significant roll in shaping the market. Large chemical companies, the manufacturers of the resins used to make the liner, had a large economical and liability interest. They provided state of the art research facilities and technical assistance. Engineering firms provided innovative designs. Entrepreneurial installers developed installation techniques and made the roll goods into functioning facilities.

Chlorosulfonated Polyethylene

Hypalon, along with PVC dominated the geomembrane market during most of this period. When someone said liner, many people thought Hypalon. Manufactured in relatively narrow sheets, it was easy to fabricate into wide panels for easy field installation. Like PVC, it was flexible and easy to solvent weld. With the added benefit of long term UV stability, it took over the exposed geomembrane markets such as ponds, emergency containment liners and floating covers.

Hypalon was not without its weaknesses. It was not chemically resistant as some other so called specialty geomembranes of the time. It was more expensive than most other materials. It tended to cross-link or cure with time, making repairs increasingly difficult. There were occasional blistering problems, particularly in floating covers. Solvent welding became more difficult as the temperature dropped. With PVC's better pricing and HDPE's better chemical resistance, Hypalon began losing market share in 1981.

Bituminous

During the last period, bituminous (asphalt) geomembranes were thick, heavy chunks of material whose installation was very labor intensive. As the other polymeric geomembranes became proven, these slabs were replaced by lighter weight geotextile impregnated, modified asphalts. They continued to be a built up technology containing several functional layers. This product was more popular in Europe than the United States.

Chlorinated Polyethylene (CPE)

Chlorinated polyethylene (CPE) and CPE alloy liners were popular for a few years particularly in exposed applications. It was used in both reinforced and unreinforced forms. It tended to have good UV and chemical resistance along with reasonable flexibility. In 1980, approximately 12,000 square meters of CPE was used in the Mt. Elbert Forebay impoundment. That installation alone was about 10% of the entire North American geomembrane market that year. Being chemically in-between PVC and Hypalon, it found use as a transition strip between the two materials.

Ethylene Interpolymer Alloy (EIA)

The first ethylene interpolymer alloy geomembrane was developed in 1975 as a coated fabric by a company making plastic coated fabrics for a variety of non-civil engineering applications. The first installation of an EIA geomembrane took place in 1976. EIA was developed in response to the need for more a more petroleum resistant liner than the CPE products being used. This product, in several variations, has been successful in substantial niche markets from its introduction through today.

Other Polymeric Geomembranes

This period saw considerable experimentation with polymer types, thermoplastic and rubber compounds. Several were of significance for a period of time, but never became main stream. For that reason, they will not be discussed here.

PHASE III. GEO-ERA, TECHNOLOGY AND PROSPERITY

I picked 1983 for the start of the third period because of all the notable activity that year. 1983 saw a number of engineers who were becoming the leaders of the industry organizing technical information and industry interactions. This period is marked by the coming of age of

geomembranes and related products. NSF published Standard 54 on Flexible Membrane Liners. The International Geosynthetic Society (IGS) was formed in 1983. The Geotechnical Fabrics Report (GFR), the first industry publication, started to be printed. Joe Fluet coined the term Geosynthetics from which the rest of the geo-terms were formed. Sponsored by the US EPA, J.P. Giroud started giving courses on geosynthetics in the United States. The first conference on geomembranes was being organized for 1984. 1984 saw the birth of the Journal of Geotextiles and Geomembranes. Manufacturers of geomembranes were pushing education of users, regulators and engineers on how to specify and use their products. Geomembrane use was just starting a rapid growth in environmental applications. Construction quality assurance (CQA) also became an area of rapid growth as everyone grappled with quality problems, failures and how to prevent them.

Wow, what a year! Still, geomembrane use in North America was just a small fraction of what it would be just a few years later. Figure 1 shows the value in millions of dollars of geomembrane sales in North America. 1983 sales were only half of what they would be in 1984 and growth continued at a brisk pace for many years.

Figure 1. Estimated geosynthetic market in North America.

During 1983 and the following years, the engineering and construction world as a whole learned about and started using geomembranes in more applications than ever. The products, the specifications and many of the designs were still fundamental in nature and were changing as people learned more about geomembranes, how to use them and what their shortcomings were. In 1985, Dr. Robert Koerner formed the Geosynthetics Research Institute (GRI) and a geomembrane manufacturer was the first company to step up to the plate, cut a check and become a member. In 1986, Dr. Koerner published the first edition of “Designing with Geosynthetics”, “the” textbook on geosynthetics design worldwide for almost 20 years.

As this period continued into the late 1980's and early 1990's, in the area of polyethylene geomembranes, friction sheet and a variety of coextruded products came to market. The significance of stress crack resistance forced resins for HDPE geomembranes to change. VLDPE appeared in the market place. Performance tests came to the forefront of test development.

Information and direction came from many organizations. ASTM committee D35 tackled the enormous needs of the industry for standard test methods. Technical Guidance came fast and furious through the EPA. Of the many very informative and useful EPA technical guidance documents, one in particular needs to be mentioned. Some of us refer to it as the bible of early geomembrane research and chemical compatibility. It is the Lining of Waste Containment and Other Impoundment Facilities by Matrecon written by Henry Haxo. It houses much of the early research that led to the US EPA specifying geomembranes for containing pollutants.

Even with these efforts, there was still a need for more research, more standard test methods and more professional guidance. GRI provided methods and specifications that ASTM could not develop or develop fast enough. The forceful, focused technical leadership from Bob, Grace and George at GRI brought the entire geosynthetic industry together and deserves much credit for the growth of the industry.

And that leadership was desperately needed. Manufacturers, while training many engineers and installers in the use of geosynthetics, also spent a fair amount of effort fighting each other. Specification wars were rampant. One up-man-ship, touting one's products while smashing the competition did so much damage that some engineers, regulators and users lost faith in any of the products. Specifications were written by manufactures as marketing tools. Specifications being written by engineers were sometimes performance and design based, but often were only a copy of a manufacture's specification. As this period comes to an end, NSF 54 was losing credibility due to neglect and opened the door for GRI specifications.

Duel Track Hot Wedge Welding

I start this section out with a discussion of welding technology instead of the materials because of the importance of welding in the successful use of geomembranes. In talking about geomembranes I frequently think about the as manufactured sheet or the finished installation. A whole lot of stuff goes on in between the two. Design, site preparation, deployment, welding and finishing off the construction are all key phases of a successful geomembrane installation. Welding is sometimes viewed as material specific, but one welding technique can be applied to most all thermoplastic geomembranes, wedge welding.

The reason for focusing on wedge welding is that it has become the preferred method of welding for many engineers and geomembrane installation owners. Wedge welding joins two sheets of plastic by passing the sheets over a heated wedge that melts the two surfaces and joins them with pressure to make a seal. No outside adhesives or chemicals are introduced. When using duel track welders, an air channel is formed between the two seals, which can be pressurized with air to check seam continuity. The process is mechanically controlled with the operator(s)

monitoring the welder functions and making sure the sheet edges going through the welder are clean. This type of welder has shown a high rate of success and is capable of consistently making good welds.

Hot wedge welding did not originate in the geomembrane industry. It was developed by a Mr. Kurylec in Czechoslovakia in 1947 for welding linoleum. In 1978, Sarnafil of Switzerland developed their version of the welder for polyethylene geomembranes and received a patent for it in 1982.

Clark Gunness, working for Sarnafil, introduced wedge welding to John Hardison of National Seal Company (NSC) in the early 1980's, granting NSC the right to use the welder for geomembranes. Even though NSC supposedly had exclusive rights to use the welder for geomembranes, Sarnafil was not enthusiastic about enforcing their patent and other companies began using the welding technology.

Clark Gunness was very active in spreading the use of wedge welding. He worked with Columbia Lining Systems in Calgary, Alberta one of the first companies to use the dual track welder. They developed a wide channel, high pressure test to really challenge the integrity of the seam, not just its continuity. Clark started developing his own welder, the Resicon R88 in 1981. It was a small welder compared to the Sarna and NSC welders and was designed to fit under the seat in commercial aircraft. In 1985, he started selling the welder commercially and their use became fairly widespread by 1988.

In Germany, the Bundesanstalt für Materialforschung und Prüfung (BAM) required both wedge welding and on-board data acquisition with respect to welding conditions such as welding speed, wedge temperature, pressure, etc.. Jack Donaldson and myself carried the technology a step further and developed the "Smart Mouse" welder. Not only did the welder monitor the welding conditions, it also controlled the speed of the welder to respond to changes in liner temperature during the course of making a weld.

In spite of an EPA conference on the subject in 1993, the smart mouse did not catch on for a couple reasons. First it cost about three times more than a normal welder. It had greater maintenance costs because of the technology. And lastly, it did not eliminate cutting holes in the liner every 500 feet because it could not eliminate weld failures. Contamination such as soil or moisture in the weld was not detected or controlled by the welder. Still, a lot was learned as a result of the research and some of the infrared sensors for sheet temperature and auto speed controls did find their way into production equipment.

PVC

The North American PVC industry grew and was prosperous, peaking out during the late 80s and early 90s. Even though the PVC lining industry was growing and doing well during that time, the rate of growth was only a small fraction of that being experienced on the polyethylene side of the industry.

The marketing, research and training done by the polyethylene manufacturers supported engineers and regulators with what they wanted, information they could hang their hats on, advance the state of practice and write specifications and regulations that they could justify with data. The PVC manufacturers, fabricators and installers did not jump on the technology band wagon and provide the same kinds of data and did not pursue education of engineers and regulators anywhere near the same extent as the polyethylene industry. The PVC group spent more effort complaining. As a result, polyethylene products became the material that was written into more and more specifications and regulations. By the time the PVC industry recognized what was happening, it was too late.

PVC technology was not stagnant during this period. The quality of plasticizers improved. In the early stages, dioctyl phthalate (DOP) was the predominate plasticizer used. During the end of this period, DOP started being replaced by less migratory plasticizers such as diisodecyl phthalate DIDP.

While the technology was available, not much dual track wedge welding was being done with PVC geomembranes, maybe none in the US. It is thought that some Canadian PVC geomembrane installers were using wedge welders in the 80's. EPI was the first US PVC installer to attempt to embrace wedge welding to at least a limited degree in the early 90's. The main driving force for using wedge welding on PVC at the time was to extend the installation season, being able to weld in cool conditions in the early spring and late fall without tents and other such measures.

Polyethylene

While I refer to this period as the Geo-Era, in the geomembrane market, it can easily be referred to as the polyethylene era. Polyethylene geomembrane producers stepped up to the plate and blasted the geomembrane market wide open with aggressive marketing to end users, design engineers and regulators. Not only did their efforts propel polyethylene use over other types of geomembranes, they also accelerated the widespread use of geomembranes as a solution for environmental and water quality problems.

The industry also had the help of some researchers and regulators that saw the inertness or chemical resistance of high density polyethylene as a distinct advantage in the lining of hazardous waste landfills. Work published by Dr. Hans August and others in Germany showed HDPE to be the only material to stand up to the wide variety of chemicals being placed in hazardous industrial landfills at the time. Similar work funded by the USEPA had Henry Haxo developing chemical compatibility procedures and comparing the available lining materials. When that testing started in the early 80's there were many types of liners being used and evaluated and not much PE. By the late 80's polyethylene was the material of choice, not just because of good performance in the chemical compatibility tests such as EPA method 9090, but also because the polyethylene suppliers participated more in the testing.

But life was not a walk in the park for the polyethylene industry. There were many problems to be solved. In that group was friction, or the lack of it. As many people learned the hard way, walking on a wet, three to one, polyethylene lined slope frequently resulted in an unexpected

quick trip to the bottom of the slope. If personal embarrassment and an occasional broken leg was the only issue with smooth PE geomembranes, textured geomembranes may never have been developed. As it turns out, heavily loaded wet soil and waste does not like to stay put on a steep polyethylene lined slope either. Neither does a heavily loaded polyethylene liner like to stay put on a wet slope. Failures occurred at both interfaces and the industry needed to provide a solution.

One of the most studied failures and one that forced friction sheet into production was the 1988 slope failure at the Kettleman Hills Waste Landfill in California. 490,000 m³ of waste was involved. The landfill design was state of the art, incorporating multiple geomembranes, drainage layers, cushion layers and a compacted clay liner. Failure occurred at more than one interface. The primary failure was at the clay-geomembrane interface. Byrne, et. al, published one of several papers analyzing the failure.

One of the first structured geomembranes (referred to as friction or textured in the US) was developed in Germany by Agru in the late 80's. It had 5 mm tall spikes embossed on the surface. Subsequently, several variations were developed with ribs and other protrusions by Agru and others.

Not everyone thought the first alternative to smooth polyethylene sheet was good enough. Besides being dangerous to fall on, the large dramatic structures significantly reduced the materials tensile strength and elongation at break. Even though HDPE is not designed to be used past its yield point of about 13%, some engineers did not like the dramatic change in properties.

One of Schlegel Lining Technology's customers, BFI, encouraged them to develop an alternative. In the US in the late 1980's, SLT developed a friction sheet by adding a spray on PE coating that was fairly well adhered, but not well enough to seriously reduce the tensile properties at break.

National Seal Company (NSC) developed yet another textured sheet, a smooth sheet coated with a thin foamed layer of polyethylene. The Foam bubbles broke open during the coating operation yielding a rough textured surface. Like the SLT sheet, this textured sheet retained more of the smooth sheet tensile at break properties and was one of the most aggressive textures on the market.

Gundle purchased their second blown sheet line in 1986. This line had coextrusion capabilities and the extruders were designed for injection of nitrogen in the outside two layers. In this way, they made a textured sheet. As the plastic came out of the die, the bubbles being stretched broke open and cooled to make a rough surface. There were many problems with this product early on (holes in the sheet, globs of foamed material sticking to the die then sloughing off onto the sheet, poor consistency, etc.). It eventually became the industry standard as the process was improved to make a better product and it proved to be the least expensive way to make a textured sheet.

With all the choices available in textured sheet and geosynthetic clay liners (use instead of compacted clay in some instances), the USEPA with the cooperation of Waste Management and the manufacturers, set up a long-term slope stability evaluation in Cincinnati. There were 14

instrumented, full scale tests performed on 2:1 and 3:1 slopes. Three of the 2:1 slopes failed. The failures along with the non-failures provided valuable information for future designs.

Another major problem was stress crack resistance. The resins used for many of the early HDPE geomembranes were hand-me-downs from the gas pipe industry. These were real HDPE resins with densities of 0.940 to 0.945. While they may have worked well for pipe, they did not stand up to the abuse taken as part of a PE lining system. Most of the failures occurred at welds that were overheated, distorted, over ground or somehow made with a stress concentrating defect.

The industry responded by making stress crack performance improvements such as lowering the density of the polyethylene resin being used. It was necessary to take the density down below 0.940 g/cm³, the lower boundary set by ASTM for HDPE (0.940 being a somewhat arbitrary number). Since HDPE was already engrained in the industry as a product, no one wanted to change the product name to medium density polyethylene liners. So the industry definition of HDPE was changed to a finished sheet density of at least 0.940 using a polyethylene with a density of at least 0.932 g/cm³. (The carbon black, used for UV resistance, brings the density up about 0.008 to 0.012 g/cm³).

While everyone realized that the stress crack resistance of the products needed to be improved and lowering the density was a good way to go, more factors effect stress crack resistance than density (average molecular weight (MW), MW distribution, distribution of comonomer on the polymer backbone, distribution of the comonomer across the different MW molecules, comonomer type, processing conditions, stabilization and so on). So a quantitative test was needed to measure the stress crack resistance of HDPE geomembranes. The “bent strip” testing being used was useless since all the materials in use had good enough stress crack resistance to stress relax before failing.

Dr. Grace Hsuan of GRI developed the notched constant tensile load (NCTL) test to differentiate materials. The test avoided the stress relaxation interference of the bent strip and had short enough failure times to be used as a quality control test (not as short as the industry would have liked, but short enough to be practically useful). By evaluating the NCTL properties of many liners, some that failed and many that did not, a specification was arrived at that is still the standard today.

Many properties were evaluated and tests developed for geomembranes in this period, often with a focus on polyethylene. Lifetime assurances were addressed with oxidation induction time (OIT), carbon black content, carbon black dispersion, air oven aging and UV aging. Durability and resistance to puncture were evaluated with large-scale hydrostatic tests and multi-axial tensile.

But some roadblocks were introduced to new innovation. One that appeared that has not gone away is viewing thickness as a performance property. Many industries have gone to better performing and more expensive grades of polyethylene to get better performance and offset the raw material cost increase by down-gauging, making a thinner product. Since thickness was viewed, at least in practice, as a performance property, minimum thickness is almost always the first property listed in a material specification.

There were some exceptions. For instance, even though HDPE was a dominant lining material, linear low density polyethylene (LLDPE) began growing in applications such as caps where its flexibility and ability to conform to moving subgrades was viewed as positive. Being a cap, it was not perceived to need the same chemical resistance as a primary bottom liner. LLDPE was not specifically addressed in the regulations and was, by default, allowed to be thinner than HDPE in some applications such as landfill liners.

Then very low density polyethylene showed up with even better extensional properties. It did not have the UV or chemical resistance of HDPE or even LLDPE but provided some unique properties. NSC patented a coextruded liner with a VLDPE core and HDPE skins so as to get the most flexibility and the best UV and Chemical resistance in one sheet.

Flexible Polypropylene

Flexible Polypropylene (fPP) geomembranes appeared on the market in the early 1990's. The resin was made with a "Catalloy" process that allowed a high percentage of ethylene-propylene rubber (EPR) to be co-polymerized with polypropylene in the reactor. This very flexible material did not resemble standard, stiff polypropylene and made an early splash in the market in both reinforced and unreinforced forms despite its high cost. By 1993, several papers had been written on the use of fPP geomembranes.

The fPP took some market away from polyethylene. It was more flexible than even VLDPE (but not as flexible as PVC). It also had better stress crack resistance than HDPE and was thought to be a good alternative for black liquor lagoons at pulp mills.

fPP took a big chunk out of the Hypalon market. It had better cold weather properties than Hypalon. It was easier to install and repair after having aged. It was easily wedge and hot air welded. It was processed on the same extrusion equipment as polyethylene and other reinforced geomembranes. Even though it cost a lot compared to PE, it was less expensive than CSPE.

Chlorosulfonated Polyethylene

Hypalon continued to lose market share during this period, being replaced more and more by polyethylene and, toward the end of the period, by fPP. CSPE had its niche markets where it dominated, such as floating covers, but polyethylene made inroads there as well and fPP was coming on strong. Still, Hypalon had a good piece of the market during this period.

PHASE IV. MATURE PHASE

Of all the dates I have selected for the phases of geomembrane growth, this is the least well defined. The beginning of this phase could be defined by a change in the growth of the market. It could be defined by a change in market profitability. It could be defined by an onset of mergers and acquisitions. It could be defined by a reduction in funds available for research and product development. It might be defined by a reduction in attendance at industry conferences and symposiums.

But it cannot be defined by an end to the need to learn, develop new products, develop new designs, develop new installation procedures, write new standards, conduct more research or find interesting topics to disagree on. After all, we still, still had not succeeded in one of the most fundamental tasks of all. One of the most annoying, counterproductive procedures that continues to haunt the industry. Taking a perfectly good geomembrane installation with good dual track wedge welds and cutting a three foot long hole over a foot wide every 500 feet. So there was definitely work yet to be done.

For the sake of attaching a general date, I would say we had progressed well into this phase by the mid-1990's and will use 1994 as year one.

Based on my description of this phase of geomembrane life, you might think that there is nothing to write about. While I claim the industry entered a mature phase, I said nothing about it entering a grave. New product development and research was alive and well. New spray on bituminous and polyurea geomembranes were introduced. Very flexible polypropylene geomembrane applications were growing. New coextruded PE products were coming to market.

The Bureau of Reclamation (Jack Haynes, Jay Swihart, Alice Comer) began monitoring the Deschutes lining project to evaluate geomembranes in rough sub grade irrigation canals (installed in 1991-1993). A workshop was held in Berlin at the BAM to work through the differences in philosophy of landfill design and construction. The International Association of Geosynthetic Installers (IAGI) was formed in 1995 to provide a voice for the installers.

Also in the period, signs of the mature stage show themselves in the merger of SLT and Gundle to form GSE. Bob Landreth sadly retires long before we wanted him to. Long after it outlived its usefulness, the once hallmark of the industry, but now outdated NSF 54 on FML's is withdrawn.

Welding

Refinement and continuous improvement is a necessary part of the "mature phase". Wedge welding continues, more than ever, to be the preferred method of making field welds in thermoplastic liners. Since the smart mouse could not stop failures or reduce the number of destructive field seam tests, the effort changed to smart people as the answer. This approach is two fold. The first is taking seam samples wisely, not just at fixed intervals. The other is to better educate and train the people making the seams.

The first effort to reduce the number of destructive seams through a variable sampling rate came from the Geosynthetics Institute GRI GM-14 guide for "Selecting Variable Intervals for Taking Geomembrane Destructive Seam Samples Using the Method of Attributes", adopted in 1998. This guide attempts to reward successful welding efforts on a job site by reducing the test frequency and it penalizes poor welding with more frequent testing.

IAGI approach the people side by setting up a certification program for welding technicians. An experience technician can go through training, take a written exam and take a hands on exam to

be certified. This program kicked off in 2002 for polyethylene geomembranes and in 2004 for reinforced geomembranes. IAGI is trying to convince engineers to specify certified technicians as a requirement and has published a White Paper on “Improving Geomembrane Installations.”

PVC

The PVC market began shrinking in this phase of geomembrane history and continues to shrink slowly today. PVC is not technically as accepted by much of the engineering and regulatory community today as polyethylene is. PVC is not a bad material and there are not many material failures. There is just a perception issue with many regulators and engineers. Many engineers can't get what they want from the material, such as the consistency of dual track field welds with air channel testing. While some material is being wedge welded today, much of it is still chemically welded. Technically, the manufacturers have not done enough to improve the perception of their product.

My opinion and the opinion of several people from the PVC side of the business that I spoke with as part of gathering information for this paper is that if the PVC industry had pursued a similar, aggressive marketing, education and technology strategy as the polyethylene industry did, the PVC geomembrane share of the market would have been and would still be much larger.

Processing and compounding improvements have been made but the manufacturers do not advertise or promote those changes. In compounding PVC, mixtures of plasticizers and stabilizers can be used to make products for different applications. South American and European manufacturers make different products for buried vs unburied applications.

There are those in the PVC FML industry that are actively working for improvement. The industry did join together to form the PVC Geomembrane Institute (PGI) for conducting research, publishing technical information on PVC geomembranes, writing a standard specification for PVC geomembranes and offering an opportunity to address the technical needs of the engineers and owners. They continue to investigate ways to improve PVC specifications such as adding a requirement for a minimum plasticizer molecular weight.

Dan Rohe and Mark Wolschon are heading up two ASTM PVC task groups. The first is an attempt to write a consensus ASTM standard specification for PVC geomembranes, something even the polyethylene industry has been shy to do. The other is a dual track weld air channel test to evaluate the peel strength of a seam to eliminate the need to cut holes every 500 feet in field seams. Hats off to them for their efforts.

For the foreseeable future, there will continue to be a need for the PVC geomembranes. It has advantages and it has a place. But it will not be on par with PE products. PE is entrenched and is inexpensive. PVC continues to do better in South America than the US.

Polyethylene

The changes that took place in the polyethylene geomembrane industry during the previous period were amazing. At the beginning of the period, it was a small specialty market that was

not well known. By the end of the period, incredible advances were made in products and technology. Equally amazing to those who took polyethylene through that period is how by the beginning of this period, polyethylene geomembranes had become a commodity product, sold by the pound as unenthusiastically as PVC pipe is sold at a home improvement store.

Technology advances were still being made at a fairly brisk rate in materials, extrusion technology, welding, installation and design. But the market had become so large that the only way the manufacturers could service it was selling standard product in mass. This has served to limit new product development for smaller niche areas by major manufacturers. Since higher raw material costs cannot be easily passed on, new materials like metallocenes are very slow to enter the market.

Flexible Polypropylene

Flexible polypropylene use grew quickly during the early part of the period and had 5% of the geomembrane market by 1995. Its high cost compared to polyethylene and PVC limited its use to places where its combination of flexibility, chemical resistance, UV resistance and ease of wedge welding allowed it to compete on performance.

There were several failures early on as the industry learned how to properly design with and use the product. Some aging concerns still have to be fully addressed at the writing of this paper and continue to be under investigation.

Hypalon

Through the early 90's Hypalon's share of the market rapidly declined and was down to only 5% of the North American market by 1995. Flexible polypropylene was rapidly replacing it. DuPont, eventually walked away from the market, not in that they quit selling the raw materials to the industry, but in that they quit promoting its use. Hypalon geomembranes are still made and installed but represent only a small amount of current geomembrane use.

Bituminous Geomembranes

A number of companies continue to make bituminous geomembranes. Their use in Europe is still fairly strong and represent over 10% of geomembrane use. Their use in North America is less than 2% of the geomembrane market but may be growing. They have a 30 year history of use and find their way into a variety of applications including waterproofing dam faces, pond liners, canals and transportation.

EPDM

Ethylene propylene diene terpolymer (EPDM) is not a new polymer or new to geomembranes but is seeing some new life in civil engineering applications. EPDM was introduced in 1963 but saw most of its use in single ply roofing products. EPDM was used in geomembrane applications in the US, but like the bituminous geomembranes, it has found more use

internationally. The exception is the home and business decorative pond market, where EPDM enjoys over 90% of the market.

EPDM is a very flexible, versatile material with good UV resistance. Because it is a fully cured rubber, it cannot be heat welded and must be glued or taped together in the field if the project is larger than what can be factory supplied. Since installation does not require any specialty equipment, EPDM is well suited to small applications. That said, it has been used in landfill caps larger than 4 hectares (10 acres).

FUTURE PHASE

I don't claim to be able to predict the future but there are a few observations I would like to make. The world population continues to grow. Land, air and water requirements for that population continue to grow. The world continues to get more polluted, not less. The rates may have been reduced dramatically in many parts of the world and the impact of select pollutants may have been reduced, but pollutants as a whole continue to spread. Popular talk about global warming is starting to be replaced by discussions of solar dimming, the reduction of sunlight reaching the earth's surface due to air borne pollutants and increased cloud cover.

Geomembranes are an important tool in conveying water, holding water, covering water, protecting water by containing hazardous materials, being a hydraulic barrier in purification processes and being a gas barrier, preventing air pollutants from escaping. Their need will not diminish during the foreseeable future. As the demand placed on geomembranes get greater, I believe new polymers will find their way into geomembranes. The polymers used today are good polymers and, for the most part are inexpensive. Many other polymers have barrier properties superior to the most common polymers being used in geomembranes today (and they cost more). Want a glimpse of the available technology, just take a look at what is going on in the booming industry of food and medical packaging. I can see five, seven and more layer coextruded geomembranes with polymers like polyamide, ethylene vinyl alcohol, polyester and other barrier materials being used in conjunction with polyethylene. We may even see breathable geomembranes that let moisture through but contain pollutants.

Through these challenges of the future and changes that are certain to come, sound research, active industry interaction and education of new and existing engineers and scientists will be needed to provide direction and high-quality information. The leadership provided by the Geosynthetic Institute, its associated institutes, Robert Koerner, George Koerner, Grace Hsuan, others at Drexel University, and many others in the industry will be invaluable in keeping us on track and focused on the key issues.

ACKNOWLEDGEMENTS

Fred Rohe and Fred Struve for their contributions from their memories and guidance in writing this paper.

THERMAL SEAMING OF POLYETHYLENE GEOMEMBRANES

Mark Sieracke, Principal, Weaver Boos Consultants
Ian Peggs, President, I-Corp International

INTRODUCTION

Seaming is the need to join geomembrane so as to create water tight containment. It is far superior to shingling and overlap! Seaming-either factory or field-is required on all large scale installations.

Discussion will primarily focus on polyethylene seaming since it has become the most common (but not exclusive) geomembrane for waste containment and related waterproofing applications. A retrospective review going back 25 years takes us to 1988 which was shortly after the double track wedge welder became well established in North America. Much had happened before then, as summarized below.

THE EARLY DAYS OF POLYETHYLENE SEAMING

It is understood from Clifford Gundle that the first joints in large deployment areas of High Density Polyethylene (HDPE) geomembranes were made in South Africa by Allan Lever using interlocking pipe sections buried in anchor trenches (Figure 1).

Figure 1. First polyethylene seam (Courtesy Clifford Gundle).

However it did not take long for the handheld rotary head extruder (Figure 2) developed by Fred Struve to appear on the scene to provide a more water tight seam taking advantage of the ability to reheat and extrude polyethylene materials onto the seam area.

Figure 2. Rotary head extrusion welder (courtesy Clifford Gundle).

At the same time Heiner Hammer of Schlegel Lining Technology in Germany was building a geomembrane manufacturing machine (Figure 3) that consisted of an indexing heated drum about 2 m diameter on which approximately 450 mm wide strips of HDPE were extruded transversely. The drum was rotated sufficiently for the next transverse strip to be laid overlapping the previous strip by about 30 mm and bonding to it while it was still hot. This process was not considered “factory seaming”, it was the process to create a continuous long roll of geomembrane up to 10 m wide was made consisting of cross-roll strips (Figure 4).

Figure 3. Schlegel's indexing drum geomembrane machine (courtesy Catrin Tarnowski).

Figure 4. Thirty year old Schlegel HDPE geomembrane with frequent horizontal welds.

Field welds for the Schlegel liners were made using a large ice-cream cart size extruder on wheels (Figure 6) loaded with HDPE pellets that extruded a bead of resin about 35 mm wide between the overlapped sheets.

Figure 6. Schlegel Lap welding machine (courtesy Catrin Tarnowski).

On the whole, the transverse overlaps made in the factory on the Schlegel geomembrane performed extremely well but the edge of the overlap area was quite susceptible to stress cracking in hot/cold environments – a function of the early pipe grade high density resins and the weld geometry. Stress cracking was first identified by Peggs and Little in 1985 (Procor Inc., private report)

The Schlegel lap extrusion weld for field installations was replaced by the rotary head extrusion welder (Figure 2) developed by Fred Struve at Gundle as the primary welding technique for several companies.

INTRODUCTION OF WEDGE WELDING

In the early 1980s Sarna (Switzerland) had developed an automated single track wedge welder for welding roofing membranes. Clark Gunness became the US representative for Sarna (and Sarnafill membrane) and introduced the fusion welder to National Seal Company. National Seal, via Hans Poetsch Sr., worked with Sarna to build a patented welding machine. However, Pfaff in Germany had already built (~1980) and patented such a wedge welding machine and claimed patent infringement. However, the upshot was that Sarna, NSC, and Pfaff all worked together on the worldwide development of the double track hot wedge welding machine, (see Figure 7).

Figure 7. Example of an early wedge welding machine.

Figure 8. Cross sections of wedge welds.

In the 1980's, National Seal began was an installer/fabricator using the wedge welder for both factory fabrication of large panels as well as for field seams. National Seal eventually began manufacturing large rolls of geomembranes and use the wedge welder for field installations.

There was a time when different installers were using different welding techniques leading to variations in quality, inspection techniques and testing approaches. Eventually, the double track wedge welder evolved into the primary production welding device for polyethylene geomembranes and the same technology has now been adopted for PVC and other geomembranes. Of course, extrusion welding of polyethylene geomembranes is still being used for repair and detail work.

Double track wedge welding provided the advantage of automation, two parallel weld tracks and an efficient non-destructive testing procedure.

Different versions of wedge welding, both single track and double track, are used for a variety of geomembrane types and a variety of thicknesses. It is not uncommon to see wedge welders used on geotextiles as an alternative to sewing.

In 1996 Leister, primarily building hot air welding machines, introduced a combined hot wedge/hot air machine which combines the best of both worlds/welds. The hot air would contribute to annealing any induced stresses at the edges of the weld.

Over the years there have been advances in the construction of the wedge welder itself with different frames, different materials for the wedge and increased equipment durability. However, the concept of wedge welding has remained the same.

Even though the wedge welder provided an option for more consistent seaming and more efficient non-destructive testing, there were still seam quality issues with wedge welding. Consensus was that wedge welding is still better than any type of extrusion welding. There are, however, human and environmental variables that could impact the quality of a seam such that destructive testing is still justified.

To address some of these variables, there has been improvement in the equipment and certification programs for the welders. Over the years, there has been significant improvement in the seaming quality, however, we continue to take destructive tests every 500 feet and repair the hole with an inferior welding technique.

To address some of the variables, the concept of “smart welders” with data acquisition for evaluation of the seaming process was evaluated and tried by one installer. The USEPA organized a workshop on “Geomembrane Seaming: Data Acquisition and Control” in 1993 (EPA/600/R-93/112). Although the smart welder is a regulated requirement in Germany, parts of Europe and South East Asia, they have not been adopted in North America. The goal of the smart welder was to raise confidence in the consistent quality of the seam leading to elimination or reduction of the non-destructive testing requirement. Both the cost and the sensitivity of the electronics of a smart welder required an offsetting savings in the testing costs. This concept was never fully adopted and the smart welder was simply not adopted.

Figure 8. Example of Smart Welder.

MICROSTRUCTURE OF WELDS

Little has been written on the microstructure of HDPE geomembrane welds, an understanding of which is necessary to understand their performance and durability. Figure 9 shows a cross section of an extrusion weld. This weld would be better if it had a smooth surface profile.

Figure 9. Cross section of extrusion weld.

Figure 10 shows a schematic cross section of the microstructure of an extrusion weld

Figure 10. Schematic of extrusion weld.

The thermal energy in the extruded weld bead should be sufficient to melt the surface layers of both geomembranes such that the molten bead and molten geomembrane mix together, cool, and solidify. Therefore the Melt Indices of the extrudate and geomembrane materials should be similar. When the surface of the geomembrane is melted its oriented microstructure (resulting from extrusion) is lost such that when it solidifies the melted and solidified material effectively becomes isotropic in structure. Adjacent to that layer is a heat affected zone (HAZ) which has not been melted but which has been heated to some degree which will affect the oriented microstructure, perhaps increasing crystallinity somewhat.

The slope of the interface between melt solidified and heat affected material, and the width of the heat affected zone may act as an internal “notch” to initiate stress cracking. Figure 11 shows how a craze, the precursor of a stress crack, is initiated at an angle, possibly the gradient of the melt solidified and HAZ interface, just under the edge of the weld bead. Steep gradients will provide a larger notch effect than a shallow gradient. In this respect the annealing effect of a hot air environment in addition to a heated wedge may be beneficial to the long term mechanical durability of the weld.

Figure 11. Craze becomes stress crack in geomembrane just below edge of weld bead.

It is for the reasons mentioned above that it is necessary to measure shear elongation in seam tests to ensure that the geomembrane at the edge of the weld has not been overheated, oxidized and embrittled.

Similar microstructural features occur and can be seen at the edge of a wedge weld at the root of the squeeze-out bead (Figure 12). In addition, when viewed with crossed polarizing filters the residual stress distributions are identified by the different colors.

Figure 12. Thin slice cross section at root of squeeze-out bead in a fusion weld viewed with crossed polarizing filters.

When a peel test is done on a poorly bonded fusion weld and separation occurs, in some HDPEs crazes can again be initiated in the separated surfaces (Figure 13). If a uniaxial tensile test is performed on such a crazed seam the break stress can be reduced about 70%. Hence the reasons for limiting the amount of peel separation in a peel test.

Figure 13. Crazes initiated in peel separated surface (arrowed). Squeeze-out bead to left.

Microstructural features have also been found useful in investigating separation in plane breaks in fusion welds. The first occurrence of separation-in-plane (SIP) was reported by Peggs in 1985. Figure 14 shows the striated microstructure that enabled the geomembrane to be delaminated by hand along the white bands. Clearly, in this case, there was a problem in uniformly dispersing the carbon black additive.

Figure 14. Striated microstructure resulting in SIP along the white lines.

Figure 15 shows a seam in which SIP occurred in a peel test.

Figure 15. SIP in peel test specimen.

A number of papers (Struve 2003, Smith 2001) have been written about the cause of SIP. The most common cause is thought to be the use of an additive package with an incompatible masterbatch carrier resin. However, the issue essentially remains unresolved and is the subject of the recent GRI white paper #25 “The Separation-In-Plane (SIP) Mode of Failure When Testing Geomembrane Seams“. (2012). GRI does not consider SIP to be a problem provided the seam peel strength requirement is met.

SEAM TESTING

We are all familiar with destructive seam peel and shear strength testing to assess seam bond strength. However, for the reasons mentioned above, Peggs (1996) and Thiel (2013), believe it more appropriate to measure shear elongation and peel separation and, in fact, to almost ignore strength values. Geomembrane strength values are a function of geomembrane thickness. Why is the strength so critical when the weld interfaces we are trying to evaluate are the same for all thicknesses? They actually do not tell us very much about bond quality. The strengths are an indicator of potential damage to the base geomembrane-not a measurement of bond quality of the two geomembrane sheets.

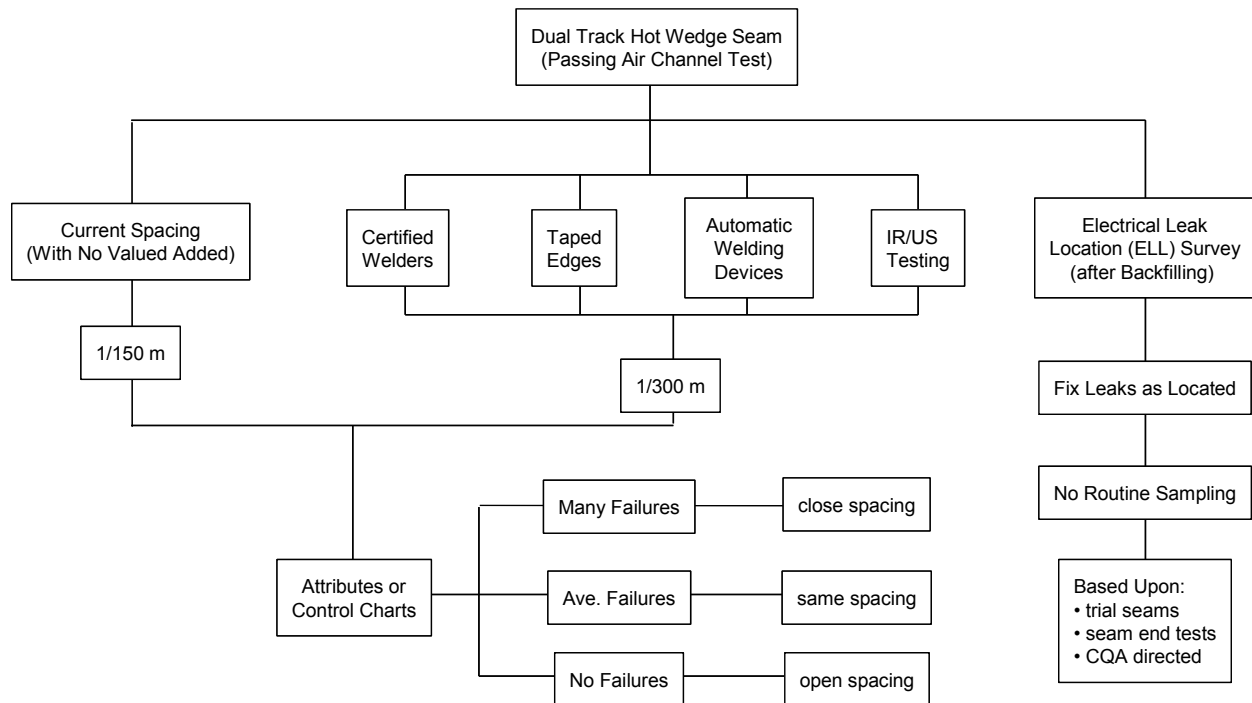

When five specimens are tested in shear and peel modes it is still not unusual to see specifications that allow one of the five to fail for acceptance of the complete seam sample. This is a 20% failure rate of a critical liner parameter which surely should not be acceptable. It is proposed that all ten specimens meet specifications of ductility at break and no peel separation

FUTURE DEVELOPMENTS/NEEDS

The two main objectives for the future still remain as they have been for many years:

- Develop a confidence level in the weld that will eliminate the need to cut holes in good seams for destructive peel and shear testing and having to make repairs using three times the length of an acknowledged inferior extrusion welded seam, and
- New techniques/methodologies to nondestructively evaluate 100% of a weld.

A strategy to increase the confidence in the weld quality to modify the destructive test frequency has been available from GRI and has been successfully used on projects and in CQA plans.

Probably the two most relevant technologies for non-destructive testing are ultrasonic and infrared thermography. The ultrasonic pulse-echo technique, essentially for thickness measurements, was first proposed for use in Germany in 1992 (Müller 2013 personal communication). In 1996 the use of ultrasonics was no longer required although some CQA firms continued to use it. In 2009 the use of ultrasonics was issued as a standard by the BAM Institute. It requires three thickness measurements on fusion seams every 10 m. With their certified HDPE resins, certified geomembranes of 2.5 mm thickness, certified welding machines, and certified welding personnel, they have found that a reduction in thickness of 0.3 to 0.8 mm from the total nominal pre-weld thickness of 5.00 mm is indicative of proper thermal energy input, welding speed, and nip roll pressure to produce an effective weld. An intermediate signal from the weld interface is indicative of an inadequate weld. Clearly, such a parameter is not necessarily appropriate for thinner materials, different resins, and different welding machines. Nor does it provide 100% coverage of a weld length.

In addition, a flat-ended transducer is required to make full firm contact with the weld surface which can be done on fusion welds but not on extrusion welds. This presents a limitation for ASTM D7006 “Standard Practice for Ultrasonic Testing of Geomembranes” for evaluating seams. The requirement for a consistent uniform pressure can also be a problem on seams in a wrinkled liner.

One hundred percent coverage on both fusion and extrusion welds can potentially be achieved if a pitch-catch technique (shadow method) is used in which the ultrasonic pulse is induced in the liner on one side of the weld, the signal passed through the weld interface, and is picked up at the other edge of the weld in the other liner using continuous contact roller transducer probes (Figure 16). Figure 17 shows the change in signal as the quality of the weld changes. However, there still remains the practical problem of variation in transducer contact pressure at wrinkles. This may be avoided by more recent “Airscan” probes that do not require contact with the geomembrane, but no work has been done in this area yet.

Figure 16. Pitch-catch ultrasonic geometry using roller transducer probes.

Figure 17. Ultrasonic signal after passing through various weld interfaces.

It is interesting to note that the first GRI geomembrane standard GRI-GM1 was “Seam Evaluation by Ultrasonic Shadow Method“, issued in 1986.

Coletanche bituminous geomembranes with their wide overlapping seams are frequently 100% tested by an array of pulse-echo transducers in a liquid-filled drum that is rolled along on top of the overlap seam (Figure 18). A continuous contour plot of weld interface quality (Figure 19) is obtained.

Details of measurement results with

Figure 19. Display of ultrasonic data. (courtesy Bernard Breul).

Infrared thermography may be a better option for assessment of 100% of seam quality. In this non-contact technique the surface of the weld is flash-heated with a pulse of IR energy then the surface of the weld is monitored using an IR camera, for a second or two, for temperature changes. Where the weld is well-bonded the surface temperature decreases as heat is conducted down through the weld. At poor weld interfaces and where there are internal flaws the surface remains at a higher temperature due to the poor conduction of heat across the weld interface. Figure 20 shows a plan view thermogram of a double track seam at a location where the speed of the welding machine was changed. The two weld tracks are different and differences can be seen along the length of each track. Red represents a hot surface and a poorer weld while green/blue is a cooler surface and a better quality weld. Peel tests were performed on the left and right sections of each weld track and the only specimen that peeled was from the red section of the bottom track.

Figure 20. Plan view of double track weld at location (dotted line) where welder speed was changed.

Ultimately, such a monitoring system could be appended to a welding machine to interrogate the weld immediately after welding, and with appropriate feedback to adjust the welding machine parameters to allow for changes in liner temperature caused by passing clouds and wind etc. The interesting challenge, of course, is to identify what features of the weld thermogram are acceptable, for not all features will be critical to the performance of the weld.

However, and to be realistic, if smart welders are not considered necessary, the addition of a sophisticated weld quality interrogation technique is even less likely to be implemented. On the other hand if, after trial weld calibration, there was no requirement for destructive testing and even no requirement for nondestructive air pressure and vacuum box testing, there may be some hope for this technology.

CONCLUSIONS

The seaming of polyethylene geomembranes has evolved from a simple mechanical connection to applying a hot extrudate to a controlled automated fusion welding process. In addition, this fusion welding process has also allowed for an efficient method to non-destructively test the welded seam.

The quality of the equipment and available certification of welders and CQA inspectors have all been instrumental in the improvements made and the quality of geomembrane seams. However, we still continue to having failing destructs. Regardless of the advances we have made, we still

need to make sure the equipment is operating properly, the seam area is clean and dry, we understand the variations in melt flow index between the geomembranes we are welding and we need to keep looking for new ways to test seams to change the status quo of cutting out the seams for purely statistical reasons.

THE LANGUAGE OF AN INDUSTRY: GEOSYNTHETICS TESTING AND MEASUREMENT

Sam Allen
Vice President, TRI/Environmental, Inc.

ABSTRACT

Geosynthetics testing activity has been a pillar of the geosynthetic industry’s history and experience. Success and challenges in laboratory measurements continue to be strongly related to both industry growth and its struggles. While ASTM and ISO are critical to permanent standards development and distribution, the Geosynthetic Institute has also played a vital role in promoting excellence in laboratory testing protocols and practice.

Figure 1: Growth of Geosynthetic Standards

INTRODUCTION

Successful geosynthetic laboratory testing provides objective measurements for material manufacturing, engineering design, product purchasing, dispute resolution, etc., etc. The industry’s core functioning depends on geosynthetic product measurement in every aspect of its operation. Testing alone is not relevant unless performed in accordance with agreed upon standards and norms thereby facilitating transparent manufacturing quality control, independent

third-party quality assurance and, most significantly, standardized international material specifications which opens up the opportunity for free and fair competition. The growth of geosynthetic materials standards over many years has been both impressive and directly linked to our industries general growth. Figure 1 shows the historical growth in geosynthetics standards.

GEOSYNTHETIC TESTING – EARLY CHALLENGES

Testing efforts in the geosynthetics community have played an integral part on the economic and technical growth of our industry. In the early days of geosynthetic product development (and the endless battle for product acceptance) manufacturers, specifiers and regulators relied heavily on borrowed test procedures from other industries, many developed by the general plastics and textile industries. Emergency laboratory testing technicians seeking to digest established ASTM test procedures were left disconcerted when the standard's text did not include the term geosynthetics nor their idiosyncrasies.

Additionally, unique features of geosynthetic materials often necessitated the modification of borrowed standards to accomplish the measurement of a relevant property. The geomembrane industry used only a very small portion of the relatively broad test procedure ASTM D638, *Standard Test Method for Tensile Properties of Plastics*, while taking great liberties with modifications not included in the standard. In addition, geonet compression strength was observed in accordance with ASTM D1621, *Standard Test Method for Compressive Properties Of Rigid Cellular Plastics*, while resulting features of load displacement curves were not always described by the standard. This left the reporting lab uncertain as to what information to record and report. Many more examples of inappropriate (aka, misfit) tests and the resulting confusion existed. What followed was a variety of loosely documented industry modifications that invited laboratory variability, apples-to-oranges product comparisons, and weak (if not completely) inappropriate material specifications.

This very real handicap to industry growth was countered in many significant ways by the Geosynthetic Research Institute (GRI), the first and legacy institute of what is now the Geosynthetic Institute. While the ASTM Committee D35 on Geosynthetics (as an outgrowth of Committee D13 on Textiles) was formed in 1984 and initiated the first development of geosynthetic specific test procedures, the GRI accelerated this process by leading the way in many needed and urgent measurement procedures described in GRI standards. For example, the needed design support test for geotextile filters, *Geotextile Filter Performance via Long Term Flow (LTF) Tests*, was the first published GRI geotextile test procedure, GRI GT1, in 1986. GRI-GG1 in 1987 on geogrid junction strength was (and for an additional 25-years) very controversial. GRI-GM1, *Seam Evaluation by Ultrasonic Shadow Method*, presented a summary of non-destructive seam evaluation techniques based on acoustic technologies. These and many other GRI test procedures worked in concert with D35 Committee work to expedite the needed and urgent response to a geosynthetics industry hungry for standardized test procedures.

This heritage of the Geosynthetic Institute and its robust commitment to geosynthetic measurement continued with the Geosynthetic Accreditation Institute (GAI). As previously described, the early geosynthetic testing laboratory experience with borrowed test procedures and newly developed and implemented measurement protocols was difficult and challenging.

The truth that all testing facilities were not meeting the challenge with equivalent success required an effort to establish a standard not only for testing procedures, but also for geosynthetic laboratory operation. The GAI was formed in 1995 and was the result of direct industry request to the GSI for a program that would credential testing laboratories active in geosynthetics testing. Unlike other accrediting services the GAI focused on a testing-centric approach making sure that equipment and procedure practiced in a geosynthetics testing laboratory were correct. An on-site audit by a testing practitioner as well as annual proficiency testing assures a robust and challenging GAI program.

GEOSYNTHETICS TEST METHODS DIRECTLY LINKED TO INDUSTRY GROWTH

The geosynthetics industry has always been, and will always be, an industry of measurement. Geosynthetic products, their properties, their applications, their technical benefits, their economic benefits, their environmental benefits, are all most powerfully expressed through the expression of measurement. When the geosynthetics industry has embraced the standardization of measurement procedure and expression, our materials and their acceptance (indeed their requirement) have followed. Conversely, when we have struggled with a variety of competing or non-standard measurements, our geosynthetic materials have continued to be a me-too or an uncertain “option”.

An example of measurement success is realized in the expression of stress crack resistance. In the early 1980’s, the use of high density polyethylene (HDPE) in geomembranes was often defined, mostly by competitive material lobbies, by the concern for the material’s resistance to slow crack growth under stress. This very real phenomenon involved the material’s response under stress as a time dependent, but certain, crack development through the geomembrane rendering it inconsequential as a barrier material. To make matters worse, the measurement of stress crack resistance at the time was performed in general accordance with ASTM D 1693, *Standard Test Method for Environmental Stress-Cracking of Ethylene Plastics*, which required excessively long test durations. The test often required 1500 hours to articulate a minimum resistance to this property and associated compliance to a given specification. Even if a specimen passed the specification, ongoing stress relaxation made the test less challenging with increasing test time.

The following years saw the HDPE geomembrane industry foster a steady pulse of newer improved resins articulated through newer more aggressive test procedures. Fully replacing ASTM D 1693 is the notched constant tensile load (NCTL) stress crack test, described in the Appendix of ASTM D 5397, *Standard Test Method for Evaluation of Stress Crack Resistance of Polyolefin Geomembranes Using Notched Constant Tensile Load Test*, shown in Figure 2. The benefits of an industry pursuing what could have been a “poison pill” have included a more meaningful and faster test procedure as well as wider material acceptance. Instead of negating HDPE as a successful geomembrane material, the robust standardized response to the concern over stress crack resistance contributed to a regulatory code requiring HDPE geomembranes in many containment applications.

Figure 2: ASTM D 5397, Appendix – Notched Constant Load Stress Crack Testing

Conversely, while geosynthetic applications in roadway design and improved performance have long been documented, required use of geosynthetics in roads has yet to be practiced or even suggested in many parts of the world. One of the many reasons is the persistent search for a standardized measurement, an agreed upon test or proof, that provides both the user community with confidence in the investment and an even playing field for geosynthetic manufacturers striving for product acceptance. While there have been dozens of large scale field studies and numerous synthesis reports summarizing field experience, the missing fundamental, so important to our materials and their use, is an accepted measurement that is worthy of this application. Recent efforts have focused on design and design parameters, helping to focus on needed measurements and worthy test procedures to provide design inputs. Even these approaches, however, are varied internationally and suggest a long road to international standardization. Again, the agreed upon, standardized measurement of geosynthetic performance has yet to be realized in this application, and the industry's sluggish growth results.

GEOSYNTHETIC TESTING AS MARKET CONTRIBUTION

The advantages of geosynthetic test development and standardized measurement of properties, accompanying the resulting culture of geosynthetic use, has always been a part of our history. The well told story of the 1988 Kettleman Hills landfill failure illustrates the need for and contribution of responsive testing. The Kettleman failure plane between a compacted clay liner and a HDPE smooth geomembrane helped to usher in a new era of shear strength characterization. The resulting evaluation of geosynthetic interfaces day-lighted the relatively weak geosynthetic interfaces involved in landfill slope design. The forensic effort to model the failure between the smooth HDPE geomembrane and the compacted clay liner was first attempted via the use of traditional 2.8 in. round and 2.0 in. square shear boxes, routinely used for the measurement of internal strength of soils. However, due partly to the use of non-

representative clay moisture contents, and also the need for measurement of resistance at large displacement values, the crucial need for large-scale interface friction testing was realized. Large scale friction testing of geosynthetic interfaces demonstrated that available shear strengths under high loads were often described by friction angles less than 10 degrees. Significantly, the use of larger scale, 300 mm square friction boxes explained the Kettleman Hills failure and contributed to the development and performance expression of textured geomembranes. Today, ASTM D 5321, *Standard Test Method for Determining the Shear Strength of Soil-Geosynthetic and Geosynthetic-Geosynthetic Interfaces by Direct Shear*, and ASTM D 6243, *Standard Test Method for Determining the Internal and Interface Shear Resistance of Geosynthetic Clay Liner by the Direct Shear Method* are in universal use.

Figure 3: ASTM D 5321/D 6243 Large-Scale Friction Test

In addition to assisting the industry in developing new materials fostering improved slope stability, the friction test also contributed many laboratory test developments including the accordion pillow for normal load application, soil and GCL clamps providing both hydration and dewatering of absorbent and compressible materials, and a host of tools to verify and document the veracity of load application. Hard lessons learned included the need for proper clamping and the use of displacement rates assuring drained test conditions.

In addition to interface friction, the investigation of other geosynthetic-soil interaction properties has been an ongoing effort for the geosynthetic testing community. From scale affects of applied test equipment to the proper handling of fine grained soils and large aggregates, the testing of geosynthetic interaction properties has been the subject of detailed standardization efforts. This category of testing has been characterized by “art” as well as standard operating procedure. The challenge has been to standardize the art practiced by the experienced “good” laboratories into detailed test procedures put into widespread practice.

The segmental block reinforced soil wall marketplace was partially propelled by robust connection testing of the block to geosynthetic reinforcement connection. This test is standardized in ASTM D 6638, *Standard Test Method for Determining Connection Strength Between Geosynthetic Reinforcement and Segmental Concrete Units (Modular Concrete Blocks)*. The sister to this test is the interaction properties of the geosynthetic within the reinforced soil zone. Pull-out testing was developed for this purpose and is now standardized in ASTM D6706, *Standard Test Method for Measuring Geosynthetic Pullout Resistance in Soil*.

Measured test results assisted the design engineer in realizing cost effective, aesthetically pleasing, engineered civil structures. However, early attempts at good quality measurements included negotiating with inconsistent block, varying grid rib thickness and a range of connection designs including frictional, looped and pinned mechanical connections. Repetitive testing experience and transparency regarding test preparation helped to provide a much needed feedback loop to the manufacturing industry to propel both the improvement of testing techniques and the growth of the technology of geosynthetic reinforced soil walls and slopes.

GEOSYNTHETIC TESTING PLANTS SEEDS OF CHANGE

Geosynthetic test procedures have sometimes been the seeds of change in the way a technical challenge was perceived or a traditionally practiced measurement was performed. This is certainly true with larger scale friction testing discussed previously. It is also certainly true with the development and standardization of the accelerated test methods, such as the Stepped Isothermal Method (SIM).

SIM

While this approach was first described in a GRI test procedure, its current standardized form is documented in ASTM D6992, *Standard Test Method for Accelerated Tensile Creep and Creep-Rupture of Geosynthetic Materials Based on Time-Temperature Superposition Using the Stepped Isothermal Method*. The birth of this test was related to the challenge associated with creep-rupture testing of coated polyester (PET) geosynthetic reinforcement products. Due to the relatively low temperature dependence of PET relative to other polymers and the inherent variability within a product, the observed creep rate at a given load was often found to be less than the creep rate observed at an even higher load. This, of course, did not make sense. The solution was found in a new perspective of the well established but largely unused (in the geosynthetics industry at the time) practice of strain shifting, the process of time-shifting recorded strain data at a given test temperature to overlap with recorded strain data from a higher temperature. The details of SIM have been described in many technical papers, but it is accurate to report that by using a single specimen test, thereby avoiding specimen-to-specimen variability, SIM literally provided a valid short-cut to the traditional strain-shifting process resulting in months if not years of creep-rupture testing being accomplished in a few days time. Because this was so unusual and difficult to absorb, much of the early standardization work focused on non-technical negotiations with various users and regulators. This very necessary and appropriate exercise in defense of a testing technology propelled its use not only in the geosynthetics industry throughout its robust product development, but also other geosynthetics-related industries such as plastic pipe. SIM fostered the keen awareness that not all high tenacity

polyesters are created equal and not all manufacturing techniques are as stressful as others to the final produced product.

Figure 4: Compressive Creep as Measured Under Shear Loading in Accordance with ASTM D 7361

SIM also fostered new and still increasingly frequent discussion of compression creep behavior of geosynthetic drainage products. The technology of SIM has proven very effective at significantly reducing the time necessary to identify or confirm the creep reduction factor of geonets and geocomposites. ASTM D7361, *Standard Test Method for Accelerated Compressive Creep of Geosynthetic Materials Based on Time-Temperature Superposition Using the Stepped Isothermal Method*, describes the relevant test procedure. Compressive SIM also contributed to new engineered drain structures and continues to foster newer measurement tools in the geosynthetic drain industry including thickness dependent transmissivity testing.

Leak Detection

Other test procedures representing significant industry change include the suite of ASTM test procedures describing electrical resistivity testing used for leak detection in geomembrane containment applications. They are as follows.

- D6747, *Standard Guide for Selection of Techniques for Electrical detection of potential Leak Paths in Geomembranes*
- D7002, *Standard Practice for Leak location on Exposed Geomembrane using Water Puddle System*
- D7703, *Standard Practice for leak Location on Exposed Geomembranes Using the Water Lance System*

- D7007, *Standard Practice for Electrical methods for Locating Leaks in Geomembrane Covered with Water or Earth Material*
- D7240, *Standard Practice for Leak Location using Geomembranes with an Insulating Layer in Intimate Contact with a Conductive Layer via Electrical Capacitance Technique (Conductive Geomembrane Spark Test)*

Figure 5: ASTM D7002 Leak Detection Testing

These procedures set the stage for aggressive adoption of this technology for unequaled quality assurance of installed geomembrane systems, and protection of our environment. For example Abigail Beck of the TRI-CORP Liner Integrity Center recently reported the following information for over thirty landfill expansions using modern construction methods and regulatory driven CQA programs:

- Landfill cells without a liner integrity survey have an average leakage rate of 13.3 gpad.
- Landfill cells that have performed a dipole method survey have an average leakage rate of 7.6 gpad
- Landfill cells that have performed both bare geomembrane and dipole method surveys have an average leakage rate of 1.2 gpad

The technology described in these procedures and practiced in the field continues to change the way we think about construction quality assurance of installed geomembrane systems, encouraging and fostering the highest achieved work effort.

Pore Size Distribution (PSD)

While the global geosynthetics industry copes with a very inconsistent practice of employing a wide range of geotextile opening size measurement procedures, the standard of pore size distribution testing, described in ASTM D 6767, *Standard Test Method for Pore Size Characteristics of Geotextiles by Capillary Flow Test*, is gaining warranted attention. This direct measurement of opening sizes based on measured pore pressures holds the promise of greatly simplifying the measurement of not only opening sizes but also water and air permeability. ASTM Committee D35 held a workshop in January 2013 outlining recent test equipment improvements, PSD correlation to other opening size test procedures and the PSD test result benefit a more robust filtration design. Also of note were reports of how PSD testing has been used forensically to explain unexpected material performance when AOS testing or permittivity testing has not been responsive.

It is now clear that the success of PSD will have implications for the practice of using AOS, COS, FOS, permittivity and air flow test procedures, inviting a significantly reduced measurement regime for geotextile filtration properties. Its implication to existing hydraulic design methods promises to see renewed analyses in this regard.

Figure 6: ASTM D 6767 PSD Test Apparatus

GEOSYNTHETIC TESTING LESSONS LEARNED

It is clear that geosynthetic testing has played a vital role in our narrative, facilitating commerce, developing products, establishing specifications and answering questions. Along the way the testing industry itself has learned a few key lessons that are expected to remain relevant. Two of the most universal of these lessons are as follows.

- 1) Testing is Humility: The best laboratory is one that experiences the full force of system failure including wrong procedure, awkward technique, inappropriate equipment, careless or ignorant process, etc., etc. There is always something to learn and nothing can ever replace the “burn” of tough experience. We simply never know enough. Materials always follow universal laws ...until they don't. Discomfort is key to a robust, alert and active geosynthetic measurement activity.
- 2) Laboratory Testing is Messy: Indeed, the best testing experience is only achieved with a lot of testing! Throughout his book *Outlier's*, the author Malcolm Gladwell often references the "10,000-Hour Rule", arguing that one of the keys to the success in any field is the performance of a specific task for about 10,000 hours. This is certainly true for geosynthetics testing work with its significant variety of materials, test procedures and awareness requirements. And in addition to test performance, a good working geosynthetic laboratory is full of non-testing activity such as sample preparation, equipment calibration, equipment maintenance, environmental control, document management, electronic system maintenance, customer interaction and audit responses just to name a few.

CONCLUSION

The geosynthetics testing industry relies upon a strong and relevant testing community in every aspect of its activity. Testing procedures and the standardization effort behind them has been of historical significance to the broad arc of geosynthetic industry experience, and will continue to be relevant to our future growth. Geosynthetic properties, performance expectations, new application efforts and their place in the family of construction materials will be largely defined by a responsive and successful testing industry relying on the language of measurement.

BACKGROUND AND DEVELOPMENT OF GRI's GEOSYNTHETICS SPECIFICATIONS

Robert M. Koerner and George R. Koerner
Geosynthetic Institute, Folsom, PA USA

ABSTRACT

When the National Sanitation Foundation ceased servicing and distributing its NSF #54 specification for geomembranes in 1991, the task fell upon the Geosynthetic Research Institute (GRI)* for continuation. With a bit of trepidation we started on HDPE but only after considerable in-house research was undertaken, particularly on stress crack resistance and oxidative induction time. After the specification was finalized in 1997, LLDPE followed in 2000 and then fPP in 2002. Upon investigating a number of fPP failures the fPP specification was withdrawn followed by a major in-house research project on exposed durability and then reinstated in 2009. Scrim reinforced polyethylene specifications were adopted between 2003 and 2009 for fPP, LLDPE and MDPE as well as for EPDM both nonreinforced and scrim reinforced. The seaming specification for all of the polyolefins was adopted in 2002.

Other specifications were developed where the need was evidenced. The geotextile tube specification in 1999, geotextile cushion specification in 2002 and 2004, geotextile separators specification 2004 and 2008, and the GCL specification in 2005. Current efforts are focused on a geocell specification.

Other possible geosynthetics specifications for geogrids, geonets/geonet composites and turf reinforcement mats have not been successful to date although many draft versions have been attempted.

In spite of the lack of a complete set of specifications, however, it is felt (and sincerely hoped) that the GRI geosynthetic materials specifications have brought a considerable amount of order to an otherwise turbulent scene. While some manufacturers are understandably reluctant to enter such efforts, the specifying community is certainly pleased with the results to date as evidenced by their widespread use. We will certainly continue to maintain and update the existing specifications and attempt to get the draft efforts into final approved status.

*The Geosynthetic Research Institute (GRI) was formed in 1986. From that time forward, all standards (specifications, guides, practices and test methods) have been prefixed GRI and continue to the present. The superseding Geosynthetic Institute (GSI) was formed in 1995 with GRI being one of its five subsidiary institutes.

BEGINNINGS

Of the various and ever-growing applications for geosynthetic materials in the late 1970's and 1980's three groups envisioned the need for generic specifications. They were the U.S. Army Corps of Engineers (COE) for hydraulically related geosynthetics, the Federal Highway Administration (FHWA) together with the American Association of State Highway and Transportation Officials (AASHTO) for transportation related geosynthetics, and the U.S. Environmental Protection Agency (EPA) for waste containment related geosynthetics. The first two groups (COE and FHWA/AASHTO) developed their generic specifications "in-house" with the majority of input coming from federal and state agency personnel. The third group (EPA) relied almost exclusively on those in private industry which had a vested interest in the outcome. It is this third group focusing on geomembranes which eventually was replaced by GSI's research arm, the Geosynthetic Research Institute, in becoming involved in the specification process.

The Resource Conservation and Recovery Act of 1976 gave the U. S. EPA the authority to control hazardous substances from cradle-to-grave. Between this time and the land disposal restrictions for hazardous wastes (commonly called Subtitle "C"), considerable research at many academic institutions was undertaken regarding barriers to contain both liquid and solid wastes. Most significant was the work of Anderson, et al. (1981) who used 100% neat chemicals to permeate different clay soils in fixed wall permeameters. The (now obvious) result was shrinkage of the clay soil test specimens such that rapid flow occurred through the clay specimen and into the effluent. This undesirable feature of clay liners caused the EPA to promulgate the following regulations on July 6, 1982:

"Prevention (via synthetic membrane liners); rather than minimization (via clay liners), of leachate migration similarly produces better environmental results in the case of surface impoundments used to dispose of hazardous wastes. A liner that prevents rather than minimizes leachate migration provides added assurance that environmental contamination will not occur."

The synthetic membrane liners in the above regulation were renamed by federal and state personnel to flexible membrane liners, or FML's, and are fully embedded in environmental regulations to date. Obviously, the above situation stimulated the growth of the FML (aka, geomembrane) industry and many *proprietary specifications* (for both thermoplastic and thermoset resin types) became immediately available.

The task of putting some order and control to the situation fell to EPA's National Environmental Research Center in Cincinnati, Ohio and specifically to its Chief, Robert E. Landreth. He co-opted the National Sanitation Foundation (NSF) to convene groups of individuals from the liner community to generate *generic specifications* within each specific resub type. Included were personnel from public health, users and industry groups which eventually developed the NSF #54 set of generic specifications (1983, 1985, 1990 and 1991). The following geomembrane materials and their seams were included:

- Polyvinyl Chloride (PVC)

- Polyvinyl Chloride-Oil Resistant Grade (PVC-OR)
- Chlorinated Polyethylene (CPE) Unsupported
- Chlorinated Polyethylene (CPE) Supported
- Polychloroprene (CR) Unsupported
- Polychloroprene (CR) Supported
- High Density Polyethylene (HDPE) Non-Textured
- Ethylene-Propylene Diene Terpolymer (EPDM)
- Epichlorohydrin Polymers (CO)
- Chlorosulfonated Polyethylene (CSPE)
- Chlorosulfonated Polyethylene-Low Water Absorption (CSPE-LW)
- Thermoplastic Nitrile-PVC Oil Resistant Grade (TN-PVC)
- Ethylene Interpolymer Alloy (EIA)
- Chlorinated Polyethylene Alloy (CPE-A) Unsupported
- Chlorinated Polyethylene Alloy (CPE-A) Supported

Subsequent to 1991, however, the committee did not meet and NSF then decided not to continue the effort in light of their many other activities. Since the Geosynthetic Research Institute was well established by now, its resin and geomembrane focus groups suggested that GRI should become involved. More specifically those geomembranes no longer used should be eliminated, newer geomembranes should be added, and all of the physical, mechanical and endurance properties should be updated to current ASTM and GRI standard test methods. This ongoing activity fell to the Geosynthetic Research Institute (GRI) which was somewhat of a “stretch” since it was a new activity (other than research, per se) which would challenge our negotiating and people-oriented skills. That said, GRI was indeed a logical choice for crafting specifications since all possible tests were conducted in-house which is a great asset insofar as credible data is concerned. Furthermore, the laboratory accreditation program, handled by George Koerner, was operational and challenges to the data that was generated were minimal.

THE GRI GM13 SPECIFICATION FOR HDPE (SMOOTH AND TEXTURED) GEOMEMBRANES

High density polyethylene (HDPE) manufacturers began operations in the Houston, Texas area in 1982. Within the next 10-years this material in various thicknesses was used for the base liner of solid waste landfills and liquid surface impoundments on a regular basis. The only generic specification was according to NSF #54 and it needed drastic revision. Two items were in dire need of updating and/or replacing; stress crack resistance and durability criteria. Perhaps most importantly was the assessment of stress crack resistance which used ASTM D1693 (the bent strip test) in the NSF #54 specification. On several occasions materials which passed this laboratory test subsequently failed in the field, Hsuan 1998 and 2000. As a result, we were awarded an EPA contract to look into the matter and Grace Hsuan was the principal investigator. Over the subsequent 7-8 years she developed the notched constant tension load (NCTL) test and its single point variation per ASTM D5397. The research was a coordinated effort with most of the sheet manufacturers and resin suppliers. Ultimately, the research effort had the effect of eliminating some ten resins from use in manufacturing HDPE geomembranes. Figure 1 presents this situation which also served the purpose of setting a minimum value for use in the eventual specification. For the single point version of the test, the original specification

value was originally set at 200 hours and subsequently increased to 300 hrs. The effect of this new test method and its numeric value was to virtually eliminate stress crack failures of HDPE geomembranes in the field.

Figure 1. Ductile-to-brittle transition points for 21 virgin geomembranes and 7 field-retrieved geomembranes (after Hsuan 1998, 2000).

In a parallel effort we were awarded a second EPA contract to estimate the durability, aka to predict field service life, of HDPE under buried conditions such as beneath a solid waste landfill. This 10-year effort, based on laboratory modeling using time-temperature superposition and then subsequent Arrhenius modeling, indicated that the lifetime of HDPE consisted of three distinct stages as shown in Figure 2.

Figure 2. Lifetime stages of polyolefin geomembranes (Koerner, et al., 1990).

These stages were subsequently quantified as given in Table 1. In it can be seen that Stage A, the antioxidant depletion time for HDPE at 20°C, is slightly over 200 years. Fortunately, the antioxidants in an HDPE formulation can be indirectly challenged using the oxidative induction

time (OIT) test, either standard or high pressure, and can thereby be included in a generic specification. These two issues, stress crack resistance and oxidative induction time, led directly into the formation of our first generic specification that being for HDPE smooth and textured geomembranes.

Table 1 – Lifetime Prediction of a Nonexposed HDPE Geomembrane as a Function of In-Situ Service Temperature (Koerner, 2012)

In Service Temperature (°C)	Stage “A” (years)			Stage “B” (GSI data) (years)	Stage “C” (Ref. 43) (years)	Total Prediction* (years)
	Standard OIT	High Press. OIT	Average OIT			
20	200	215	207	30	208	445
25	135	144	140	25	100	265
30	95	98	97	20	49	166
35	65	67	66	15	25	106
40	45	47	46	10	13	69

*Total = Stage A (average) + Stage B + Stage C

At a December 13, 1998 meeting in Philadelphia, work began in earnest on a table of required test methods, values and frequency of testing. In the group were resin producers: Rex Bobsein of Phillips, Nolan Edmonds of Novacor, Phil Dunaway of Solvay, Frank Nagy of Mobil, Adel Haddad of Quantum, Pam Maeger of Chevron, and geomembrane manufacturers: Fred Struve/Bill Walling of Gundle, Gary Kolbasuk/George Zagorski of NSC, Jim Nobert/George Yazdani of Poly-Flex, Bob Otto of Serrot, Dave Eakin of S.D. Ent.

Following this meeting, intense testing was performed by all of these organizations in assessing the stress cracking performance of their materials via the new ASTM D5397 notched constant tensile load (NCTL) test. In addition, the standard and high-pressure OIT initial values and subsequently after oven ageing and ultraviolet fluorescent exposure were major durability items worked on by all. Note that both stress cracking and OIT performance are both resin and additive related, thus the large group of resin producers was extremely active, and the geomembrane manufacturers as well. Simultaneous with the durability criteria development was the physical and mechanical property development. Here the geomembrane manufacturers played the major role, as did George Koerner, in evaluating and homogenizing the data into a single set of acceptable values. It should be noted that many nominally significant tests which were in the NSF #54 specification were purposely omitted. They were as follows:

- volatile loss
- dimensional stability
- coefficient of linear expansion
- resistance to soil burial
- low temperature impact
- bent strip ESCR test
- wide width tensile
- water vapor transmission
- water absorption

- ozone resistance
- modulus of elasticity
- hydrostatic resistance
- tensile impact
- multi-axial burst

After three meetings and countless telephone calls among the parties involved, the HDPE specification tables were completed. Text was then added and agreed upon by the two focus groups. The complete draft specification was then sent to the general membership for comments, and there were many. The focus groups then assessed these comments and agreed to the final specification. It was launched June 27, 1997, under the title:

GRI-GM13, Standard Specification for “Test Methods, Test Properties, Testing Frequency for High Density Polyethylene (HDPE) Smooth and Textured Geomembranes”. Subsequently, this specification has had eleven minor revisions.

For additional detail see Hsuan and Koerner (1997, 1999) and Koerner (2008).

THE GRI-GM17 SPECIFICATION FOR LLDPE (SMOOTH AND TEXTURED)

The same two focus groups involved in the HDPE specification transitioned directly into the development of a lower density polyethylene specification. This was initially called very low density polyethylene (VLDPE), which was a bad idea of Bob Koerner, but then relabeled more appropriately as linear low density polyethylene (LLDPE). Some major differences between it and the HDPE specification are as follows:

- tensile yield strength and elongation are not required for LLDPE, only break strength and elongation
- 2% modulus as a maximum value is required so as to ensure flexibility
- initial OIT values are the same as HDPE however, lower percentages are required after oven aging and ultraviolet exposure
- a large three-dimensional axi-symmetric break strain test is required

This last test method was developed so as to simulate out-of-plane deformation of geomembranes and was originated by Koerner, et al. (1990). They unfortunately used a very high pressurization rate of 6.9 kPa/min. This was then copied as the default pressurization rate in the current ASTM D5716 test method. It is presently felt to be much too fast to give a representative performance value for the various geomembrane materials. Additional work is presently ongoing to observe slower pressure rates thereby allowing stress relaxation of the molecular structure to occur during the test. The LLDPE specification was adopted on April 3, 2000, under the title:

GRI-GM17, Standard Specification for “Test Methods, Test Properties, Testing Frequency for Linear Low Density Polyethylene (LLDPE) Smooth and Textured Geomembranes”. Subsequently, this specification had nine minor revisions.

THE GRI-GM18 SPECIFICATION FOR fPP GEOMEMBRANES (NONREINFORCED AND SCRIM REINFORCED)

Having both HDPE and LLDPE specifications ongoing, we felt that the third polyolefin geomembrane, namely flexible polypropylene, would be similar. Considerable overlap was indeed the case in physical and mechanical properties for unreinforced fPP, however, a new set of test methods and test values were needed for the scrim reinforced types, namely, for fPP-R. This was accomplished by considerable in-house testing and also testing by different focus groups of GSI members. The polyethylene groups now transitioned to polypropylene resin suppliers and sheet manufacturers. They included the main resin producer Bob Butala/Stan Bialowas of Basell; the geomembrane manufacturers Chris Taylor of Carlisle, Joe Kalbas/John Heathcote of Firestone and consultants Ron Frobel and John Cowland.

We unfortunately (as was to be seen) extended the OIT values for the polyethylene specifications to the durability criteria for polypropylene. The original fPP specification was adopted on February 18, 2002, under the title:

GRI-GM18, Standard Specification for “Test Methods, Test Properties, and Testing Frequencies for Flexible Polypropylene (fPP and fPP-R) Nonreinforced and Reinforced Geomembranes”.

Within a year of its adoption we had a fPP field failure which unfortunately passed our OIT durability criteria. Several other failures occurred subsequently and this specification was temporary suspended on May 3, 2004 and then withdrawn on January 22, 2007, due to concerns about OIT being able to predict long-term durability. Apparently, the antioxidant depletion mechanism characterized by OIT tests in HDPE and LLDPE geomembranes is more complicated and less reliable for fPP geomembrane formulations.

An intense research program followed using the fluorescent ultraviolet light weathering devices (ASTM D5238) subjecting samples until their halflife occurred in either strength or elongation. Using a correlation factor from four field failures (see Figure 3 and Table 2 where 1.0 year in a hot climate equals 1200 light hours at 70°C) we used a 20,000 light hour criterion as being the minimum acceptable durability value. The resulting exposed lifetime predictions using this protocol for fPP and most other commonly used geomembranes are given in Table 3. The GRI GM18 specification was reinstated on March 20, 2009. It has had six minor revisions.

(a) Two field failure sites in West Texas

(b) Two field failure sites in Southern California

Figure 3. Ultraviolet incubation times versus strength retained for four archived fPP geomembranes taken from field failures sites; Koerner, Koerner and Hsuan (2012).

Table 2 - Laboratory-to- Field Correlation Factor (using ASTM D7238 @ 70°C); GRI (2012)

Method	Thickness (mm)	Field (yrs.)	Location	Lab halflife (lt. hr.)	Correlation Factors (lt. hrs./1.0 yr.)
fPP-1	1.00	≈ 2	W. Texas	1800	900
fPP-R1	1.14	≈ 8	W. Texas	8200	1025
fPP-R2	0.91	≈ 2	So. Calif.	2500	1250
fPP-R3	0.91	≈ 8	So. Calif.	11200	1400
					1140 (ave.)

Table 3 - Predicted Geomembrane Lifetimes Based on 50% Reduction of Strength and/or Elongation; Koerner, R. M., Koerner, G. R. and Husan, Y. G. (2012)

Geomembrane Type	Nominal thickness (mm)	Applicable Specification	50% reduction* (light hours)	Predicted lifetime (years)
fPP	1.00	GRI-GM18	40,000	33
HDPE	1.50	GRI-GM13	≈ 60,000	≈ 50
LLDPE	1.00	GRI-GM17	40,000	33
EPDM	1.14	GRI-GM21	37,000	30
PVC-N.A.	0.75	ASTM D7171	8,000	7**
PVC-Euro	2.50	proprietary	38,000	32

*Using ultraviolet fluorescent weathering devices at 70°C set at 340 nm wavelength and 0.78 W/(m²-nm) irradiance for a daily cycling of 20 hours light and 4 hours dark with condensation.

**Only recommended for “buried applications”.

THE GRI-GM22 SPECIFICATION FOR PE-R EXPOSED GEOMEMBRANES

The GM22 specification is focused on lightweight scrim reinforced polyethylene geomembranes used for temporarily exposed conditions. It covers 0.2, 0.3 and 0.5 mm thickness sheet. The resin density is unspecified with the exception that it must be 0.930 g/cc or greater. High pressure OIT is required of 1000 min. and a minimum of 50% strength and elongation retained is required after 10,000 light hours in fluorescent light exposure per ASTM D7238 at 70°C. The specification was adopted on November 9, 2006 under the title:

GRI-GM22, “Test Methods, Required Properties and Testing Frequencies for Scrim Reinforced Polyethylene Geomembrane Used in Exposed Temporary Applications”. It has had one revision. It has had two minor revisions.

THE GRI-GM25 SPECIFICATION FOR LLDPE-R GEOMEMBRANES

This specification for scrim reinforced linear low density polyethylene (LLDPE-R) geomembrane could well have been coupled to GRI-GM17, but several members wanted it to be separate. Different, however, is that the thickness categories of 0.61, 0.91, and 1.14 mm are

coupled with serviceability commentary of standard, moderate and severe conditions, respectively. The commonality of the sheet properties to GM17 and the scrim properties to GM18 is to be expected. The specification was adopted on September 18, 2009 under the title:

GRI-GM25, “Test Methods, Required Properties and Testing Frequencies for Reinforced Linear Low Density Polyethylene (LLDPE-R) Geomembranes”. It has had four minor revisions.

THE GRI-GM21 SPECIFICATION FOR NONREINFORCED AND REINFORCED EPDM GEOMEEMBRANES

The only non-polyolefin geomembrane specification we have is for the thermoset polymer ethylene propylene diene terpolymer, or EPDM. The specification covers both nonreinforced and scrim reinforced types in several thicknesses. The physical and mechanical tests and required properties follow the polyethylene and polypropylene specifications but the durability criteria are different. After oven aging and ultraviolet light exposure (either Xenon arc or fluorescent tube devices) percents retained for strength and elongation of the nonreinforced types are required. For the scrim reinforced types, a bend test was developed and at a 7X magnification no surface cracking can be observed. This specification was adopted on October 27, 2003 under the title:

GRI-GM21, “Test Methods, Required Properties and Testing Frequencies for Ethylene Propylene Diene Terpolymer (EPDM) Nonreinforced and Scrim Reinforced Geomembrane”. It has had four minor revisions.

THE GRI-GM19 GEOMEMBRANE SEAM SPECIFICATION

The NSF #54 specification included seam test requirements with each of the respective sheet resin types. We decided to have a separate seam specification since we were dealing almost exclusively with polyolefins, the exception being EPDM which is totally different in its seaming requiring adhesive bonding or an adhesive tape.

As with accepted practices, the relevant seam tests for the polyolefins were shear and peel for both fusion and extrusion welding of the various sheets. The first issue raised by several specifiers was why require 90% of the sheet strength in shear and only 62% of the sheet strength in peel? These values stemmed from Henry Haxo of Matrecon (1988) who performed the earliest EPA research on the topic. As found by Struve and Koerner (2005), however, when the parent unseamed sheet is pulled over a 90° rod (as in the peel seam test) its strength decreases significantly compared to the standard linear tension mode. It is such that 62% of the sheet in the peel test compared to the standard tension test mode is about 90% of the sheet in a similar mode. Thus, the 90% in shear and 62% in peel are reasonably logical values for a seam specification. That said, the general agency and specifying engineer’s concern over seam strength (as contrasted to seam uniformity and consistency) was felt to be somewhat excessive. For this reason the GRI-GM19 specification values are somewhat lower than most specifications based on the above percentages. We felt that this lower strength approach was somewhat justified based on the leak location data of Table 4. Here it was seen that only 6.32% of

geomembrane holes in the field were caused by the welding of the seams. Conversely, the balance of the holes were in the sheets themselves. This leads one to conclude that perhaps our general focus for quality assurance purposes should be more than simply testing geomembrane seams?

Table 4 – Holes in Geomembranes Located by the Electrical Leak Location Method; Nosko and Touze-Foltz (2000)

(a) Location of Holes

No. of Holes	Flat Floor (1)	Corners and Edges (2)	Under Drainage Pipes (3)	Pipe Penetrations (4)	Other (5)
4194 100%	3261 77.8%	395 9.4%	165 3.9%	84 2.0%	289 6.9%

(b) Cause of Holes vs. Size of Holes

Size of Holes (cm ²)	Stones	%	Heavy Equip.	%	Seam Welds	%	Cuts	%	Worker Directly	%	Total
<0.5	332	11.1	-	-	115	43.4	5	8.5	195	-	452
0.5-2.0	1720	57.6	41	6.3	105	39.6	36	61.0	105	84.4	2097
2.0-10	843	28.2	117	17.9	30	11.3	18	30.5	36	15.6	1044
>10	90	3.0	496	75.8	15	5.7	-	-	-	-	601
Amount	2985		654		265		59		231		4194
Total	71.17%		15.59%		6.32%		1.41%		5.51%		100%

The GRI-GM19 seam specification addresses the required strength and related properties of thermally bonded polyolefin geomembranes; in particular, high density polyethylene (HDPE), linear low density polyethylene both nonreinforced (LLDPE) and scrim reinforced (LLDPE-R) and flexible polypropylene both nonreinforced (fPP) and scrim reinforced (fPP-R). It became available on February 18, 2002 under the title:

GRI-GM19, “Seam Strength and Related Properties of Thermally Bonded Polyolefin Geomembranes”. It has had six minor revisions, one of which addressed the separation-in-plane (SIP) mode of failure. In this regard SIP is acceptable if the seam passes all other criteria of the specification.

THE GRI-GT12 GEOTEXTILE CUSHION SPECIFICATION

This specification was prompted by two facts; namely, that holes in geomembranes are primarily made from stone punctures (71.17% according to Table 4b) and that no available geotextile specification addressed very high mass per unit area (weight) geotextiles. These

cushioning (or protection) geotextiles are invariably needle punched nonwoven polypropylene fabrics.

The variation in mass per unit area as indicated in the specification is from 340 to 4000 g/cc. Using this range of geotextile weights mechanical tests were conducted in-house leading to grab tensile strengths and elongations, as well as tear and puncture resistance test. Since puncture behavior is at the heart of the material’s performance in a cushioning specification three alternative puncture tests are allowed. The pin puncture (ASTM D4833) is the standard, but pyramid puncture (ASTM D5494) and CBR puncture (ASTM D6241) are possible alternatives. Figure 4 shows the interesting interrelationships between the three puncture tests.

Figure 4. Puncture test method interrelationships for needle punched nonwoven geotextiles.

The specification is listed as GRI-GT12(a) “ASTM Version” and titled “Test Methods and Properties for Nonwoven Geotextiles Used as Protection (or Cushioning) Materials”. The ASTM version was approved on February 8, 2002 and has had two minor revisions to date.

Subsequent to the ASTM test methods being exclusive to the specification we were requested to have an alternative ISO test method which was developed accordingly via George Koerner’s correlation testing.

The equivalent specification is listed as GRI-GT12(b) “ISO Version” under the same title, but with only one puncture method that being ISO 12959. The ISO version was approved on March 10, 2004 and one revision has been made to date.

THE GRI-GCL3 SPECIFICATION FOR GEOSYNTHETIC CLAY LINERS

This specification covers geosynthetic clay liners (GCLs), describing types of tests, the specific test methods, minimum and sometimes maximum values, and the minimum testing frequencies. Geosynthetic Clay Liners (GCLs) are also called Clay Geosynthetic Barriers (GBR-Cs). There are two general categories of GCLs covered in this specification: internally reinforced and nonreinforced. Within each of these categories there are geotextile related, polymer coated geotextile related, and geomembrane/geofilm related types.

Being one of our most complicated specifications due in large part by the large variation in the manufactured products, there are separate test methods for the clay component itself, geotextiles themselves, and the geomembrane/geofilm themselves. Then there are also tests required for the manufactured composite material. In crafting the specification there were many specific issues most of which required considerable compromise for the different manufacturers (primarily Kent von Maubeuge of NAUE and Jim Olsta of CETCO) and the authors in convening the group. They were as follows:

- mass per unit area of geotextiles
- scrim component within geotextiles
- geofilm thickness
- mass per unit area of bentonite
- peel strength of the composite
- permeability testing of geomembranes and geofilm related GCLs
- maximum alkaline liquid permeability
- broken needles in manufactured product
- minimum field overlap distance
- GCL wrapping material and thickness

Further discussion on each of these items is available in Koerner (2010). That said, there are still three unsettled issues which are being investigated. They are swell index, moisture content and alkalinity permanent. Commentary on each follows.

It is generally known that high quality field deposits of sodium bentonite are becoming more scarce and more costly to excavate, transport and process from their geologic origin. That said, the bentonite in some GCL's is presently a "peptized" calcium bentonite which introduces sodium ions into the bentonite structure. Such processing can change the swell index which is presently set at 24 ml/2g. The current value is under review and discussion.

The as-manufactured moisture content of the bentonite in different GCL's is an active point of disagreement among manufacturers and users. The range of values is from 10% to 40%, which is obviously enormous. To simply take the average of all manufactured products serves no one and is therefore not an option. The specification lists the value as being "both site-specific and product-specific and is currently being evaluated".

Presently the alkalinity permeant required in the specification is a 0.1 M CaCl₂ solution. This arbitrary value is quite contentious. Efforts are ongoing to evaluate other permeants, such

as different leachates (from landfills, shale gas operations and coal combustion residuals), to see if a more typical alkaline permeant can be used.

The specification has been finalized as of May 16, 2005 under the designation GRI-GCL3 and is titled “Test Methods, Required Properties, and Testing Frequencies of Geosynthetic Clay Liners (GCLs)”. It has had two minor revisions to date.

THE GRI-GT10 SPECIFICATION FOR GEOTXTILE TUBES

Not covered in the FHWA/AASHTO specification for commonly used geotextiles is one designated for geotextile tubes. This specification covers high strength geotextile index test properties for subsequent use to form coastal and riverine structures in the form of a soil filled geotextile tubes. The specification sets forth a set of minimum physical, mechanical and hydraulic properties that must be met, or exceeded by the geotextile being manufactured. In a few cases, a maximum value is specified. The specification covers not only the main geotextile tube, but also the scour apron(s), if so required in the design. Also the numeric tables are in categories for “aggressive” conditions or Class 1 and for “typical” conditions or Class 2. The manufacturers group which interacted in the crafting of the specification was Tom Stevens and John Henderson of TenCate, Tom Collins of Huesker and Gary Willibey of Propex.

Perhaps the greatest item of concern was the tension testing of the high strength geotextiles in this specification. Such testing is highly dependent on the grip type vis-à-vis the strength of the fabric and its seams. A special guide was crafted in this regard, GRI-GT9, and in Table 5 the various grip types for different strength geotextiles are readily seen.

Table 5 – Recommended Grip Types for Wide Width Testing of Geotextiles and Their Seam Connections, see GRI-GT9 for Details

Grip Type	Examples or Description	Ultimate Wide Width Tensile Strength (± 25%)	
		kN/m	lb/in
(1) standard	<ul style="list-style-type: none"> • mechanical • serrated surfaces • commonly available 	< 50	< 300
(2) special	<ul style="list-style-type: none"> • air or hydraulic activated • special friction or shaped surfaces • many have a keeper behind grips 	< 90	< 500
(3a) wedge	<ul style="list-style-type: none"> • mechanical • serrated • epoxy/soft metal 	< 180	< 1000
(3b) split barrel	<ul style="list-style-type: none"> • internal keeper 	< 180	< 1000
(4) roller	<ul style="list-style-type: none"> • capstan type • internal keeper 	unlimited	unlimited

This specification was adopted on September 27, 1999 under the title of: “Test Methods, Properties and Frequencies for High Strength Geotextile Tubes Used as Coastal and Riverine Structures”. It was revised one time since its inception.

THE GRI-GT13 SPECIFICATION FOR GEOTEXTILE SEPARATORS

In general, we do not craft generic specifications in cases where another credible group has the topic covered. This is certainly the case for the AASHTO M288 specification on commonly used geotextiles in the transportation industry. In it geotextile separation between subgrade soil and stone base aggregate is covered insofar as required test methods and properties are concerned. That said, the installation survivability classifications of Class 1, 2 or 3 geotextiles are listed but left open to the specifier as to how to differentiate between them. We have had many questions in this regard. Table 6 following is the essential contribution that our specification brings to the user. The class of geotextile is completely defined insofar as the construction site conditions and proposed installation equipment are concerned.

One other addition to this specification is that both ASTM and ISO versions are available with their respective test method designations.

These two specifications GRI-GT13(a) – ASTM Version and GRI-GT13(b) – SI Version are titled “Test Methods and Properties for Geotextiles Used as Separation Between Subgrade Soil and Aggregate” and they were adopted in 2004 and 2008 respectively. The ASTM version has seen two minor revisions since adoption.

Table 6 - Required Degree of Survivability as a Function of Subgrade Conditions, Construction Equipment and Lift Thickness
 (Class 1, 2 and 3 Properties are Given in the AASHTO M288 Specification;
 Class 1 + Properties are Higher than Class 1 but Not Defined at this Time)

	Low ground-pressure equipment ≤ 25 kPa (3.6 psi)	Medium ground-pressure equipment > 25 to ≤ 50 kPa (>3.6 to ≤ 7.3 psi)	High ground-pressure equipment > 50 kPa (> 7.3 psi)
Subgrade has been cleared of all obstacles except grass, weeds, leaves, and fine wood debris. Surface is smooth and level so that any shallow depressions and humps do not exceed 450 mm (18 in.) in depth or height. All larger depressions are filled. Alternatively, a smooth working table may be placed.	Low (Class 3)	Moderate (Class 2)	High (Class 1)
Subgrade has been cleared of obstacles larger than small to moderate-sized tree limbs and rocks. Tree trunks and stumps should be removed or covered with a partial working table. Depressions and humps should not exceed 450 mm (18 in.) in depth or height. Larger depressions should be filled.	Moderate (Class 2)	High (Class 1)	Very High (Class 1+)
Minimal site preparation is required. Trees may be felled, delimited, and left in place. Stumps should be cut to project not more than ± 150 mm (6 in.) above subgrade. Fabric may be draped directly over the tree trunks, stumps, large depressions and humps, holes, stream channels, and large boulders. Items should be removed only if placing the fabric and cover material over them will distort the finished road surface.	High (Class 1)	Very high (Class 1+)	Not recommended

*Recommendations are for 150 to 300 mm (6 to 12 in.) initial lift thickness. For other initial lift thicknesses:

- 300 to 450 mm (12 to 18 in.): reduce survivability requirement one level;
- 450 to 600 mm (18 to 24 in.): reduce survivability requirement two levels;
- > 600 mm (24 in.): reduce survivability requirement three levels

Note 1: While separation occurs in every geotextile application, this pavement-related specification focuses on subgrade soils being “firm” as indicated by CBR values higher than 3.0 (soaked) or 8.0 (unsoaked).

Source: Modified after Christopher, Holtz, and DiMaggio (1984)

OTHER GRI GENERIC SPECIFICATIONS

Admittedly, our track record for other geosynthetic specifications has not been good. There is indeed a demand by the user/specifier community, however, product variation for some geosynthetics is so great and entrenched interests are so compelling that many are in draft form and not yet finalized. They are as follows:

- Specification for Uniaxial Geogrids in Permanent Reinforcement Applications, e.g., Reinforced Walls and Steep Soil Slopes (18 revisions to date)
- Specification for Biaxial Geogrids in Reinforcement Applications, e.g., Pavements, Foundations and Bases (9 revisions to date)
- Specification for Biplanar Geonets and Geonet Composites (countless revisions to date)
 - Approach A – No Transmissivity
 - Approach B – With Transmissivity Values
 - Approach C – With Transmissivity Values and Default Reduction Values
- Specification for Turf Reinforcement Mats (4 revisions to date)

SUMMARY AND CONCLUSIONS

In 1991 when the National Sanitation Foundation ceased servicing and distributing its NSF #54 specifications for geomembranes we had no idea that GSI/GRI would become so involved since then and apparently into the future as well. To be sure, it is a most difficult process to craft a credible generic specification for a given category of geosynthetic material. If required test properties are too low then utility to the regulator, owner, designer and specifier is compromised, and if too high then constraints to the resin/additive supplier, manufacturer and sales representatives are unacceptable. Indeed a realistic “middle ground” is necessary on the part of all involved and particularly for the negotiator; that being GSI/GRI in the case of these specifications.

Upon reflection, however, there are several powerful reasons why GSI/GRI should be involved in crafting of generic geosynthetic specifications.

1. The membership of the institute is open to all segments of the industry. Regulators, owners, consultants, testing laboratories, resin suppliers, additive suppliers, manufacturers/representatives and contractors/installers are all involved which has the decided advantage that at the end of the process one has arrived at an industry-wide specification.
2. From its very inception in 1986 GRI has been developing and distributing detailed test methods. Therefore, if a specification calls for a new test method we can develop it almost immediately in comparison to the extremely long times for ASTM and ISO. Afterward, such a GRI test method can be transitioned to ASTM (or ISO) as have been 26 of them to date.
3. By virtue of the institute’s Laboratory Accreditation Program we can perform every ASTM, ISO and GRI test method that is known to exist. Thus, *opinion* in the negotiations is minimized and *factual data* is maximized. Even further, it is difficult to

criticize the in-house data since we are the deciding laboratory in proficiency testing as well as in countless conflict-resolution decisions.

4. The monetary issue is largely non-existent since GSI does not do independent laboratory testing or consulting. Of course, it is the member organizations who initiate, interact and approve the specifications, however, there are many cases where non-GSI organizations have had meaningful input to the process.
5. The specifications are completely free to anyone with an interest in using them. They are on the open section of our website at www.geosynthetic-institute.org/spec.htm and it is always the most recent revision that is presented.
6. Each of the specifications on our website is accompanied by a power point tutorial showing all of the test methods and the numeric values required.
7. We are not offended in any way if users of our generic specifications modify them for site-specific applications so long as the modifications are appropriately designated. In this regard, revisions (if common) are an excellent indication to us that the matter or item should be re-investigated.

In conclusion, the crafting of generic specifications by GSI/GRI was never in our original “business plan” but we are glad to have embarked on the venture. While negotiations were and are often contentious, we at the institute have been made better and we certainly hope that the geosynthetics industry as a whole has been properly guided as well.

ACKNOWLEDGEMENTS

We sincerely thank all of our sponsoring organizations. Without them, GSI/GRI simply could neither happen nor exist. This paper is part of the activity ongoing at the institute. The current GSI member organizations and their contact members are given on the institute website at www.geosynthetic-institute.org. Board of Director members are identified accordingly.

GEOTEXTILE FILTERS--25+YEARS OF RESEARCH AND EXPERIENCE

Robert D. Holtz
University of Washington

Barry R. Christopher
Roswell, Georgia

ABSTRACT

The paper is a personal memoir of the Authors' experiences as consultants and researchers on geotextile filters. The paper outlines the work leading to the development of the FHWA Geotextile Filter Design Criteria in 1983-1985. Experiences at Purdue University and the University of Washington on the determination of the pore size distribution of geotextiles is recounted, as is the work on developing a filter criteria based on measured pore sizes. Finally, the development of a flexible wall gradient ratio device for determining the gradient ratio of fine grained soils is described and some test results with the device are presented.

INTRODUCTION AND SCOPE

Geotextiles have been an attractive alternative to graded granular filters from their earliest days. Of course engineers wanted to use the Terzaghi graded granular filter criteria, but how does one determine the grain size distribution of especially a nonwoven geotextile? Wovens were a bit simpler; i.e., the size of the openings between the filaments could be related to the grain sizes of the protected soil.

The title of this paper is a bit misleading, because we begin our review in the late 1950s; however we wanted to provide a little background for our involvement with geotextile filters. Because this article emphasizes research and development work done at STS Consultants, Purdue, and at the University of Washington, it is personal and not intended to be a comprehensive review. Several books and articles are available that give a much more complete review of the entire spectrum of research on geotextile filters including those which did not perform as anticipated (e.g., Koerner and Koerner, 2013).

BEFORE THE FHWA GEOTEXTILE ENGINEERING MANUAL

In an obituary we prepared about Robert J. Barrett, we called him the "Father of Geotextiles" (Holtz and Christopher, 1990), because in the late 1950s he first had the idea to use a fabric to replace graded granular filters in erosion control revetments (Barrett, 1960). Bob Barrett's employer, Carthage Mills, sponsored some laboratory development work at Soil Testing Services, Inc. of Northbrook, Illinois, starting in 1957. Silvio Pollici, a laboratory engineer at STS, developed a soil-fabric permeameter (Pollici et al., 1961-1969) that was later refined and standardized as the Gradient Ratio test by C. C. Calhoun (1972) of the US Army Corps of Engineers. About the same time, Barrett convinced the Corps to do some large-scale field tests to really prove the efficacy of geotextile filters under armor stone on the inland waterway in Florida.

That work was the basis for much of the design, testing methods, installation procedures, and material specifications that we use today for geotextile filters in erosion control revetments.

When Christopher joined STS Consultants in 1977 as a project and laboratory engineer, he of course learned about the early work at STS for Carthage Mills, and he did some basic laboratory tests on geotextile permeability and filtration. Bob Barrett, who was changing companies to help a new European manufacture (Nicolon) to enter the US market, approached Christopher shortly after he joined STS to repeat the gradient ratio tests they had previously performed on these new geotextiles. Shortly after completion of that work, Carthage Mill's retained Christopher to evaluate ten of their early geotextile filter projects, document project performance, and perform field evaluation for case histories on selected projects (e.g., see Christopher, 1983). These early projects had a significant influence on Christopher's future work in geosynthetic filters as well as his dedication to advancing geosynthetics technology in general.

After Barrett's pioneering efforts, there were a few others involved in the development of geotextiles for drainage and filtration (see e.g., Agershou, 1961). In Europe during the 1970s, pioneering work on geotextile filters was done by H. J. M. Ogink (1975) at the Delft Hydraulics Laboratory in Holland, H. J. List (1973) at the Federal Hydraulics Bureau in Germany, and Alan McGown and David Sweetland (1973) at Strathclyde University in Scotland. About the same time, some European polymer and textile manufacturers interested in developing alternative markets for their products came in the US and Canada through their North American subsidiaries or through licensing agreements. The most notable research in the US at that time was by Dan Marks and Bob Carroll; their work is now classic (see Marks, 1975; Rosen and Marks, 1975; and Carroll, 1983).

The first research sponsored by FHWA began in 1977 at Oregon State University (Bell and Hicks et al., 1980 and 1982). (Holtz was on the board of advisors and acted as a reviewer-consultant for this project.) The OSU research focused on the evaluation of existing and the development of new test methods and procedures for determining the engineering properties of geotextiles, including those appropriate for filtration and drainage design.

In the late 1970s, specifications for all geotextile applications including filtration, drainage, and erosion control, were not generic nor were they often based on sound engineering research or experience. The FHWA realized that to improve practice, state highway engineers would need formal training in geotextile engineering. The first FHWA geosynthetics courses were developed and taught by Professor T. Allan Haliburton of Oklahoma State University, who unfortunately passed away after only a few courses were taught.

The authors were awarded the second contract in 1983, and part of our charge was to update Haliburton's draft course materials (Haliburton, Lawmaster, and McGuffey, 1981) into the *Geotextile Engineering Manual* (Christopher and Holtz, 1985). We were not particularly happy with their treatment of geotextile filters, although to be fair, we used many of their concepts and construction procedures. It was during this rewrite that we developed what became known as the FHWA Geotextile Filter Design Criteria. This criteria was further refined after 1983-1985 in the FHWA Geosynthetic Design and Construction Guidelines of 1989, 1996, and 2008. The 1996 version was turned into a textbook published by BiTech (Holtz, Christopher, and Berg, 1997).

THE FHWA GEOTEXTILE FILTER DESIGN CRITERIA

We began by reviewing and summarizing all the previous work we could find on geotextile filters, including the STS reports mentioned above (Pollici, et al., 1960-1969). We also found the books by Cedergren (1977), Koerner and Welsh (1980), and Rankilior (1981), as well as the proceedings of a few early conferences and symposia, very helpful in providing case histories and some design procedures. Three early conference proceedings were particularly noteworthy: the 1977 Paris *International Conference on the Use of Fabrics in Geotechnics*, the *First Canadian Symposium on Geotextiles* in Calgary (1980), especially the paper by Bell (1980), and the 1982 *Second International Conference on Geotextiles*, in Las Vegas. We also reviewed those earlier papers and reports on geotextile filters and filtration mentioned above (Barrett, Pollici, Calhoon, Marks, Carroll, Ogink, List, McGown and Sweetland, Bell et al.), as well as the US Army Corps of Engineers (1977) *Guide Specification for Engineering Fabrics*. Finally the papers by McKeand (1977), McGown (1978), Schober and Teindl (1979), Lawson (1982), Hoare (1982), and Giroud (1982) were especially influential.

Our discussion of geotextile filters began with a summary of the properties of both graded granular materials as well as geotextiles required for filtration and drainage. We also discussed the problem of a grain size versus pore size distribution of the filter, and we discussed the influence of fiber size, fabric structure, and porosity of the geotextile. Most of this summary is still valid today.

Although Haliburton, et al. (1981) mentioned the criteria for critical nature of the project and severity of the soil and hydraulic conditions, they did not emphasize them for design. During our rewrite, we included these conditions, as defined by Carroll (1983), as a formal part of the design process. These conditions are summarized in Table 1, because we believe they are not only very important for filtration and drainage design, but they can apply as well to virtually all aspects of civil engineering design.

Table 1 - Guidelines for Evaluating the Critical Nature or Severity of Drainage and Erosion Control Applications (after Carroll, 1983)

A. Critical Nature of the Project		
<u>Item</u>	<u>Critical</u>	<u>Less Critical</u>
1. Risk of loss of life and/or structural damage due to geotextile failure:	High	None
2. Repair costs versus installation costs of feature:	>>>	= or <
3. Evidence of geotextile clogging before potential catastrophic failure:	None	Yes
B. Severity of the Conditions		

<u>Item</u>	<u>Severe</u>	<u>Less Severe</u>
1. Soil to be protected:	Gap-graded, pipable, or dispersible	Well-graded or uniform
2. Hydraulic gradient:	High	Low
3. Flow conditions:	Dynamic, cyclic, or Pulsating	Steady state

In reviewing the background and comments in the GEM during the preparation of this paper, it is quite remarkable that we apparently had such a clear understanding of all the factors that influence soil retention, permeability, and filtration characteristics of geotextiles in 1983. For example, we noted that no single evaluation technique can be used to determine all of the factors, conditions, and intended uses of a geotextile filter, and thus design must consider site-specific conditions, especially in critical design situations. And this is still true today.

We should also mention an NCHRP study performed by Koerner and Koerner (1994), in which they evaluated 91 sites with 84 involving some type of edge drain installations around the US. Many of these cases were failures or had experienced problems. They took soil and geotextile samples, performed appropriate tests, and applied several design criteria to see which procedures would have predicted the observed performance. We quote: "It was determined that the currently used Federal Highway criteria are excellent predictors (i.e., design methods) in all cases. These criteria should be disseminated to the widest possible audience and utilized accordingly."

The FHWA Criteria performed the best of all procedures, never once predicting success when a failure had occurred. In four successful cases, however, it predicted failures, which in effect means the criteria is conservative, something that designers of geotextile filters should really appreciate.

RESEARCH AT PURDUE AND UW ON THE PORE SIZE DISTRIBUTION OF GEOTEXTILES

The work at Purdue University on determining the pore size distribution (PSD) was largely based on a considerable amount of previous work using mercury intrusion porosimetry (MIP) to measure pore sizes in concrete, compacted and stabilized soils, and other materials. For example, Holtz had supervised the PhD work of C. H. Juang on the PSD of sand-clay mixtures (Juang and Holtz, 1986a, b, and c). Could a similar technique using MIP be used for nonwoven geotextiles? If this would work, then we could design geotextile filters based on their pore sizes.

About that time Christopher became involved with Chemie Linz, a nonwoven manufacturer, and it seemed reasonable to approach them for some funding to investigate this technique. A letter proposal was sent to Mr. Gerhard Werner, the lead engineer with Chemie Linz, and he checked with André Rollin at École Polytechnique in Montréal, who at that time, had done the most work on the PSD of nonwovens. André had used image analysis for his investigations, he did not believe MIP would be feasible for geotextiles, and he advised against

funding the proposal. So Holtz approached Joe Luna who at that time was an engineering manager with Hoescht-Celanese and he was willing to fund a post-doctoral student S. Prapaharan to do some preliminary analysis with MIP. It worked quite well, as we reported in Prapaharan, Holtz, and Luna (1989). In addition to MIP, Prapa was able also to do some comparative image analyses, and we showed that even with compression up to about 50% of the ASTM thickness, the PSD was essentially unaffected. Figure 1 shows the PSD diagrams as determined using MIP as well as image analysis.

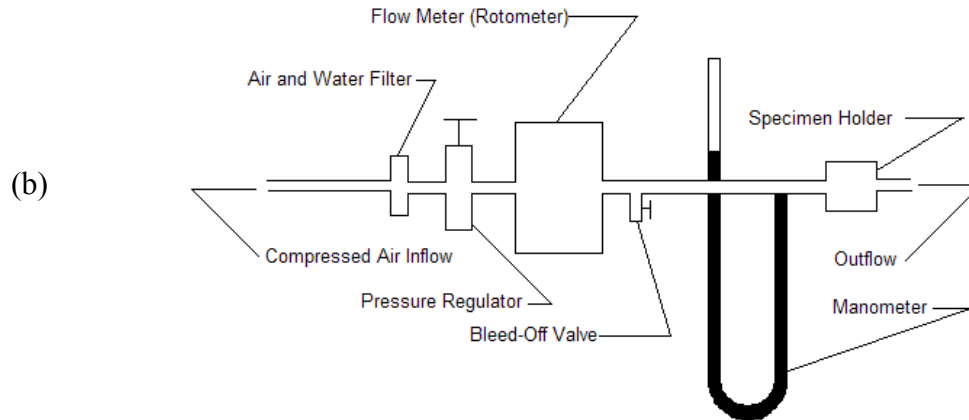

Figure 1. Comparison of MIP and image analysis on a nonwoven polyester (from Prapaharan, Holtz, and Luna, 1987).

As part of his PhD research at the University of Washington, Gregory Fisher showed that the critical pore size in filter behavior was the *constriction* pore size, and that this was true for both geotextiles as well as graded granular filters. He also developed a design method for geotextiles based on the PSD. To determine the pore size distributions of the filters, he also used the “bubble point method,” not the MIP, to determine the PSD of both woven and nonwoven geotextiles (Fisher, 1994).

Why the bubble point method (BP)? Well, for one thing, the BP method measures the constriction pore size as well as the distribution of pores in geotextiles. We also think it measures the true pore size, but that is subject to some debate. And finally, the BP method provides a direct relationship with the hydraulic conductivity of the geotextile, which is also very useful for filter design. Most of these issues are discussed at length in Fischer and Holtz (1991) and Fischer, Holtz and Christopher (1993, 1996a and b).

Figure 2a is a schematic diagram of the BP apparatus and Fig. 2b is a photograph of the apparatus Fischer used.

(a)

(b)

Figure 2. (a) Schematic diagram, and (b) photograph of the bubble point test equipment (from D'Hondt, 2005).

Recognizing that comparative research was needed to support these findings, Christopher encouraged Dr. Shobia Bhatia of Syracuse University to perform additional research to confirm the validity of using the BP method. Bhatia and her student (and now her colleague) Jennifer Smith evaluated various test methods for determining the pore size characteristics of geotextiles including sieving methods, the BP method and MIP techniques (Bhatia and Smith, 1994 and 1996, and Bhatia et al., 1996).

Based on this early research, Christopher initiated an ASTM task group to develop a standard test method for the determination of the PSD of geotextiles and relate PSD to filtration performance. In 2002, ASTM standardized the BP test procedure for determining the pore size characteristics of geotextiles (ASTM D-6767-02).

Fischer (1994) had suggested that some additional work was necessary to improve the BP method, because there were still some questions regarding the fluid used in the test, the shapes of the pores, and whether the pores were constructed upon entrance or exit. This additional work

was done by UW student Douglas P. D'Hondt. He drilled holes of various sizes corresponding to the AOS of geotextiles (70 to 850 μm) into specimens of PVC, aluminum, and HDPE; some of the solids had single holes, one with a countersink, while others had multiple holes and a range of hole sizes. He then used water and mineral oil as the BP test fluids. Details of these tests and the results are described in D'Hondt (2005). Principal conclusions are the following:

1. Specimens should be oriented with the air pressure applied in an upward direction, especially for large pore sizes.
2. BP procedures is accurate even when the pores are not perpendicular to the plane of the specimen
3. BP test was repeatable, especially on nonwovens and wovens with smaller holes. However, it does not reliably replicate the AOS values reported by manufacturers.
4. The accuracy of the BP method is dependent on the contact angle used: ASTM D-6767 should be modified to allow different contact angles for different test fluids and polymers.
5. D-6767 should also be able to account for temperature variations and the possibility of compressed specimens of thick nonwovens.

As part of D'Hondt's research, we cooperated with Prof. Ahmed Aydilek of the University of Maryland, who at that time was also doing research on the PSD of geotextiles, but using image analysis. Figure 3 presents a comparison of some of the results determined by Aydilek, D'Hondt, and Holtz (2007).

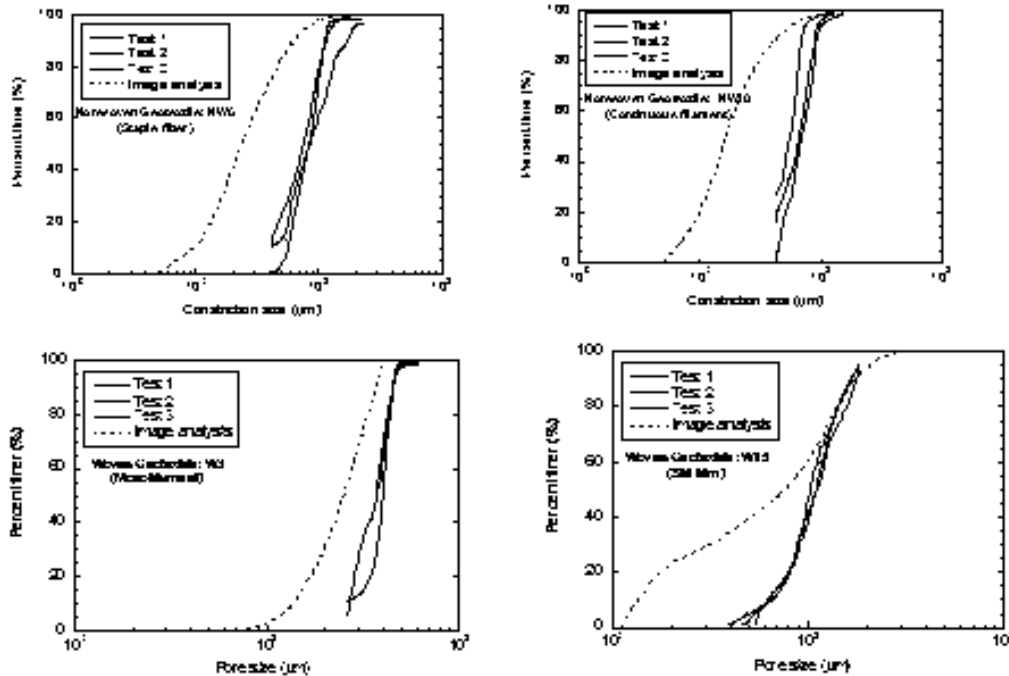

Figure 3. Comparison of the PSDs or CSDs (constriction pore size distributions) of four geotextiles determined by the BP method as well as image analysis (Aydilek, D'Hondt, and Holtz, 2007).

Some of the conclusions of Aydilek et al. (2007) and Aydilek et al. (2008) are as follows:

1. The O_{95} of wovens by image analysis is approximately equal to the AOS of the same geotextiles as determined by ASTM D 4751
2. The bubble point O_{95} for nonwovens is not the same as the AOS.
3. ASTM D 6767 for the bubble point test is the best available test to determine constriction sizes of nonwoven geotextiles

Other researchers who have advanced the use of BP for determining the PSD of geotextiles include David Elton (e.g., Elton, et al., 2007, and Elton and Hayes, 2008) and Karen Henry (Henry and Patton, 1998). ASTM Committee D-35 is currently updating the BP standard considering all of this research, especially recommendations related to the pore fluid.

RESEARCH AT UW ON THE GRADIENT RATIO TEST

The gradient ratio test discussed at the beginning of this paper was standardized by ASTM in 1990 (ASTM D 5101), largely because of the diligence of Don Shanklin and the support of the USDA, Soil Conservation Service laboratory. However, the test tended to produce variable results and additional work to refine the test was needed.

Filtration research at the University of Washington by Gregory Fischer and others was largely influenced by a summary of research needs on geotextile filters at that time, as described by Christopher, Holtz, and Fischer (1993). Because Fischer was a practicing consulting geotechnical engineer, he also wanted to study some of the broadly graded glacial tills that are common in the Seattle area. The local geotechnical consulting community assumed that “Geotextiles don’t work in our soils, because our soils are different!”

Fischer started with a critical review of all previous work on graded granular filters, and then on geotextile filters. The work on granular filters was summarized by Fischer and Holtz (1996).

For the long-term flow tests, Greg used the Gradient Ratio (GR) Test because it was an established ASTM standard (D-5101) that is fairly straightforward to run, and the apparatus is simple and inexpensive. Furthermore, measurements of the gradient could be made at several locations in addition to the standard locations of 25 mm and 50 mm. It was also possible to collect any fines that might happen to pass the filter, and it can accommodate relatively large flow rates anticipated in the soils he tested. Mare (1994) also conducted some long term GR tests to complement Fischer’s work. A critique of the GR test is in Fischer, Holtz, and Christopher (1994).

The grain size distributions for the two glacial till soils tested are shown in Fig. 4, while Fig. 5 is a photo of four of the GR devices used. The soils were tested at very low densities to enhance filter clogging. Water filters were utilized to insure that any decrease in flow rate observed was due clogging of the geotextiles and not due to contaminants in the water. To aid in the saturation of the soil specimens, CO₂ was used to displace the air in the voids. Because the tests were expected to take several weeks, an algaeicide was also used. Table 2 lists the four geotextiles tested along with some of their characteristics.

Figure 4. Grain size distributions of two broadly graded glacial till soils from the Seattle area (Fischer, 1994).

Figure 5. Gradient Ratio test equipment used by Fischer (1994).

Table 2. Geotextiles Tested by Fischer (1994) and Mare (1994).

Geotextile type	Polymer	type	Mass/unit area (g/m ²)	AOS (mm)
Needlepunched nonwoven	polypropylene	Continuous filament	281	0.12-0.21
Needlepunched nonwoven	Polyester	Continuous filament	254	0.12-0.21
Heatbonded nonwoven	polypropylene	Continuous filament	213	0.08
Multifilament woven	polypropylene	Continuous filament	220	0,21

Examples of some of Fischer's (1994) and Mare's (1994) results are shown in Fig. 6. Additional long term filtration results were reported by Fischer, Mare, and Holtz (1999).

a)

b)

Figure 6. Long-term GR filtration tests on soils (a) OLY, and (b) MUK1 (after Fischer, 1994, and Mare, 1994).

Some of the practical implications of our filtration research are that the Seattle area glacial soils are not really that different. It is possible to design a successful geotextile filter for them by using the FHWA filter criteria (Christopher and Holtz, 1983), although a GSD of the soils to be filtered is required—no surprise there—as are filtration tests for critical designs (Table 1).

ASTM used this research, along with that of others, to update the gradient ratio test standard in 2001.

Other research in the last 25 years on filtration performance using the gradient ratio tests should also be recognized. Mark Wayne working with Bob Koerner evaluated the long-term

filtration performance versus current design practice (Wayne and Koerner, 1993). Studies by Jonathan Fannin on cyclic GR testing (Fannin and Srikongsri, 2007) is especially noteworthy. We are also aware that GR tests have been performed by practicing engineers to assess the most appropriate geotextile(s) for critical applications, and we hope their work will influence fellow engineers to use this best practice.

Development of Filter Criteria Based on PSD

Fischer (1994) also developed a design procedure based on the pore size distribution of geotextiles. This procedure was described by Fischer, Christopher, and Holtz (1990) and Holtz (1992).

Development of the FWGR

One of the more important developments by the UW group is the flexible wall gradient ratio test (FWGR). The test and its development were first reported by Harney and Holtz (2001) in a paper based on Michael Harney's MSCE thesis (Harney, 2001). The FWGR is basically a combination of the standard GR test with the flexible wall permeameter (ASTM D-5084), as shown conceptually in Fig. 7. The test was developed to overcome some of the disadvantages of the two conventional filtration tests, the GR and the hydraulic conductivity ratio (HCR, ASTM D-5567) tests. Specimens can be saturated using backpressure; stress conditions can be controlled during testing; and piping along the walls can be eliminated. Thus the FWGR should be more appropriate than the GR alone for soils with appreciable fines. These advantages were also shown by Henry and Holtz (2003).

FWGR specimen preparation is no more complex than that required for conventional triaxial testing, and only minor modifications or upgrades to existing flexible wall permeameter equipment were necessary. Two required modifications were the development of a latex membrane with pressure ports (Fig. 8) and a flexible wall permeameter cell base with multiple pressure lines. Rather than trying to apply backpressure to standpipe manometers, we also built a pressure transducer manifold (Fig. 9) with multiple transducers for measuring the head at different elevations above the geotextile specimen. The FWGR is evaluated identically to the GR, as shown in the equation

$$F G \equiv G \equiv \frac{i_{soil}}{i_{soil+filter}}$$

Figure 7. Basic concept of the FWGR; also shown are the locations of head measurement ports.

Figure 8. FWGR 71 mm diameter latex membrane with pressure ports.

Figure 9. FWGR specimen in mold and pressure transducer manifold.

Typical results from Harney (2001), Bailey (2004), Bailey, Harney, and Holtz (2005), and Harney, Bailey, and Holtz (20??) are summarized in the following paragraphs. First, a comparison of the FWGR and GR test results are shown in Fig. 10.

Figure 10. Comparison of FWGR and GR test results on the OLY soil (Fig. 4) and the geotextiles in Table 2.

Figure 11 compares results of FWGR and HCR tests and FWGR and GR tests on a needle-punched nonwoven.

A)

B)

Figure 11. Comparison of (a) FWGR and HCR test results with (b) FWGR and GR test results, all on a needle punched nonwoven (NP1).

Results of similar comparative tests on another nonwoven, a slit-film woven, and a monofilament woven are shown in Harney (2001), Bailey (2004), Bailey, Harney, and Holtz (2005), and Harney, Bailey, and Holtz (20??). All these test results indicate that the two tests give very similar results, that the FWGR test is repeatable, and that it stabilizes much faster than the GR tests. These tests were performed on well-graded granular soils, soils that typically are difficult to

test in the conventional GR apparatus. For the two soils tested, the FWGR gives more reliable results than the HCR test, and it provides a reliable and repeatable direct determination of the soil and system hydraulic conductivity.

FINAL REMARKS

In his 2008 Terzaghi Lecture, Jean-Pierre Giroud made two, at first glance, rather surprising assertions:

1. Geosynthetics are the single most important development in civil engineering in the 20th Century; and
2. Because of our research on geotextile filters, we now have a better understanding of Terzaghi's graded granular criteria.

The summary of our research and development experience with geotextile filters summarized in this paper validates both statements. On the other hand, we are confident that PSD will dominate geosynthetic designs of the future and that the design of geosynthetic filters will advance well beyond the basic graded granular filter criteria.

A BRIEF HISTORY OF GEOSYNTHETIC DRAINAGE MEDIA: FROM ROCKS TO SIM TESTED, PATENTED, STRAND GEOMETRIES

Boyd Ramsey
GSE Environmental LLC

In the beginning, there were rocks...after that; there was sand...but then!

I would believe that most of you have attended a “Mercer” lecture during your attendance at a conference or tradeshow. Frank Brian Mercer (O.B.E.) was a prolific British engineer. Born in 1927, he did groundbreaking work in multiple fields and his accomplishments include the primary basic invention of both geonets and geogrid materials.

Mercer’s work in Britain resulted in the creation of Netlon Corporation in the USA and the issuing of US patent 2919467 titled: “Production of Net-like Structures” on January 5, 1960. This patent addresses the general production of geonets used today, although the level of sophistication has advanced dramatically, as one would expect.

The commercialization of the geonet and geocomposite materials was taken up by “Netlon” in Britain and in the United States, the Minnesota based company “Wood Conversion Products” began to be involved in the manufacture of these materials. This organization later changed its name and is more popularly known as “Conwed Ltd.” An early schematic of a geonet production line (from “Austin”) is pictured here:

Figure 1. Schematic view of geonet production line.

In one of the first major “field tests” of these materials, in 1987, Tony Eith and the leadership and staff of the Geosynthetic Institute conducted an examination of a geonet installation. A section of a commercial landfill was constructed with a geonet collection system and was evaluated in the “real-world” environment by application of ~2600 liters (700 gallons) of water and subsequent measurement of the timing and quantity of materials collected at the sump. This testing was repeated with multiple and increasing overburden loads of municipal waste with

depths of near zero (essentially unfilled), 14 meters (46 feet) and 28 meters (92 feet). The measurements allowed the calculation of a field transmissivity and accurate validation of the flow rates and response times of the system. Obviously the system performed well, or we would not be discussing this 25 years later. To quote from the conclusions; ” *The full scale flow test results of a geonet leak detection system illustrated in this paper indicate that geonets are effective in their liquid transmissivity capabilities and can function as designed and intended.*”

It was obvious that to be effective in most applications the geonet would need some filtration media to protect the net from clogging, thus the creation of geotextile – geonet laminates that are commonly known as geocomposites. The vast majority of those used today are manufactured with needle punched nonwoven polypropylene geotextiles as filtration media, commonly 6 or 8 ounce per square yard (200 to 270 grams per square meter), although it should be stated that several companies hold patents and have developed technology to laminate other fabric types with differing filtration properties. Additionally, recognition should be given to past usage of polyester fabrics as filtration media. In the early 1990’s polyester was the fabric of choice primarily due, to ease of lamination. Subsequently polyester became over-priced for the geosynthetic marketplace and has fallen out of common usage.

Also, a few words must be given to the bonding of the geonet and geotextile materials. The original production lines used flame bonding where the geonet was exposed to open flame. Advancements in technology led to what is described as “wedge” lamination, where the surface of the geonet is exposed to a heated wedge or metal plate. In both cases, the geotextile is then exposed immediately to the heated surface of the geonet and light pressure is then used to assure sufficient bonding takes place.

In 1993 Tenax began production in the United States, Tenax (now Syntec) has a well-deserved reputation for innovation in this field and pioneered several important product design and application engineering concepts over the years.

At the 8th GRI conference in 1994, Richard Austin of Netlon presented a paper titled: “The manufacture of Geonets and Composite products” in which he described the manufacturing process for geonet and geocomposite production in some detail. This was an excellent foreshadowing of the technical issues that would surround the testing, performance requirements and engineering of these materials. To quote one section of the paper:

“By using different size dies, die slots and mandrels, and changing the rotation of the dies, a wide variety of different net products can be manufactured using the above process”.

He went on to discuss net geometry, rib sizes, references to both to “straight strand” configurations and increasing net thicknesses. In the Quality Assurance portion of the paper, he discussed compressive creep, thickness dependent transmissivity, temperature dependent transmissivity, interface variability, geotextile intrusion, peel strengths and interface frictional performance. A photograph of several current geonet varieties is below:

Figure 2. Various types of geonet drainage cores currently in use.

At the 13th GRI conference held in 1999, Pietro Rimoldi of Tenax was charged with predicting the future of geonet and geocomposite products. Predictions are always a difficult task. He laid out the case for the substitution of geocomposite for sand, an argument that many of us are still presenting today and he covered nearly all of today's "selling points" with the only real new advantage being the "green" value of geocomposite materials. He correctly pointed out the issue of low "shipment density"; one can only cover a small area with the contents of a standard shipping container of geocomposite materials. He accurately predicted growth of product types, and consolidation within the industry. He also did a great job of predicting additional applications in earthen and concrete dams, transportation and other infrastructure applications as well as introducing the concept of cusped geonets and other strand geometries.

The late 1990's and early 2000's were a period of many innovations within this marketplace and during this period, the race to the patent office was rejuvenated. Nearly all of these advances were made in pursuit of the same common goal; to get the highest flow rate (transmissivity) for the longest time (in-service duration) with the minimum amount of material. This fairly simply stated goal however, resulted in a rich and complex range of designs invoking variation in a very broad range of geonet characteristics. Most critical in this author's opinion were and are strand shape, geonet thickness, geonet strand orientation and materials (geonet and geotextile) composition.

In 2000, the publication *Geosynthetics International* devoted a special issue (Volume 7, Nos. 4-6, 2000) to liquid collection systems. Authors included J.P. Giroud, Jorge Zornberg, Aigen Zhao, Rudy Bonaparte, Ennio Palmeira, Gregory N. Richardson, Rick Thiel and others. This publication summarized the engineering foundation for the use and performance of these materials and explored concepts such as thickness dependent flow, radial performance, hydraulic transmissivity equivalency between geosynthetic and granular liquid collection layers and others. In 2001, the Geosynthetic Institute published GRI–GC8, Determination of the Allowable Flow Rate of a Drainage Geocomposite (2001). This document provided guidance and documented the application of reduction factors to assure that the real-world performance of these systems would have both adequate flow rates and sufficient longevity.

Another important milestone was the publication in GFR magazine (now Geosynthetics Magazine) of a multipart article and associated discussions on the engineering of lateral drainage systems. These articles and engineering advances were authored by Gregory N. Richardson, J.P. Giroud, and Aigen Zhao. The principle article was titled “Lateral Drainage Design Update” and was presented in two parts in the January /February and March 2002 issues of GFR.

In 2004, Dhani Narejo and Sam Allen outlined an accelerated procedure to measure compressive creep properties of geonet and geocomposites using the Stepped Isothermal Method (SIM). This concept became embodied in ASTM D7361, Standard Test Method for Accelerated Compressive Creep of Geosynthetic Materials Based on Time-Temperature Superposition Using the Stepped Isothermal Method and is used widely today to determine the long term performance characteristics of these materials and assist in engineering design.

At the GRI-22 conference held in 2009 in Salt Lake City, an important paper, which the author believes deserves more attention, was jointly presented by Bob and George Koerner. The paper, titled: “Geocomposite Drainage Material Connections and Attachments” addresses the termination constructions and the flow of liquids out of these types of products and into piping; a critical aspect of the installations that has been occasionally overlooked to significant consequences.

In 2011 Sam Allen published an article in Geosynthetics magazine titled “Accelerated flow testing of geosynthetic drains” that summarized the state of the practice in evaluations and predictions of the behavior of these materials.

A final word should also be included regarding market size. Over the past decades, several individuals, and organizations have tracked the size and growth of the geonet and geocomposite marketplace; while the general goals have been the same, the methodologies and specific details of these efforts have differed and some details have been lost to the vagaries of history. In overview, the market for geocomposite drainage products (geonets and accompanying geotextiles) roughly doubled between 1999 and 2004 to a total of approximately 67 million pounds per year. Since 2004, the market has not quite doubled again and the latest market estimate for geocomposite products (including geotextiles) is approximately 125 million pounds per year.

The level of sophistication from Dr. Mercer's era has increased substantially; details such as initial flow rate, reduction factors to accommodate various types of clogging and intrusion, effects of thickness changes, benefits of specific strand geometries and geotextile variations and other factors are regularly addressed. Standardized test protocols and techniques are available and can be used to reliably compare materials performance and to predict the long term behavior of materials. In short, geocomposites have passed the "look at this new stuff" era and are aging well into an innovative material with a well-defined and engineered performance.

ENGINEERING CHARACTERISTICS OF GEOSYNTHETIC CLAY LINERS: QUESTIONS ASKED AND ANSWERED OVER TIME

David E. Daniel

University of Texas at Dallas, Richardson, Texas USA

ABSTRACT

Geosynthetic clay liners (GCLs) evolved from subsurface waterproofing materials that are manufactured in small panels and typically affixed to the earthen backfill side of basement walls. A transformative event occurred when GCLs were first used in a waste containment application in the mid 1980's. Soon thereafter, intensive research was launched to investigate and document the engineering characteristics of GCLs. A number of specific questions about GCL behavior were asked and answered, though nearly all issues will continue to benefit from further research. New questions will be posed and answers developed as new materials evolve and new applications are explored.

In the late 1980s and early 1990s, the cost and practical advantages of GCLs compared to compacted clay liners quickly became evident. As a result, the use of GCLs in waste containment applications grew rapidly. Today, GCLs are widely used and are an important element not only in waste containment applications but in various other sealing and waterproofing uses, as well.

The main technical and engineering issues regarding GCLs can be grouped into seven broad categories: (1) hydration of GCLs; (2) hydraulic properties of bentonite in GCLs; (3) composite action of GCLs with a geomembrane; (4) stability of GCLs on slopes; (5) the physical integrity of GCLs; (6) transport of chemicals through GCLs and the equivalency of GCLs to compacted clay liners; and (7) advances in materials and designs.

This paper traces understanding of engineering characteristics over time for a few key parameters. At the close of the paper, the author looks forward regarding future uses of GCLs. He would like to see more use of bentonite sandwiched between two geomembranes, more use of a protective layer beneath GCLs to mitigate impact of any unforeseen puncture and to limit diffusive migration of chemicals, more consideration of site-specific conditions in GCL design, better management of wrinkles in geomembranes that overlie GCLs, and more considered use of GCLs for some near-surface applications.

INTRODUCTION

Geosynthetic clay liners (GCLs) evolved from subsurface waterproofing materials that were manufactured in the early 1960s and are still in widespread use today. The thin waterproofing panels typically measure roughly 2.4 m by 1.2 m in length and width, and are

affixed to a basement wall, which is then backfilled to cover up the panel. The bentonite in the waterproofing panel provides the desired sealing.

A transformative event occurred in the mid 1980s when GCLs were first used in a waste containment application (Schubert, 1987). Shortly thereafter, intensive, independent research was initiated worldwide to investigate and document the engineering characteristics of GCLs. In addition, the cost and practical advantages of GCLs compared to compacted clay liners quickly became apparent. The amount of GCL material used in waste containment applications grew rapidly throughout the world. This growth was driven by the significant advantages of GCLs compared to compacted clay liners, which include:

- Lower cost of GCLs in most cases;
- Much faster construction times with GCLs;
- Far less uncertainty and risk regarding schedule and cost with GCLs;
- Less volume of landfill space consumed by GCLs;
- Potentially lower hydraulic conductivity and, hence, lower seepage rates with GCLs; and
- Opportunity to engineer high-performance materials either through modification of the bentonite or design of the overall geosynthetic system.

Geosynthetic clay liners exhibit some fundamental drawbacks compared to compacted clay liners, the most significant of which are:

- Very low shear strength of hydrated bentonite;
- Because of the thinness of GCLs, vulnerability to physical damage (e.g., thinning of bentonite by stones in the subgrade, puncture, or penetration by plant roots);
- Vulnerability to chemical alterations of the bentonite that can result in a significant increase in the hydraulic conductivity of the bentonite; and
- Limited impedance to chemical diffusion due to thinness of the bentonite layer.

Over the past 25 years, a number of specific questions about GCL behavior were asked by owners/operators, design engineers, researchers, and regulatory officials. Over time, many of these questions were answered (at least partially, if not entirely) from the results of research studies, though many issues will continue benefit from further investigation, and a few are considered “hot topics” today. New questions will inevitably be posed as new materials evolve and as new applications develop.

In this paper, attention is focused on several issues as follows:

1. Hydration of GCLs.
2. Hydraulic properties of bentonite in GCLs.
3. Composite action of GCLs with a geomembrane.
4. Stability of GCLs on slopes.
5. The physical integrity of GCLs and vulnerability to damage
6. Equivalency of GCLs to compacted clay liners.
7. Advances in materials and design

At the close of the paper, the author will look forward regarding use of GCLs. He would like to see more use of bentonite sandwiched two geomembranes, more use of a protective layer beneath GCLs to mitigate impact of any unforeseen puncture and to limit diffusive migration of chemicals, more consideration of site-specific conditions in GCL design, better management of wrinkles in geomembranes, and more selective less use of GCLs in near-surface environments.

HYDRATION OF GCLs

An issue that perhaps has not been given as much attention as it should have received is the hydration of GCLs placed in contact with earth materials. Geosynthetic clay liners are manufactured using relatively dry bentonite, although in the early days of GCL manufacturing, bentonite mixed with a water-soluble adhesive in some commercial products occasionally left the factory with sufficient high water content that they underwent considerable dimensional shrinkage upon drying in the field. But for the most part, the issue with GCLs is not drying of the product but, rather, hydration of bentonite once the GCL is installed in the field.

Bentonite is an inherently hydrophilic material that has great affinity to absorb water. It is this characteristic that is one of bentonite's most unique and desirable characteristics. If given access to water in almost any form, relatively dry bentonite will absorb the water.

Water absorption or desorption, like all fluid movement, is driven by gradients in energy. Essentially, water moves from a location of higher energy to one of lower energy (or "downhill" in more simplistic terms). The pore water pressures in bentonite are strongly negative compared to atmospheric pressure. This very large "suction" pressure of relatively dry bentonite gives bentonite the ability to absorb water from almost any moisture-holding material (e.g., soil or rock). For practical purposes, except perhaps for the driest materials imaginable in nature, bentonite will absorb moisture from the adjacent material until the two materials reach equilibrium in terms of water energy.

For a given material, a relationship exists between water content and soil water potential, although the relationship may not be unique and usually depends on the wetting path, i.e., the relationship is slightly different for materials that are being wetted compared to materials that are being dried. Few engineers seem to grasp basic concepts of soil moisture potential and water content-suction relationships, perhaps because of relatively little instruction in most universities on the subject of "unsaturated soil mechanics." In any case, GCLs are sometimes placed on the subgrade with little understand as to what will happen next.

When a GCL is placed on a damp or moist subgrade with only a geotextile (at most) separating the bentonite from the subgrade, the GCL absorbs moisture from the subgrade, as indicated in Figure 1. The process can be slowed with a thicker geotextile separating the bentonite from the subgrade, but hydration will occur nevertheless. Note that the hydration time is on the order of days to weeks.

Figure 1. Water content of bentonite vs. time for geotextile-encased GCL placed on sand (Daniel, Shan, and Anderson, 1993).

When the bentonite reaches equilibrium with the adjacent soil, the equilibrium will be in terms of energy (water potential), not water content. This is seen clearly in Figure 1 where the water content of the sand is between 1% and 17% and, over time, the water content of the bentonite equilibrates between 50% and 200%. The relationship between suction and water content of bentonite can be measured in the laboratory, as shown in Figure 2. As a practical reference, it may be noted that plants wilt and die when the suction is approximately 15 bars (1 bar of pressure \approx 1 atmosphere of pressure). At a suction of 15 bars, the equilibrium water content of the bentonite is on the order of approximately 50%. At this moisture content, bentonite is moist with a shear strength similar to saturated bentonite (Daniel, Shan, and Anderson, 1993).

Several devices are available to measure soil suction. Daniel et al. (1993) used a thermocouple psychrometer, which is a relative-humidity measuring device for determining soil water potential. Southen and Rowe (2007) employed the more widely utilized axis translation technique. Beddoe, Take, and Rowe (2011) employed both high-capacity tensiometers (axis translation) and relative humidity measurements to measure the soil moisture retention curve. There exist enough published data for one to obtain at least a preliminary estimate of the relationship between soil suction and water content for the bentonite component of GCLs from published information. This aspect of GCL material behavior is reasonably well understood.

Figure 2. Relationship between soil suction and water content of bentonite in a geotextile-encased GCL (Daniel, Shan, and Anderson, 1993).

Research has pointed to some of the subtleties of soil-moisture retention. A recent investigation by Sarabian and Rayhan (2013) found that the GCL hydrates to a lesser extent if there is cyclic wetting and drying. Sarabian and Rayhan also found that the ability of the soil to conduct moisture to the GCL is important; moist, sandy soils promote more rapid conduction of water and hydration of the adjacent GCL than lower permeability, clay-rich soils. Chevrier et al. (2012) found that hydration was slowed, and moisture absorption reduced, when the process occurs at low temperature ($\approx 5^{\circ}\text{C}$). Rayhani et al. (2011) as well as Anderson, Rayhani, and Rowe (2012) report similar findings but additionally note that the method of GCL manufacture can have a significant impact on the amount of water absorbed.

In summary, with rare exception (the exception being bentonite placed in contact with exceptionally dry materials found rarely in nature), bentonite placed in contact with natural materials in the subsurface will absorb moisture from the subgrade and hydrate. In an overlapped section of GCL, with two layers of GCL, both layers hydrate (Jahangir and Daniel, 1999).

The hydration process can be essentially stopped by separating the bentonite in a GCL from the adjacent soil materials with a geomembrane (Estornell and Daniel, 1992). Water vapor may diffuse through some geomembranes, but the rate is typically extraordinarily slow especially with hydrophilic geomembranes such as HDPE that absorb little or no water.

Hydration has practical implications. For example, suppose a geotextile-encased GCL is placed on a wet subgrade and covered with a geomembrane. Within a few days, the bentonite will have absorbed water and become moist. Walking over the geomembrane could thin the bentonite where people have walked, though foot pressures are seldom large enough to cause damage. Heavier loads such as from construction equipment could do damage if the GCL is not adequately covered and protected. On the positive side, bentonite must be hydrated to achieve low hydraulic conductivity, and the hydration process can “activate” the bentonite and result in low hydraulic conductivity.

HYDRAULIC PROPERTIES OF BENTONITE IN GCLs

Permeation with Water

When the U.S. EPA approached the author in the late 1980s and initiated university-sponsored research on GCLs, he was not especially concerned with whether bentonite had low hydraulic conductivity to water because the low hydraulic conductivity of bentonite was well known. At the time, the author’s attention focused on the overlapped sections of the GCL panels. The manufacturers claimed that these overlaps “self sealed” and required no physical bonding. The author was skeptical and focused initial research on determining whether this was true.

Estornell and Daniel (1992) conducted large-scale tests and concluded that, indeed, the overlaps do self-seal if installed as recommended by the manufacturer. For some GCLs with comparatively thin geotextiles, no additional bentonite may be needed in the overlap because as the bentonite hydrates, it extrudes through the openings in the geotextiles and provides the sealing mechanism. For thicker geotextiles, extra bentonite may be needed in the overlap to provide the seal.

Numerous investigators have reported information about the hydraulic conductivity of GCLs, e.g., Shan and Daniel (1991) in the early days of GCL research. For permeation with water, the testing methods are now reasonably standardized and typically involve a flexible-wall permeameter (e.g., ASTM D-5887). The ranges of hydraulic conductivity reported are reproducible and consistent with data obtained from larger-scale tests.

A point sometimes overlooked is the influence of vertical effective stress on the hydraulic conductivity of GCLs, as shown, for instance, in Figure 3. An increase in compressive stress causes a reduction in porosity and in hydraulic conductivity.

Bentonite is well known not only for its swelling characteristics, but shrinkage properties, as well. Bentonite swells when wetted but tends to shrink and crack when dried. Boardman and Daniel (1996) conducted large-scale tests on GCLs that were allowed to desiccate underneath approximately 0.5 m of cover material. Hot air was circulated to dry the GCL *in situ*. Boardman and Daniel found that the GCLs cracked severely but, upon rehydration, swelled and completely recovered their low hydraulic conductivity when permeated with tap water.

Figure 3. Hydraulic conductivities of GCLs, or the bentonite component of GCLs, as a function of effective confining stress for GCLs permeated with tap water.

Azad et al. (2011) conducted experiments involving GCLs that were configured in a composite liner system, buried, and subjected to high temperatures (39 to 45°C). Desiccation and even some cracking were noted, but upon permeation of the desiccated GCLs, little if any alteration in hydraulic conductivity was noted. The self-healing is attributed to the swelling characteristics of bentonite, absent any deleterious factor (such as chemical alteration a low confining stress) that might inhibit the swelling capacity of the bentonite.

Kraus et al. (1997) and Hewitt and Daniel (1997) investigated the effects of freeze-thaw on the hydraulic conductivity of GCLs. Both studies indicated no damage from multiple cycles of freeze-thaw. Podgorney and Bennett (2005) were concerned that the earlier studies did not extend to a sufficiently large number of freeze-thaw cycles and, thus, performed tests out to 150 freeze-thaw cycles, finding no significant change in hydraulic conductivity. Although there may be some extenuating circumstances in which repeated freeze-thaw might be of concern, these studies are an example of research addressing and largely putting to rest a question about GCLs.

Another question that has been investigated is the hydraulic integrity of GCLs subjected to deformation, such as differential settlement in a landfill cover system. LaGatta et al. (1997) conducted experiments in which a bladder was deflated beneath a large specimen of GCL that was covered with about 0.5 m of gravel. This set-up produced severe differential settlement while the GCL was being permeated, thus enabling deformation to be related directly to hydraulic conductivity. LaGatta et al. found that GCLs could withstand large differential settlement (Δ) over horizontal distance L with essentially no harmful impact on hydraulic

conductivity so long as $\Delta/L \leq 10\%$. Koerner, Koerner, and Eberle (1996) used a different methodology but found essentially identical results. These two studies reinforced one another and answered the basic question about how much deformation a GCL can withstand and maintain hydraulic integrity.

Permeation with Chemical Solutions

Much has been written about GCLs permeated with chemical solutions. Shackelford et al. (2000) provide an excellent overview. Early work by Petrov and Rowe (1997), Petrov, Rowe and Quigley (1997), and Ruhl and Daniel (1997) focused primarily on the effects of organic liquids on the hydraulic conductivity of GCLs. Work expanded to include inorganics (e.g., James, Fullerton, and Drake, 1997; and Shackelford et al., 2000).

In early work, Ruhl and Daniel (1997) permeated five different GCLs using seven permeant liquids (real and simulated waste liquids) and three hydration conditions. When dry GCLs were permeated directly with the real or simulated waste liquids, very high hydraulic conductivities were measured for a simulated leachate with high Ca^{++} concentration. Large increases were also observed when the permeant liquid entering a dry GCL was a very strong acidic or caustic solution. However, when the GCLs were first hydrated with water and then permeated with these same liquids, far lower hydraulic conductivities were observed, although the tests did not continue long enough to develop full breakthrough of the permeating liquids. In contrast, low hydraulic conductivity was observed regardless of the prehydration condition for more dilute, real-world leachates. Guyonnet et al. (2005) found similar effects but studied microstructure and gel phenomena associated with various permeant liquids and prehydration conditions.

The study by Petrov, Rowe, and Quigley (1997) was particularly significant because the investigators mention that effective confining stress could influence the susceptibility of a GCL to chemical alterations when permeated with various chemicals. Few data were presented, however. This is an area ripe for further research. The application of effective confining stress tends to compress and close any cracks or macropores that might tend to form in the bentonite from chemical alterations. For example, data in Figure 4 for a compacted clay demonstrate the potential for large compressive stress to minimize the vulnerability of clay soils to increases in hydraulic conductivity when permeated with aggressive organic liquids.

One of the challenges of hydraulic conductivity testing is the need for long testing time. Jo et al. (2005) took great care to permeate to full breakthrough and equilibrium, but testing times were up to 2.5 years and the tests required as many as 686 pore volumes of flow. Some investigators have tried to correlate the results of relatively fast and inexpensive index tests (e.g., liquid limit and swell index tests) with hydraulic conductivity results to screen bentonite for potential changes in hydraulic conductivity (Lee et al., 2005). Chung and Daniel (2008) experimented with a modified fluid loss test as a rapid indicator for effects from certain liquids. Further research is needed. However, most index tests are performed at zero effective confining stress and may have limited utility because effective confining stress may be one of the most important parameters affecting hydraulic conductivity.

Figure 3. Effect of applied confining stress on hydraulic conductivity of a compacted clay permeated with either water or methanol followed by heptane (after Broderick and Daniel, 1990).

Shackelford, Sevick, and Eykholt (2010) provide a comprehensive assessment of the impacts of tailings liquids on the hydraulic conductivity of GCLs. The tailings liquids tested caused multiple orders of magnitude increase in hydraulic conductivity. The researchers commented on how essential it is to test the GCL with the actual liquids from a project site.

Tests on liquids from other projects (e.g., Lange, Rowe, and Jamieson, 2009b) have not always shown an adverse impact from the waste liquid. Benson, Ören, and Gates (2010) describe tests with a hyperalkaline solution, along with less aggressive solutions, and discuss some of the subtleties involved in this type of testing. Kashir and Yanful (2000) permeated a GCL with a strongly acidic mining drainage liquid and found a significant increase in hydraulic conductivity, though the effect was greatly reduced with the application of high effective confining stress. The actual chemistry of the waste liquid, and the vertical stress to which the test specimen is subjected, can have a significant effect, with the range of impact on the hydraulic conductivity ranging from nil to devastating, depending on the waste liquid.

A special case of occasional interest is the use of GCLs to retain (perhaps temporarily) spilled hydrocarbon fuels or other non-water-soluble organic liquids. Daniel, Shan, and Anderson (1993) and Jahangir and Daniel (1999) demonstrated that the ability of GCLs to retain such liquids (i.e., have a low initial hydraulic conductivity when the liquid contacts the GCL) depends almost entirely on the water content of the GCL at the time when the hydrocarbon liquid

is exposed to the GCL. At low water contents in the bentonite, the hydrocarbon passes readily through the GCL without hydrating the bentonite or causing it to swell. On the other hand, if the bentonite is hydrated with water, capillary tension at the water-hydrocarbon interface tends to exclude the hydrocarbon from even entering the GCL. Rowe, Mukunoki, and Bathurst (2006) tested a GCL that was exhumed from an actual site and exposed to multiple freeze-thaw cycles prior to permeation with jet fuel; results were consistent with other research findings.

To summarize, a tremendous amount of research has been performed on a broad range of liquids that are potentially incompatible with the bentonite component of GCLs. The testing procedures are well established (e.g., ASTM D-6766). The major variables are known. The critical importance of certain parameters such as prehydration with water is understood. The potential for Na^+ to be replaced by polyvalent cations and cause deleterious impacts on hydraulic conductivity is well documented (in fact, this was known decades earlier!). Having acknowledged this large body of knowledge, there still remain considerable uncertainties, which the author views as follows:

- Can quick, simple testing methods be developed and employed to show definitively how the water of hydration in the field at a particular site will influence the hydraulic characteristics of GCLs?
- What are the effects of vertical compressive stress on the behavior of a GCL?

Gas Permeability

The flow of gas through GCLs may be a relevant issue in some situations. Several investigators have examined gas permeability: Didier, Bouazza, and Cazaux (2000), Shan and Yao (2000), and Vangpaisal and Bouazza (2004) were among the early investigators. These studies demonstrate what one would expect: dry bentonite is highly permeable to gas, but once the bentonite absorbs enough water to cutoff continuous air-filled passages through the material, the gas permeability plummets to a very small value. In addition to moisture content, the presence of gas-permeable structure (e.g., needle-punched fibers) and the confining stress (larger confining stress produces lower gas permeability) influence the permeability of GCLs to gas.

Applications in Landfill Covers: Wet/Dry with Chemical Alteration

Melchior (1997) published the results of field tests on landfill covers that had a significant impact on the research community. Melchior found that infiltration rates through low-permeability barriers in landfill cover systems were low for the first several years and then skyrocketed following a severe summer drought. When the materials were exhumed, it was found that cracks had developed and hydraulic conductivity increased. In addition, it was discovered that calcium had replaced sodium as the exchangeable cation in bentonite, causing a significant increase in hydraulic conductivity.

Subsequent studies, primarily by Prof. Craig Benson and his team, demonstrated that wet/dry cycles tend not to be deleterious if there is no alteration of pore water chemistry, but can be very damaging if sodium is replaced by calcium or another polyvalent cation (Lin and

Benson, 2000). The same is true even with gas permeation (Bouazza, Vangpaisal, and Jefferis, 2006).

One of the most important studies was that of Meer and Benson (2007), who exhumed samples of GCLs from four landfill cover systems. At all four sites, Na^+ in the bentonite had been replaced by Ca^{++} and Mg^{++} . Hydraulic conductivities of the exhumed materials varied over 5 orders of magnitude. Meer and Benson report that, "...hydraulic conductivities on the order of 10^{-6} to 10^{-4} cm/s should be expected if exchange occurs coincidentally with dehydration, and the effects of dehydration are permanent once the water content of the GCL drops below approximately 100%." Meer and Benson (2007) as well as Benson et al (2007) note that field results demonstrate that covering a GCL with 760 mm of cover soil does not prevent ion exchange from occurring.

In an even more far-reaching investigation of GCLs exhumed from landfill covers, Scalia and Benson (2011) report that:

- "In most environments, divalent cations likely will replace the native Na^+ in GCLs deployed in composite barriers. Exchange appears to occur more rapidly and completely when the GCL is installed on a subgrade with higher water content."
- GCLs hydrated to a water content of at least 50% seemed to be less vulnerable to changes in hydraulic conductivity caused by ion replacement – one may want to design the GCL to hydrate to this water content or higher, for example, by managing the water content of the underlying or overlying material.

COMPOSITE ACTION OF GCL's WITH A GEOMEMBRANE

"Composite action" refers to the intimacy of hydraulic contact between a geomembrane and underlying low-permeability-soil material. If the geomembrane is in intimate contact with the clay material, liquid will not spread laterally at the interface between the geomembrane and clay even if there is a defect (hole, defect in seam, etc) in the geomembrane. This is the desired situation because intimate hydraulic contact minimizes seepage rates. On the other hand, if there is a highly permeable layer separating the geomembrane from the clay (e.g., layer of sand, transmissive geotextile, or gap such as an opening beneath a wrinkle in a geomembrane), liquid will spread laterally at the interface, and the seepage rate will be much larger because the area of flow through the clay material will be much larger.

Harper, Wilson-Fahmy, and Koerner (1992) performed an early study that quantified the effect of a geotextile at the interface. The results of this and other studies have demonstrated the obvious: flow is much less with intimate contact, and any horizontally transmissive stratum or material between the geomembrane and clay soil is detrimental. The key is the lateral transmissivity of the interface. Transmissivity of compressible materials, such as non-woven geotextiles, is dependent upon the compressive stress. Bouazza and Vangpaisal (2006) demonstrated that the same principles that apply to intimate contact for gas flow, as well.

The need for intimate contact between a geomembrane and clay material is well recognized in the industry (Wilson-Fahmy and Koerner, 1995), and data illuminating the technical parameters are found in various publications, e.g., Barroso et al (2006). Unfortunately, the behavior that promotes excellent hydraulic contact and outstanding composite behavior often requires thin geotextiles that plug from hydrating, swelling bentonite; in such conditions the bentonite swelling into the geotextile may “lubricate” the interface between the geotextile [particularly woven geotextiles, Vukelic, Szaots-Nassan and Kvanicka (2010)] and an adjacent geomembrane. Materials and designs that address the intimate contact problem may be creating another one: low interface shear strength. This remains an area of research opportunity.

One exacerbating factor working against good intimate contact between a geomembrane and underlying GCL is the tendency for geomembranes to wrinkle. Such wrinkles may not be compressed when backfilled (Soong and Koerner, 1998), leaving a transmissive zone between geomembrane and clay. Take et al. (2007) developed a technique to map geomembrane wrinkles from aerial photographs. Prof. Kerry Rowe’s group has documented how extensive the interconnected wrinkles can be (e.g., Chappel et al., 2012), raising further concerns about the deleterious impact of geomembrane waves and wrinkles on composite behavior with GCLs or any other type of low-permeability liner adjacent to the geomembrane.

For many years, the author has been an advocate of encasing bentonite between two geomembranes to achieve maximum hydraulic performance. Giroud and Daniel (2004) provide analytical tools to assist in calculating leakage rates through such systems. The power of such a system, if intact and undamaged, is undeniable. Even with occasional imperfections in the overlying geomembrane, so long as the underlying geomembrane remains intact, the seepage path is typically very long from entrance point in the defect to exit point, which would typically be an overlap in the GCL. Figure 5 depicts the concept.

Figure 5. Concept of a geomembrane-backed GCL installed with geomembrane component facing down, and an overlying geomembrane, creating a long, tortuous seepage path through the bentonite in a manner that tends to minimize seepage.

STABILITY OF GCLS ON SLOPES.

The extraordinarily low shear strength of wet bentonite has been very well known for decades. Shan and Daniel (1991) provided some of the earliest data on shear strength of unreinforced, hydrated GCLs. Gilbert, Fernandez, and Horsfield, D.W. (1996) and Stark and Eid (1996) were among the first to publish shear strength results for internally reinforced GCLs.

For the author, the most significant experience with GCLs on slopes was the construction under EPA sponsorship of multiple test plots in Cincinnati, Ohio (Daniel et al., 1999). The project team included the author, Dr. Robert Koerner, and Dr. Rudolph Bonaparte, with guidance from the EPA project officer, David Carson. Numerous GCL industry sponsors provided materials and installation crews. Multiple test plots were constructed on 2H:1V and 3H:1V slopes, challenging not only the GCL materials but also the interface between GCLs and an overlying geomembrane. All the 3H:1V slopes remained stable for years, but two of the test plots on 2H:1V slopes exhibited failures about 2 months after construction. Failure occurred at the interface between the woven geotextile side of GCLs and a textured geomembrane. In hindsight, it was not surprising that the failures would have occurred because laboratory shear testing performed later indicated interface angles of friction near the slope angles. Gradual hydration was the reason for failure after 2 months and not immediately upon completion of construction. The findings pointed many in the industry toward use of GCLs with non-woven geotextiles on both surfaces to deliver enhanced interface strength for slope applications.

Much research has recently been performed, and continues, to investigate the internal and interface shear strength of GCLs. For example, Fox and Ross (2011) performed extensive testing on critical GCL interfaces and studied the large deformations. McCartney, Zornberg, and Swan (2009) present a database of 534 large-scale direct shear test results for interface strength test results between GCLs and geomembranes.

From the author's perspective, the key question is whether the engineering design community has the capacity to employ GCLs on slopes in a safe, cost-effective manner. For the most part, the author believes that the community has this knowledge and capacity. Testing methods are now well developed, e.g., ASTM D-6243 for direct shear testing. Experience with this type of testing is extensive, and databases have been published in the open literature. Field cases have correlated reasonably well with laboratory-measured results. Laboratory testing has helped clarify various critical parameters, such as impact of hydration, confining stress, and deformation, when in turn has pointed designers toward thinking holistically about design. There is need for further research, but from the author's perspective, the first-order questions about GCL shear strength have been asked and answered, and we are now in the process of exploring some of the finer points at issue.

PHYSICAL INTEGRITY OF GCLs

One of the issues identified early in the study of GCLs is the potential for stones or other objects to displace bentonite and thin the GCL. Koerner and Narejo (1995) studied the bearing capacity of GCLs and concluded that if a load of width B is placed a distance H above the bentonite layer (separated by a layer of sand, for instance), there was little or no thinning so long as the H/B ratio was greater than 1 to 2. Fox et al. performed independent research with similar study objectives but different technique, and came to essentially the same conclusion, i.e., there

is not much problem so long as $H/B \geq 1$ to 1.5. This general area of research is an example of a question that has essentially been asked and answered.

Several researchers have studied the penetration of gravel particles or stones into hydrated GCLs. Fox, De Battista, and Mast (2000) placed gravel with a particle size up to 50 mm directly above the GCL, and applied vertical stress. Although there was thinning beneath gravel particles, the hydraulic conductivity was within acceptable limits. Dickinson and Brachman (2006) measured the thinning of GCLs from gravel (50 mm) placed above a geomembrane/GCL composite liner. Thinning was significant without adequate protection. Dickinson, Brachman, and Rowe (2010) examined the intrusion of GCLs into a geonet, and thinning of the GCL caused by ribs in the geonet indenting the GCL. The investigators found some thinning of the GCL, but no deleterious impact on hydraulic conductivity. An object that tends to penetrate into and thin the bentonite may also tend to consolidate the bentonite into a lower-porosity, less permeability material that offsets impacts of thinning. The thinning of GCL accompanied by lateral flow of bentonite away from the thinned zone is the primary source of concern.

Shrinkage of GCLs can cause problems, independent of changes in hydraulic conductivity, such as reduction in the width of overlaps. Many variables influence the shrinkage of GCLs, as described by Rowe, Bostwick, and Take (2011).

A GCL placed at shallow depth without protection such as that afforded by an overlying geomembrane may be vulnerable to penetration by and damage from plant roots. In shallow environments, a suitable geomembrane or other barrier over the GCL may be the most effective way to prevent roots from penetrating the GCL.

EQUIVALENCY OF GCLs TO COMPACTED CLAY LINERS

In the early days of GCL use for waste disposal applications, the regulatory agencies did not know how to deal with evaluating GCLs. The very first use by Schubert (1987) involved use of a GCL that went beyond the minimum requirements – thus, there was relatively little difficulty in gaining regulatory acceptance. The real issue was whether a thick, compacted clay liner could be replaced with a GCL. As mentioned earlier, the advantages of GCLs over compact clay liners represent considerable motivation for owners.

To gain regulatory acceptance, the argument was advanced that if a GCL's performance could be shown to be equivalent to or better than that of a compacted clay liner, then the regulatory agency might approve substitution of a GCL for a compacted clay liner. Most of the attention focused on demonstrating the hydraulic equivalency of a GCL to a compacted clay liner, which must typically have a hydraulic conductivity of $\leq 1 \times 10^{-7}$ cm/s. Equivalency analysis for this factor is a straight-forward calculation of seepage quantity based on Darcy's law. Generally speaking, there was not much difficulty demonstrating this efficiency for low hydraulic heads acting on GCLs with hydraulic conductivities in the 10^{-8} to 10^{-9} cm/s range.

No standardized set of ground rules exist for how to establish equivalency.. Publications such as Koerner and Daniel (1994) may provide some guidance. The sticking point in such analyses is the set of parameters that will be considered. For example, will chemical release from

the liner be considered, even though it is not mentioned in the regulations? Because most U.S. regulations for waste containment focus almost entirely on thickness and hydraulic conductivity of the compacted clay liner, an argument can be made that such considerations are beyond the scope of the regulations and beyond the scope of an equivalency demonstration.

One of the areas in which GCLs are different from compacted clay liners is their ability to retard release of chemicals via diffusion. Diffusion is the transport of chemicals across a barrier in response to a chemical gradient. The key parameters, for a given chemical and concentration of the chemical in a landfill or lagoon, are diffusion coefficient in the barrier material (bentonite in the case of a GCL) and thickness. The thicker the barrier, the less the diffusive release. The thinness of GCLs makes them inherently a comparatively poor barrier to diffusive release, unless the chemical itself tends not to diffuse readily through bentonite. Most chemicals do diffuse through bentonite, but some species will be absorbed by bentonite and diffuse more slowly.

Lake and Rowe (2000) provide a useful primer on diffusion of inorganic elements through GCLs. Lange, Rowe, and Jamieson (2009a) provide an extensive compilation of information regarding the diffusion of metals through GCLs. Diffusion coefficients for a range of metals did not vary a great deal from one another. The techniques for measuring diffusion coefficients are well developed (Rowe et al., 2000), as are methods for analyzing diffusive transport through the bentonite component.

The diffusion of VOCs through relatively thin GCLs may be of more concern than diffusion of metals because VOCs can migrate in liquid or gaseous phase. Gaseous-phase diffusion presents a risk for transport away from many waste containment facilities. Paumier et al. (2011) investigated the impact of calcium exchange, which is known to have potentially significant deleterious impact on hydraulic conductivity, upon the rate of diffusion of VOCs through bentonite. Although there was a small change in diffusion rates for Na and Ca-rich bentonite, the impact was small and the authors note that, “The increase in the diffusion coefficient of VOCs, thus, does not seem to be of concern for the range of GCL hydraulic conductivities generated by cation exchange in this study.”

The author considers this area of research relatively mature and well developed – the primary questions relate to complexities in the system, such as coupled effects from large thermal gradients, coupled liquid/vapor transport, biological processes integrated with physical and chemical processes, and complexities from multiple landfill components, e.g., composite action of a geomembrane and GCL.

ADVANCES IN MATERIALS AND DESIGN

Over time, there have been many advances in GCL design, including use of different types of geotextiles, heat burnishing surfaces of geotextiles to strengthen the material, incorporating a geomembrane in the GCL system, and others. The creative use of geosynthetic materials will undoubtedly continue to evolve and to create even more options for GCLs.

Engineering the bentonite itself has been the subject of much research. These efforts have included study of different types of bentonites (e.g., Lee and Shackelford, 2005), additives (chemical and physical), and well as chemical alteration of bentonite. For instance, with respect to physical additives, Schmitt et al. (1977) tried adding two granular materials (expanded shale and recycled glass) to strengthen the bentonite and ameliorate the problem of low shear strength of GCLs. They found that very low hydraulic conductivity was observed in the mixtures with up to 50% additive to the bentonite, and that the additives significantly improved the shear strength of the mixture, particularly at high normal stress. It is perhaps a little surprising that, over the years, more work has not been performed to examine additives that would strengthen the bentonite, especially since low strength of hydrated bentonite is such an important issue for GCLs. Probably the practical reason is that there are other ways to deal with shear strength challenges.

Much research, proprietary and public, has been performed regarding the use of polymers as additives to bentonite, and several forms of commercial products are available with polymer additives. Polymers are discussed in the literature (e.g., Ashmawy et al., 2002; McRory and Ashmawy, 2005, and Razakamanantsoa, Barast, and Djeran-maigre, 2012). The proprietary nature of these additives makes broad conclusions difficult, other than to note that polymer additives almost always tend to reduce hydraulic conductivity to water and to improve resistance to alterations from many chemicals. Perhaps their main drawback is cost.

Organo-bentonites are another material alteration designed to minimize the vulnerability to deleterious alterations in hydraulic conductivity caused by certain chemicals. Test results typically show that the bentonite can be stabilized against degradation from permeant liquids (e.g., Lorenzetti, Bartelt-Hunt, Burns, and Smith, 2005; and Katsumi et al., 2008).

LOOKING TO THE FUTURE

As the author prepared this paper and reflected on 25 years of research on GCLs, he was struck by how much has been learned. An entire body of knowledge has been created from essentially nothing. To the many researchers, manufacturers, and design engineers, he offers sincere congratulations on a job well done. The profession has methodically identified questions, studied them, and sorted through the findings to reach conclusions. Engineering practice associated with GCLs rests on a solid base of knowledge.

As the author looks forward, several areas of change and advancement may be desirable and are offered for consideration:

1. More use of bentonite sandwiched two geomembranes (Figure 5) is encouraged. This type of liner offers the opportunity for significantly enhanced hydraulic performance compared to many other systems. The potential for enhanced performance is not just a little – the system may be orders of magnitude less permeable than a single geomembrane overlying a bentonite layer. Concerns include slope stability if the bentonite hydrates (which should occur exceedingly slowly).
2. More use of a protective layer beneath GCLs to mitigate impact of any unforeseen puncture and to limit diffusive migration of chemicals is suggested. In some ways, the

author's favorite composite liner system would be the one shown in Figure 5 underlain with perhaps 300 mm of a moderately low-permeability material (say 10^{-6} to 10^{-7} cm/s). This low-permeability material serves as a fail-safe material in case the geosynthetic liner system is punctured, and also serves to enhance diffusion impedance of the system. By using a hydraulic conductivity greater than 10^{-7} cm/s, cost can be controlled.

3. More consideration of site-specific conditions in GCL design is recommended. This suggestion is focused primarily on the hydration of the GCL and the impacts that the site-specific soils, pore fluids, and overall conditions will have on GCL performance. This issue deserves more research but, ultimately, simple methods are needed by the design engineer.
4. Better management of wrinkles in geomembranes is advised. Geomembrane wrinkles exacerbate the challenge of achieving intimate contact. It seems unwise to the author to go to great lengths to engineer a high quality GCL and then not go to great lengths to ensure intimate contact of the geomembrane with the GCL.
5. More selective less use of GCLs in near-surface environments is recommended. Experience shows that the application of vertical compressive stress tends to compress bentonite and enhance its stability. More research on this effect, particularly for permeation with chemicals, is needed. But placing GCLs near the surface with very little vertical confining stress and sometimes very little protection creates an inherently challenging situation. More thought should be given as to whether GCLs are really the best design choice in near-surface applications with very limited protection afforded the GCL.

ACKNOWLEDGMENTS

The author's early work on GCLs was supported by the US EPA without whose support so many advances in GCL knowledge and use would not have been possible. Special thanks are due to Bob Landreth, Walter Grube, and David Carson.

In the early days of the author's GCL research, several industry representatives provided critical collaboration, information, and in many cases research support. Special thanks are due to Jim Anderson, Richard Erickson, Tom Stam, Jim Olsta, and Kent von Maubeuge.

The author had the pleasure of collaborating with numerous consulting engineers on various projects, and he is grateful to all for these opportunities. Special appreciation is extended to Rudy Bonaparte, J. P. Giroud, Mario Manassero, Greg Richardson, and Rick Thiel.

None of the author's research contributions would not have been possible without the insights, creativity, and dedication of numerous graduate students working with the author. Special thanks are given to Paula Estornell, Tom Boardman, Mark LaGatta, Mark Gleason, Ben Cooley, Juniran Lai, Heather Scranton, Hsin-yu Shan, Karen Schmidt, Ashraf Jahangir, and Jin Chung.

The group of academic researchers involved in study of GCLs has been is a relatively small, close-knit group of individuals with whom the author has deeply enjoyed sharing research findings and ideas. Special thanks are extended to Bob Gilbert, Steve Wright, and Ed Kavazanjian, and Grace Hsuan.

Three individuals have had a particularly profound impact on the author's career and thinking about GCLs. The author thanks Roy Olson for teaching him a way of thinking (about bentonite and many other things), to Steve Trautwein for numerous helpful ideas for testing materials and for his superb equipment, and to Robert Koerner for his brilliant mind and deep wisdom that helped to guide the thinking and practice of not only this individual but numerous others, as well.

GEOFOAM: HISTORY OF THE LIGHTWEIGHT CONTENDER

Archie Filshill
InterGEO Services, Trevoise, PA

ABSTRACT

Although geofoam has been around for over 40 years, it has not been utilized fully in the United States until the last 10 years. The growth in the US market can be attributed to the growing need to build on sites that were previously considered “unsuitable” for construction activity. Highway realignments, backfill against existing structures, increased fill over existing utilities and underground structures are examples for the recent growth of geofoam applications in the USA. In recent years, as geofoam has become more accepted, it has gained visibility in textbooks and short courses. A definition of Geofoam from “Designing with Geosynthetics” defines the product as follows: “A block or planar shaped rigid cellular foamed polymeric material used in geotechnical engineering applications.”

INTRODUCTION AND BACKGROUND

There are several materials capable of being used for geofoam applications but for the purposes of this paper, expanded polystyrene geofoam will be focused upon. Expanded polystyrene (EPS) is created by sand sized particles of styrene resins being supplied to a geofoam “molder”. The molder expands the styrene resin into small cellular spheres using pentane gas. These gas filled spheres are expanded in bulk into a mold. This mold creates relatively large blocks of polystyrene. Standard blocks sizes are approximately 1m x 1m x 2.5m.

Various types of rigid plastic foams were first developed circa 1950 and used mainly for thermal insulation. Thermal insulation properties are created by the 98% gas by volume within the expanded polystyrene. The two most commonly used foams in construction are extruded polystyrene (EXP) and expanded polystyrene (EPS). EXP is more commonly used as insulation boards in 25 to 50 mm thicknesses in foundation applications. The primary function is insulation and puncture protection of foundation waterproofing.

Today, the primary applications of geofoam include lightweight fills, compressible inclusions, thermal insulation, vibration damping, fluid transmission, and structural support. Geofoam is often capable of combining several of these functions into one application; see Figure 1.

Figure 1 - First picture author remembers seeing geofoam used in an advertisement.

TIMELINE OF MAJOR APPLICATIONS

The first geotechnical application (other than of thermal insulation) was for roadway, airfield and railroad foundations in Europe. The application was of particular interest in Scandinavia where permafrost was causing severe damage to roadways. The application used geofoam as an insulator to reduce the effects of permafrost in subgrades. Dr. G.A. Leonards, Professor of Civil Engineering at Purdue was granted a patent in 1966 for this application. Geofoam is the lightest of all the lightweight fill options from 1 to 3% of the weight of soil. A major recent application includes backfill behind bridge abutments as shown in Figure 2, so as to reduce lateral loads and/or reduce surcharge loads on underling soils.

Figure 2 – Lateral load reduction on bridge abutments (Courtesy of Geofoam Research Center).

Use in such geotechnical applications started in the 1960's. The first use of EPS in a geotechnical application in 1965 was done in Norway. To date, there have been over 500 roadway projects completed in Norway.

Late 1960s – Frost Protection was utilized in Germany

1965 – Oosterbaan, M. D. and Leonards, G. A., "Use of insulating layer to attenuate frost action in Highway Pavements", Highway Research Record No. 101, Highway Research Board, Washington, D.C., U.S.A., pp. 11-27.

1972 – First road embankment project in Norway

The Flom Bridge in Norway was the first roadway application for geofoam. The effects of permafrost and reconstruction with geofoam are shown in Figure 3.

Figure 3 – Reduction of permafrost effects at the Flom Bridge (Courtesy of Norwegian Public Roads Administration).

Early 1970s – First EPS geofoam projects in The Netherlands

Mid to Late 1970's –EPS used during the famed oil-pipeline construction in Alaska

1985 – First Abutment backfilling and road construction on soft ground in Japan

1985 – First Conference on Geofoam held in Oslo. Norway

The conference was a one day event held on June 25th sponsored by the Directorate of Roads, Norwegian Road Research Laboratory and Norwegian Plastics Federation. The title of the conference was "Plastic Foam in Road Embankments, A New Way of Solving Soft Ground Problems". There were 150 attendees, 5 papers presented and 12 case histories that reviewed the past 13 years of experiences.

1987 – First known highway use in USA, was in Durango, Colorado, on a landslide repair for Highway 120

The Colorado Highway 160 slope stabilization project between Mesa Verde National park and the City of Durango in southwestern Colorado is the earliest known use of EPS-block geofoam for slope stabilization and repair. Details of this case history can be obtained from Yeh and Gilmore (1992). The slide, covered an area of approximately 0.4 ha and involved about 8,410 cubic meters of slide material. The soils that failed were removed and the embankment was rebuilt with geofoam.

1990 – 14th Green at Coeur d' Alene Resort, Idaho

One of the more popular well known uses of geofoam, although not geotechnical, is the floating green at Coeur d'Alene Resort in Idaho; see Figure 4.

Figure 3 – A geofoam floated golf course green (Courtesy of WorldGolf.com).

1992 – The word “Geofoam” was termed within the geosynthetics industry

1994 – Second Conference on Geofoam held in Honolulu, Hawaii

An international symposium on polystyrene geofoam in below ground applications was organized by Prof. J. S. Horvath of Manhattan College. Seven papers were presented along with a field trip to a lightweight embankment.

Late 1990’s – First Levee - Torne Levee in the United Kingdom

1995 – A 217 page book by J. S. Horvath titled “Geofoam Geosynthetic” was published.

Horvath’s book includes an overview of materials, current standards, a comprehensive description of the types of geofoam products available, constituent materials, and manufacturing processes. It describes the material properties of different geofoam products in the context of geotechnical engineering applications and discusses recommendations for additional standards development and for future research.

1996 – Third Conference on Geofoam held in Tokyo, Japan

This conference had 300 attendees and 33 papers submitted. The conference was titled “International Symposium on EPS Construction Method”.

1997 – Geofoam Research Center was established.

The Geofoam Research Center (GRC) at Syracuse University was formed by Prof. Dwight Negussey. It is dedicated to research of geofoam properties, development of innovative applications, dissemination of technical information and technology transfer through education. The center has assisted manufacturers, engineers and contractors with both large and small projects. GRC has given technical seminars to state department of transport staff, consulting engineers and university audiences. Development of standards and performance verification of geofoam projects are also areas of interest of GRC. The center was established in 1997 through industry support.

1997-2001 – I-15 project Salt Lake City, Utah using 0.28 million cubic meters of geofoam

The I-15 project was a \$1.5 billion design/build project to reconstruct 27 kilometers of roadway through Salt Lake City in preparation for the 2002 Winter Olympic Games. The project required 160 MSE walls with vertical fills. Geofoam was selected to minimize settlement under the fill and eliminate damage to underground utilities; see Figure 5.

Figure 5 – I-15 lightweight fill project in Salt Lake City, Utah.

2001 – First Geofoam Bridge Approach in the USA- Buffalo Road Bridge, Warsaw, NY

A replacement bridge consisting of pre-stressed concrete box beams with a composite concrete deck having a span length of 26 m utilized expanded polystyrene (geofoam) fill and a large spread footing. This was the first use of geofoam for bridge structural support in the United States. The bridge is currently being monitored by the Geofoam Research Center.

2001 – Fourth Conference on Geofoam held in Salt Lake City, Utah
There were 160 attendees at the conference with 44 published papers.

2005 – ASTM D6817-11 Standard Specification for Rigid Cellular Polystyrene Geofoam

Abstract from ASTM D6817 - This specification presents the types, physical properties, and dimensions of rigid cellular polystyrene (RCPS) intended for use as geofoam. This specification, however, does not address the layout, placement, and workmanship for proper installation and performance of the geofoams. RCPS geofoams shall be formed by the expansion of polystyrene resin beads or granules in a molding process (EPS), or by the expansion of polystyrene base resin in an extrusion process (XPS). They may also be manufactured with reprocessed polystyrene foam (regrind). The RCPS geofoams shall meet combustibility and curing requirements and, when tested, shall adhere to physical property requirements such as dimensions and density, compressive resistance, flexural strength, and oxygen index. Final products should also meet surface damage, volume damage, and UV degradation limits.

2005 Woodrow Wilson Bridge – Route 1 Bridge Approach using 20,000 CY Geofoam

In this project, geofoam was selected as a lightweight fill so as to expedite construction of the US Route 1 bridge approach along the Washington DC beltway. Existing soft soils and underground utilities made geofoam a natural choice for Virginia Department of Transportation and the Federal Highway Administration (FHWA). The project used over 20,000 m³ of geofoam and resulted in a 10 m embankment with the roadway placed directly on top of the geofoam; see Figure 6.

Figure 6 – Rt. #1 bridge approach in Washington, DC (Courtesy of InterGEO Services).

2006 – FHWA Priority; e.g., “Market Ready Technology”

Benefits listed by the FHWA with regard to geofoam include:

- Accelerates foundation construction.
- Reduces project schedules times.

- Saves money.
- Requires limited labor for construction.
- Exerts little to no lateral load on retaining structures.
- Can be constructed easily in limited right-of-way areas and in adverse weather conditions.

2008 – FHWA New Technology; e.g., “Functional Technology”

2010 – Geofoam had been used on State DOT projects in most states in the U.S.

2011 – Fifth Geofoam Conference in Lillestrom, Norway

The two day conference was titled “Geofoam Blocks in Construction Applications”. It had 42 papers submitted and 38 papers presented.

NEW APPLICATIONS AND RESEARCH

New applications in Norway include the use of geofoam as the entire embankment fill for a temporary bridge over “quick clay” as shown in Figure 7a and detailed in Figure 7b.

Figure 7a – Temporary bridge abutment over quick-clay (Courtesy of Norwegian Public Roads Administration).

Figure 7b – Cross section of both temporary bridge abutments (Courtesy of Norwegian Public Roads Administration).

Current research on geofoam is focused on long term creep resistance and use of recycled materials. Additionally, the use of geofoam as a seismic buffer, was started in 2007 at Queens College by Richard Bathurst.

CONCLUSIONS

Although geofoam has a long successful history throughout the world, it has not been used extensively until recently in North America. As exhumed samples from early projects show excellent performance, market acceptance is growing. The interest of the technical community regarding geofoam continues to challenge its material properties so as to increase the type of applications, including high risk projects. This lightweight contender continues to prove itself 40 years after its initial introduction into the civil engineering community.

A 25-YEAR PERSPECTIVE ON WASTE CONTAINMENT LINER AND COVER SYSTEM DESIGN USING GEOSYNTHETICS

Richard Thiel

Thiel Engineering, Oregon House, CA USA

1. INTRODUCTION

This paper presents the perspective of one design practitioner regarding changes that have occurred in the industry over the past 25 years – particularly as related to the design of waste containment systems using geosynthetics. An effort has been made to present practical changes that have taken place in approaches to design, rather than advances in academic theory. Given the practical limitations of a single person writing an overview of this topic, there are bound to be biases in emphasis and subject matter related to the author's perspective and experience. In this regard the author asks forbearance from the readers, and welcomes any feedback from industry peers.

The author entered the field of waste containment engineering in 1986, at the very beginning of the 25-year retrospective period addressed in this paper, and his first projects were the design and evaluation of two major double-lined hazardous waste landfills, one in Illinois and one in California. It is interesting to observe that there is no significant difference between what we see looking at a set of design drawings from the Kettleman Hills Hazardous Waste Landfill project from 1987 (a detail is shown in Figure 1), and a set of drawings for a landfill design that would be produced today. We know, however, that there has, in fact, been a significant increase in the understanding we bring to current design approaches for these types of facilities, compared to the understanding we had 25 years ago. The aim of this paper is to highlight these changes in our approach to design that have taken place in the past generation.

Despite these advances over the past 25 years, important and fundamental questions continue to linger in the minds of designers, regulators, and owners, albeit tempered with greater understanding. Some examples of these persistent questions are:

- How long will these materials last?
- How much redundancy do we need?
- What should be the factor-of-safety? (or reliability?)
- Do we really need CQA?
- What kind of liner system is best, and how thick should it be?

Figure 1. Detail of actual hazardous waste liner system design from 25 years ago.

2. WHAT IS A CONTAINMENT LINER SYSTEM?

What is a liner system? This is a fundamental question that deserves brief mention. In general, the author defines it as a barrier layer that has a lateral drainage layer above and/or below it, as illustrated in Figure 2. This simple concept helps us focus our discussion on the value of materials that serve as a barrier to fluids (e.g., geomembranes and GCLs), versus those that provide a transmissive layer to fluids (e.g., geonets and geocomposite drainage layers), or that serve as a protective layer for one of these two functions (e.g., a geotextile filter, or a geotextile puncture-protection layer).

Figure 2: Schematic of author's definition of a liner system.

3. A COMMENT ON REGULATIONS GOVERNING WASTE CONTAINMENT LINERS AND COVERS IN THE USA

The containment industry is largely driven by regulations, as good regulations have proved essential for the proper long-term stewardship of our environment. Using U.S. regulations as a benchmark, we can generally say that the regulations that require liner systems for waste containment facilities came into being at the beginning of the 25-year period we are reviewing, as RCRA Subtitle C (hazardous waste) was promulgated in the early 1980's, and RCRA Subtitle D (municipal waste) in the early 1990's. These regulations essentially required single-composite bottom liners (with an extra geomembrane liner and lateral drainage layer for Subtitle C), with an overlying lateral drainage layer to collect leachate. The cover systems were also required to be single-composite liner systems. Very few changes have been made in these basic regulations since that time, other than allowing for some alternative design approaches. From this point of view, it is not surprising that a set of design drawings for a Subtitle C landfill in 1987 looks quite similar to a set of design drawings for a landfill today.

The environmental performance record of landfills constructed in the past 25 years has indeed been quite good, confirming the wisdom of the regulatory approach outlined in the 1980's. Indeed, we have definitely gotten our arms around the issues, and have them more or less contained (!). Meanwhile, as we examine new understandings gained from continued academic research, material improvements developed by manufacturers, experience gained in construction and operations, ingenious engineering solutions, lessons learned from failures, and approaches being developed by our neighbors around the world, we see definite indications that the industry has steadily advanced in its understanding over the past generation. And these improved materials, practices, and understandings will certainly continue in the next generation. Any suggestions for improvement that may be implied in this paper should by no means be considered as criticism of past implementations and approaches. Far from it. The U.S. - its industry regulators, owners, operators, engineers, technicians, contractors, and citizen-users - has done an excellent job of implementing a great infrastructure for "housecleaning" and environmental management that should be, and often is, the envy of other nations.

4. LIST OF TOPICS ADDRESSED IN THIS PAPER

To provide the reader with a quick reference of the topics that are addressed in this paper, the following list presents the order of the topics presented. Since the topics have been numbered to provide easy location, the headings before this section are included for completeness.

1. Introduction (previous to this section)
2. What is a containment liner system? (previous to this section)
3. A comment on regulations governing waste containment liners and covers in the USA (previous to this section)
4. List of topics addressed in this paper (this section)
5. Brief discussion of geosynthetic materials

6. Contaminant transport
7. Aging durability and geomembrane service life
8. Slope stability
9. Steep-slope bottom liner systems
10. Piggyback liner systems
11. Lateral drainage design
12. Details related to penetrations and attachments
13. Details related to anchor trenches
14. Exposed geomembrane covers
15. Ponds
16. Secondary containment around tanks
17. Construction, CQA, and specifications with regard to design considerations
18. Moving into the future

5. BRIEF DISCUSSION OF GEOSYNTHETIC MATERIALS

In deciding what to write about in greater detail and what to skim over with a passing reference, the author has elected to focus narrowly on specific design approaches. Several excellent papers are being presented at this conference that discuss our past generation of experience regarding different types of geosynthetic resins, additives, manufacturing methods, standards for testing, standards for specifying, and standards for installation and CQA. For this reason, geosynthetic materials in themselves are discussed only briefly in this section.

The following is a concise list of topics relative to geosynthetic materials which, from the author's perspective as a design practitioner, are significant relative to design. A check mark (✓) appears beside those topics that are described in more detail. Where there is no (✓), the reader is encouraged to review other papers from the proceedings of this conference to learn more about those subjects.

Geomembranes

A list of geomembrane-specific issues of acknowledged significance that have been addressed to a greater or lesser degree in the past 25 years, includes:

Long-term chemical compatibility: This was a major effort early on, and a lot has been learned in this regard. Early chemical immersion and index testing, which was developed by Dr. Henry Haxo, resulted in EPA Test Method 9090. That has since been superseded by ASTM D5322 and D5747 and related standards. Chemical compatibility charts are typically available from

manufacturers, and these test methods are available for testing against specific chemical environments.

Advances in resins and products. Manufacturers have been the driving force for the development of an ever more efficient and useful selection of geomembrane materials, and market dynamics have conspired to retire some of the less efficient products. A good example of this is chlorosulphonated-polyethylene (CSPE), long-marketed under the trade name of Hypalon. Initially a major player in the exposed geomembrane market, its high cost and a number of technical issues caused it to all but disappear from the North American market (though the formulation is still available from an Asian producer), and its function has largely been replaced by reinforced polypropylene (PP-R). The PP-R material suffered a temporary setback in popularity in the early 2000s as durability failures started to show up. It turned out that a number of manufacturers had skimmed on the antioxidant additive packages, but this problem has since been recognized and corrected. Another significant product development that has had a major impact on the design and use of geomembranes, and which did not exist at the beginning of our 25-year review period, was the use of textured surfaces on polyethylene geomembranes. These new surfaces provided much greater interface shear strength characteristics against various soils and other geosynthetics, which the industry has aggressively utilized ever since. These are only a few examples of numerous product developments that have occurred in association with geomembranes, and others will undoubtedly continue to be developed in the future.

Installation and seaming: There have been significant advances in our understanding of good installation and seaming practices, and of seaming equipment for thermoplastics. Perhaps the most significant development in seaming equipment was the introduction of hot-wedge welding for thermoplastic geomembranes, which took place near the beginning of our 25-year review period. Since that time, various improvements to seaming equipment have been made by different manufacturers, but the fundamentals of providing good welds have essentially remained unchanged over these past 25 years. Now as much as ever, good operator training, attentiveness, and CQA are the keys to successful welding.

Testing and specifying: Refined methods of testing and specifying have been developed through the efforts of GRI and ASTM, and the collaboration of manufacturers, designers, and testing laboratories. As an example in our industry, GRI GM13 became an industry cornerstone for specifying HDPE, and serves as an ongoing example for other materials. ASTM subcommittee D35 has developed a plethora of standards and guides for the testing and installation of geomembranes.

Wrinkles: An increased understanding of the development and control of wrinkles, and wrinkles as a design consideration. (√)

Allowable strain: An increased understanding of puncture protection and long-term durability issues. (√)

Soil cover: An increased understanding of procedures for covering with soils.

ELL surveys: An expanded use of electrical leak location (ELL) surveys on both bare and covered geomembranes.

Slope stability: An increased understanding of slope stability. (√)

The desiccation of materials underlying exposed geomembranes: An increased appreciation of the dynamics involved.

Ponds and Reservoirs: Not much fundamental change in the approach to pond design, but a refined understanding of pond design issues. (√)

Development and use of Exposed Geomembrane Covers (EGCs). (√)

Contaminant transport: An increased understanding of leakage prediction and contaminant transport. (√)

Penetration and Connection Details: Increased appreciation for details related to connections and penetrations – an area where the industry can find great room for improvement. (√)

Repairability of aged and exposed liners: We are continually learning in this area, as facilities are continually aging.

GCLs

The past 25 years could be said to be “the generation of GCLs”, since this is the period in which they were introduced and developed, and standards were established for hydraulic conductivity testing, index and performance testing, seaming, needle issues, deployment and handling, construction, and durability issues. The major technical issues that affect liner design, and which are still the subject of ongoing evaluations, include:

Product innovations: Many different types of products have been promoted that include different bentonites and different carriers, including polymer-amended bentonites.

Equivalency with compacted clays.

Cation exchange: Much attention has been given to cation exchange in bentonite for different conditions of hydration, normal loads, liquids, soils, peptized bentonite, polymer-amended bentonite, and solo GCL vs. composite vs. encapsulated GCLs.

Shear strength: An increased understanding of interface vs. internal shear strength; peak vs. post-peak; effects of different hydration methods; encapsulation. (√)

Hydration mechanisms: Advances in our understanding of the hydration of GCLs set on a subgrade; encapsulated GCLs, and the quantification of hydration mechanisms and rates (see Thiel et al., 2001).

Panel shrinkage. The issue of GCL panel shrinkage has received a lot of attention since the author first reported gaps in GCL panels that had originally been overlapped (Thiel & Richardson, 2005). Although there have been numerous published studies and great advances in our understanding of this issue since that time, the author of this paper feels satisfied that a pragmatic solution has been found, which is to simply heat-tack all fabric-based GCL seams, as described in Thiel & Thiel (2009).

Geonets and Geocomposite Drainage Layers

Geosynthetic drainage layer products have been available since the early 1980's. New products continue to be developed, which include bi-planar and tri-planar products, as well as cusped sheets, nubbed-surfaces on geomembranes that are then covered with a geotextile, and drain-tubes encapsulated in geotextiles that are offered as alternatives. Stouter materials that are able to handle long-term high loads are also available.

Laminated geotextiles that form a 'geocomposite': In the late 1980's, geonet products laminated with geotextiles were not even available, and today they are so pervasive that the term "geocomposite" is used almost synonymously to refer to a geonet laminated with a geotextile. The techniques and specification for lamination (viz. peel strength) has improved over this time, along with our understanding. (√)

Transmissivity: We have seen greatly improved understanding of how to measure and how to design, using the transmissivity offered by these products for lateral drainage in different situations. (√)

Clogging: There is lack of long-term data regarding chemical and biological clogging of these materials, especially in bottom liner applications, and we can expect that more studies and understanding will be gained in the future.

Geotextiles (specifically those related to filtration and puncture protection)

Filtration: Over the past 25 years there has been improved understanding and elucidation of the geotextile filtration function (Giroud 2010). The science and theory of geotextile filtration has been greatly advanced in terms of a better understanding of the relationship between granular and geotextile filters, the role of the hydraulic gradient in filtration, the relationships between fiber geometries, minimum thickness and porosity requirements (or the percent of open area for woven geotextiles), the effective filtration opening size, etc. That said, there may be a gap between the available knowledge base versus the actual practices used in containment engineering (this might be different in another field such as dam engineering, where filters are much more critical, JP Giroud, pers. comm.). In general, there has not been a great incentive for sophisticated filter design in landfill engineering, so any number of older standard methods or rules of thumb are often utilized in material selection in this commodity-driven market. The author tends to use Leuttich et al. (1991), which is over 20 years old, as his filter design reference.

Puncture Protection: An improved understanding and improved specification for puncture protection (cushioning) methods. Rational approaches have been developed for evaluating the effectiveness of candidate geotextiles for specific puncture-protection applications. The long-term applicability of the different approaches remains an open question, as the advocates of different views can present significant differences in their final recommendations. (√)

NWNP Manufacturing: Although the manufacturing capabilities for nonwoven needlepunched (NWNP) geotextiles allow for the creation of fairly specialized products in terms of denier size, fiber cross-sections, fiber lengths, wettability, polymer, and degree of needle punching, in North

America, these products have been, and continue to be widely commoditized using the same polymers (primarily PP in North America, though PET was formerly used and is still used in China; this is a market decision), with relatively fine 6-denier fibers. While there have been and will continue to be product innovations, the majority of products will likely continue to be offered in much the same fashion as they have for the past two decades.

Testing and specifying: Specified index and performance tests have remained relatively constant over the period, albeit with some fine tuning.

Durability. Geotextiles are used by themselves, as well as in conjunction with products such as geosynthetic drainage layers and GCLs. The long-term durability of geotextiles relative to their intended functions of providing filtration, separation, and interface shear strength is still a question of interest. Research is being conducted in this regard, and its outcomes will undoubtedly influence the practice of design in the future.

6. CONTAMINANT TRANSPORT

The goal of designing containment systems is to reduce the transport of contaminants into the groundwater to an acceptably low level for the contaminating life of the facility. Models of contaminant transport mechanisms and rates are used to make permitting and design decisions. In general, two different mechanisms of contaminant transport through landfill liners are actively discussed in today's literature: advection and diffusion. Advection, commonly referred to as 'leakage', is governed by Darcy's law, in which the flow through defects and soils is governed by the head buildup on the top of the liner system. Diffusion involves the migration of chemical constituents through intact media based on Fick's law; it is concentration-driven, independent of gravity and head conditions. Both transport mechanisms increase with an increase in temperature, so that landfill operating temperatures have a significant effect on contaminant transport. See Rowe (2005) for further discussion of these mechanisms.

The USEPA regulations for MSW landfill base liner requirements (RCRA Subtitle D as codified in 40 CFR Part 258, paragraph 258.40) are written to cover two different approaches. Paragraph 258.40(a)(1) is a performance-based standard to protect groundwater. Paraphrased, the regulation in 258.40(a)(1) states that contaminant transport through a liner system must result in no more than the specified prescriptive maximum contaminant levels stated in the regulation. This performance-based regulation requires the applicant to demonstrate, usually through the modeling of contaminant transport, that the proposed design will comply with its terms. As an alternative to the performance-based approach, paragraphs 258.40(a)(2) and (b) provide a prescriptive design basis for the liner and leachate collection system. If the prescribed design criteria are fulfilled, the design is presumed to meet the groundwater protection standards and no contaminant-transport modeling is required. These are the two well-known design standards for a single-composite liner and overlying leachate collection layer in the U.S.

The EPA (1993) provides technical background and guidance related to the Subtitle D ruling. Guidance is provided related to the contaminant transport modeling required to demonstrate compliance with the performance-based regulation, and an extensive list of computer modeling codes that were available at that time is provided in the reference. While many complex contaminant-fate-and-transport mechanisms were recognized by the EPA (1993), including

diffusion, it is interesting to note that this guidance document puts a clear emphasis on advective-only transport through the liner system. In two distinct places the guidance states that “the factor that most strongly influences geomembrane performance is the presence of defects...or penetrations of the liner.” The guidance suggests, for example, that the HELP model Version 3 (Schroeder et al., 1994), which incorporates the landmark Giroud leakage equations for composite liners (Giroud & Bonaparte, 1989, Giroud et al. 1989, and Giroud et al. 1992), should be used to estimate advective leakage through the liner, and that a model such as MULTIMED, developed by the USEPA (<http://www.epa.gov/ceampubl/mmedia/multim2/>) should then be used to evaluate the fate and transport of the leakage through the underlying hydrogeologic strata (the vadose and saturated zones) up to the defined point of compliance. Thus, for many years and even up to the present day, in many projects and many jurisdictions, contaminant transport modeling through liner systems focused exclusively on estimating the number and size of defects in the geomembrane liners, estimating the head over the geomembrane liners, and applying some form of the Giroud equation in order to estimate advective leakage through the liner system. Subsequently, significant efforts and advances in the application of the analytical and empirical equations for estimating advective flow were made in order to consider various types of overliner and underliner conditions (Giroud et al. 1997b,c), estimates of leakage and hole probabilities through double-liner systems (Giroud et al. 1997a), the effect of high head levels up to 3 m (Giroud, 1997), the effect of very large holes (Touze-Foltz & Giroud, 2005), long defects (Giroud & Touze-Foltz, 2005), the difference between the leakage rates of GCL and clay liners below geomembranes (Giroud et al., 1997d, and Rowe et al. 2004), statistical data on hole size and frequency (Marcotte et al., 2009; Forget et al., 2005; Darilek & Laine, 2001), the effects of wrinkles on calculations (Rowe, 1998), and various assumptions on the number of holes per hectare (e.g. see Giroud & Touze-Foltz, 2003). The effectiveness of these models has been confirmed, if not calibrated in hindsight, by field performance data reported by Bonaparte et al. (2002).

Although the theory and modeling ability to consider diffusion was available well before the 25-year period we review here, the author’s perception is that only in the past dozen years or so has there has more serious consideration been given to contaminant transport through liners via the mechanism of diffusion. This perception is by no means universal. A number of jurisdictions in various locations around the world may have seriously considered it earlier, and some jurisdictions do not consider it even to this day. That said, it was as recent as 2001 that the author was first required to consider diffusion as part of an alternative liner demonstration. See an interesting discussion of the state of consideration of this issue in 2002 in Giroud & Touze-Foltz (2003).

Rowe et al. (2004) suggest that under design conditions prior to termination of the operation of a leachate collection system and/or failure of a geomembrane liner, the primary transport mechanism through modern liners is usually chemical diffusion, most notably for certain organic constituents. As leachate collection systems age and clog, leachate mounding may occur. At the same time, geomembrane liners age and potentially develop more defects as they approach the end of their service life. As these ‘elderly’ system failures occur, and depending on the nature of the natural underlying hydrogeology, the issue of advective transport will become more significant. Rowe (2005) documented several cases in which diffusion resulted in measurable contaminant transport even over relatively small timeframes. Rowe et al. (2004) demonstrated

that there can be significant diffusion of certain organic compounds through geomembrane liners even while the volume of advective leakage is negligible. They further argue that calculations should be performed to assess the adequacy of a liner system combined with the underlying attenuation-layer soils, to determine if adequate environmental protection is provided over the contaminating lifespan of the facility.

Summary: It is commonly acknowledged that all liners leak, with or without geomembrane defects. The concept of composite liners is well founded, and industry feedback has vindicated the rationale for these liner systems in the results obtained by performance monitoring. At the same time, we recognize that even though we have been installing composite liners with good results for more than a generation, the lifetime of many facilities will far exceed this initial 25-year period, in terms of their operating lifetimes as well as their post-closure lifetimes.

Future: Given the modest cost impact of adding a secondary liner and leakage collection system, it is reasonable to expect that the benefits of the long-term redundancy provided by double liner systems will continue to be recognized. These systems will therefore be promoted more broadly than they already are, both for the control of advective leakage and the greater reduction in diffusion that they provide. Because of our recognition that contaminant transport risks might be a function of the age of a particular infrastructure, some of the considerations described in the next section of this paper, which addresses aging durability, will likely come into play. The inclusion of diffusion considerations in contaminant transport analyses is likely to become increasingly prevalent in the prediction of performance. Also, ELL surveys will likely become more and more of a norm in the specifications for new liner construction, in order to reduce the number of geomembrane defects that appear early in the facility life.

7. AGING DURABILITY AND GEOMEMBRANE SERVICE LIFE

The industry is indebted to the service provided by Dr. Henry Haxo for contributions he made in the mid-1980s to our understanding of the long-term compatibility between various polymers and various chemical environments. This was the beginning of our understanding of the durability of aging polymeric materials in waste environments, and there have been many advancements and studies since that time. Although other papers in this conference may touch upon some of these same topics, the author felt obliged to include those aspects of the continuing research in this area that may influence immediate design decisions.

For buried applications that are intended to be a quasi-final solution (i.e., for which there is no long-term plan to replace, upgrade, or decommission the installed liner system), there have been few studies regarding the expected lifetimes of liners, except for those used with polyethylene materials. Polyethylene is the most studied and accepted polymeric material for long-life (multi-generation) projects (see interesting discussion on this in Giroud & Touze-Foltz, 2003). Although bituminous materials could perhaps be considered long-life as well, given that they are analogous to natural asphaltic material, they have not received a fraction of the attention and market share for containment lining systems as compared to polyethylene. Other polymeric membrane materials have also been used for long-term buried applications, PVC in particular, but estimated quantifications of their lifetime and aging-durabilities are lacking, and field exhumations have turned up mixed results. Other flexible membrane liner materials, such as PP, EIA, etc. have found excellent utilization in exposed applications such as reservoirs, ponds, and

exposed secondary containment applications where there is an expectation of a finite-design lifetime on the order of one generation (i.e., 25 years, more or less). Though it would be fortuitous if some of these other materials had even longer lifetimes in service, at the present time they probably could not be used as design criteria, in the absence of more comprehensive aging-durability studies. There are a few excellent references on the selection of geomembrane materials for various uses, including Rollin et al. (2002), and Scheirs (2009). A number of attempts have been made in the past to create a selection matrix based on weighted or absolute criteria, and the author has even been involved in creating and evaluating such matrices. The author's experience with these matrices, though, is that they are too simplistic and do not usually lend themselves to an appropriate manner of evaluating materials. The best manner of evaluating materials is to clearly define the chemical, aging, and durability requirements for both long-term service and short-term construction survival. If more than one material happens to meet these requirements, then other considerations, such as cost, and the offsetting pros and cons can be used for the final selection.

Chemical compatibility aside (which is a large area in itself), prediction of the lifetime the various materials used in liners has been a holy grail from the beginning – how long will these materials last? However, the question itself requires some clarification if we are to answer it, for what does the question imply? Rowe (2012) has answered the question definitively for the industry: The lifetime of a geomembrane can be considered to have ended when it cracks so extensively that its presence as a fluid barrier is compromised on a massive basis over large areas.

Thus, to answer the question, “how long will the liner last?”, we might do better to ask: “what will cause it to crack, and what will accelerate the appearance and propagation of cracks?”

Research related to the factors that affect the service life of a polyethylene geomembrane is described in the following paragraphs. For materials other than HDPE, insufficient data is available to assess their long-term performance in buried liners or covers (NRC, 2007).

The basic chemical engineering of the resin itself. Resins that are more crystalline, and therefore more chemically resistant, tend to have a lower stress-crack resistance. To this end, a great deal of work related to the development of stress-crack resistant resins has been done in the past 25 years, with perhaps the greatest changes made in the early 1990's. As a result, the term “high-density” polyethylene is now widely recognized as being a slight misnomer, because the density of all of the major “HDPE” geomembranes produced by the various manufacturers have been lowered to the point that they are technically considered a “medium density” polyethylene material, according to strict chemical engineering definitions. Nonetheless, the term “HDPE” is so ingrained in common usage that this semantic nuance is almost universally disregarded. The defining test with regard to stress cracking is the Notched Constant Tensile Load test, developed by the Geosynthetics Institute, and now the test standard established by ASTM as D5397. Just as a point of reference: while many resins in the late 1980s had NCTL transition times of less than 100 hrs, today one can easily obtain a resin with a transition time of greater than 1000 hrs.

The anti-oxidant (AO) package in the resin formulation. The effectiveness and lifetime of the additives that serve to protect the geomembrane from oxidation have been found to be a fundamental key to the ultimate lifetime of the geomembrane. While it is difficult for civil

engineers to keep abreast of the nuances of polymer engineering, the GRI-GM13 standard guide is a good reference to use for specifying a good formulation for a geomembrane. The critical test in this regard has to do with the Oxidative Induction Time. Two tests are available that address this factor: Standard (ASTM D3895) and High-Pressure (ASTM D 5885). It appears that the High-Pressure test is much more indicative of the important anti-oxidants that contribute to long life (versus protecting against the high-temperature manufacturing process), and test values of 800 minutes are available from manufacturers.

Temperature. Temperature is a key factor in making long-term lifetime predictions for geomembranes. For example, it is estimated that the effective lifetime of HDPE at 40° C may be only 15% of its effective lifetime at 20° C (ref GRI 2010, or Rowe, 2005). Even short durations of exposure to high temperatures may significantly affect a geomembrane's lifetime (Rowe, 2012). In this regard, we would note the data from Koerner & Koerner (2006), which indicate that bioreactor landfill temperatures are significantly higher (on the order of 45-50 °C) than standard 'dry' landfill cell temperatures (on the order of 25-30 °C). Rowe (2012) also reported elevated landfill temperatures for wastes containing fly ash mixed with MSW, or wastes containing high aluminum content mixed with MSW (Stark et al., 2012a). Given the very significant effect of high temperatures on geomembrane service life, Rowe (2012) has suggested that the redundancy provided by secondary liners, considered separate from their operating temperatures, may effectively increase the service life of the overall liner system. The author would suggest that the monitoring of leachate temperatures just as they exit the landfill into sumps or pump stations can provide useful information feedback for site operators.

Allowable stresses and strains. Ongoing studies indicate that stress concentrations become the crack initiation sites for PE resins. Thus, the time-to-cracking, and the locations of cracks, will be largely influenced by the number of localized strains in the geomembrane. These types of strains may occur at all locations where gravel particles, which are present either in the subgrade or in the overlying leachate collection layer, cause the geomembrane to deform. Strains will also be found where there are wrinkles, which in North American installations are commonly prevalent in geomembranes as they are being covered. There is continuing debate and discussion regarding allowable strain level. For example an upper limit of 6-8% has been recommended by Peggs et al. (2005) and others, while the Germans are very conservative in their requirements, aiming for a design strain of 0.25% (Bishop, 1996) through the use of sand puncture-protection layers, and strict controls for the deployment-and-covering sequences used with geomembranes, in order to avoid burying wrinkles, for the reasons discussed above.

Past standard industry guidelines for allowable subgrade preparation and allowable overliner and puncture-protection materials have historically been established to promote geomembrane survivability and longevity of service. In light of ongoing research, these past standard practices were laudable and appropriate, and should be continued to be respected.

Recent research (Rowe, as yet unpublished) has shown that the highest quality subgrades are very stiff and smooth. Smoothness can be created using very well-graded materials that contain sands and silts, and even some fraction of gravel. Athanassopoulos et al. (2012b) have shown that subgrade soils that have a largely fine-grained soil matrix (e.g., clay liners) but some significant gravel content, can potentially result in significant geomembrane damage if there is

some relative movement (e.g., due to seismic shaking), but that this potential damage can be avoided if a GCL is installed between this subgrade and the overlying geomembrane.

The author has repeatedly verified in the field that almost every soil subgrade over which GCLs and geomembranes are being deployed benefits from the application of water spraying and smooth-drum rolling within a narrow window of time before the geosynthetics are deployed. In this way, the displacement of soils and rocks caused by the geosynthetic deployment activities is minimized. It may be useful to include a general requirement of this method of execution in project specifications.

Regarding puncture protection from overliner materials, the industry standard for many years, and up through the present time in the USA, has been the geotextile puncture-protection formula developed by Koerner et al. (1996), and recently updated by Koerner et al. (2010). While geotextiles that are selected based on this approach may result in materials having a mass/area of 500-1000 g/m², the approaches used by the Germans (e.g., Witte, 1997) suggest that a minimum mass/area of 3000 g/m² is required, or in a more favorable approach, that sand blankets be used. Brachman and Sabir (2012) have shown that with coarse 50 mm drainage stone, even multiple layers of heavy NWNP geotextile protection totaling 2780 g/m² may allow exceedance of the suggested allowable strain values over time periods typical of a landfill design life. This has led to the suggestion that geomembrane service life can be extended by the use of a sand layer to provide puncture protection. Brachman and Gudina (2008) arrived at similar conclusions for drainage stones of sizes of 25 mm and 50 mm. The degree of geomembrane strain can be kept lower if a finer gravel, or a more well-graded gravel, or more rounded as opposed to angular gravel is used, or if a firmer subgrade is created. We would note that the tendency towards a smaller, more well-graded gravel size is in conflict with the desire for a larger, more well-sorted gravel size to resist leachate collection system clogging. Designers thus need to weigh the trade-offs involved and provide appropriate puncture protection for a given situation. More definition can be expected in the future with regard to the use of acceptable overliner gravel sizes in conjunction with various puncture-protection strategies.

Wrinkles. The subject of wrinkles is mentioned many times in this paper, partly because they are so endemic to liner installations, and partly because they affect many aspects of the function and integrity of the liner systems. Giroud & Morel (1992) provide an excellent theoretical understanding of the cause and prediction of wrinkles for different types of geomembrane materials in different conditions. NRC (2007) makes the simple observation that “wrinkles are common in North American landfills”. In the author’s experience this is likewise true in most of the world, except for Germany, where they insist on wrinkle-free geomembrane installations. While there has been no definitive standard on the control of wrinkles in geomembranes in North American installations, research over the past 25 years has progressively shown more and more why wrinkles are undesirable. The reasons for this include strains in the geomembrane that result in accelerated stress cracking at the locations of wrinkles (Rowe 2005), greatly increased leakage potential due to the loss of intimate contact with the underlying clay or GCL liners over significant areas (Rowe 2005), the reduced effectiveness of lateral drainage layers on top of geomembrane wrinkles, and the increased potential for construction damage, because wrinkles protrude upwards into the path of grading equipment blades. Thus, the most likely places where leaks will originate are also the worst places. Daniel and Koerner (2007) indicate that “the

geomembrane must be flat when it is backfilled”, and they provide a list of proactive measures that can be taken to minimize the incidence of wrinkles. Scheirs (2009) suggests that at times, a compromise must be sought between the conflicting requirements of minimizing wrinkles while avoiding ‘trampolining’. The author’s practice in North American installations has been to set a maximum allowable wrinkle height of 2-3” (50-75 mm) during covering operations, and to use variations in daily temperatures to maximum advantage during this process. Using daily temperature as a primary control makes sense, since fundamentally, a geomembrane must be covered at or below its deployment temperature in order to achieve a wrinkle-free installation (Take et al., 2012). The question thus arises: on what basis should an acceptable wrinkle height be set? Chappel et al. (2012) showed that when the total area of wrinkles is less than 8-10% of the total area, then the maximum interconnected wrinkle length will generally be less than 200 m, which they considered an acceptable maximum length for the control of advective leakage due to random holes. At the sites that they studied, they observed that at geomembrane surface temperatures below 37 °C, the interconnected wrinkle length was typically less than 100 m. A related study by Take et al. (2012) indicates that the wrinkle height at this same temperature was estimated to be between 50-75 mm, which precisely corroborates the author’s experience-based specification. This approach cannot be taken so simply, though. If one reads the references and field studies carefully, it is actually the *onset of wrinkling to those heights* where the interconnectivity between wrinkles becomes a problem. In general, soil covering over polyethylene geomembranes needs to be halted a few hours after sunrise and can be begun again a few hours before sunset, with the exact times being specifically related to the maximum interconnected wrinkle length. Other approaches to limiting this maximum length could be as simple as placing sandbags between wrinkles to prevent their interconnection. This simple concept, however, may be not so simple to implement. We would note that these various approaches do not address the reduced service life at the locations of wrinkle. Take et al. (2012) suggest that any wrinkles with a height of 20 mm or more at the time of burial are likely to remain forever trapped, and will thus likely become sites of stress concentrations to varying degrees, depending on the particular wrinkle geometry.

Thickness. All other things being equal, thicker geomembranes will be more durable during construction, and will last longer (Rowe et al. 2010).

8. SLOPE STABILITY

Significant advances in our understanding, testing, and evaluation of slope stability have been made in the past 25 years. In landfill slope stability issues, the distinction is often made between bottom-liner stability and veneer (e.g., final cover) stability. Although the underlying geomechanics that govern stability are the same in both cases, the normal loads and sensitivities to pore pressures are vastly different, so it is useful to discuss them separately.

Bottom Liner Stability Issues

At the beginning of this paper’s 25-year retrospective period, we had a major bottom-liner failure at the Kettleman Hills landfill in 1987. This was, and still is perhaps, the largest permitted hazardous waste landfill in the world. The liner system was fairly complex, as shown in Figure 1. This event created a great awareness of slip surfaces and the need to check the slope stability in lined containment systems, and perhaps inspired more technical papers on slope stability than

any other containment project (e.g., Filz et al., 2001; or Stark and Poepple, 1994). The key lessons learned from this failure include:

- The importance of phasing and fill planning relative to slope stability. The failure would never have happened if the filling of the landfill had been performed in a proper sequence. The landfill operations essentially attempted to fill one side of a slippery bowl. If the other side of the bowl had been constructed sooner, and if the landfilling had been more balanced between the two sides, the failure would never have occurred. Since that time, this same lesson, unfortunately, has been learned the hard way at a few other major landfill projects. There is really no need for anyone else to have to learn this lesson; we can all definitely learn from this one mistake that occurred in 1987.
- Stark and Poepple (1994) used this failure to suggest to the industry that it might be good to use post-peak shear strengths on the backslopes of lined containment areas, while peak strengths may or may not be acceptable on the base areas, depending upon the seismic hazard. Ten years later, Stark and Choi (2004) elegantly refined this discussion.
- Filz et al. (2001) and Esterhuizen et al. (2001) wrote a pair of landmark papers on the progressive mobilization of shear strength in lining systems, using the Kettleman Hills failure as their case study. A similar paper was written by Reddy et al. (1996). The key lesson we can learn from these papers is that the mobilization of shear strength is not equal and uniform as is assumed by limit-equilibrium analyses. It is of overwhelming importance for practitioners to understand that the rigid-block modeling of slope stability, which is what is done in all 2-D limit-equilibrium models, does not represent the dynamics of reality. In fact, the shear strength is mobilized in a very specific localized fashion, such that all failures are essentially progressive failures. This is a significant reason why it is prudent to assume post-peak shear strengths for significant portions, especially the backslopes, of lined facilities. While the author does not advocate that slope stability analyses should use the finite-element approach in general, it is valuable for practitioners to study these references in the literature in order to gain an appreciation of the true mechanics of shear strength mobilization.

In the same vein as the lessons learned from the fill sequencing at Kettleman Hills, Smith and Giroud (2000) and Breitenbach (1997) emphasized that heap leach mining projects have also demonstrated that filling considerations for the first lift are the most important, relative to slope stability, and are typically more critical than the final fill configuration.

Based on the Kettleman Hills and similar solid waste failures, as well as numerous failures in the mining industry, it has become clear that the critical situations for slope stability risk are during construction, in the early phases of filling, and in the critical intermediate phases of filling. This concept must be borne in mind, even though many regulatory requirements have historically required only the examination of the final fill configurations to ensure slope stability. Thus, a key message for geotechnical practitioners involved in such projects is that not only do these different stages of geometry need to be modeled, but the shear strength testing for critical interfaces needs to be conducted at normal loads appropriate to these different conditions.

Peak vs. Post-Peak Strength. Partly as a result of the Kettleman Hills failure, but also because of the greater awareness and emphasis on slope stability evaluations in general, much work and many publications have been dedicated not only to understanding the shear strength characteristics of different materials and interfaces, but also to coming to grips with which shear strengths should be used relative to peak strength, post-peak strength, or residual strength. Some key publications in this regard include:

- ASTM D7702 - Standard Guide for Considerations When Evaluating Direct Shear Results Involving Geosynthetics. This recent guideline provides a very good discussion of the relevant issues related to the commissioning and interpretation of shear strength testing, and provides a good list of references that include many key related publications. This ASTM Standard reviews important issues such as the fundamental aspects of measuring and reporting shear strength using ASTM direct shear methods; evaluation of the Mohr-Coulomb envelope over appropriate normal load ranges; how to evaluate the subject of cohesion (or adhesion); how to evaluate the shear-displacement curves reported from tests; suggestions for reviewing results and test methods against historical data and published guidance; the value of inspecting specimens after testing; and multi-interface test approaches.
- For a modern reinforced GCL-geomembrane interface, and internal GCL shear strengths at moderately high normal loads, the author considers Fox and Ross (2011) to be the most comprehensive and relevant paper, as it provides useful insights on hydrated GCL shear strengths. This publication also includes references to numerous other key papers on the subject.
- In the same vein, an interesting publication on geomembrane and GCL interfaces under ultra-high normal loads, such as those that are experienced in large heap-leach facilities, was published by Athanassopoulos et al. (2012).
- A comprehensive discussion of unreinforced GCL shear strength, under both hydrated and dry (encapsulated) conditions was published by Thiel et al. (2001).
- There has been discussion of different approaches to the selection of peak versus post-peak, or even residual, shear strength parameters for use in slope stability analyses, as discussed by Thiel (2001). The Ohio EPA (2004) presented the interesting approach of requiring residual interface shears strengths for all liner systems on slopes steeper than 5%. GRI (2011) considered the selection of shear strength to be the “most-sensitive-unknown-variable” in performing stability analyses.
- When assigning post-peak shear strengths, a standard industry approach has been developed (Thiel 2001) that uses the post-peak shear strength of the interface that has the lowest peak strength. It is important for this concept to be applied for specific normal load ranges, since the lowest peak strength may shift from one interface to another under different normal load ranges. For example, for interfaces involving textured geomembranes with reinforced GCLs, it is commonly acknowledged (e.g., Athanassopoulos et al. 2012) that at increasing normal loads there comes a point at which the peak GCL internal shear strength is lower than the strength of the interface between

the textured geomembrane and the hydrated GCL. Thus, if a post-peak strength analysis were being conducted, it would be necessary to determine the normal load at which the transition from the interface to the GCL internal strength would take place.

- A number of designers and academics (e.g., Gilbert and Byrne 1996) recommend that a factor of safety greater than one be achieved in all containment system slope designs, assuming that residual strengths are mobilized along the entire slip surface. This view was later echoed by Stark and Choi (2004).

Pore Pressure. There has been an increasing recognition of the importance of considering pore pressures in landfill and heap leach stability analyses (Thiel, 2001; and Castillo et al., 2005). In its 2011 report on 20 large landfill failures, GRI found that liquids were considered a major mobilizing factor in more than half of the failures, and liquids in general were involved in all the failures. It is thus worth highlighting the fact that after gravity, pore pressures are the single most significant destabilizing element, especially for sites practicing liquid recirculation. It is known that at least one major landfill failure was caused by the aggressive recirculation of leachate (Hendron et al. 1999).

Method of Analysis. The actual methods of analysis that are used have not changed appreciably over the past 25 years. Slope stability analyses are most commonly assessed using computer programs that evaluate the limit equilibrium of a 2-D cross-section. Although 3-D and finite-element analysis methods are available, from a pragmatic point of view, the everyday stability analysis has been and will continue to be 2-D in actual practice. There are three main reasons for this, which are clearly laid out by Duncan (1996): the inherent conservatism of the practice, its ease of application, and its avoidance of errors. One aspect of this practice worth noting is that the judgement of experienced practitioners is required in order to select critical cross-sections.

Acceptance Criteria. Apart from the mechanics of selecting appropriate material properties, geometries, phreatic surfaces, and methods of analysis, the other significant decision that must be made by the geotechnical practitioner regards the acceptance criteria. Traditionally, static stability analyses were evaluated on the basis of a “factor of safety” (FS); based on the historical practices in the profession, a value of 1.5 is commonly considered acceptable. For seismic analyses (in California, for example), 25 years ago the industry was commonly using variations of a “pseudo-static” analysis that used a predetermined horizontal acceleration roughly on the order of 0.15 g, and required that $FS \geq 1.0$ under those conditions. While both of these acceptance criteria are still in use, more sophisticated and appropriate approaches have been developed in the past 25 years.

The legacy of requiring a minimum static factor of safety of 1.5 is still a relatively universal standard in the solid waste industry, although the author has noted that in many heap leach facilities, values of 1.3 are commonly accepted. The acceptance of a specific value implies a certain reliability of all of the factors that comprise the analysis, such as the geometry, shear strength parameters, and phreatic surfaces. Given that every single input going into an analysis involves some degree of uncertainty, a more intelligent manner of evaluating slope stability is based on the concept of ‘reliability’, or its inverse, namely ‘probability of failure’. The implementation of a reliability analysis was made very approachable for the industry at large by a landmark publication by Duncan (2000). In this paper, Duncan provided the tools (spreadsheet

equations) and approaches needed to create the necessary input to estimate the reliability of just about any type of engineering analysis, including slope stability. Design practitioners in all disciplines are highly encouraged to obtain this reference and follow its methods for all significant calculations. The output of the exercise will result in a “most-likely-value” factor-of-safety, as well as a reliability value (or its inverse, probability of failure). A significant benefit of this approach is that the manner in which decisions that affect slope stability are made can be easily communicated to the project sponsor, and the risks involved in making those decisions can be shared. While this approach will give both the designer and the client a feel for the sensitivities of certain parameters related to the project’s reliability, it still begs the question of what is an appropriate probability of failure. Guidance on this can be found in other industry publications, such as Whitman (1984) or D’Hollander (2002).

Seismic. Seismic analyses for landfills and leach pads have undergone significant advances. The “design earthquake” definition used in the 1980s used concepts of ‘maximum-probability’ and ‘maximum-credible’ earthquakes. With the enactment of Subtitle D in 1993, the design earthquake for permitted landfills was defined as an event that would have a “10% probability of occurrence in 250 years”. Since that time, the USGS has developed excellent online seismic hazard analysis tools, which are available at <http://earthquake.usgs.gov/hazards/>. If one inputs a latitude and longitude, the website will provide the peak ground acceleration for the selected probabilistic design event, mean and modal moment magnitudes, as well as spectral accelerations for a range of fundamental periods.

Early in the 25-year period under discussion, in addition to the pseudo-static method described above, the solid-waste industry adopted a chart-based deformation-analysis approach that was based on the use of the estimated yield acceleration and the assumed Richter magnitude of the design earthquake. This approach was based on the Newmark method (Newmark, 1965) as developed by Makdisi and Seed (1978), which is used to estimate the earthquake-induced deformation of dams and embankments. Bray et al. (1998) significantly advanced and refined this chart-based deformation concept. The most recent widely used chart-based approach is the one published by Bray and Travaserou (2007). More sophisticated approaches include performing a 1-dimensional seismic response analysis using an actual or simulated earthquake motion that is input to a computer program such as SHAKE, and performing double-integration on the acceleration vs. time response in order to estimate Newmark-type sliding magnitudes, or conducting 2-dimensional finite-element site-response analyses for actual or simulated time histories. The latter approach is typically used only in situations in which the more simplified conservative analyses do not provide acceptable results. Regardless of the method used, there is still the question of what constitutes an acceptable result. At this point, the main reference that is cited in the industry is by Seed and Bonaparte (1992), who conducted a survey of leading engineering firms, and found a general consensus that acceptable deformation under a design earthquake should be limited to no more than 150-300 mm.

Future: Going forward, the key questions relative to slope stability will continue to revolve around the selection of an appropriate shear strength and the consideration of appropriate pore pressures. Questions still remain regarding the appropriate selection of peak vs. post-peak shear strength parameters, long-term durability with regard to interface and internal shear strengths, and controls and impacts of waste saturation on stability. The importance of these issues still

remains to be fully appreciated, especially as bioreactor technology continues to expand, and as leachate collection and removal systems (LCRS's) continue to clog.

Veneer System Stability Issues

Veneer systems in landfills that might experience stability issues are those on sloped locations of final covers systems, or bottom-liner sloped areas that have a geomembrane and/or GCL barrier that is/are covered with relatively thin layers of leachate collection and/or operational soil materials during construction. Because this layer is often relatively thin compared to the slope length, these systems are commonly and conservatively treated as 'infinite slopes' from a slope stability point of view, although toe-resistance can be incorporated if desired. From this point of view, a veneer situation can be simply considered to be a block on a sloping surface.

While significant failures of landfill bottom liners may number only a couple of dozen in the past 25 years, veneer failures undoubtedly number in the hundreds. Many of these probably go unreported, and those that make the industry news-circuit are sufficient testimony that they are a significant problem. The geotechnical aspects of final cover system slope stability follow the same principles as those used for other geotechnical stability problems. What is unique and important to recognize relative to final cover systems is their sensitivity to relatively small changes in loading, slope angle, pore pressures, or shear strengths, all of which make them more susceptible to sliding failure (Thiel 2008).

While the author does not have a statistical list to quantitatively present the causes and triggering mechanisms of such failures, his familiarity with industry issues and discussions with peers over the past 25 years indicate the following reasons for veneer failures:

- Pore pressures acting at the liner interface. There are two types of pore pressures that can act at the veneer-cover interface: those from above, and those from below.
- Pore pressures above the geomembrane. The most pervasive cause of veneer failure is liquid (namely, rain) from above that percolates through the topsoils and builds up over the liner. It is easy to demonstrate that if there is no drainage layer between the geomembrane and the cover soil, the factor of safety for the stability of the soil sitting on the liner is in one stroke cut roughly in half. This is explicitly described, along with a number of design solutions, by Thiel and Stewart (1993), and in several other follow-up publications by others in the industry, such as Giroud et al. (1995b) and Koerner and Soong (1998). The main principle of the design solution is clearly to provide a dependable transmissive layer, such as gravel or a geocomposite drainage layer, between the geomembrane and the soils. The author notes that one of the changes in the industry over the past 25 years has been the elimination of the misnomer "cap-net", which was used to refer to less expensive geonets that were being promoted for landfill caps, under the perceived view that a lower level of performance would be needed in caps than in bottom liners. Analyses very often prove that the transmissivity requirements for landfill covers may significantly exceed the requirements for bottom liners due to slope stability concerns. The largest transmissivity reduction factor for these applications is typically "biological", as plant roots have been demonstrated to reduce transmissivity by 50%.

- Pore pressures below the geomembrane. Landfill gas pressures that are exerted upon the bottom surface of a cover geomembrane have caused several documented veneer-cover slope failures in the industry. Again, the design solution is to provide a lateral drainage layer below the cover system that collects and ultimately vents these pressures. The only industry design methodology published to date is that of Thiel (1998).
- Lubrication at the geomembrane interface. The author is aware of two types of “lubrication”-induced veneer failures. One is caused by the extrusion of bentonite from the woven side of a needle-punched GCL against a geomembrane. Such a failure was well-documented at a test site in Cincinnati (Daniel et al., 1998). A GCL was placed on a moist subgrade with the woven side face up, and was then covered by a geomembrane and 3 feet of soil on a 2:1 slope. Shortly after installation, two of the test plots slid. This demonstrated that bentonite extrusion from the woven side of a GCL needs to be taken into account if it is placed against a geomembrane, or perhaps that it is best to use a non-woven geotextile-based GCL against a geomembrane. The other “lubrication” failure, which was documented by Thiel (2009), involved a PVC geomembrane that slid on a nonwoven geotextile on a 4:1 slope about three months after being covered with soil. In the forensic investigation it was discovered that the condensation of moisture between the PVC geomembrane and geotextiles significantly decreased the interface shear strength, as compared to the dry interface. The lesson in this case is that interface shear tests with geomembranes should always be sprayed with water before assembling the test sandwich, because this truly replicates field conditions.
- Equipment-loading-induced failures. It has been documented that inertial forces from equipment can locally cause the peak interface strengths to be exceeded, resulting in post-peak interface strengths. Progressive failures of this type, which have eventually led to large-area slope failures, have been evaluated by the author and documented in the literature (e.g., Stark et al. 2012b, Thiel and Narejo, 2005). The lessons learned in general are that small, wide-track, low-pressure equipment should be used to spread cover soils over geosynthetics, and that the pushing of soils should be done in an uphill, not a downhill direction. Also, the failure evaluation presented by Thiel and Narejo (2005) led to a change in the industry-standard for geocomposite peel strength, which was upgraded from 0.5 pound-per-inch (ppi) to a MARV value of 1 ppi for projects in which shear strength is a critical factor.
- Simple failures due to inadequate shear strength. ‘Simple’ veneer-type failures due to inadequate interface shear strength, without any other extenuating factors, have been regularly experienced in the industry. These are typically non-dramatic and are not popularly documented because they are corrected as soon as they are discovered.
- Other. There are other types of veneer slope failures, such as veneer-reinforcement failures, that are less common and more specialized.

As with bottom-liner systems, perhaps the “most-sensitive-unknown-variable” is again the assumed shear strength parameters. In veneer cover design, it is critical for testing to be performed within the low normal load ranges under consideration. One of the most significant abuses of the interpretation of laboratory shear strength data is the cavalier backwards-

extrapolation of the cohesion intercept. This is typically a very unconservative approach that should really never be used, especially for the low normal load regimes for cover systems.

Seismic analyses for final cover systems can use the same chart-based methods described in the preceding section. The author recommends the Bray et al. (1998) reference as the most appropriate method, since it offers explicit solutions for the tops of landfills, taking into account amplification up through the waste mass.

As described in the preceding section, a significant decision that must be made by the geotechnical practitioner regards the acceptance criteria. As with bottom liners, $FS = 1.5$ is a commonly accepted basis of design for covers. As regards the allowable deformation in seismic analyses, the most germane reference is Kavazanjian (1998), who suggests that deformations of 1 m or more are allowable, as long as the responsible party is ready, willing, and funded to make repairs. If it is desired that the damage caused by the design earthquake would be relatively insignificant, then the estimated deformations should be less than 150-300 mm.

Future: Going forward, the key questions relative to veneer slope stability will continue to revolve around the selection of an appropriate shear strength and the consideration of appropriate lateral drainage layers above and below the barrier layer (viz. geomembrane). The long-term reliability of the assumed drainage layer transmissivity is also a subject of concern, as is described later, in the section 'Lateral Drainage Design'.

9. STEEP-SLOPE BOTTOM LINER SYSTEMS

As the industry has developed more confidence in liner-system construction over the past generation, and as the challenge of siting new waste repositories has become more difficult, steep-slope locations such as sidehills, canyons, and quarries have become more common disposal sites. Steep-slope bottom liner systems require special consideration not only in terms of slope stability, but also in terms of subgrade preparation, installation challenges, wrinkle management, covering, and the effects of settlement and downdrag on the liner systems. Each of these issues is discussed briefly below.

Subgrade preparation. The specifications for appropriate subgrade preparation should really be no different for a steep-slope application than they are for a flat-bottom application, and yet the achievement of a firm, smooth surface is much more difficult on a steep slope. The contractor's resourcefulness often makes it possible to successfully prepare firm, smooth surfaces on soils as steep as 1.5(H):1(V). At other times, engineered solutions such as puncture-protection layers, geofoam, or shotcrete may be in order.

Installation challenges. Installer ingenuity is required to safely deploy and seam geosynthetics on steep slopes. Special considerations include the effort to avoid overly disturbing the prepared subgrade, welding machine burnouts, CQA access, and wrinkle management. Because of the effect of gravity and daily expansion and contraction, the management of wrinkles at the toes of long slopes can be troublesome, especially for multiple layers. Often there is no good choice but to cut out the multiple layers of wrinkles and add a repair-seam near the toe of the slope. This activity is best done after the soil cover layers have been placed on the bench at the toe of the slope, so that trampolining of the lining system across the bench does not occur. For several

reasons, including the problem of wrinkles, it is advisable for benches to be installed at maximum vertical intervals of approximately 15 m.

Settlement and downdrag. Settlement and downdrag along steep-lined slopes will occur to varying degrees during initial construction, initial landfilling, and long-term waste settlement. The key questions in this regard are: “how much downdrag will occur?” and “at what degree of slope inclination does downdrag become a concern?” There has been little field monitoring and limited research on this subject. The research that has been done indicates that at a slope inclination of perhaps 2(H):1(V) or steeper, downdrag could be a significant concern (Jones and Dixon, 2005), but it could occur on flatter slopes as well, depending on the forces and the relative interface shear resistances within the liner system (Lui and Gilbert, 2003).

The occurrence and amount of downdrag that will ultimately occur is acknowledged to be a quite complex matter, and perhaps beyond our ability to accurately predict. In the design of steep slopes, the author believes it is necessary for the design to be able to accommodate downdrag without incurring any damage to the primary liner system. In the author’s opinion, protection of a steep-slope liner against downdrag damage can be accomplished in two ways. One is to provide one or more preferential slip surfaces above the primary liner. The second is to provide a veneer-reinforcement layer above the primary liner. The two methods can also be combined. For example, a slip surface consisting of a single-sided geocomposite could be deployed over a geomembrane on a steep slope (see Snow et al., 1994, as perhaps the first published example of this). The interface between the bare geonet and the geomembrane is much more slippery (i.e., has less shear resistance) than any other interface in the lining system, and will therefore slip when there is relative movement above the primary liner due to waste settlement and downdrag. In a geocomposite, the greatest stress due to interface slippage will be located near the crest of the slope, and at some point it will rip at that location. If a high-strength geotextile is anchored on the bench at this location, directly beneath the geocomposite, then as the geocomposite continues to be dragged down-slope, an ever-greater window-area of the high-strength geotextile will be exposed to the overlying soil that is engaging the downdrag forces. As this is taking place, a high-strength geotextile can provide two functions: (1) it can protect the underlying primary geomembrane from being directly exposed to the overlying soil materials, and (2) it can bear the downdrag load. Depending on the normal forces and downdrag forces, the high-strength geotextile would eventually reach its load-bearing capacity when the window of exposure reaches a certain size, and at this point the high-strength geotextile would rip. The design engineer would have to make an estimate whether or not the total amount of downdrag movement would exceed the ripping-point of the high-strength geotextile. If it was deemed probable that the downdrag movement would continue past this point, then a second layer of high-strength geotextile could be installed below the first layer, thus allowing another sequence of downdrag movement before this layer, in its turn, has its tensile strength challenged. This paper presents the first reported description of this technique; a more complete and publicized exposition is planned in the coming year.

The Future: We can expect more finite-element modeling of stresses and strains in steep-slope liner systems, and hopefully, more controlled instrumentation and reporting of actual steep slope liner systems.

10. PIGGYBACK LINER SYSTEMS

As old landfills reach their capacity and new sites become difficult to find, the practice of filling a new lined landfill against the side, or on top of, of an old existing landfill has become an attractive option that is routinely considered, and will always be a potential choice in local solid waste management plans. While these “piggyback” lateral and vertical expansion designs may not be everyday events, they will also not be rare. In addition to the typical design issues related to slope stability, the design goals for such systems are generally to allow the leachate and gas generated from the new waste mass to be effectively captured and directed to the new leachate collection and removal system, without leaching through the old waste mass that likely has a less reliable, or nonexistent leachate collection system. The collection of landfill gas from the old waste mass below the new liner system may also be an issue, but this is a separate discussion that is outside the scope of this paper.

A piggyback liner system has to be able to withstand the anticipated future total and differential settlements from the underlying waste foundation upon which it is constructed. Thus, one of the design tasks would be to model the future settlement of the waste mass upon which the piggyback liner will be installed, in order to verify that the anticipated total settlement would not result in a substandard slope (which would mean a generally established minimum of 2% of residual slope), for drainage of the new leachate collection system on the piggyback liner. Design approaches could include compacting the existing waste (which could even be as extreme as deep dynamic compaction), and steepening the slope of the existing waste using soil or non-putrescible waste, so that when it settles, there is less of a chance of it becoming too flat.

Localized differential settlements, e.g., sinkholes that might develop due “rusty refrigerators” and thus create a void in the underlying waste, can potentially be managed with ‘brute force’, i.e., a geogrid or high-strength geotextile reinforcement below the new liner system. The lateral extent of effective protection provided by subgrade reinforcement is limited to something on the order of 3 m in diameter, plus or minus, depending on the depth of the overlying new waste and the type of reinforcement selected. Original discussion and details can be found in Giroud et al. (1990), and excellent summaries are presented in a number of informative PowerPoint presentations that are available from the Geosynthetics Institute (Folsom, PA) and Koerner (1994).

11. LATERAL DRAINAGE DESIGN

The intelligent use of lateral-drainage design elements is recognized as an aspect of containment-system design that requires perhaps the most insightful and experienced engineering talent that can be brought to bear, because their impacts on slope stability and containment are so highly significant. In the world of geosynthetics, it is traditionally understood that geonets provide a lateral drainage function. Although cusped drainage panels have also been used to provide lateral drainage, their use in containment systems is relatively rare, and the author has never used them in these applications. There is one ‘nubbed-surface’ geomembrane product that, when covered with a geotextile, provides in-plane drainage, and the author has successfully used this. While some very specialized, loosely needle-punched, very-heavy denier nonwoven fabrics have been used for the lateral drainage of gases, in general geotextiles are not by themselves appropriate for lateral drainage applications.

At the beginning of the 25-year period under discussion, only a limited selection of bare bi-planar polyethylene geonets was available for geosynthetic lateral drainage materials. If a geotextile filter was needed adjacent to the geonet, it had to be deployed separately. Beginning in 1988, the ability to heat-laminate nonwoven needlepunched (NWNP) geotextiles to one or both sides of geonets was developed, and many different thicknesses and cross-sections of bi-planar and tri-planar geonets are now being offered. The heat-lamination of a geotextile to a polyethylene geonet is performed by melting the outside of the polyethylene geonet and then pressing the NWNP geotextile onto the melted surface. The lamination is actually created by the mechanical grip of the cooled polyethylene around the geotextile fibers. The hotter the melted surface, and the more pressure that is applied while it is melted, the more securely the geotextile fibers will be 'gripped' by the cooled polyethylene, though to the detriment of the geonet's transmissivity. The integrity of the lamination is measured in an index test called a 'ply-adhesion' or 'peel' test (ASTM D7005). Originally, manufacturers only specified a minimum average roll value (MARV) of 0.5 lb/inch (ppi) for this property. As described above in the section 'Veneer System Stability Issues', a couple of slope stability failures where this interface failed led to a new industry MARV of 1.0 ppi. The manufacturing control of this heat-laminated interface has greatly improved over the years, to the point where a more uniform and consistent peel strength is achieved, with less 'holidays'. The lamination of geotextiles over geonets has become so common that one rarely finds bare geonets being used anymore. The ability to laminate geotextiles not only provided a commonly needed filter against one side of the geonet, but also provided a good frictional interface against textured geomembranes on the other surface. The combination of a geotextile laminated to a geonet forms a 'geocomposite', and these have become so prevalent that the term 'geocomposite' is practically an industry synonym for this type of product, even though the term 'geocomposite' is generic and could refer to any number of geosynthetics that are combined together. In the discussion that follows, the author will use the term 'geocomposite' to intend both geonets that are laminated with geotextiles, and nubbed-geomembranes that create a transmissive layer when covered with a separate geotextile.

The most important performance property of a geonet or geocomposite is its transmissivity, which is essentially equivalent to its in-plane hydraulic conductivity multiplied by its thickness. Units of transmissivity are gallons per minute per foot of width (English units), or cubic meters per second per meter of width, which ends up being reported as m^2/s . Testing and specifying the transmissivity of geonets and geocomposites has been greatly refined and improved over the past dozen years. The most significant advance came with GRI Test Standard GC8 - Determination of the Allowable Flow Rate of a Drainage Geocomposite (Geosynthetic Institute, Folsom, PA) in 2001. In this test method, the manufactured material is tested against geosynthetic or soil super- and sub-strates that are representative of the field conditions, under normal pressures that are representative of field conditions, for 100 hrs. The material should also be tested under a gradient equal to or greater than the design gradient (never at a lower gradient), in accordance with ASTM D4716 (Test Method for Constant Head Hydraulic Transmissivity (In Plane Flow) of Geotextiles and Geotextile Related Products). The GC8 method provides that appropriate reduction factors should then be applied to the test results in order to account for long-term geotextile and soil intrusion, biological clogging, chemical clogging, and creep. Finally a global factor of safety should be applied to this value. Excellent discussions regarding this approach are provided in Giroud et al. (2000a).

A very fundamental aspect of the discussion of the use of lateral drainage layers in all applications is the fact that all design methods assume an unconfined in-plane flow. If this assumption is violated, then all the calculated benefits of lateral drainage layers in terms of reducing leakage, or reducing pore pressures to preserve slope stability, may be invalidated. To this end, Giroud et al. (2000a) has provided simple and elegant design approaches for designing the required transmissivity of the lateral drainage layers for given conditions of liquid input, slope, and drainage outlet spacing. In addition, Giroud et al. (2000b) has shown that a relatively thin geocomposite drainage layer requires a greater transmissivity than a much thicker granular drainage layer in order to obtain an equivalent flow capacity and maintain unconfined flow. Additional design equations for compound slopes, stacked double-drainage layers, and radial flow can be found in the same special publication as the Giroud et al. (2000a and 2000b) references.

Five specific areas of containment engineering design in which lateral drainage plays a major role are described below, along with advances in our understanding, and current design approaches that employ geosynthetic lateral drainage layers.

Bottom-liner primary LCRS in landfills (or “overliner” drain layer in heap leach pads). A cornerstone of the USEPA Subtitle D and C regulations is the requirement of an LCRS (which is a lateral drainage layer) that limits head buildup on the liner to a maximum of 30 cm. The initial recommendations in the 1980s for minimum required permeabilities of $1E-03$ cm/s were much too low to ensure good long-term performance, and tended to result in short- and long-term clogging. Primary landfill LCRS's clog to a significant degree over time. Rowe (2005) presents several examples and literature citations that document cases in which systems lost over 3 orders of magnitude of permeability over a 4-10 year period. Clogging is cited as being caused by the combination of biological and inorganic precipitate, with the inorganic precipitate being a long-term clog residue that is composed primarily of calcite.

A landmark paper was provided by Koerner et al. (1994), regarding large-scale drainage correction factors (DCF) for LCRS's, in which DCF was defined as the total area of the LCRS divided by the geotextile filter flow area. The extremes of this factor are $DCF = 1$, for the case in which a blanket filter covers the entire LCRS gravel collection layer, and $DCF = 24,000$, for when a perforated pipe is wrapped with a geotextile filter and all the leachate must flow through the portions of the geotextile filter that cover the perforations in the drainage pipe. An intermediate value of $DCF = 40$ might exist where the geotextile filter is wrapped around the gravel envelope immediately surrounding the leachate collection pipes. Experience has shown that relatively thin blanket filters, with $DCF = 1$, provide a leachate-treatment function that reduces the clogging of the LCRS layer (Rowe 2005), without becoming overly clogged themselves. Wrapping geotextiles around pipes or constrained areas is not recommended. Rowe & Van Gulck (2003) describe how the presence of a blanket filter performed better than no filter, and how a NWNP filter performed better than a woven filter. The author's practice is to provide a lightweight (135 g/m^2) NWNP geotextile as a compromise, thus providing a filter material that will provide the filtration/treatment benefit and will be less prone to clogging than heavier materials.

The author has found that designers use geonets and geocomposite drainage layers in primary LCRS's with caution, because of the clogging issue, and with even more caution in the case of

‘wet’ landfills in which liquids are recirculated. Even if new geocomposite drainage layers can be shown to permit a flow equivalent to that of a 30-cm-thick coarse granular system, they may have only one-tenth of the total porosity, and are therefore much more susceptible to clogging when put into service. Also, it is commonly accepted that a 60-cm-thick layer of soil material is typically required as a minimum protective layer above a geosynthetic liner prior to waste placement, so using a 30-cm -thick granular drainage layer already satisfies at least half of that requirement. If gravel drainage materials are not readily available, and there is a temptation to use geosynthetic drainage layers as the primary LCRS material, the author would still suggest providing, in general, ‘gravel windows’ that are 60-cm thick by approximately 4-m wide (the width of construction equipment) that cover the major leachate collection pipes and sump area, and a total coverage of at least 15% of the surface area of the landfill bottom.

In the future, we can expect more research related to reduction factors for clogging, and recommendations for providing greater redundancy in permeability, slope, pipe size, and spacing in LCRS’s.

Leakage detection layer in landfill bottom liner systems (secondary collection). Double-lined landfills with leakage detection layers (also called secondary LCRS) are common in the USA because they provide redundancy of environmental protection and performance feedback. Indeed, the limited feedback we have on the excellent performance of composite liner systems is mainly a result of the double-lined landfill data provided from New York landfills (Bonaparte et al., 2002).

There are generally two key design criteria for properly designed leakage collection layers: (1) provision for rapid reporting of a significant leak in the primary liner system to the secondary sump (a 24-hour detection time is commonly specified), and (2) limiting of the head acting on the secondary liner system to less than the thickness of the secondary lateral drainage layer, or less than 30 cm, whichever is less.

One of the main benefits of using a geocomposite lateral drainage layer material for the secondary collection system is that its high transmissivity is conducive to very rapid reporting of leakage to the sump. Methods of calculating the travel time of a leak through the secondary lateral drainage layer to the sump are provided in Giroud et al. (1997a) and Richardson et al. (2000), and perhaps the only reference that provides a method for calculating the head buildup on a secondary liner subjected to leakage from above is provided by Giroud et al. (1997a).

Leakage detection and management layer in a double-lined pond. The discussion later in this paper on ‘Ponds’ provides a background discussion of why on most important pond projects, double-liners with intervening leakage detection layers are used. Geosynthetic drainage layers are often used for the leakage detection and collection layers. Thiel and Giroud (2011) also discuss how it has been proven that the air space between two textured geomembranes has been successfully utilized to provide leakage detection and control in a number of pond cases.

Groundwater underdrain systems. The use of underdrains to provide hydraulic control of groundwater conditions is a standard practice in geotechnical foundation engineering. Advances made in geocomposite drainage materials over the past generation have certainly given us increased flexibility in addressing these design issues.

Final-cover lateral-drainage layer above the cover geomembrane. As described in the section ‘Veneer System Stability Issues’, the provision of a lateral drainage layer directly above a geomembrane’s final cover is often essential for maintaining the vegetative soil cover stability. The methods described by Thiel and Stewart (1993) and Giroud et al. (2000a) allow geocomposite lateral drainage layers to be properly designed to preserve the cover veneer stability. Experience has shown that it is important to maintain good outflow conditions that allow the lateral drainage layers to discharge. Freezing conditions, for example, are suspected of having precipitated localized failures due to water backup in the drainage layer (Bonaparte et al., 2002, and the author’s personal experience).

Final cover lateral-drainage layer below the geomembrane. As described above in the section ‘Veneer System Stability Issues’, providing a lateral drainage layer directly below a geomembrane’s final cover is often essential for maintaining the final cover stability, as described by Thiel (1998). Geocomposite drainage layers have been found to be perfectly suited for this application, and in addition, suited for providing gas relief and enhanced landfill gas collection. The author has also found that they provide a secondary benefit of capturing side-slope leachate seeps, which can then be directed to the toe, or to a collection gallery beneath the final cover system, and then conveniently reintroduced into the LCRS at an appropriate location.

Note on installation issues. The installation of geonets and geocomposites is relatively simple, but there are a few aspects of the process that must be performed with care to avoid defeating its intended purpose. One aspect that has historically received very little attention from manufacturers and was not addressed in the earlier literature concerns geocomposite butt seams. Butt seams require the laminated geotextile to be stripped back from the bottom of one roll and from the top of the other roll in order to provide net-to-net contact at the seam. On several jobs I have heard the installers, when asked to do this, make the ‘remarkable remark’: ‘...but we never do this’. This means that their standard practice has always been to incorrectly overlap the geocomposites with the geotextiles intact, which severely reduces their transmissivity. Only recently has this issue been correctly addressed in the literature, by Koerner & Koerner (2009). A second aspect that is often overlooked is that geocomposites have flow-directionality, with the maximum flow occurring in the machine direction. The flow capacity can be reduced between 30% and 90% in the transverse direction, depending on the type of geonet. Thus, panel placement instructions may need to be provided in the design and verified by CQA. Thirdly, the outlet condition details of geocomposites are critical for their proper long-term functioning. This issue is partly addressed by Koerner & Koerner (2009).

12. DETAILS RELATED TO PENETRATIONS AND ATTACHMENTS

Experience in the review, design, and performance of field inspections, and in the attachment of geomembrane boots and connections to structures, reveals that a wide variety of standards and approaches are employed. The execution of the details involved is very much an art of workmanship, and depends a great deal on the experience and understanding of the installer. There has historically been very little guidance in the literature regarding the fine points of specifying and implementing these critical details. The typical manufacturer’s details and guidelines are not much more than concepts that have been repeated for over two decades. Thus, there is a big difference between what we assume and expect, versus what is actually

constructed, in terms of the leak resistance of geomembrane penetrations and attachments to structures. Before 2009, the only substantive references on the subject were the ASTM Guide D6497, Standard Guide for Mechanical Attachment of Geomembrane to Penetrations or Structures, and Wells (1993). Thiel & DeJarnett (2009) touch upon some of the detailed and critical aspects that should be addressed when specifying and constructing geomembrane seals around penetrating pipes (referred to as “boots”) and attachments to structures. In addition to specific recommendations, Thiel also provides the following general recommendations as guiding principles for the design and construction of geomembrane penetrations and boots:

- Penetrations and attachments are more susceptible to leakage than a free-field geomembrane liner. Owners and designers should always be prepared to manage leakage at these locations. Critical applications should always be designed with redundancy (double liners, double boots, leakage detection layers, etc.).
- For exposed and serviceable installations, it is prudent to have a regular inspection and maintenance program for geomembrane penetrations and attachments.
- Penetrations and attachments require a great deal of care and craftsmanship to construct. Designers and CQA personnel should give extra attention to detailing and inspecting these items. Installers should develop in-house standards to assure the quality of their own installations.

Giroud & Soderman (1995a) provide guidance for the connections between a geomembrane and rigid structures, and propose a method to determine the amount of wall batter that is required to decrease the tensions and strains in the geomembranes to an allowable level. Giroud & Soderman (1995b) provide guidance for analyzing the mechanism of deformation of a geomembrane that is supported by a soil dike and is subject to differential settlement at its connection to a rigid structure.

It is clear that the subject of leak-resistant details is complex and cannot be taken for granted. The few technical guidance documents that are available related to these critical aspects of containment construction suggest that more development can be expected in the future in this area. Meanwhile, a lot of faith will continue to be put in the skill and craftsmanship of the installer.

13. DETAILS RELATED TO ANCHOR TRENCHES

Geomembrane anchor trenches are often a matter of convenience for general contractors and installers, and are probably commonly over-designed. For common types of anchor trenches where the liner system will be buried, not much has changed in the past 25 years. Good practices to consider when designing and specifying standard anchor trenches are:

- It may be good to design standard-type anchor trenches so that the geomembrane pulls out before tearing, so that more material stays intact in the undesirable event of slope movement.

- Keep anchor trench designs simple and flexible. Since they are generally for the convenience of the contractor, it may be good to allow for the contractor to suggest alternatives.
- The author believes that for double-liner systems, it is always best to seam the primary and secondary liners together in the anchor trench. This then rules out the possibility that liquids will enter the leakage detection system through this avenue.
- Backfilling in anchor trenches should be performed carefully so as not to damage the geosynthetics, and should always be done well and in a controlled fashion. Loose backfill has the potential to become water-logged, which can only create problems of various sorts.

Critical anchor trenches are required for exposed geomembranes (e.g., ponds and EGC's) or high-strength anchorage applications (e.g., reinforcement). For these applications, a more detailed engineering analysis may be necessary in order for such trenches to resist the tension forces that may develop in the geomembrane due to forces such as wind (see the next section on EGC's). Historically, most textbook methods for evaluating anchor trench pullout only considered the shear resistance along the planar surfaces of the anchor trench (e.g., the trench walls), and they assumed "frictionless rollers" at the corners. The most common approaches, such as those suggested by Koerner (1994) and Qian et al. (2002) were perceived as providing inadequate consideration of the pullout resistance around the corners of an anchor trench. The most significant advance in anchor trench design methodology in the past 25 years was proposed by Villard and Chareyre (2004). Based on a combination of analytical reasoning, finite element modeling, and laboratory testing, they recommended a design approach for L- and V-shaped anchor trenches that accounts for corner forces using the Euler-Eytelwein equation for belt-friction. The analytical methodology that they proposed is considered by the author to be far superior to any other methodologies that were previously proposed. Thiel (2010) presents a case study that provides some refinements to the Villard and Chareyre (2004) method and shows how their method could be used to optimize construction on large projects.

14. EXPOSED GEOMEMBRANE COVERS (EGCs)

Within the past 25 years, the concept of having a relatively long-term exposed geomembrane cover (EGC) has found a definite niche in real-world applications, and such installations that have been designed to last at least one generation are proving successful. A good summary of the rationale and justification for such covers is provided by Koerner (2012).

Design challenges in the installation of an EGC include: (a) providing adequate anchorage of the geomembrane so that it can resist the typically strong wind forces; (b) making sure that all important geomembrane welds are constructed so that they would only be stressed in a shear mode, and not a peel mode; (c) managing intense stormwater runoff from the exposed geomembrane area; (d) ballast for low-wind conditions; and (e) managing the large number of penetrations through the cover geomembrane that would cause localized stresses during wind storms. Exposed conditions also mean that the cover is susceptible to damage from animals (birds, deer, etc.), meteoric events (e.g., hail), vandalism, and fire. Even so, many successful and

substantial EGCs have been constructed, some now approaching 20 years old, including some in Florida and Louisiana that have survived major hurricanes.

As mentioned above, one of the largest challenges in the design of an EGC is accounting for wind loads. At high wind velocities, all geomembranes are likely to be uplifted. In this regard, Giroud et al. (1995a) presented a landmark paper that provides a method for evaluating the tension, strain, and deformation of a geomembrane that is uplifted by the wind. Zornberg and Giroud (1997) provided refinements to the original method, and Giroud et al. (1999) provided additional discussion regarding anchorage design.

15. PONDS

The primary difference between containment liner systems involving ponds versus landfills is the intentional design of the operational conditions of relatively high heads. Leakage under high head conditions will produce more consequences than it will under low heads.

Ponds are designed and constructed for many different uses; these include architectural or decorative purposes, golf courses, recreation or sport facilities, habitats, fisheries, stormwater detention, sedimentation, water storage, chemical containment, and wastewater containment. Different types of ponds can have different design criteria related to liquid containment. Most ponds are intended to contain liquids with the desirable goal of having as little leakage or infiltration to the ground as is reasonably possible. In the extreme case of chemical and strong-wastewater ponds, significant leakage to the environment is unacceptable and may also be illegal, depending on the specific circumstances. Leakage from a pond can be undesirable for the following several reasons, according to Thiel and Giroud (2011):

- Potential contamination and pollution of soils and groundwater from the leaking fluids.
- Possible underground erosion and/or formation of solution cavities, which is one type of “geotechnical damage”.
- Possible slope instability due to phreatic surface buildup below the liner, which is a second type of “geotechnical damage”.
- Potential uplifting of the liner, reducing the pond capacity and exposing the liner to mechanical damage and excessive stresses due to the pressure of gas and/or liquid present under the liner and/or to the buoyancy of the liner.
- Potential loss of valuable clean water, or potential loss of a valuable solution (in the case of chemical and production ponds).
- Potential difficulty in maintaining an acceptable liquid level, which may be important in decorative ponds, water reservoirs for recreation or sport activities, reservoirs for pump-storage stations, etc.

The basic design of pond liner systems has not substantially changed in the past 25 years. Digging holes in the ground to contain liquid is not a particularly new idea, and lining these holes with synthetic liners to reduce leakage losses has been done for over 80 years. In fact,

Koerner (1994) reports that the term '*pond liner*' was eventually superseded by the term 'geomembrane', which tells us how geomembranes were originally used. Single geomembrane liners constructed over a smooth, firm, relatively low-permeability subgrade, and covered with a ballast layer of at least approximately 30 to 60 cm, may provide a high degree of resistance to leakage, even when the geomembrane contains defects. The reason for this is that the ballast layer will generally prevent gas pressures from uplifting the geomembrane, and will maintain intimate contact between the geomembrane and the soil subgrade, thereby keeping the leakage rate at a very low level, even where there are defects in the geomembrane. Depending on the ballast type, the size of the geomembrane defects, and the degree of liquid head in the pond, the leakage rate from this type of pond can be estimated using empirical equations that are available in the literature. There are also other considerations that must be considered in the installation of soil ballast layers over pond geomembranes, such as soil type, placement method, pond volume impact, cost, and veneer stability.

Ponds that are important from a geotechnical, commercial, or environmental point of view are typically double-lined with intermediate leakage detection and collection layers. These types of ponds have been in use and have been regulated for at least the past 25 years. Thiel and Giroud (2011) describe in detail how deductive engineering and operational experience clearly show that any critical pond design using an exposed geomembrane primary liner requires a well-designed, well-monitored, and well-maintained leakage collection system if one expects the pond to function properly. Often, geosynthetic drainage layers are used. The key design features for ponds typically include (top-to-bottom) a properly anchored primary geomembrane sloped down to a sump, a lateral drainage layer that controls leakage by efficiently draining to an extraction sump, a secondary geomembrane, and a prepared foundation. Thiel and Giroud (2011) discuss four levels of leakage control, why it is important that the leakage collection layer be designed so that it has adequate transmissivity to control the head buildup in the leakage collection layer to a level that is less than the thickness of the leakage collection layer, and the concept of an Action Leakage Rate (ALR) for ponds.

Empty ponds, especially large ones, may present significant wind uplift considerations for exposed geomembranes. Anchorage for these liners can follow the methods discussed above for EGCs. The author has been involved in projects in which intermediate anchor trenches were created across the bottoms of very large ponds to manage the wind uplift.

The range of geomembrane materials used in pond applications is typically much more diverse than that used for landfills. In fact, for potable-water applications, the use of polyethylene geomembranes is in the minority, as compared to the use of other materials such as reinforced polypropylene. The manufacturers and installers of flexible geomembranes typically promote their products for pond applications because their satisfactory performance in these applications has been verified for periods of up to 20 years, and also because of the much smaller number of field seams that are needed due to the use of prefabricated panels. As with any project, specific geomembrane resins must be chosen that will provide appropriate chemical compatibility, exposure and construction durability, and repairability.

Wrinkles are often endemic to pond designs in which the geomembrane is exposed. Because of the undesirable consequences of hydrostatic forces on geomembranes that 'bridge' or 'trampoline' across the corners and toes of slopes, exposed geomembranes are often installed

with enough slack to prevent bridging in the coldest conditions. As a consequence, the exposed geomembranes in ponds typically exhibit different degrees and patterns of wrinkling during warm periods. Wrinkles that experience hydrostatic forces typically take the shape of flattened ‘fins’ protruding normal from the subgrade planar surface. The largest ‘fins’ will typically occur with HDPE geomembrane materials, because of that material’s relatively high thermal expansion coefficient, and its propensity to have larger wrinkles further apart than more flexible materials. The author is aware of at least two large pond projects in recent years (one reported by Peggs, 2012; the other not published) in which very strange cracking failures occurred at the tops of these fins. The hypothesized explanation for this is twofold: (1) the protruding exposed tips of these fins finally stress-cracked because they had experienced numerous cyclic stress-strain reversals, and (2) they had also potentially experienced localized loss of anti-oxidants at the surface, possibly exacerbated by being exposed and stretched passed the yield point at the tip of the fold. While these types of failures are rare in the author’s experience, and while numerous successful exposed HDPE-lined ponds have provided 20 or more years of service without such events, the fact that this has recently occurred twice on very large ponds is worth noting by any engineer who is considering the lining of large ponds.

16. SECONDARY CONTAINMENT AROUND TANKS

Diked secondary containment that is used to contain potential spills around the outside of fuel and chemical storage tanks is commonly provided using geosynthetic materials such as geomembranes. The use of single GCLs to provide this function has not seemed popular, probably because of the need to provide a minimum of 30 cm of overburden soil confinement on top of the GCL, and the propensity of shallow-buried GCLs exposed to variable meteoric conditions and wet-dry cycles to experience a degradation of their low hydraulic conductivity in these applications. In the author’s experience, geomembranes used in these applications are most often exposed and are not buried, with some exceptions. Because of the need for chemical compatibility with fuels and strong chemicals, the geomembrane materials typically used for this application are HDPE, reinforced ethylene-interpolymer-alloy (EIA), and thick bituminous geomembranes. Spray-on liner materials, such as polyurea, are typically the most expensive, but have also been used in these applications.

HDPE offers the advantages of lower cost, compatibility with HDPE pipe for welding boots and embedment strips, and good repairability. The disadvantage of HDPE is its expansion and contraction characteristics. Since an exposed secondary containment diked area is similar to an empty pond, as described above, numerous wrinkles are endemic to these installations. These wrinkles trap stormwater and create extra opportunities for wind damage and stress concentrations.

The advantage of reinforced EIA material is its greatly reduced expansion and contraction that is the result of its reinforcement. Its disadvantage, in the author’s experience, is that the large number of hand-welds that must be made using hot air guns and rollers seems to result in numerous small adhesion failures over time; these are essentially sites where leakage takes place.

The advantage of thick, roll-out bituminous geomembranes is that they seem very durable for foot and light equipment traffic and for maintenance activities, and are highly resistant to wind

uplift. There may be some disadvantages to these materials if exposed to chronic fuel exposure, such as drips that sometimes occur at these installations.

Numerous attachments and penetrations are endemic to these installations, which require a lot of attention to detail (see discussion on ‘Penetrations and Attachments’).

17. CONSTRUCTION, CQA, AND SPECIFICATIONS WITH REGARD TO DESIGN CONSIDERATIONS

Although there will be other papers at this conference that discuss the experience of the past 25 years related to specifications, installation, and the seaming of geosynthetics, the author feels obliged to mention a few items as they relate to design.

CQA. The author would like to acknowledge the continued need now, as much as ever, for construction quality assurance (CQA). The author’s extensive and ongoing experience in performing designs and CQA in this industry has shown that there is no less need for CQA today than there was 25 years ago.

Conformance Testing. Related to CQA, the author believes that there is a continued need for conformance testing of geosynthetic products, but that this could perhaps be done in a more intelligent manner now than it was 25 years ago. There are a number of index tests that continue to be performed with relatively high frequency that were established 25 years ago (e.g., ‘every 100,000 sq ft’). Perhaps with GAI-LAP accreditation and extensive MQC reporting, there could be relaxation of many of the industry standard requirements for certain conformance tests, and more acceptance of MQC results and manufacturer certifications. On the other hand, there are certain index and performance tests that may be more critical for design performance criteria that still require frequent testing. Depending on the project-specific requirements, these tests could include items such as peel strength for various materials, transmissivity testing, interface shear strength, oxidative induction times, and other critical properties.

ELL. This conference would not be complete without mentioning the progress that has been made in the past 25 years in the use of electrical geophysical methods to locate defects in installed geomembranes. This activity goes by various names, including electric leak location (ELL), which is the acronym used in this paper. Development of the ELL method began in 1980 at the Southwest Research Institute in San Antonio, Texas under cooperative contracts with the U.S. Environmental Protection Agency. Commercial surveys conducted on water-covered geomembranes began around 1985, and on soil-covered geomembranes around 1988, right at the beginning of the 25-year period we are discussing (Laine & Darilek, 1993). Since then, the capabilities of this method and its relatively low cost have propelled it to the forefront of the geosynthetics world as the most state-of-the-art quality-control/quality-assurance method for installed geomembranes. Required by an increasing number of regulatory boards for new landfill expansions, it is now also being applied worldwide to heap leach facilities in the mining industry.

The basic method of ELL is to connect an electrical power supply to electrodes above and below the liner, and to then detect areas where there is localized electrical current flow through leaks in the otherwise insulating liner. ELL methods are standardized by ASTM D7002; Standard

Practice for Leak Location on Exposed Geomembrane Using the Water Puddle System, and ASTM D7007; Standard Practices for Electrical Methods for Locating Leaks in Geomembranes Covered with Water or Earth Materials. The ELL method has the ability to detect defects that would not ordinarily be detected using standard CQA methods, especially those caused by placement of the initial soil layers over the top of the liner system. It has been known for some time (see Nosko et al., 1996) that most significant geomembrane damage is caused by construction machinery during the placement of earth materials on the geomembrane. Smith et al. (2007) describe specific measures that can be included in the design and specifications to enhance the electrical leak- location signal and improve the quality of the survey. For over a decade, these techniques have been part of the author's standard design practice in bottom liner systems for landfills and heap leach pads.

Experience. A general word of advice, based on our last 25 years of experience, is to recommend that an experienced, responsible party who is intimately familiar with construction procedures be involved in decisions related to design details, and to any issues related to slope stability (this could be different professionals for different parts of the design).

Along the vein of experience, a lot can be learned by studying failures that have occurred in the industry over the past 25 years. Many of the references cited in this paper contain discussions of failures with observations of useful lessons that were learned. Perhaps the largest compendium of containment-system failures of various sorts is contained in Appendix F of Bonaparte et al. (2002).

18. MOVING INTO THE FUTURE

The discussions in the preceding sections suggest that while we have come a long way, significant questions remain to be answered, and there are areas that show clear room for improvement. While regulations assume a certain static immobility once they've been established, the understandings we gain through experience never stop growing. It is only natural and desirable, then, for new understandings to eventually render existing minimum compliance regulations inadequate, and to inspire designs that are more effective and efficient.

Key items discussed in the preceding sections that could contribute to more effective designs include:

- An emphasis on high-performance, very highly stress-crack-resistant resins for geomembranes (and other geosynthetics) with more robust AO packages.
- More robust leachate collection (lateral drainage) layers.
- Greater deliberation given to long-term allowable strain in geomembranes, with greater attention given to puncture protection and wrinkle management.
- Further investigation into the long-term durability of shear strength interfaces and appropriate acceptance criteria for slope stability for the full range of bottom liners, covers, static conditions, and seismic conditions.

- More requirements with regard to monitoring the impacts of operations on liquid levels and temperatures, especially in light of the bioreactor concept.
- More consideration for shortening the post-closure care period by weighing the benefits of enhanced waste degradation and waste stabilization using anaerobic versus aerobic methods.
- More consideration of design redundancy in specific design elements (e.g., extra pipes, closer spacing) and for the design as a whole (e.g., double liner systems).
- More attention to robust details.

One might well ask: “If the industry’s performance has been so stellar in the past 25 years, why consider changing a winning game? Especially since any of the proposed so-called-improvements might lead to increased cost of construction or operations, why would we want to change?” The answers to these questions can be found in the learning process we are all engaged in. Part of this learning is the realization that our excellent track record over the past 25 years may only represent a relatively small fraction of the life legacy presented by constructed landfills. For this reason, we should continue to query the durability and aging characteristics of our designs in light of the expected duration of the operational life and post-closure care period, especially for the very large, regional facilities that are now being constructed. The recommendations in the NRC (2007) report mainly focus on increased funding and requirements for the monitoring of existing facilities, with the aim of assessing the long-term performance of engineered systems.

ABSTRACT

The use of geosynthetic reinforced soil walls and slopes has grown significantly over the past 25 years. Though, surprisingly, the materials, design procedures, and construction techniques used with these structures have only modestly changed. This paper provides a historical review of many of the activities over that period of time that brought us to where we are today in the implementation and maintenance of this technology. This era started off with some of the most significant changes, with a number of suggestions for design improvement, but as with many civil engineering activities such improvements are slow to materialize. Good practices developed during this period have led to significant success in the use of geosynthetic reinforced walls and slopes as highlighted in this paper. However, a number of issues were identified during this era, primarily resulting from bad practices. In this paper, best practices are reviewed along with design improvements and current progress on implementing those improvements. The outcomes resulting from not following good practice established during this period will also be reviewed.

INTRODUCTION AND SCOPE

Geosynthetic reinforcement has been used for reinforced soil wall and slope construction in North America since the mid 1970s, although the number of early reinforced soil walls and slopes was rather small. From only a few hundred walls constructed by 1987 (Yako and Christopher, 1987), the beginning of this 25 year period, thousands of structures are currently constructed each year. This paper provides a historical review of many of the activities over that period of time that brought us to where we are today in the implementation and maintenance of this technology. Much of the early practice, before this period, was documented in Christopher and Holtz (1985) and Berg et al. (1998) provided a very good review of those early design methods, a summary of which is included later in this paper. During the 1980s, a number of advancements were made in the US practice, which are also reviewed later in this paper. While research and instrumented studies since the 1980s have supported further advancements, few have been incorporated into current design models (although current activities may soon be moving these efforts to the forefront.)

THE EARLY YEARS BEFORE THIS 25 YEAR ERA

The Federal Highway Administration (FHWA) Geotextile Engineering Manual (Christopher and Holtz, 1985) provides a summary of design methods that were available at that time for both slopes and walls and provides detailed case histories of early projects. As identified in the manual, there were no standard design methods within the public or private sector at that time. Four methods were identified for slopes and five methods were identified for walls, each having different assumptions for developing the load in the reinforcement and resistance provided by the reinforcement. There was a method developed by the US Forest Service (Steward et al., 1977) and most other methods had been developed by academic researchers or proprietary system developers. Although all of the design methods appeared to be theoretically sound and test cases were typically used to verify adequate performance, none of the design methods could be completely validated through instrumented structures (i.e., what was the actual factor of safety and corresponding uncertainty). Therefore, several different detailed design methods were included in the manual for users to evaluate with a suggestion that more than one be considered as a check.

At that time, most structures were constructed with wrapped facings, although some experiments with timber facing and full-height panels were used with geotextile reinforcement in Glenwood Canyon, Colorado in the early 1970s (Robert Barrett, personal communication). A block-face geosynthetic reinforced soil wall was constructed in the late 1970's, see Figure 1.

Another detailed report on reinforced walls and slopes was published in the 1987. The National Cooperative Highway Research Program (NCHRP) 290 Reinforcement of Earth Slopes and Embankments report (Mitchell and Villet, 1987) provides comprehensive state-of-the-art discussion on earth reinforcement principles, materials, design procedures and construction materials. Steel and geosynthetic reinforcements and

systems are addressed this report.

Figure 1. First geosynthetic reinforced soil, block-faced wall constructed in the late 1970s (Courtesy of Professor J.R. Bell)

A new geosynthetic – *geogrid* – was introduced in North America in 1982. This geosynthetic was specifically developed for soil reinforcement applications such as walls and slopes. Early wall and slope applications in North America are included in proceedings of the 1984 Polymer Grid Reinforcement Conference (Forsyth and Bieber; Busbridge; Bonaparte and Margason; Bell et al.; 1984). The first precast panel faced geogrid reinforced soil walls in North America were constructed in 1984 and 1985 (Berg et al., 1986) in the US and in 1985 in Canada (Berg et al., 1987). The tie-back wedge method of analysis with an internal lateral pressure equivalent to active Rankine was used for design of these and subsequently geogrid reinforced soil walls. Masonry wall (a.k.a., segmental retaining wall

(SRW); and, modular block wall (MBW)) units introduced in the mid 80s for construction of gravity walls were soon (i.e., 1986) combined with geosynthetics for design and construction of reinforced soil walls. Since then, the geogrid and the MBW unit manufacturers and suppliers have spurred the use of geosynthetic retaining walls.

BEHAVIOR OF REINFORCED SOIL (1983 – 1989)

The absence of a validated design standard was not only an issue with geosynthetics, but all other types of reinforced soil systems. FHWA identified eight different generic reinforcement systems, including three generic geosynthetic systems (i.e., geotextiles, geogrids and smooth plastic strips), ribbed and smooth steel strip reinforcements, bar mat reinforcements, welded wire mesh reinforcements, and woven wire (e.g., gabion) mesh reinforcements. Structures using these reinforcements were designed using completely different methods for determining both the reinforcement strength and reinforcement interaction (i.e., pullout resistance) requirements. Many of the approaches were developed by proprietary interests. FHWA had identified all of these systems under one umbrella term Mechanically Stabilized Earth walls (partly to avoid conflicts with proprietary names for wall supplier systems). Under the sponsorship of the FHWA, a study on the “Behavior of Reinforced Soil” was undertaken to verify the adequacy of existing design methods to accurately predict performance. Based on the review of existing methods, comprehensive guidelines were to be developed for evaluating and using soil reinforcement techniques considering the absence of consistent design methods and the difficulties in comparing the stability of different systems. The end product was a manual of practice for design and construction of reinforced soil structures.

The scope of the FHWA study encompassed five principal tasks:

- A review of the technology and design methods at that time, primarily based on the extensive literature study performed (by Mitchell and Villet, 1987).
- A laboratory testing program to evaluate reinforcement variables and stress distribution patterns, consisting of:
 - Reduced scale (approximately 1 m high) models.
 - Forty-seven small scale (150 mm high) centrifuge model tests.
 - Five large scale (500 mm high) centrifuge model tests.
 - Pullout tests to evaluate stress transfer and develop standard methods for obtaining design input parameters.
- Full scale, fully instrumented field tests (Figure 2) to evaluate the existing design approaches. Field models included:
 - Eight, 11 m wide by 6 m high, reinforced soil walls using steel strips, steel bar mats, geogrids, woven wire mesh and geotextiles as reinforcement. Facing systems for walls included 5 walls with concrete facing panels, 2 walls with gabion faces, and one wrapped faced wall. A privately funded ninth wall, using geogrid reinforcements and modular block facing units, was added near the end of the study.
 - Four, 15 m wide by 7.6 m high slopes constructed at 1 horizontal to 1 vertical and 1 horizontal to 2 vertical using geotextile and geogrid reinforcement.
 - Well graded sand and gravel, cobbles, and silt for reinforced fill.
 - Field pullout tests on each wall reinforcement.

- Concentrated footing type loads on select walls and embankment surcharge loading on all of the wall systems.
- Preliminary analysis of the field results along with a parametric study using the finite element method.
- Preparation of a design manual of practice (Christopher et al., 1989).

Figure 2. FHWA-Study, Instrumented walls constructed in Algonquin, Illinois by STS Consultants (from Christopher, 1993)

The data from each of the phases was primarily reviewed in relation to the goal of the project (e.g., verification of existing design techniques) and planning the next phase. During the performance of the study, it became apparent that a unified design approach for all reinforcement systems should and could be developed based on the results of the study. The results indicated that the different reinforcement systems when designed according to a unified approach, behave in a similar and predictable manner, provided that the “density” of reinforcement (amount of reinforcement per area of the reinforced section) is similar. The principal difference in performance can be attributed to the extensibility of the reinforcement, or stiffness of the reinforced soil composite.

Based on the results of the field and laboratory work, a method was advanced based on the preliminary analysis of the data (Christopher et al., 1989). The resulting design method for MSE walls was based on a stiffness approach for quantifying the lateral pressure coefficient (i.e., the stiffness of the reinforcement based on its modulus and the density of reinforcement in the reinforced soil mass). The design method provided the basis for the *Simplified Method* currently used in the AASHTO and FHWA design documents. An in-depth comparative review of the data from all phases of this study including the development of the design model is presented by Christopher (1993).

For reinforced soil slopes, a rotational limit equilibrium analysis, with the assumption that the geosynthetic reinforcement acted tangential to the failure surface, predicted well the magnitude and location of the maximum stress in the reinforcement and was determined to be a suitable method for design. This method was incorporated into both the FHWA MSE design

manual (Christopher et al., 1989), and the second edition of the FHWA geotextile design manual (Christopher and Holtz, 1989). A detailed evaluation of the design approach is presented by Christopher and Leschinsky (1991) and a reliability analysis of the procedure is presented by Cheng and Christopher (1993). FHWA also developed an Interim Guidelines for Design, Specification, & Contracting of Geogrid Mechanically Stabilized Earth Slopes on Firm Foundations (Berg, 1991).

The FHWA study recognized that both the wall and slope design methods were conservative (i.e., safe) as demonstrated by the instrumentation results. However, as noted in the report, all things considered, variability in construction procedures, fill and backfill, foundation material, and construction control would suggest only moderate changes in the design procedures at that time, and that it was more important to use this information to improve design consistency. Even though a broad range of soil types was evaluated, for these same reasons, the design guide recommended the use of select granular fill with minimum fines (< 15% finer than 0.075 mm) for wall structures. A number of recommendations were offered for improvement, several of which were related to reductions in the conservatism in the calculated tension from the standard wall design method versus measured soil values for geosynthetic reinforcements. These included use of more uniform loading such as a trapezoidal versus triangular distribution of stress in the reinforcement, use of confined stress strain for evaluation of reinforcement tension and deformation response, the influence of face stiffness on overall wall deformation, and development of composite design models (Christopher et al., 1989, also see Collin, 1986 and Christopher, 1993).

As a demonstration of the conservatism, the actual factor of safety for the FHWA-study retaining walls (i.e., removing many levels of conservatism) were evaluated by Christopher et al., 1992. Although the systems were designed for an internal factor of safety of 1.5, the geogrid wall had an actual factor of safety of 3.3 or greater, and the factor of safety for the slopes constructed with woven geotextiles and extruded geogrids had factors of safety ranging from 2.1 to 7.0. One wall constructed with a nonwoven geotextile had a design and actual factor of safety of 0.94. Although 900 mm of horizontal movement (i.e., 15% times the height of the wall) was measured near the top of the wall after construction, the wall did stop moving and did not fall down, again indicating inherent conservatism in the design approach.

FHWA was also concerned about the durability of reinforcements. Much of the early methods for calculating the allowable strength were based on reduction factors, but the factors were based on polymer durability charts (as opposed to exposure testing), some creep testing and in some cases, a factor for installation damage. Both the FHWA research report (Christopher et al., 1989) and the FHWA Geotextile Design and Construction Guidelines Manual (Christopher and Holtz, 1989) advocated a method using a similar partial reduction factor approach advanced by Bonaparte and Berg (1987):

$$LTADS = \frac{T_{ult} \times CRF}{RF_{ID} \times RF_D \times FS}$$

Where, LTADS = Long Term Allowable Design Strength
 T_{ult} = Ultimate strength of the geosynthetic

- CRF = Creep reduction factor (ratio of the creep limit strength obtained from creep test to ultimate strength)
- RF_{ID} = Reduction factor for installation damage
- RF_D = Reduction factor for polymer durability
- (Note. The creep factor is in the numerator as it was not considered to be a degradation mechanism unless that level of strength was exceeded – it was eventually moved to the bottom of the equation.)

However, there were no test standards for durability, creep or installation damage at that time and the actual longevity of the polymer was questioned by some engineers. In 1990, FHWA published a study on Durability/Corrosion of Soil Reinforced Structures (Elias, 1990) that proposed criteria for evaluating reinforcement material. The geosynthetics section was primarily based on a literature study with the exception of installation damage, where extensive field tests were performed to support information from the literature.

There were a number of well documented geosynthetic reinforced soil wall and slope case histories in the 1980's, several of which are documented in the in the Geosynthetics Case Histories (Raymond and Giroud, 1987). Summaries of 54 projects are presented by Yako and Christopher, 1987. Those reviews included project details, design information, reinforcement properties and design methodology, and, where available, instrumentation and results. Two other significant case histories were the Tucson, Arizona wall (Berg, et al., 1986), which uniquely used geogrid reinforcement connected to full height precast concrete facing, and the 15.2 m high Rainier Avenue wall (Holtz et al., 1991; Allen et al., 1991; and, Christopher et al., 1990). This second case, at the time, was the tallest reinforced soil wall in the US, and it was fully instrumented to evaluate internal and external performance. The instrumentation results from both of those walls confirmed the current conservative design models and the excellent performance of geosynthetic reinforced soil walls. In the case of the Rainier Avenue wall instrumentation results, even though the design factor of safety was 1.2, the face deformations were only about 10 mm, and post-construction creep was about one-half that amount after 9.5 months. The measured strains of the geotextile reinforcement were very small, typically about 0.5 percent; the maximum observed by only one gage was slightly more than 1 percent.

The tallest reinforced soil slope in the US was a 33.5 m structure constructed in 1987 for large scale contour land forming for the Ridgegate subdivision, La Jolla, California.

Other projects are described in a number of International and North American Geosynthetic conferences that took place in the 1980's. One very significant event was a NATO workshop in Canada where a number of international reinforced soil experts (consultants, academics and proprietary systems experts) met and reviewed the state of the art and the state of the practice (see Jarrett and McGown, 1987). Two specialty conferences also took place in 1990 that provide very good case histories and research studies of this period. One was an international specialty conference on "Performance of Reinforced Soil Structures" (McGown et al., 1990) that took place in Glasgow, Scotland. The other conference was the American Society of Civil Engineers (ASCE) conference on "Design and Performance of Earth Retaining Structures" in New York City (Lambe and Hansen, 1990).

And the best news, there were few documented failures during this period. The few that were reported were typically on test walls (e.g., the FHWA study) or connection failures in attempts to develop alternate facing systems. Those not documented in the literature include walls backfilled with fine grained soils and surficial failure of reinforced soil slopes. A harbinger of what was to come.

THE 90'S

During and after the FHWA study, several alternate wall design methods were proposed. During the late 80's AASHTO established a task group (Task Force 27) that developed design guidelines based on a literature review (e.g., Mitchell and Villet, 1987) and wall supplier input (AASHTO 1990). For geosynthetics, the tie-back wedge method of analysis was recommended, which was similar to the approach evaluated in the FHWA study and that used by geogrid manufacturers and suppliers since the mid 80s. The 1990 procedures formed the basis for the 1991 AASHTO Standard Specifications; however, geosynthetics were in a separate section from the MSE (e.g., steel reinforcement) wall section of the manual. In the 1994 AASHTO Standard Specifications, the stiffness approach was introduced as an alternate design method. However, several wall suppliers objected to using the new, more complicated stiffness method of analysis, (primarily, at least the lead author suspects that this rejection was due to the unification of the design, which took away some of their uniqueness.)

In 1994, representatives from AASHTO and FHWA met to review the methods for calculating the backfill reinforcement loads that were available at that time in the AASHTO Standard Specifications for walls. Their objective was to unify the design methods and to simplify and clarify the specifications. Full scale MSE wall case history data (i.e., from the FHWA study, as well as other instrumented structures) was reviewed, such that the method could be calibrated to the empirical data, since all of the methods available were empirical in nature. The effect of simplifications in the method, such as how vertical soil stresses are calculated and how reinforcement stiffness is considered in the design, could also be evaluated with this full scale wall data to ensure that the unified method developed had adequate accuracy. From this effort, the FHWA/AASHTO Simplified Method was developed as published by Elias and Christopher (1996/1997) and AASHTO (1997). Also, see Allen et al., 2001 for a full description of this effort along with a review of additional instrumented case histories to support the method. These changes also put geosynthetics on an equivalent level with steel reinforced soil systems in the AASHTO guidelines, as they were evaluated using the same methodology.

The durability guidelines from FHWA (Elias, 1990) were also being revisited. An extensive research program on geosynthetic durability was undertaken in the early 1990s that involved national geosynthetic specialist expertise from industry, academia, transportation agencies and consulting engineers. The objective was to gain a better understanding of the mechanisms and environments which affect the strength degradation rate of geosynthetic reinforcement, and to develop a practical methodology for comparing geosynthetic products. This program was funded as a FHWA HP&R National Pooled fund study, which was led by FHWA and Washington State DOT. The results of the test program and the degradation testing protocol were documented in the FHWA Corrosion and Degradation/Degradation of Soil

Reinforcements for MSEW and RSS (Elias, 1997). GSI also played a role in this study by validating some of the test protocol results (Koerner et al., 2006).

While the public sector was getting organized, so was industry. In 1993, the National Concrete Masonry Association (NCMA) published a design manual for segmental retaining wall (SRW) gravity and SRW-face reinforced soil walls (a.k.a. modular block walls), for use in the private sector (Simac et al., 1993). A tie-back wedge method of analysis, but with the use of Coulomb active lateral pressure and failure line for internal and external design, is used in this manual. Coulomb theory (versus Rankine theory used by FHWA and AASHTO) is used to take advantage of the beneficial effects from wall facing batter and interface friction between the reinforced fill and wall face. The manual, which covers everything from short landscape walls to taller (i.e., 20⁺ feet high in 1993) walls, also allowed for the use of less select material with up to 35% < 0.075 mm fine grained soils, if carefully evaluated and approved by a geotechnical engineer. The manual was updated in 1997. A complementary Segmental Retaining Wall Seismic Design Manual was published by NCMA in 1998 (Bathurst, 1998).

The use of up to 35% fines in the reinforced fill has been extensively discussed in each edition of the NCMA manual. Again, the scope of the manual is for a wide variety of wall uses and heights and, thus, use of finer grained soils is, and has been, acceptable for many applications. Each edition of the manual has stated that cohesionless free draining (less than 10% fines) backfill materials are preferred. However, soils with low plasticity (i.e., CL, ML, SC with $PI \leq 20$) may be used provided the following four additional design criteria are implemented:

- Proper internal drainage is installed.
- Only soils with low to moderate frost heave potential are used.
- The internal cohesive shear strength parameter, c , is conservatively ignored for stability analysis.
- The final design is checked by a qualified geotechnical engineer to ensure that the use of cohesive soils does not result in unacceptable time-dependent movement of the SRW system.

The manual editions further promote the use of granular wall fill by listing their advantages of:

- Easier to place and compact.
- Higher permeability which assists drainage.
- Greater shear strength, which reduces applied stress.
- Generally less susceptible to creep.

Assessment that the use of fine grained soils will not result in unacceptable time-dependent movement requires proper understanding of the conditions leading to wetting of the fill, the associated loss in strength and increased deformability, and the influence of pore water pressures on the internal and external loads, connection stresses, and pullout resistance.

A very good review of all of the design methods previously mentioned in this paper, as well as a wall suppliers design approach, with respect to the calculation of the loads in the reinforcement and the resistance provided by the reinforcement is included in Berg, et al., 1998.

An example is used to compare the conservatism in each approach. A somewhat unique method was used to evaluate conservatism, comparing the resistance (R) to load (L) ratio developed from each design method, which clearly shows the range of conservatism for each of the design methods as shown in Figure 3. Based on this review, the transportation specific AASHTO and FHWA procedures were shown to be more conservative (about 30% more reinforcement required) than non-transportation specific procedures such as NCMA.

Figure 3. Resistance – Load Ratio Trends and Ranges (from Berg et al., 1998)

Another very thorough comparative review of several of the design approaches, including design details, factors of safety and reduction factors, can be found in Koerner and Soong (2000). Their evaluation includes: 1) a modified Rankine approach as illustrated by Koerner and Soong (1999), which is similar to the previously mentioned Forest Service method; 2) the FHWA 1998 approach; and the NCMA 1997 approach. In addition to the internal design for reinforcement load, they also evaluated pullout and facing connection requirements, as well as external stability design (e.g., stability against sliding, bearing capacity and overturning). Again a design example was used for direct comparison and it again clearly showed that the FHWA method was more conservative than the NCMA method for both internal and external stability, while the Modified Rankine method was about the same for tensile strength and slightly more conservative for pullout requirements than the FHWA method. They also noted that the public agencies have traditionally been more conservative than the private sector.

Reinforced soil slope design is covered in the above referenced FHWA guidelines document, as well as in the updated FHWA Geosynthetics Design and Construction Guidelines Manual (Holtz et al., 1998). A computer program, RSS, was developed by FHWA for the design and analysis of reinforced slopes following the design procedures in the reference manual (Geocomp Corporation, 1996). The FHWA manual was incorporated as the help screens within the program. These guidelines were often cited for both public and private sector work. Private sector also relied on geosynthetic manufacturers' design methods, as well as on several text books (e.g., Koerner, 1994 and Holtz et al., 1997) and commercially available software. Virtually all of the RSS design methods were based on limit equilibrium theories (e.g., slope stability approach extended to reinforced soil).

It should be noted that there were other proprietary design methods for both walls and slopes promoted during this same period, but they were not usually validated by instrumented structures, and, in some cases, were somewhat theoretically deficient. Also during this decade, there was a proliferation of wall suppliers. Remember that modular block facings (also known as segmental retaining wall units) were first used in 1985. By 1995 there were at least 10 modular block wall systems, and by the end of the 90's there were at least 10 additional systems. The number of geosynthetic walls constructed by the end of the 1990s was on the order of 25,000 in the US and 35,000 worldwide (Koerner et al., 2001). With this number of walls there were bound to be a few unsuccessful structures. Unfortunately there were more than a few, as discussed later in this section.

Before we review failures, there were a number of well documented successes, again many of which are contained in the proceedings of conferences that were held during the 90s (e.g. the 5th and 6th International Conferences on Geosynthetics, the North American Geosynthetics conferences held biannually during the 1990s and the GSI annual conferences (like GRI-25). Although all of these case histories are important in qualitatively documenting performance, several North American case histories were fully instrumented and noteworthy, as the results quantitatively verify performance and the design procedures. One of these projects is a 15.2 m high, 1H:1V geosynthetic reinforced soil slope (Salmon Lost Trail Pass) shown in Figure 4, which at the time was one of the tallest reinforced soil slopes and one of the few that had been instrumented (Zornberg et al., 1995). The structure was constructed as an FHWA experimental features project and was instrumented with inclinometers within the reinforced zone, extensometers on the reinforcement, and piezometers within and at the back of the reinforced section, and survey monitoring. The results of the instrumentation were used to verify both the design method and a new RSS slope stability program developed by the FHWA for reinforced soil slopes called RSS. Centrifuge models of this slope with instrumented reinforcement were also constructed to evaluate both the working stress and at failure conditions (Zornberg, 1994). This study confirmed the validity of the limit equilibrium approach for predicting internal failure of reinforced soil slopes.

Another project is a 15 m high, instrumented reinforced soil slope for repair of a failed slope on Pennsylvania SR54, which was reconstructed using wet, nearly saturated sandy clay type soils, the spoil from the previously failed slope (Wayne and Wilcosky, 1995). Instrumentation included deformation response of the needle punched nonwoven geotextile reinforcement and pore water pressure dissipation within the reinforced fill during construction. The pore pressure measurements confirmed that consolidation of the slope would be completed by the end of construction due to the pore water pressure dissipation provided by the in-plane drainage characteristics (i.e., transmissivity) of the geotextile.

A third, equally relevant reinforced soil structure is the 6 m high Test Wall built by the Louisiana Transportation Research Center (LTRC) (Figure 5). The test wall was constructed to evaluate the design procedure and performance of geosynthetic-reinforced structures constructed with silty-clay backfill on a soft clay foundation. The instrumentation program involved monitoring wall deformations, foundation settlements, reinforcement strains, vertical and horizontal soil stresses near the wall facing, and pore water pressures under the wall (Farrag and Morvant, 2001). The instrumentation results from the LTRC walls were also used in another

numerical modeling study to evaluate walls with poor draining backfill on soft soil (Saidin, 2007). The results of the study showed that numerical simulations (using FLAC) could predict very well the performance of geosynthetic reinforced soil walls with complex conditions including fine grained reinforced fill and foundation soils, significant settlement (over 0.2 m), and compaction and infiltration effect. The results emphasized the importance of adequate drainage under these conditions.

Figure 4. Salmon Lost Trail Pass instrumented reinforced soil slope on Hwy 93, designed by the Western Federal Lands Highway Division (FHWA) using decomposed granite soils.

Figure 5. Louisiana Transportation Research Center (LTRC) Test Wall Built with Silty-Clay Reinforced Fill over Soft Soil

There was also a significant amount of research conducted in the 1990s to improve the understanding of reinforced soil and to more thoroughly evaluate issues such as the conservatism in design, composite behavior and deformation response. The excellent performance of the Rainier Avenue wall described in the previous section led to some experimental and analytical research at the University of Washington. A plane strain in-soil test apparatus, the Unit Cell Device (UCD), was developed by PhD student S. R. Boyle to directly measure strains in the reinforcement and thus provide the soil-geosynthetic interaction moduli necessary for accurate numerical modeling of GRS. Two examples from Boyle (1995) and Boyle et al. (1996) are shown in Figures 6 and 7. Figure 6 shows some in-soil stress-strain results from UCD tests conducted at a confining pressure of 10 kPa on specimens of the Rainier Avenue sand alone and reinforced with different geotextiles. Because no other in-soil stress-strain results were available to compare with these data, Boyle (1995) also conducted a UCD test with a sheet of stainless steel as reinforcement. Its yield stress was 0.23 percent and its modulus was very close to 200 GPa. These values gave confidence that at least the measured in-soil stress-strain behavior was in the right order and approximately correct.

The results shown in Figure 7 have important implications for design. Boyle (1995) conducted a relaxation test on a specimen of the Rainier Avenue sand reinforced with a 2-layer stitch bonded polypropylene slit-film geotextile. After loading to about 4 percent strain, the load was held constant while continuing to measure the tension in the geotextile. As shown in Figure 7, strain continued, as would be expected, but most interestingly, the tension reduced (relaxation) and then all movement ceased. The specimen and reinforcement were at equilibrium under the applied stresses and no additional strains occurred as long as no additional load was applied. The same thing must happen in the field at working stresses that are well below the failure

stresses. This suggests that creep of the geotextiles in full-scale structures is not a problem because of stress relaxation. Similar results have also been shown by field measurements of real GRS walls, e.g., the Rainier Avenue Wall and a steep slope reinforced with geogrids constructed in Norway (Fannin and Herman, 1990; Fannin, 1994; and Fannin, 2001). One wonders, are the recommended default creep reduction factors really justified?

Figure 6. UCD stress-strain results on the Rainier Avenue sand at a confining pressure of 10 kPa; sand alone (NONE), two nonwoven geotextiles (NW1 and NW2), four woven geotextiles (PP1, PP2, PP3, and PET1), and stainless steel sheet (SS) (Boyle, 1995).

Figure 7. Results of a UCD test conducted on a specimen of Rainier Avenue sand at 20 kPa reinforced with one of the Rainier Avenue reinforcing geotextiles, a two-layer stitch bonded woven polypropylene slit-film.

A number of papers on this research are contained in the conferences previously mentioned. In addition, there were several international symposiums on this topic, including a specialty symposium in Denver, Colorado, 1991 (Wu, 1992a) and a series of conferences held annually in Kyushu starting in 1991. One of the major research undertakings during this period was the construction of full scale walls in a highly controlled laboratory environment. One such wall was constructed for the Denver, Colorado international symposium, which was fully instrumented and loaded to failure, with prediction of the failure load provided by many of the conference attendees (Wu, 1992b).

The most significant test wall program was established at the Royal Military College of Canada in the late 80s. A specially constructed 3.6 m high by 3.3 m wide by 6 m deep instrumented retaining wall test facility at the Royal Military College has been used to construct a number of full-scale walls and slopes. In the 1990s, 17 geosynthetic reinforced soil walls, two reinforced and two unreinforced soil slopes had been constructed and taken to collapse under staged surcharge loading. The results have been used to examine the accuracy of current methods of design and analysis of reinforced walls and slopes. The data has also proved useful to calibrate analytical and numerical models (Bathurst et al., 2000 and 2001; Lee et al., 1999; Lee, 2000; and Holtz and Lee, 2001). The Lee work is interesting because he first calibrated his constitutive models with field and laboratory data from the Rainier Avenue wall. He then was able to make true "Class A" predictions of wall face deflections and reinforcement strains for three RMC test walls with excellent agreement. An additional benefit of the RMC work and the Lee (2000) study was the development of the K-Stiffness method, described later.

While reinforced soil wall design is conservative, as indicated by practically all of the research, it is only conservative in relation to internal strength requirements for the reinforcement. By the end of the decade, it was apparent that the overall reinforced soil wall design with geosynthetics was much less conservative than assumed by most engineers. In a study by Soong and Koerner (1999), 26 failures were identified from the literature. However, as noted in their study, many failures go unreported. In a paper by Christopher and Stulgis (1999), based on information from engineers around the country, they indicated that the unreported failure rate could easily be on an order of magnitude greater than the reported number. A significant majority of which were in the private sector. It should be noted that many of the noted problem projects are excessive movement problems (i.e., serviceability failures). Also, most of the reported failures and most of the unreported failures that the authors are aware of typically used high fines soil for the reinforced fill and they occurred immediately following (or soon after) extensive water events (i.e., rainfall, snowmelt or flooding). Even so, 1 in 130 (i.e., 1 in 35000/260) is still well above the typical failure rates for non critical civil engineering structures (e.g., on the order of 1 in 1000 as indicated by Whitman, 1984).

This issue was getting the attention of owners. Several agencies (state and local – e.g. Dekalb County, Georgia) placed moratoriums on constructing geosynthetic reinforced soil walls and some established height restrictions (e.g., no greater than 3 m, Missouri DOT). As a result, the subject also gained interest from wall suppliers, design engineers and of course researchers, and will be discussed in the next section.

THE 2000s

In the 2000s, there were three major efforts related to design activities, including efforts to improve the current design methods, to resolve the issues with using fine grained soil, and to reduce the number of wall problems. One of those activities was to develop sufficient calibration to reduce the inherent conservatism in the FHWA/AASHTO design model. This effort was initiated through the development of resistance factors for the Load and Resistance Factor Design (i.e., limit state design) in the AASHTO 2002 interim LRFD design specifications. Although the resistance factors in the LRFD approach were backcalculated from the existing design method, that effort quantified the conservatism and uncertainty in the current design methods through an extensive review of instrumented structures (see Allen et al., 2001). There was significant resistance to the LRFD approach in the private sector, but, by end of the decade, AASHTO no longer supported the allowable stress design in the AASHTO 2002 Specifications and were on their 4th edition of the LRFD specifications (AASHTO 2007 with 2008 and 2009 interims) and the design methods in the FHWA MSE wall design guidelines had been converted to LRFD (Berg et al., 2009).

In recognition of issues resulting in poor performance of structures, the new FHWA manual also incorporated significantly more information on design details and included a series of checklists for design and various aspects of construction including drawing review, specification compliance, and construction. Another significant change was the position on drainage requirements. The FHWA manual previously indicated that the design engineer should evaluate the project conditions and determine if drainage is required. In recognition of the consequences in not following good drainage practices, **the new position recommends that adequate drainage features be required for all walls unless the engineer determines that such features are not needed for a specific project.** Along with these additions to the design manual a new course was also added to the National Highway Institute training program on inspection of reinforced soil structures.

NCMA was equally proactive, especially with respect to drainage requirements for walls; publishing a complementary Segmental Retaining Wall Drainage Manual (Collin et al. 2002). The current, 3rd edition of the NCMA Design Manual for Segmental Retaining Walls was published in 2009, and incorporates materials from the 1998 seismic and 2002 drainage manuals, and refers to the drainage manual for good drainage practice.

Three new design methods were also proposed. Based on the information from an extensive review on performance of existing structures (Allen et al., 2002; Allen and Bathurst, 2002), a newly developed lateral earth pressure method called the K_o Stiffness Method (Allen et al., 2003 and 2004) was developed and is currently being calibrated by instrumenting structures designed using that approach. An extensive treatise on MSE walls was published in the 2002 *Geosynthetics International* journal special issue on Geosynthetic-Reinforced Soil Wall Performance and Design Implications, and highlights work by Bathurst and Allen.

The second new design approach was to use an empirically derived composite model for geosynthetic reinforced soil walls integrated with bridge system (GRS-IBS). The geosynthetic reinforced soil system in this case consists of closely spaced layers of geosynthetic reinforcement and very select compacted granular fill material. IBS is a fast, cost-effective method of bridge support that blends the roadway into the superstructure. GRS-IBS includes a reinforced soil foundation, a GRS abutment, and a GRS integrated approach. This method has significant value when employed for small, single-span structures meeting the criteria described in an NCHRP Report No. 556 on its development (Wu et al, 2006).

The third method was to use the limit equilibrium analysis conventionally used for slopes to design walls (Leshchinsky et al., 2004 and Leshchinsky and Han, 2007). This method determines the distribution of required tensile resistance along each reinforcement layer such that the factor of safety on the strength of the soil is uniform everywhere within the reinforced soil mass. By optimizing the reinforcement resistance, the method reduces the reinforcing requirements and the inherent conservatism in the lateral earth pressure approach.

The 2000s also saw the movement of numerical modeling from research to practitioners, with the development of less computationally intensive, simplified programs with canned inputs for reinforcement interaction and facing elements. The ability to evaluate failure in newer models allows the methods to be used to confirm limit equilibrium solutions, in addition to providing an indication of deformation response for different conditions (e.g., see Figure 8). The down side is that they still require good characterization of all elements composing the problem and accurate modeling of the problem or else it may lead to nonconservative results, and, unlike the other empirical design methods, there is no inherent conservatism.

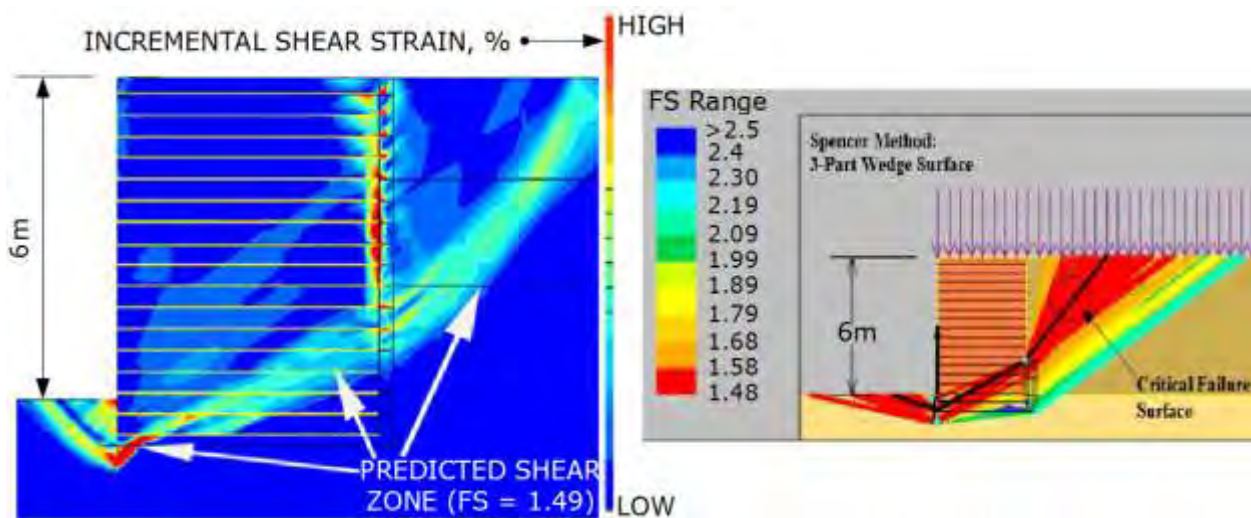

Figure 8. Comparison of a) predicted in-service shear strains and failure surface using a Finite Element Method (PLAXIS) and b) Critical failure surface obtained from a limit equilibrium solution of the same problem using ReSSA (from Christopher et al., 2005).

Another significant development this decade was the calibration of the existing earth pressure models and correspondingly the establishment of safeguards in construction to expand the use of marginal soils. Even though there were reported problems in using fine grained soils, there was also a significant rise in the cost of select granular materials. In fact, in some states MSE walls and thus also geosynthetic reinforced soil systems no longer had a cost advantage over other wall systems (e.g., concrete cantilever walls). In order to relax the more rigorous AASHTO and FHWA reinforced fill requirements, a significant public sector research project was initiated, NCHRP Project No. 24-22 "Selecting Backfill Materials for MSE Retaining Walls", with private sector (NCMA) participation, to evaluate marginal soils in reinforced soil walls.

The focus of the NCHRP 24-22 project was to develop material selection guidelines, soil parameters, testing methods, and construction specifications that would allow the use of more fine-grained backfill materials within the reinforced zone of mechanically stabilized earth (MSE) retaining walls. Figure 9 presents the layout and pertinent details of the NCHRP full-scale test walls.

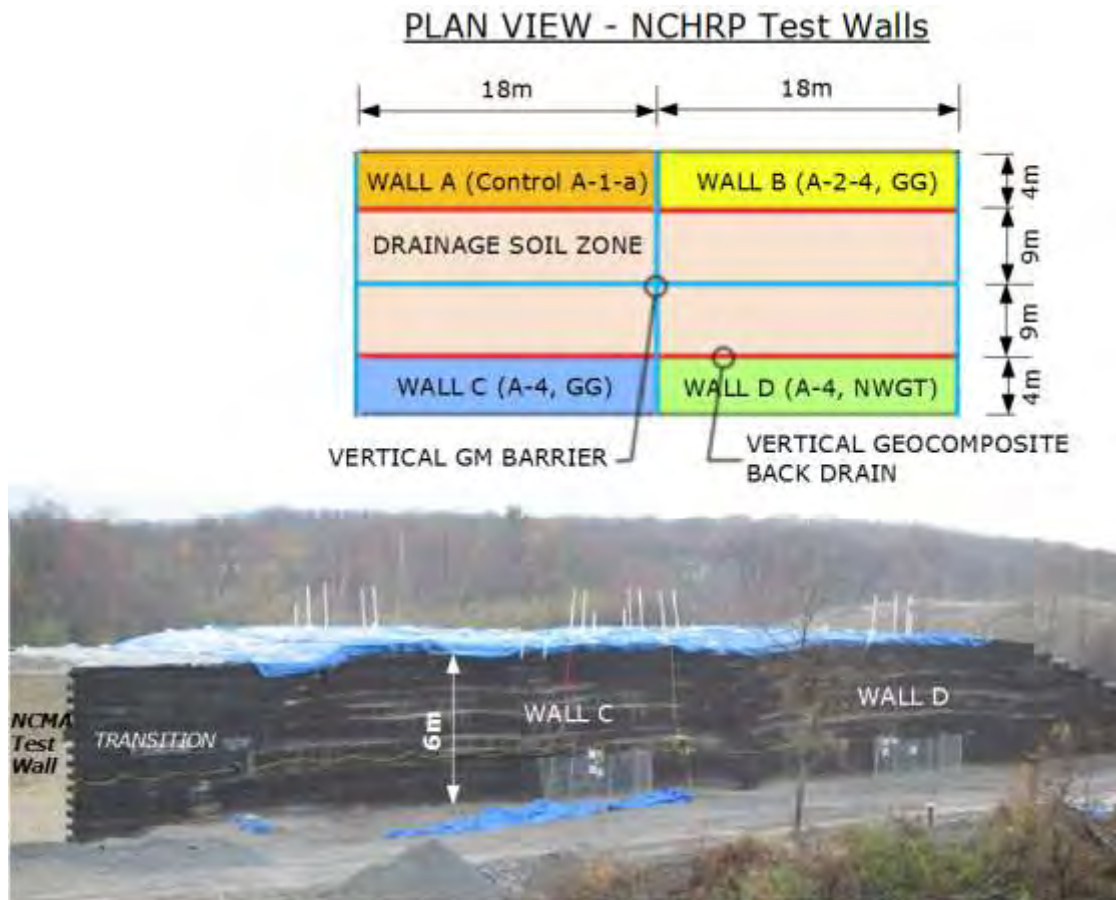

Figure 9. Full-Scale Field Test (NCHRP 24-22)

The test walls rigorously evaluated the seepage issue associated with the use of “high fines” reinforced fill. Several hydrotests were conducted over a 2-year period during which water was pumped into the drainage soil zone of each of the test walls. The test walls were fully instrumented. Most instruments were electronic and connected to automatic data logging equipment that provided data 24/7 over the two year test program.

The research clearly demonstrated that MSE structures with higher fines soils in the reinforced fill than currently allowed by AASHTO will provide excellent performance. This work demonstrates that the current AASHTO limit on maximum fines content can be increased (for walls reinforced with geosynthetic materials) from 15% to 25% subject to the following considerations:

- Soils with less than 25% fines and a Plasticity Index not greater than 6% are used.
- All potential sources of pore pressure build-up in the reinforcing zone should be addressed by the design.
- Good practices are used to control the quality of material selection and placement, as the performance of higher fines soils is more susceptible to as-placed density and moisture content than free draining materials.

As in previous decades, there were a number of published case histories in conferences and journals. Two case histories stand out as the most significant of this era. The first project is the Founders Meadows Bridge project in Colorado (Abu-Hejleh, 2000). In July of 1999, the Colorado Department of Transportation (CDOT) successfully completed the construction of the new Founders/Meadows Bridge near Denver, which is a two-span bridge over an Interstate highway supported by geosynthetic-reinforced segmental, modular block retaining walls. The reinforced soil system was designed using geogrid reinforcement to provide bridge support and to support the roadway approach embankment, which would also alleviate the common bridge approach bump problem. A comprehensive material testing and instrumentation program was conducted due to the experimental nature of this wall. Three sections were instrumented to provide information on external movements, internal soil stresses, temperatures, moisture content, and geogrid strains during various construction stages and after the structure opening to traffic. The instrumentation results to date indicate the overall performance of this structure has been satisfactory and that the design was conservative, partly attributed to the use of conservative soil strength values.

The second project is the 74 m high, 1V:1H geosynthetic reinforced soil structure constructed to extend the runway at Yeager Airport in Charleston, WV as shown in Figure 10. This is currently the tallest reinforced soil slope in North America and maybe the world. Due to the mountainous conditions, the ground surface around the airport slopes down steeply over 91 m to the surrounding Elk and Kanawha Rivers, roadways, churches, houses and other structures. In order to meet recent FAA Safety Standards, upgrades to the airport runways required extending Runway 5 approximately 150 m to create an emergency stopping apron for airplanes. Engineering evaluation indicated the reinforced slope provided the most cost effective and easiest constructed option. It has a vegetated facing that blends into the surrounding green hills of Charleston, WV. Unfortunately the structure was not instrumented, but clearly demonstrates the potential of using geosynthetic soil reinforcement to build green structures for the future.

Figure 10. 242 ft (74 m) High 1H:1V Reinforced Soil Slope for Airport Runway Extension (Lostumbo, 2009)

2010 - 2013

Well, this decade is just getting started, but there have already been some significant activities, which will clearly impact the future of geosynthetic reinforcement technology. As a result of the demonstrated performance of GRS-IBS, the technology was selected for the FHWA's Every Day Counts initiative, aimed at accelerating implementation of proven, market-ready technologies. A design manual, FHWA-HRT-11-026 (Adams et al., 2011) was developed for the implementation of the technology, which outlines design approach and construction requirements of GRS-IBS. A second document provides a synthesis report to substantiate the design method.

Over 100 bridge structures have been designed today, and a majority have been constructed, several of which have been instrumented. A comprehensive data base is being maintained. More information on the utilization of this technology can be obtained from http://www.fhwa.dot.gov/everydaycounts/technology/grs_ibs/ and an FHWA design guidance document is available at:

<http://www.fhwa.dot.gov/publications/research/infrastructure/structures/11027/index.cfm>.

A second program that was generated over the past several years is Geotech Tools, a large toolbox for the engineering and construction of earthworks and ground improvement. This was developed under the second Strategic Highway Research Program (SHRP 2) *Project R02 Geotechnical Solutions for Soil Improvement, Rapid Embankment Construction, and Stabilization of the Pavement Working Platform* by a team of university researchers from Iowa State University, Virginia Tech, and the University of Kansas and nationally recognized ground improvement consultants. It is a readily accessible web-based system that contains a catalog

with detailed information on 46 geoconstruction and ground improvement techniques, including geosynthetic reinforced soil walls and slopes as well as support technologies for soft ground support. Users will find that the value of the system is that it has collected, synthesized, integrated, and organized a vast amount of critically important information on these geotechnologies. Eight engineering tools are available for each geotechnology and include guidance for design, QC/QA methods, specifications, and cost estimating. This system can be accessed at www.GeoTechTools.org and is free to use.

Recently, AASHTO T-15 Committee, in cooperation with FHWA, formed a task force to assist in future decision making for the AASHTO LRFD specification articles related to MSE wall design. The primary purpose was to develop a strategy for addressing recognized gaps in the design specifications with regard to MSE walls and incorporating key aspects of a significant amount of research that has been developed and published in the last 5 to 10 years. This task force will provide an opportunity for leaders in the development of reinforced soil design, specifically as applied to walls, to work toward consensus on key MSE wall design issues and how they should be handled. It is envisioned that the findings and recommendations of this Task Force will help chart the future direction of the design practice in North America.

Unfortunately the ugly part of the practice continued to emerge, with the 2012 count at 141 documented cases of MSE wall failures resulting in either excessive deformation or actual collapse (Koerner and Koerner, 2012). As with previous assessments of the primary causes, inadequate or improper design and/or construction were the apparent issues. Again, the major design inadequacy appears to be the lack of proper drainage procedures and the placement of water bearing utilities (i.e., “plumbing”) within the reinforced soil zone. Based on the findings, the authors recommend shifting the utilities out of the reinforced soil zone, which is also the recommendation in the FHWA MSEW/RSS manual (Berg et al., 2009). Again, a preponderance of the failures were found to be the result of *major construction inadequacy* in the use of fine grained silty and clayey backfill soils and furthermore their inadequate placement and compaction. One other final point that was noted from the data base is that 140 of the 141 cases were in the private sector.

Other factors that often result in poor performance include inadequate global or external stability, unexpected surcharges, lack of proper inspection, poor training for workers, and little or no control of the construction by the designer. “Value engineered” or “contractor supplied” designs, with no budget for checking alternates by competent professionals can also result in poor performance. In some jurisdictions (e.g., Seattle, Washington) require GRS “wall” designs to be stamped by a registered structural engineer. Although well qualified in structural engineering practice, they may have limited experience with and knowledge of soil reinforcement principles and practices, geosynthetic reinforcements, and/or drainage issues and detailing. Furthermore, they are often not retained for construction inspection.

Large developments involving reinforced structures are a potential source of difficulties and occasional failures. There often is a disconnect between the GRS wall designer, the geotechnical engineer of record, and the site civil engineer. The lines of responsibility are often unclear and the contractual relationships fuzzy as to who is responsible for what and when. This relationship is further complicated by wall designs supplied by materials suppliers and

distributors who are not responsible for the soils, drainage, or construction. Note that in recognition of these responsibility issues, the current NCMA Design Manual for Segmental Retaining Walls (2009) now contains specific chapters on: roles and responsibilities on projects involving SRWs; design guidelines for site civil engineers; and design guidelines for project geotechnical engineer. Also note that detailed discussions on procuring, designing and constructing MSE walls to minimize problems and ensure long service life were published in a 2007-2008 series of articles in *Geosynthetics* magazine by Simac and Fitpatrick.

Clearly, fixing problems is always more expensive than proper inspection and control by the designer, but practitioners are often not adept at convincing clients of this fact. It has been estimated that the cost of fixing a failure is about ten times greater than the cost of the original design and construction! The high cost of all the ugliness mentioned above is unnecessary, costly, and potentially tragic.

IN RETROSPECT

Figure 11 provides a timeline of many of the more notable activities over the past 25 years, which have had a significant impact on the implementation and maintenance of this technology. Although there was much success over the last 25 yrs in implementing this technology, we can and should learn from the past. The following provides the retrospect of the past 25 years from the authors' perspective. We hope others can also glean additional insights from this brief history of geosynthetic reinforced soil walls and slopes. From this historical perspective, we have concluded:

1. The historical review of these activities and developments shows how far we have come in the implementation and maintenance of reinforced soil technology. Best practices were identified during this period that have led to significant success and design improvement in using geosynthetic reinforcement. A number of issues were identified that have resulted in poor performance and even failures, which could be significantly reduced by the broader application of those best practices.
2. The design methodology currently used in the design of reinforced soil structures (walls and slopes) results in structures with conservative reinforcement against internal failure.
3. MSE walls on transportation projects are generally conservatively designed using granular soils, i.e. with "low fines" soil in the reinforced zone. Private MSE walls are less conservatively designed, and use a variety of reinforced soils. The majority of walls that have performed poorly, due either to collapse or excessive deformation of the walls, are in the private sector and consisted of reinforced fill comprised of silty sand and clayey soils, with pore water pressure in these reinforced fill materials contributing to the excessive deformation or collapse of the walls.
4. Drainage - Drainage - Drainage: All designers should follow the recommendations in the FHWA design manual: All walls should include good drainage unless the engineer can prove that it is not required.

5. All designers should follow the advice of Koerner and Koerner, 2012 and the recommendations in the FHWA design manual: Keep the utilities out of the reinforced fill.
6. We should have maintained a taskforce of experts from both the private and public sector (like the AASHTO Task Force 27, the NATO group of experts, and the newly formed AASHTO T15 Taskforce) as a permanent standing body to provide a forum for review, evaluation and implementation of new design methods and provide better consistence between public and private practice.
7. The key to the future use of geosynthetics in reinforced soil lies in improved communication. Communication can best be achieved through education, and not only by academic institutions. Education is a challenge to the entire industry. Once everyone involved with MSE wall design and construction understands the issues associated with the proper use of this technology, we will indeed reach new heights in terms of the advancement and application of this technology.

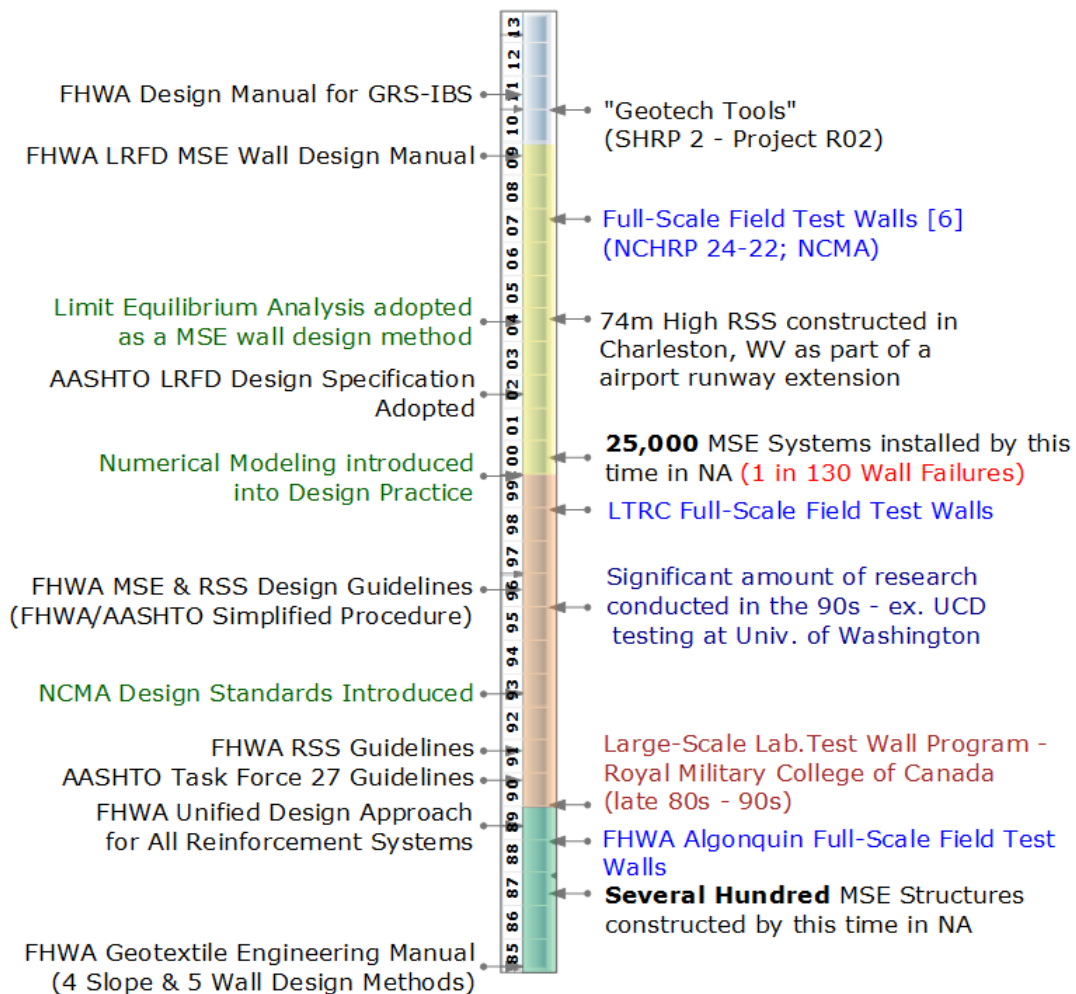

Figure 11. Timeline in the Development, Implementation and Maintenance of MSE Walls and Reinforced Soil Slopes

GEOTEXTILES IN MARINE ENGINEERING: PAST, PRESENT AND FUTURE

Chris Lawson
TenCate Geosynthetics Asia, Malaysia

ABSTRACT

Geotextiles have been used in marine engineering for over 50 years. From their early beginnings as filters in simple revetment structures geotextiles have grown to be currently used in a wide variety of different marine structures with increasing sophistication. The paper reviews the development history of geotextile revetment filters as well as highlighting the current usage of geotextiles in a wide range of marine engineering techniques. In the future, it is expected that this variety of use will increase further, along with increased sophistication as access to conventional materials becomes more difficult and environmental sustainability becomes more important.

INTRODUCTION

When Bob Barrett published his paper on the use of “plastic filters” in coastal structures in USA in 1966 (Barrett, 1966) it provoked early interest internationally in the possibility of using geotextiles (not known then by the term “geotextiles”) for coastal and marine engineering applications. While the application of (the fore-runner to) geotextiles in these structures had started in Europe in the 1950’s the Barrett paper provided the first formal reference on this subject. At the time (and over the succeeding 15 years), geotextiles faced much suspicion and skepticism, not only because of the perception that the material appeared to be made from “the same type of plastic as my children’s toys”; but also because of a lack of familiarity and performance knowledge, and a lack of rational design procedures.

Over the subsequent 45 years geotextiles have not only overcome these early obstacles, but have gone on to become integral parts of many modern marine engineering projects. Today, geotextiles are considered as standard materials in a wide variety of marine structures. Further, over the last 10 to 15 years we have witnessed a considerable increase in the sophistication of geotextile use in marine engineering projects. This combination of increasing variety and sophistication has led to many innovative marine solutions involving geotextiles.

In examining the past, present and future of geotextiles in marine engineering it is proposed to look at the past through the introduction of geotextile filters in revetment and reclamation structures which began some 40 to 50 years ago, and are considered standard practice today. For the present it is proposed to look at examples of the wide range of geotextile applications in marine engineering that currently exist. This will demonstrate not only the variety, but also the sophistication of many of these current applications. For the future, it is proposed to look briefly at some of the trends going forward in the use of geotextiles in marine engineering.

GEOTEXTILE FILTERS IN MARINE ENVIRONMENTS: 1960'S TO PRESENT

Revetment and reclamation filters

An early use of geotextiles in marine engineering was as filters in simple revetment (slope protection) structures. It is uncertain exactly when this began, but there are European propositions of use as early as the 1950's. However, this paper will take the examples of use given by Barrett (1966) from the early 1960's as the early reference examples. As stated already, Barrett's paper created interest around the world in coastal and marine engineering circles to the extent that by 1970 geotextile filters had been employed in revetments in Europe, Australia and Japan, including the USA.

The concept of using a geotextile filter in a revetment is shown in Figure 1 where the geotextile substitutes for the conventional fine and coarse filter. In the past revetments utilized multiple layers of sand, gravel and rock to create an erosion resistant surface (see Figure 1a). Each granular layer in the revetment had to be small enough to prevent the material from below being eroded while at the same time be large enough to prevent it from being eroded out of the coarser layer above. Meeting these requirements required multiple granular layers which proved expensive and difficult to install, in many cases under water.

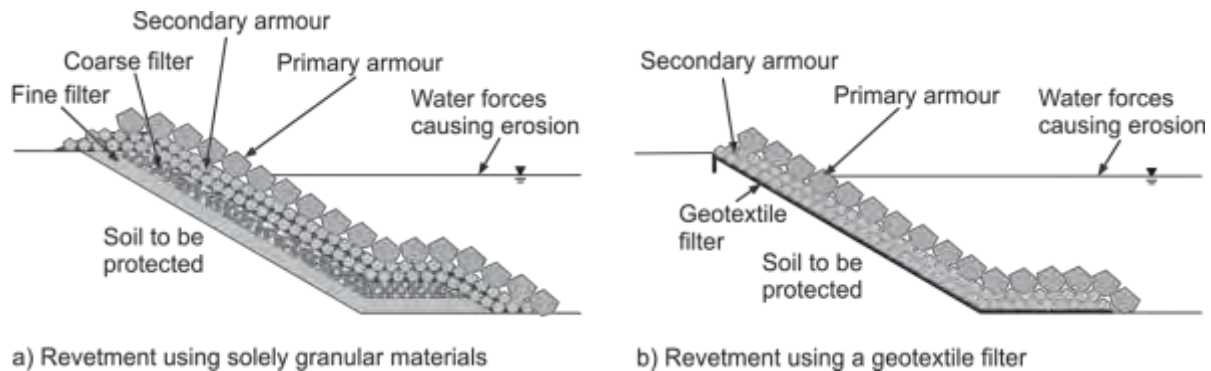

Figure 1. Revetment using solely granular materials and comparative structure using a geotextile filter.

The use of geotextile filters in revetments is very cost-effective; in fact, this has one of the highest cost-benefit ratios of any geotextile application. The geotextile has relatively fine pores which prevent the erosion of fine soils beneath it, and at the same time it is a “sheet-like” material and cannot be washed out through the coarse layers above. Thus, a single geotextile filter layer can substitute for multiple granular layers as shown in Figure 1b.

Even early in the use of geotextile revetment filters it was recognized that well-defined design criteria was necessary in order to quantify the appropriate geotextile filter properties. The geotextile had to meet specific hydraulic criteria in order to prevent soil erosion and allow free water flow. It also had to meet specific mechanical criteria in order to prevent mechanical damage. Further, it had to meet specific durability criteria in order to last for the design life of the revetment structure. Quantifying these different geotextile criteria has defined the 40 years history of geotextile revetment filter research.

The earliest research in USA on geotextile hydraulic criteria was carried out by Calhoun (1972) of the US Army Waterways Experiment Station. Besides establishing filtration limits under a unidirectional flow regime for a very limited range of soil types and geotextiles, one conclusion reached was to have a profound effect on geotextile filter selection for many years to come in the USA. This conclusion was that nonwoven geotextiles should not be used as filters because “it was difficult to determine their appropriate hydraulic properties” compared to woven geotextiles which had easily identifiable properties of Equivalent Opening Size and Percent Open Area. While there was much subsequent filter research in USA and Europe in the intervening years that demonstrated the good performance of nonwoven geotextile filters, it was not until the late 1980’s that nonwoven geotextiles were accepted as suitable revetment filter geotextiles in the USA. Even today, the requirements established by Calhoun in 1972 can be seen in some US Government (specifically US Corps of Engineers) geotextile specifications.

In Europe and the rest of the world the development of geotextile hydraulic criteria under unidirectional flows began in the mid 1970’s and continued on into the early 1990’s. These are reported in another paper by Bob Holtz delivered at this conference. Much of this work was carried out using nonwoven geotextiles and a large database of nonwoven geotextile filter performance with a wide range of soil types was built up.

Revetments are subject to a variety of hydraulic forces depending on their location. These can range from hydraulic drawdown (unidirectional flows) to water currents (surface shear flows) to waves and tides (reversing flows). The geotextile filter must be designed for the most critical hydraulic condition occurring. Much of the physical modeling that has been used to develop geotextile hydraulic criteria over the last 40 years has been carried out under unidirectional flow conditions. The reason for this is that the conditions are relatively simple to replicate in the laboratory (only a unidirectional water flow) with the equipment being relatively simple to develop and operate. Modeling wave and tide conditions (reversing flows) is much more complex, especially for revetment structures. Not only is there the complexity of varying reversing flows (disturbing forces of different wave heights and wave periods) but also the complexity of the confining effect of the weight of the revetment armor on top of the geotextile filter (stabilizing forces of the armor overburden stress). It has only been over the last 5 to 10 years that laboratory modeling equipment has been developed with the sophistication and precision to evaluate the performance of geotextile filters under reversing flow conditions. Results under reversing flow conditions published by Srikongsri (2010) show regions of different geotextile filter retention behaviour according to different external stress ratios (see Figure 2). It is interesting to note that the proposed recommended “safe” retention limit for reversing flow conditions shown in Figure 2 is virtually identical to the retention limit for unidirectional flow conditions published many times over. It would appear that the increased erosive forces caused by wave forces are counterbalanced by the added confining stress caused by the presence of the rock armor thus resulting in overall conditions very similar to that of (simpler) unidirectional flow regimes.

Early in the use of geotextile revetment filters it was recognized that mechanical criteria played a very important role in the performance of the geotextile filter. Puncturing and tearing of the geotextile during installation resulted in soil erosion and fairly quick failure of the revetment. Clearly, to perform well the geotextile filter has to resist these mechanical stresses that occur

during installation. Historically, a variety of approaches have been adopted to develop suitable mechanical criteria. These have ranged from the development of empirical relationships based on geotextile properties, e.g. Lawson (1992); to the development of empirical relationships based on energy absorption properties, e.g. Wong et al. (2002); to the development of classification systems, e.g. AASHTO (2005). Today, much is known about the mechanical criteria for geotextile revetment filters under a wide variety of installation conditions.

Figure 2. Geotextile filter retention criterion for waves and tides condition.
(After Srikongsri, 2010)

Early in the use of geotextile revetment filters it was recognized that durability criteria were also important requirements. Geotextiles are composed of polymers which remain very stable over long periods of time when buried in varied soil environments. However, when exposed to UV radiation these polymers oxidize, become brittle and lose elongation and strength. Clearly, to avoid this occurrence the geotextile filter must have adequate UV resistance during the revetment construction procedure and there needs to be an adequate rock covering to ensure that no UV radiation penetrates the revetment structure (to the geotextile) during its design life.

While revetment structures using geotextile filters may have been considered very novel 40 to 50 years ago, today they are standard practice, and commonly in use the world-over. We see them constructed in varied hydraulic environments and see them composed of different armor systems. By far the most common form of revetment is one that utilizes rock armor. However, revetments using geotextile filters are also constructed using concrete armor, concrete blocks and concrete forms depending on the local prevailing conditions.

The use of geotextiles as reclamation filters is also as old as that for revetment filters. Here, rather than placing the geotextile on the soil to be protected and then placing the rock armor on top, a rubble-mound containment dyke is first constructed and then the geotextile filter placed on the inside slope followed by the placement of the reclamation fill (see Figure 3). The geotextile filter prevents the placed reclamation fill from being eroded out through the rubble-mound dyke of the reclamation. This technique is normally used where water depths and water forces do not justify the placement of the fill material before the placement of the protection

layers (the protection layers must be placed before the placement of the fill material to prevent loss of the fill).

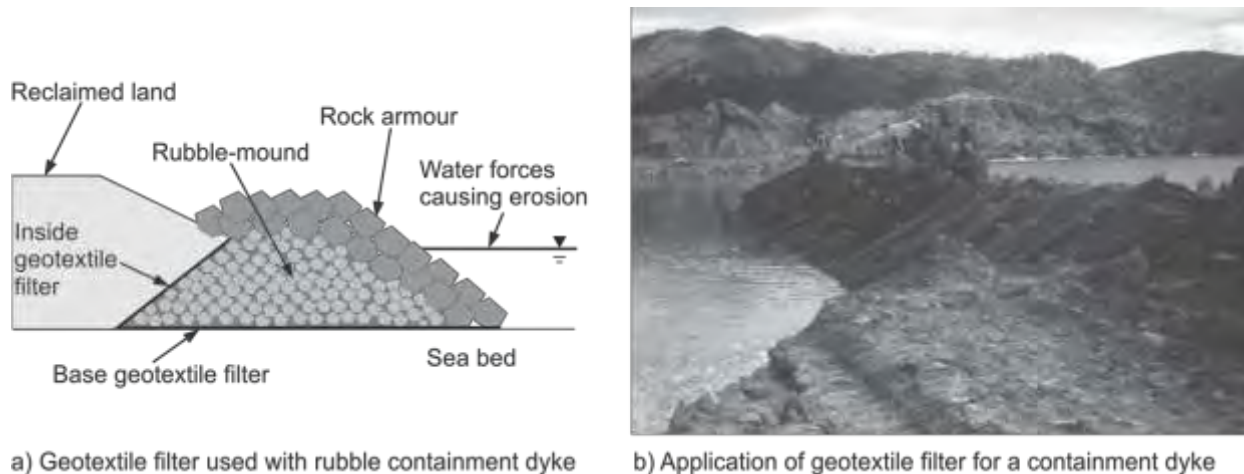

Figure 3. Geotextile filter used in conjunction with rubble containment dyke.

While the inside geotextile filter shown in Figure 3a does not have to resist rocks being dropped on it (as is the case for revetments), it does have to be robust enough to span across the rough surface of the rubble-mound dyke. This normally requires a robust geotextile filter to be used in this location. Depending on the foundation conditions a base geotextile filter may be also required beneath the containment dyke (Figure 3a). This can arise in situations where the sea bed consists of soft soils or of sand.

Basal filters beneath rubble-mound breakwaters

Where rubble-mound breakwaters are located on rock or overconsolidated clay foundations erosion across the base of and at the toes of the breakwater generally does not occur. However, if the breakwater is located on a sand foundation then erosion and scour at the toe of the breakwater and across its base can occur which may lead to undermining and instability. In these situations a geotextile filter, located across the base of the rubble-mound breakwater, is included to prevent erosion and scour of the sand foundation. The typical layout of a rubble-mound breakwater with a basal geotextile filter is shown in Figure 4a.

Depending on the location of the rubble-mound breakwater the basal geotextile filter may need to be installed at appreciable water depth and in diverse water current and wave conditions. To facilitate this, the basal geotextile filter is normally first fabricated on-land into what is known as a “fascine mattress” prior to floating to site and sinking into place. Historically, this technique was originally developed in Europe using “fascines” (brushwood) as a form of filter for the base of rubble breakwaters. With the advent of geotextile filters in the 1970’s this original technique was modified with the fascines forming a “floating skeleton” structure for the geotextile filter to facilitate the installation of the basal filter to considerable water depth. This technique has become the standard form of rubble-mound breakwater construction on sand foundations.

a) Basal geotextile filter in rubble-mound breakwater

b) Fabrication of fascine mattress on land

c) Towing fascine mattress into place

d) Sinking of fascine mattress on the seabed

Figure 4. Basal geotextile filter and fascine mattress installation technique.

The modern fascine mattress technique involves the on-land fabrication of large geotextile sheets attached to a lattice fascine (or bamboo) network, Figure 4b. The “fascine mattress” is then pulled into the water and floated to its installation location (Figure 4c) and then sunk into place on the seabed by the application of rock on top of the mattress (Figure 4d). The deployment and installation procedure normally imparts quite high tensile loads to the geotextile filter, and consequently, woven geotextiles with tensile strengths ranging from 100 kN/m to 200 kN/m are commonly used for this application. However, it should be noted that higher strength woven geotextiles have also been used.

REINFORCED SOIL STRUCTURES IN MARINE ENVIRONMENTS: 2000’S TO PRESENT

Reinforced soil structures using geosynthetics have been in use on land for almost 40 years. Today, basal reinforced embankments, reinforced slopes and reinforced retaining walls are standard forms of construction on-land, and well-recognized design Codes exist for them, e.g. BS8006-1:2010.

Over the last 10 years there has been interest in transferring the economies of reinforced soil construction achieved on-land to in-water (i.e. marine) construction. Constructing reinforced soil structures in and under water is more complex than constructing them on-land. However, with the advancement in marine construction techniques and installation accuracy marine reinforced soil structures have become a viable alternative to conventional structures.

When designing reinforced soil structures in-water two important considerations must be taken into account. First, the out-of-balance forces can be of different magnitude and second, more robust surface protection and coarser fills may be required because of the presence of external water forces. In determining the out-of-balance forces the bulk density of the reinforced fill is used for on-land calculations while the buoyant density may be used for in-water calculations, Figure 5a. This makes the out-of-balance forces in-water considerably less than on-land, and would normally mean considerably less reinforcement required for stability. However, the designer needs to consider if these conditions will remain the same over the design life of the structure. The presence of external water forces creates an erosive environment which normally requires more robust surface protection and special (more-coarse) reinforced fills than would normally be the case for on-land construction, Figure 5b. Further, external water forces may impart higher stresses on the reinforced soil structure than occurs on-land. These differences have to be taken into account at the design stage.

Figure 5. Two differences between on-land and in-water reinforced soil techniques.

Basal reinforced breakwaters and seawalls

To perform their function breakwaters and seawalls must maintain their shape and height. Consequently, where possible, these structures are located on stable foundations so they do not undergo deformations (change in height) over time. However, in certain situations, locating these

structures in areas of soft foundation soils may be unavoidable, especially where the precise location of the breakwater is critical.

Historically, where breakwaters and seawalls have to be located in areas of soft foundation soils the conventional construction procedure has been to first dredge the soft soil and replace it with sand-fill prior to construction of the breakwater, Figure 6a. For large breakwaters this is still the preferred procedure (or the use of a deep foundation improvement technique), however, for smaller breakwaters and seawalls the dredging of the soft foundation and its replacement with sand-fill makes the structure very expensive (in certain cases prohibitively so).

Figure 6. Comparison between a conventional breakwater located on a soft foundation and a basal reinforced breakwater or seawall.

There are two problems with constructing breakwaters and seawalls directly on soft foundation soils. First, there is the problem of stability where the soft foundation cannot support the weight of the breakwater or seawall. Second, there is the problem of settlement where the soft foundation consolidates and the height and shape of the breakwater or seawall changes. The problem of stability may be overcome by the use of basal geotextile reinforcement, Figure 6b. Here, the basal reinforcement enhances the short term stability of the breakwater until such time as the soft foundation has gained adequate shear strength to support the breakwater by itself.

The use of basal reinforcement to enhance the stability of breakwaters and seawalls is identical to the technique used to enhance the stability of embankments on-land, and there is a long history of this (some 40 years).

Breakwaters and seawalls are designed to maintain a specific height and shape. When these structures are constructed on soft foundation soils consolidation of the soft foundation leads to settlement of the breakwater, a reduction in height and a change in shape. To prevent this performance loss either the breakwater height is over-compensated during initial construction to allow for future settlements, or subsequent placement of rock is programmed sometime after construction to maintain the design height of the breakwater.

Ameratunga et al. (2006) report on a basal reinforced seawall constructed on soft marine clay for the expansion of the Port of Brisbane, Australia. The seawall was constructed to contain dredged maintenance spoil which would then form the land area for the port expansion. A significant length of the 4.6 km long seawall was located on a very soft marine clay layer up to 30 m in thickness with an undrained shear strength as low as 5 kPa at the surface and increasing

linearly with depth. The surface of the soft marine clay layer was approximately 3.5 m below average water depth.

To ensure short term stability of the seawall basal reinforcement was included as shown in Figure 7a. The basal reinforcement used was a 700 kN/m woven polyester geotextile placed on top of the soft marine clay layer by means of a special installation barge, Figure 7b. Sand-fill was dredged and placed on top of the basal reinforcement up to mean high water level. Following this a geotextile filter was placed across the top of the sand-fill prior to placement of the rock armouring, Figure 7c. It was anticipated that settlement of the seawall would approximate 1 m so the height was over-compensated by this amount during construction.

Reinforced slopes

While the construction of reinforced slopes in marine environments is uncommon compared to other forms of marine structures, they do nevertheless demonstrate the level of sophistication currently possible in practice. The choice of the appropriate materials and their accurate placement in water is critical to the performance of the resulting reinforced soil structure.

Van Miegheem et al. (2006) report on the design and construction of a submerged reinforced slope that formed part of a partially submerged containment dam constructed in an existing dock basin (“Doeldok”) at the Port of Antwerp, Belgium. The containment dam, shown in Figure 8a, was constructed to retain dredged spoil from port expansion and maintenance dredging operations and had a total height of 27 m, of which 19 m was constructed below water.

The major challenge for this project was that the containment dam had to be constructed on very soft sediments, of thickness approximately 9 m, in the base of the existing dock; and these could not be removed for environmental reasons. Due to the very low bearing capacity and undrained shear strength of these sediments (2 to 4 kPa), it became clear that some kind of foundation layer reinforcement was required to ensure stability of the containment dam. The solution used was to combine deep soil mixing beneath the side-slopes of the containment dam with geotextile reinforcement in the outer (steeper) slope of the dam (see Figure 8a). The inner slope of the dam was constructed with a flatter side-slope, and thus only deep soil mixing was carried out here. The combination of the two treatments at the outer slope of the dam ensured there was adequate stability during the controlled construction of the containment dam.

b) Fabrication of the block facing and reinforcement on land

c) Installation of the prefabricated facing and reinforcement under water

Figure 8. Submerged reinforced slope for partially submerged containment dam (After Van Miegheem et al., 2006).

Once the deep soil mixing had been carried out beneath the future side-slopes of the containment dam, construction of the dam was carried out using sand-fill placed in stages to control stability. On the outer side of the containment dam stability was maintained by using sand-cement segmental block facing units attached to layers of woven PET200 geotextile

reinforcement (200 kN/m in strength). The use of the block facing units enabled the outer side-slope to be constructed at an angle of 2.5H:1V, and also prevented erosion of the sand-fill. The use of polyester geotextile reinforcement was considered important as it would enable the geotextile to sink easily in water and thus facilitate placement. To provide the required stability, eight layers of woven PET200 geotextile reinforcement were installed at 2 m vertical spacings, and extending continuously between 65 m and 100 m into the containment dam. The fabrication of the facing blocks and the attached woven polyester reinforcement was carried out on land (see Figure 8b) prior to installation in the dock.

On the outside of the containment dam slope, the large block facings with the attached geotextile reinforcement were installed using a large capacity floating crane (see Figure 8c). Once the block facing unit had been placed under water the woven PET200 geotextile reinforcement was then completely rolled out across the sand-fill surface in one continuous sheet, to the length required, using a second floating crane. The sand-fill used for the filling operations was obtained from excavation works for the construction of a new dock nearby in Antwerp harbour. The sand was selected on the basis of its grain size distribution and fines content. The sand-fill was placed in layers 2 m thick using hydraulic filling. At each 2 m lift, the foundation was allowed to consolidate for a period of 1 to 2 months. Following this, another block facing layer was placed along with the woven PET200 geotextile reinforcement and the sand filling procedure repeated.

GEOTEXTILE CONTAINMENT IN MARINE ENVIRONMENTS: 1950'S TO PRESENT

Geotextile containment, where sand-fill is encapsulated inside a geotextile, provides a variety of effective mass-gravity protection units that are differentiated on the basis of shape and mass. The geotextile skin provides the containment strength and integrity, and prevents loss of the sand-fill. The fabrication of the geotextile skin provides the shape and size of the containment unit. The sand-fill provides the contained mass of the unit. The use of sand-fill for these units is important as it ensures a permeable unit as well as a stable unit that does not undergo volume change with time. Three types of geotextile containment units are used in marine engineering. These are geotextile bags (Figure 9a), geotextile tubes (Figure 9b) and geotextile containers (Figure 9c).

Geotextile bags, Figure 9a, are small-volume containers that are filled on land or above water and then pattern-placed either near water or below water level. They are manufactured in a range of shapes, and range in volume from 0.3 m³ to 8 m³. Geotextile tubes, Figure 9b, are tubular (sausage-shaped) containers that are formed insitu on land or in water. The tubes are filled by hydraulically pumping sand-fill into the tube. Geotextile tubes range in size from 4 m to 25 m in circumference, and up to 200 m in length for marine applications. Geotextile containers, Figure 9c, are large-volume containers that are filled in barges above water and then deposited into submarine environments. The volumes of these containers more commonly range from 100 m³ to 700 m³, although containers as large as 1,000 m³ have been installed.

b) Geotextile tubes

c) Geotextile containers

Figure 9. Types of geotextile containment units used in marine engineering.

Geotextile bags

Peoples' normal perception of geotextile bags is that they are the small, ubiquitous "sand-bags" seen the world-over shoring up flood defenses in times of natural calamity. These bags are small in volume ($< 0.3 \text{ m}^3$) and are not considered here. Rather, the geotextile bags covered in this paper refer to those types specifically developed for, and used in, marine engineering applications. These are larger, more-robust and durable than the conventional "sand bag". In a modern context, these larger geotextile bags started to be used for marine applications in Europe in the 1950's. At the time, these bags were manufactured from woven nylon materials and ranged in volume from 0.5 m^3 to 1 m^3 . Since that time geotextile bags have evolved to larger volume units (up to 8 m^3) of varying shapes (pillow, mattress and box shaped), along with the use of specially developed, highly resistant, geotextile skins.

For best performance it is essential that the geotextile bags be filled to maximum density and volume. This becomes more difficult as the volume of the bag increases, but can be enhanced by using water to compact the sand-fill hydraulically within the geotextile bag. Filled density and volume is important from the viewpoint of maximising stability, but it is also important from the viewpoint of minimising the effects of fill liquefaction and internal movement, and the subsequent loss of shape of the geotextile bags. To ensure the contained fill is

maintained in its dense state the geotextile skin should have adequate tensile stiffness and not undergo stretching and deformation over time.

One major advantage of geotextile bags is that these small-volume units can be used to construct marine structures that require good geometrical tolerances. This can make them preferable to large-volume units such as geotextile containers when specific slope and height tolerances are required. Another advantage of the small-volume geotextile bag units is that maintenance and remedial works can be carried out easily by replacing the failed bag(s). This is simpler than carrying out remedial works on larger-volume containment units such as geotextile containers.

Figure 10. Applications for geotextile bags (After Lawson, 2008).

Geotextile bags are used for a range of marine applications. These are shown in Figure 10 and described briefly below. Geotextile bags are used for revetments (Figure 10a) where their contained fill is used to provide stability and prevent erosion. Geotextile bags have been used for

both submerged as well as exposed revetments (the same as geotextile tubes). Much of the details concerning geotextile bag revetments also apply to geotextile tube revetments.

Geotextile bags may be used as groynes (Figure 10b) to prevent the littoral movement of shoreline sediment. Geotextile bags can also be used to construct artificial reefs (Figure 10c). Here, the same conditions apply for geotextile bags as for geotextile containers. A major advantage of geotextile bags is that they can be installed to better geometric tolerances than relatively large-volume geotextile containers. Also, being relatively small in volume and having considerably better fill density, the geotextile bags are less prone to liquefaction from waves (or its effects) than the relatively large-volume geotextile containers.

Geotextile bags can be used to provide buttress support to an unstable slope in a hydraulic environment (Figure 10d). Here, the geotextile bags act as a mass-gravity berm providing additional restraint to the toe of the unstable slope. One advantage of geotextile bags for this application is that installation can be carried out by simple lifting equipment; thus geotextile bags can be installed at shallow water depths if necessary, unlike geotextile containers, which have to be installed at relatively greater water depth.

Geotextile bags are used as expedient means of scour prevention to prevent undermining of nearby structures (Figure 10e). They can be easily installed using simple machinery. The bags conform to the shape of the scour hole and thus provide good sealing qualities. Protection dykes (Figure 10f) are one of the original applications for geotextile bags. This expedient use of geotextile bags comprises the most basic, and common, form of geotextile containment application. However, geotextile bags may also be used for more sophisticated and substantial protection dyke structures where they may be required to perform over long periods of time. Here, the geotextile bags are required to perform in the same manner as geotextile tubes for this same application. The pattern-placement of geotextile bags forms a stable mass-gravity structure that is resistant to erosion when subjected to hydraulic forces.

While Figure 10 shows a range of marine applications for geotextile bags, by far the most common use is for revetments where the bags provide the primary armor protection. Critical to the design of geotextile bag revetments is the revetment extent and slope; local bag stability; sand stability within the bags; geotextile strength; geotextile abrasion resistance and geotextile durability. Recognized design procedures exist for geotextile bag revetments, e.g. Pilarczyk (2000), Bezuijen and Vastenbergh (2012).

Geotextile tubes

Geotextile tubes first began to be used for hydraulic and marine structures in the 1960's. These tubes (known as "Longard" tubes) were of relatively small circumference (less than 5 m) and proved of limited use due to instability problems in hydraulic environments (they did not have the required mass-gravity to resist normal hydraulic and wave forces). Longard tubes also utilized an impermeable lining inside the woven geotextile skin in order to pressurize the tube with water before introduction of the sand fill.

In a modern context, the geotextile tubes that are familiar today began to be used in the 1980's. These geotextile tubes are manufactured in much greater circumferences than the earlier

generation Longard tubes which make them very stable in hydraulic and marine environments. Also, the woven geotextile skin is permeable, enabling the water from hydraulic filling to easily pass out of the tube, with the sand-fill being retained inside.

Geotextile tubes are fabricated in the factory prior to delivery to site. Over the years since their original development much has been learned regarding the performance of these materials, the intricacies of filling them successfully, and the methodology of fabrication. The nature of the tensile loads generated in the tubes during filling and their magnitude determines the required strength of the geotextile used, the nature of the sewn seams and their location. The judicious use of high capacity seams and their location governs the level of tensile loads that can be sustained by the geotextile tube. Further, an adequate factor of safety (minimum of 3.5) should be applied to the generated tensile loads in order to arrive at a safe tensile strength for the sewn seams in the geotextile tube.

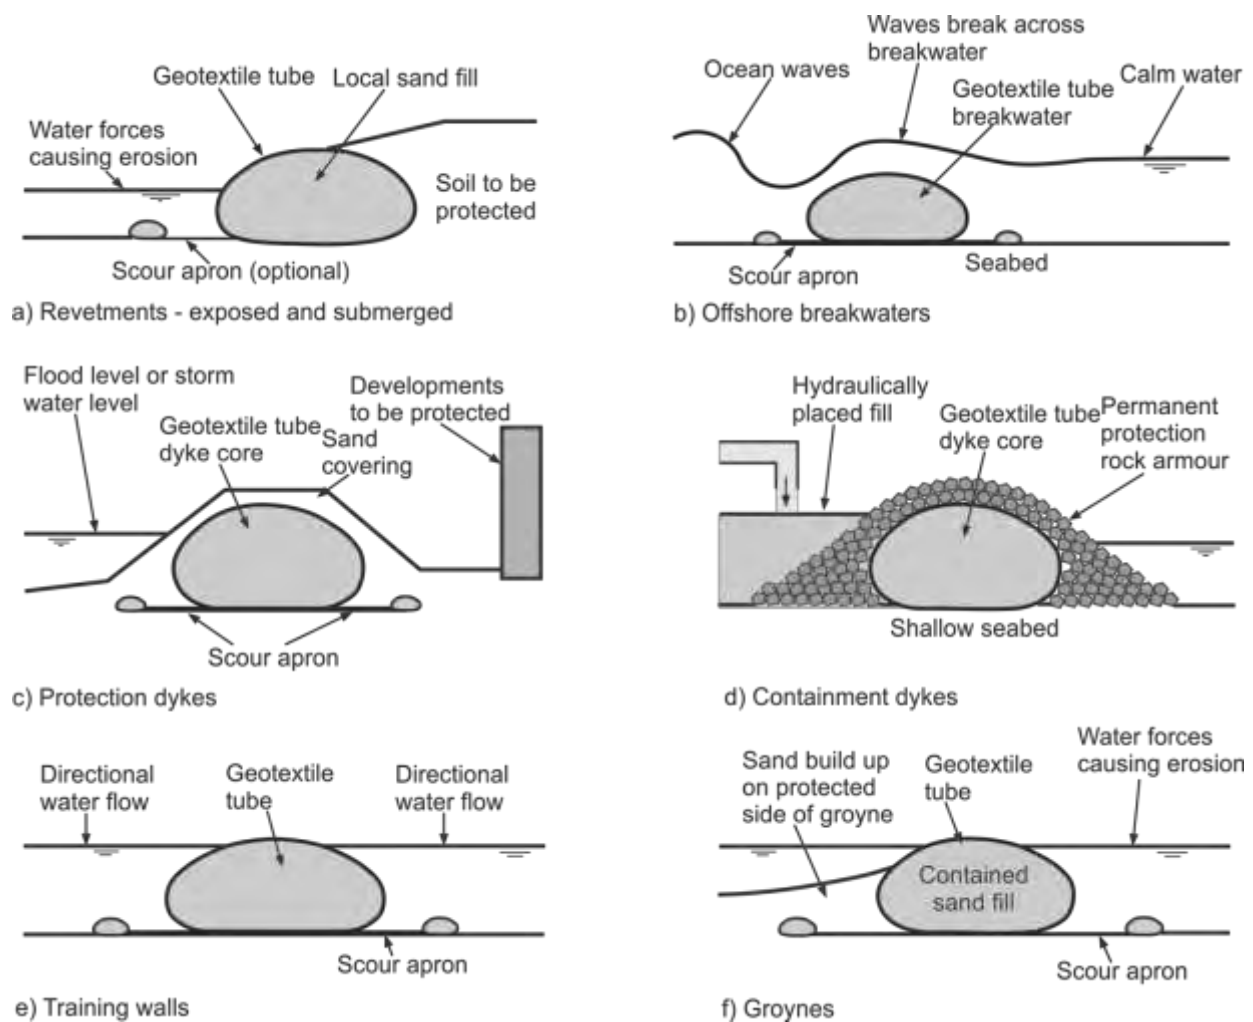

Figure 11. Applications for geotextile tubes (After Lawson, 2008).

Geotextile tubes are used for a variety of marine structures where their mass-gravity provides the primary protection. These are shown in Figure 11. Geotextile tubes are used for

revetment structures (Figure 11a), where their contained fill is used to provide mass-gravity stability. They are used for both submerged and exposed revetments. For submerged revetments the geotextile tube is covered by local soil, and is required to provide protection only when the soil cover has been eroded during periods of intermittent storm activity. Once the storm is over, the revetment is covered by soil again, either naturally or by maintenance filling. For exposed revetments the geotextile tube is exposed throughout its required design life. Scour aprons are normally included to prevent scour of the geotextile tube toe.

Geotextile tubes are also used for offshore breakwaters (Figure 11b) to prevent the erosion of shoreline developments. Here the filled geotextile tube is located a certain distance offshore in order to dissipate wave forces before they can reach the shoreline. Again, scour aprons are used beneath the geotextile tube breakwater to ensure that local erosion does not undermine the breakwater structure.

Geotextile tubes are used for protection dykes (Figure 11c), where they prevent flood and storm damage to valuable structures and real estate. Where geotextile tube protection dykes are constructed it is common to cover the geotextile tube with local soil. The geotextile tube is required to function only intermittently during storm or flood periods when the soil cover is eroded. The use of the soil cover provides several advantages to the geotextile tube core. First, it hides the geotextile tube core, thereby providing an aesthetic environment and ensuring no damage due to vandalism. Second, it protects the geotextile tube from long-term exposure to direct sunlight (UV degradation).

Geotextile tubes are used for the cores of containment dykes (Figure 11d) where water depths are relatively shallow. Here, the tube structure contains a filled reclamation area, the reclamation fill being dry-dumped or placed hydraulically. The advantage of this approach is that the same hydraulic fill used in the reclamation can also be used inside the geotextile tubes, thus avoiding the need to import granular fill for the dykes. Containment dykes constructed from geotextile tubes provide an economic alternative to other forms of construction, such as sheet-piled walls, especially where the foundation soil is soft. Where water forces dictate, and where longevity is required, rock armouring can be placed around the geotextile tube core (see Figure 11d).

Geotextile tubes are suitable for training walls (Figure 11e) where they are used to isolate and redirect water flows. Where geotextile tubes are used for training works it is common to leave the tube exposed except for major structures, where rock armour layers may be placed over it to dissipate and redirect hydraulic forces. Where the tubes are left exposed, a geotextile shroud may be used across the top of the tube, or a coating applied, to enhance its longevity in an exposed environment.

Geotextile tubes can be used as groynes (Figure 11f) to prevent the littoral movement of sediment. In most cases the geotextile tubes are left exposed, but coatings or a rock covering may be applied, depending on the circumstances and the required life expectancy.

Geotextile tubes behave as mass-gravity units when installed. Thus, the design of geotextile tube structures lends itself to the limit mode approach. Lawson (2008) has detailed the

various design limit modes for geotextile tube structures and Bezuijen and Vastenberg (2012) provide current detailed design guidelines.

Lawson (2008) reports on the construction of an artificial island using geotextile tubes for the containment dyke as part of the Incheon Grand Bridge Project in Korea. The artificial island was constructed in order to construct the bridge viaduct in the dry and was to be left in place following completion as it will later be enveloped by a large land reclamation scheme to build a new high technology city – Songdo City.

The foundation conditions where the artificial island is located consist of very soft marine clay to an approximate depth of 20 m. Further, in this area the tide range is very high, with a maximum difference in level of 9.3 m. This results in the exposure of the soft clay foundation at low tide and inundation to around +4.64 m at high tide. As a result of these difficult local conditions it was decided to construct the containment dyke for the artificial island out of geotextile tubes, as it was considered that the alternative of using sheet pile walls would not be feasible considering the low shear strength of the soft foundation and the height to which the artificial island would have to be raised to account for high tide level.

Figure 12a shows the typical cross section through the artificial island following construction. The base of the wall has two tubes side-by-side, with a third tube placed on top. Later, a fourth and fifth tube was then placed to bring the island up to the required design height. Figures 12b and c show the installation of the base geotextile tube layer. The tubes were laid out at low tide, and then at high tide the sand fill for the geotextile tubes was brought to the site by barge, mixed with water, and pumped hydraulically into the geotextile tubes.

Locally available residual soil was used for the fill material for the island, Figure 12d. Figure 12e shows the completed island with the freeway viaduct being constructed in the dry.

The performance of the geotextile tube structure on this project has been evaluated in some detail. The results show that the filled tubes themselves underwent very little deformation once filled. The structure itself has remained very stable, even allowing for an apparent heave of around 0.5 m of the soft foundation in the vicinity of the toe of the geotextile tube wall (see Figure 12a). The geotextile tube wall has settled around 0.7 m, while the centre of the island fill has settled around 2.8 m, all due to the high compressibility of the soft foundation beneath the artificial island.

Geotextile containers

Geotextile containers first started to be used in the early 1990's where it was necessary to provide "soft" offshore submarine structures that wouldn't damage ship traffic in the event of a collision. The essence of these units at that time was to provide large mass-gravity structures whose geometry was not considered to be of prime importance. Consequently, for economic reasons, this led to the deployment of large-volume containers (500 m³ to 1,000 m³) which generated high tensile loads in the containers during installation. This resulted in a relatively large proportion of failures (container ruptures) as the analysis methods and the specialist fabrication technology for these units was still in its infancy.

b) Installing initial geotextile tube

c) Installing base geotextile tube layer

d) Final filling of artificial island

e) Construction of viaduct

Figure 12. Construction of artificial island for viaduct construction using geotextile tubes, Incheon Bridge Project, Korea.

Over the succeeding years the analysis methods, fabrication technology and installation techniques have been greatly refined. Also, there has been increased emphasis placed on the finished geometry of completed container structures. As a consequence of this the most common geotextile container units currently used range in volume between 100 m^3 and 600 m^3 .

Because of their large volume geotextile containers are installed by means of a split-bottom barge. Figure 13 shows the typical formation and installation of a geotextile container. It entails the placing and filling of the geotextile container in the split-bottom barge; the container is then sealed and the barge positioned at the correct dumping location. The split-bottom barge opens, and the geotextile container passes through, and descends through the water to the seabed. Depending on its source, the container fill may be dry-placed, wet-placed or hydraulically pumped into the container. For marine works the type of fill used is normally sand, or of sand consistency, as this doesn't change in shape once the container has been installed. More recently, cement stabilized cohesive fills have also been used.

Figure 13. Installation procedure for geotextile containers (After Pilarczyk, 2000).

Geotextile containers are fabricated to fit the specific dimensions of the split-bottom barge. The tensile loads generated in the container during installation, the level of fill in the container, the tensile strength of the geotextile and the seaming technology used all govern the success of the geotextile container solution. Lawson (2008) and Bezuijen and Vastenberg (2012) provide design guidelines for geotextile containers.

The type of container shown in Figure 13 takes the form of an envelope where the container is closed and sealed once it is filled in the barge. More recently, containers of tubular shape have been used. These are hydraulically filled in the split-bottom barge, with the inlet ports sealed after filling, prior to installation of the container on the seabed. This type of

geotextile container is normally of smaller volume compared to the conventional envelope geotextile container; being between 100 m³ and 300 m³ in volume.

Figure 14 shows the range of marine engineering applications for geotextile containers. Geotextile containers are used as part of offshore breakwaters to prevent the erosion of the shoreline (Figure 14a). The technique here is the same as that for geotextile tube offshore breakwaters except that geotextile containers are used at greater water depth and a rock covering is normally placed across the top of the containers to raise the breakwater to its required height.

Figure 14. Marine applications using geotextile containers (After Lawson, 2008).

Geotextile containers are used for containment dykes where the water depth facilitates the placement of the containers (Figure 14b). The technique is the same as that for geotextile tubes except that the geotextile containers are used at greater water depth. A rock covering is normally placed across the top and down the outer face of the geotextile containers to raise the containment dyke above water level. Where the dyke is to remain submerged geotextile containers may be the sole units.

Geotextile containers can be used to construct artificial reefs (Figure 14c). Here, the containers provide a raised platform (a reef) that forces waves to break over the top of the reef. This prevents erosion of the protected shoreline. As well as dissipating wave energy artificial reefs also can be used to refract waves and alter the normal waveform. However, to do this successfully requires the reef to be constructed to a specific plan geometry with specific side slopes and platform height. This level of placement accuracy is normally outside the limits of large-volume geotextile container placement, and is more suited to the application of smaller-volume geotextile bags. Further, the nature of geotextile containers makes it difficult to fill them

to maximum volume and density. Consequently, it is to be expected that if the filled geotextile containers are to be exposed to continual wave activity then liquefaction of the sand fill will cause a change in shape of the exposed containers and a subsequent lowering of the surface level of the artificial reef. This then alters the shape of the waveform across the top of the reef, and thus the structure may require periodic maintenance to maintain the existing waveform.

Geotextile containers are used for the underwater buttressing of unstable slopes (Figure 14d). Here, the weight of the geotextile containers is utilized to provide a counter-weight berm for a potentially unstable slope. The advantage of using geotextile containers is that a “soft” buttress structure is provided that won’t damage shipping.

Geotextile containers are large volume mass-gravity units. At considerable water depth their placement accuracy maybe limited due to water currents etc. Consequently, geometrical tolerances are normally limited for these types of structures unless special techniques are applied.

Kamada (2010) and Chew et al. (2011) describe the construction of a temporary marine containment dyke using geotextile containers in Singapore. The containment dyke was used to retain reclamation fill and control sediment plumes with the reclamation location being close to busy shipping lanes, coral reefs and a nature reserve.

Figure 15a shows the plan layout of the reclamation works with the primary temporary containment dyke running some 1,800 m down the spine of the port reclamation area. The periphery of the reclamation consists of concrete caisson retaining walls. As the caisson wall installation progresses, the area between it and the central containment dyke was filled using locally dredged material and construction waste.

Figure 15b shows a cross section through the temporary marine containment dyke. It consists of stacked geotextile containers filled with cement mixed soil as the outer layer of the dyke. The soil fill was obtained from excavation projects on-land and in-sea in Singapore. Also, the same cement mixed soil was used for the core of the dyke between the geotextile containers. The containment dyke was constructed in water depths ranging from 5 m to 30 m. Because of local ocean currents of up to 2.5 m/s the accurate placement of the geotextile containers was considered a major issue, especially at water depths over 15 m. At all depths, container placement accuracy was required to be within 0.5 m, and the geotextile containers were not to rupture during placement.

To meet the container placement accuracy requirements and prevent container rupture during placement a specially designed installation barge was built, Figure 15c. The barge had a special container releasing cradle that could be lowered into the water enabling accurate placement and limiting the mechanical stresses on the containers. For water depths up to 15 m the releasing cradle remained at the water surface during geotextile container release, while for water depths over 15 m the releasing cradle was lowered to the appropriate depth before container release.

b) Cross section through containment dykes

e) Geotextile tube crest of containment dyke

Figure 15. Layout of port reclamation and geotextile container installation technique.
(After Chew et al., 2011 and Kamada, 2010)

The geotextile containers used were tubular in shape and of 300 m^3 in filled volume. The method of filling the containers was as follows. The geotextile container was rolled out in the barge release cradle. A second barge was used to mix the soil fill with the appropriate amount of

cement, and then this mixture was pumped into the geotextile container in the installation barge to fill the tubular container (Figure 15d). The installation barge was then positioned using GPS, and the release of the geotextile container carried out. The procedure was then repeated. During installation an average of 6 geotextile containers were installed per day.

Near the water surface the dyke was completed by using geotextile tubes, see Figures 15b and 15e. Once this central dyke was completed reclamation fill was placed between the (progressing) caisson wall and the dyke. Later, foundation improvement techniques were applied to the reclamation fill in order to improve its strength and deformation characteristics.

THE FUTURE: 2013+?

During the last 50 years the use of geotextiles in marine engineering has evolved from simple revetment filters to a wide range of sophisticated engineered structures today. Geotextile revetment filters have evolved from being “novel” materials, and greeted with some suspicion and skepticism, 40 years ago to being standard practice today. Other geotextile techniques such as geotextile containment are also becoming standard marine engineering practice after 25 years of development. Over the succeeding years it is expected that these existing techniques will be utilized on an ever-widening scale in marine engineering as they provide very cost-effective solutions.

Over the next 10 years it is expected that access to conventional materials, e.g. sand and rock, will become much more difficult. Already we are seeing in certain regions of the world that local access to conventional materials is non-existent or prohibitively priced, and consequently, these materials have to be transported in by distances that can be over 1,000 km. In order to conserve these materials for local projects, countries have even banned the export of sand and rock to neighboring countries, which have made the cost of conventional materials very high. To alleviate this reliance on conventional materials alternative solutions and techniques have been developed, many of these utilizing geotextiles, to arrive at more cost-effective marine engineering solutions. It is to be expected that this drive for alternative solutions will become more important over succeeding years.

Also, over the next 20 years it is expected that environmental sustainability will become an important issue in marine engineering. Already the acquisition of conventional materials, such as sand and rock, are becoming difficult to source, necessitating long transport distances. This results in a large carbon footprint when using wholly conventional (i.e. granular) materials compared to solutions using geotextiles. As environmental sustainability becomes a more important issue, more emphasis will be placed on those solutions that create lower carbon footprints. Geotextile solutions are well-placed for this.

With the future direction placing more emphasis on the use of alternative materials and techniques for marine engineering, the requirement for geotextiles to have improved performance (compared to those readily available today) will become a necessity. Already, we are seeing the development of composite geotextiles to meet specific marine application requirements. As the level of marine application sophistication continues geotextiles will be

required to exhibit improved structural and durability performance compared with those in common use today.

Much of conventional marine engineering occurs near and around coastlines. While offshore engineering has existed for 50 years (associated with the offshore oil and gas industry) it has remained a very specialized engineering area. Over the last 5 years conventional marine engineering techniques have moved further offshore where it has now become synonymous with offshore engineering in many respects. This has involved the construction of marine structures in deeper water, and has required the development of sophisticated installation procedures and techniques. It is expected that this offshore sophistication will continue over the following years.

CONCLUSIONS

There has been considerable evolution in geotextile use in marine engineering over the last 50 years. In that time, early innovations in the use of geotextile revetment filters have become standard practice and there has been an ever-widening variety of geotextile solutions being used in marine engineering. This current wide variety of use has required increased sophistication in application and installation. For the future it is expected that geotextile solutions will continue to evolve in marine engineering (in terms of use and sophistication) and this will be driven by better cost-effectiveness, improved performance and environmental sustainability.

A BRIEF HISTORY OF HEAP LEACHING

Monte A. Christie, PE, GE

President, RRD International Corp., Incline Village, NV USA

ABSTRACT

Heap leaching has had wide success allowing mines to profitably recover metals from very low grade (metal content) ores that were previously uneconomical with traditional milling operations. Heap leach facilities rely on the performance of geosynthetic products to provide efficient solution recovery and environmental containment, of which a critical component is the liner system. The liner system not only functions as the barrier between the facility and open environment, but also directly affects metal recovery and thus operating revenue.

Due to skyrocketing metal prices and the resulting increased demand on reserves, mines have been pushed to more remote and difficult locations - sites are becoming more and more challenging at the same time that regulatory and community criteria is increasing around the world. In Latin America especially, where ore reserves are plentiful but terrain and climate complex, some of the challenges faced are remote areas, aggressive terrain, availability of qualified contractors and work forces, high elevation, extreme weather, as well as many others. This article explores a few of those.

HISTORY

There are two main methods for extracting metals from ore: crushing and grinding (milling) followed by either leaching or flotation (concentration), and heap leaching followed by extraction of the metal from the aqueous phase using several technologies (the most common being solvent extraction / electro-winning, or SX/EW, for copper, and either carbon absorption or zinc precipitation for gold and silver). Milling circuits require large capital investments and incur higher operating expenses (per tonne of ore processed) as compared to heap leaching, and thereby require higher feed grades to be cost effective (1 tonne equals 1,000 kg). On the other hand, milling can recover 85% to over 90% of the contained metal while heap leaching generally achieves 50% (uncrushed or run-of-mine ore) to 75% (crushed ore). Thus, low grade deposits tend to be processed by heap leaching and high grade by milling; projects with a wide range of ore grades will often have both types of recovery circuits.

The mining industry utilizes heap leach technology on a very large commercial scale for the extraction of gold, silver, copper, uranium, and on a smaller scale (pilot scale and limited commercial production) for nickel and other minerals. It is also used for nitrate, iodine and other salts. The technology requires a lined leach pad to provide containment of the ore and recovery of the leach ("pregnant" or "PLS") solutions, as illustrated in Figure 1. The heap leach facility may be designed as a conventional pad (permanent, multi-lift heap), on/off or reusable pad (dynamic heap), or a valley leach pad, depending on the site conditions and characteristics of the ore to be processed.

The actual principle of heap leaching has a long history. For example, mines in Hungary recycled copper-bearing solutions through waste dumps (the earliest form of “heaps” where non-engineered dumps) in the mid-sixteenth century, and Spanish miners percolated acid solutions through large dumps of waste rock containing very low concentrations of oxide copper on the banks of the Rio Tinto (“red river”) in 1752. By 1900, leaching operations were employing such techniques as leach/rest cycles to maximize copper recovery. Dump leaching using both acid and alkaline solutions has been practiced by uranium producers since the late 1950’s. Modern heap leaching (that is, engineered heaps, containment systems and modern metallurgical processes) of precious metal ores using the cyanidation process was originally suggested by the U.S. Bureau of Mines in 1967. The first commercial application of gold heap leaching occurred in the late 1960’s by the Carlin Gold Mining Company in northern Nevada. Cortez Gold Mines started the first large scale operation in the early 1970’s by leaching marginal grade ore (www.miningandmetallurgy.com).

In the mid-1970’s, heap leaching technology was improved in order to handle low grade, clayey deposits that were not amenable to conventional milling. The principal improvement, agglomerating of the ore, was prompted by increased exploration for low grade deposits as the price of gold increased dramatically; especially starting in about 1979 after the US liberalized the domestic gold market. Many of the deposits discovered could not be processed by the conventional heap leaching techniques because the clays or fines generated during crushing, or gauge material within the deposit, impeded uniform percolation of solution through the heaps. Pelletizing of iron ore had long used a binder-based process for binding fines to improve handling characteristics, and that agglomeration technology was adapted to gold heap leaching. Crush ore is agglomerated most commonly by pre-wetting and adding chemical binders (such as Portland cement for gold and silver ores and concentrated sulfuric acid for copper, uranium and nickel) and then mixing in a drum. This process causes the finer particles to adhere to the aggregate, and the chemical binders give those agglomerates enough strength to survive the transportation and stacking process. Agglomeration technology is applicable to most crushed ore, wastes, and milled tailings. An adaptation of tailings co-disposal technology (Leduc, et al 2004) was first commercialized at the Ruby Hill gold mine in Nevada, and subsequently tested on other projects, wherein milled ore (“pulp”) is mixed with heap leach ore and binder to create what has been called “pulp agglomeration;” this allows either a low-cost method of disposing of mill tailings (when the quantities are sufficiently low relative to the volume of heap leach ore) or the use of fine grinding to improve leaching of the higher grade ores in the heap without adversely affecting percolation.

The results of the technological improvements which have occurred throughout the 1970’s and into the 1980’s can be seen in dramatic production increases. By the mid of 1980s, production of gold from heap leaching had increased to over 30 percent of total U.S. gold production from an estimated 6 percent at the beginning of 1980s and negligible in the 1970s. Heap leaching unlocked previously uneconomic deposits by reducing both capital and operating costs, allowing grades as low as 0.5 g of gold per metric tonne of ore (gmt) to be profitably mined and processed.

Chile became the next logical place to apply the emerging technology due to its’ abundant, large copper resources, dry climate and friendly political environment. In addition to the advantages found in gold heap leaching, copper oxide deposits were simply not amenable to

conventional milling and concentration except in the rarest of cases. Heap leaching, on the other hand, was tailor-made for these deposits. Large-scale copper heap leaching began in Chile in 1980 with the Lo Aquirre project. By the early 1990's Chile had about 10 major copper heap leach projects, most using conventional lined leach pad technology. Copper heap leaching in the USA started with unlined run-of-mine leach dumps and only three lined copper heap leach pads were constructed in the USA during the 1980s. Chile is now home to most of the world's largest leach pads, measured both in containment area (several million square meters each) and contained ore tonnage (heaps with design capacity in excess of 1 billion tonnes). The average leach pad area is now over 1 million m² and projects are in the planning stages for leach pads in excess of 10 million m² in Turkey, Burma, and Africa. Essentially all of these are geomembrane lined (Breitenbach & Smith, 2006 & 2012).

This growth of copper production and heap leaching is shown below in Table 1. The importance and increase in heap leaching to now (nearly half of all copper being produced by heap leaching) shows the tremendous success of the technology. Copper heap leaching has climbed from an obscure idea in the 1980s to 40% of world copper production today.

Table 1 - Copper Production – SX/EW (heap leach) versus Concentrate (mill and smelting)

Year	SX/EW Prod. (KT Cu/year)	Concentrate Prod. (KT Cu/year)	Total Production (KT Cu/year)	SX/EW as % of total
1970	11	5,889	5,900	0.2%
1975	109	6,791	6,900	1.6%
1980	255	7,395	7,650	3.3%
1985	356	7,444	7,800	4.6%
1990	801	7,349	8,150	9.8%
1995	1,563	8,437	10,000	15.6%
2001	2,844	10,356	13,200	21.5%
2005	4,990	9,910	14,900	33.5%
2010	6,335	9,565	15,900	39.8%

HEAP LEACHING ECONOMICS

This reason for the increase in heap leaching as shown above in Table 1 can be illustrated by an example that shows how the technology not only increases ore reserves, but increases revenues as well. Consider an idealized large gold deposit as follows (gold is simpler in every aspect than copper and thus makes for a simpler example, but the fundamentals apply equally to copper and uranium):

EXAMPLE: Given the following information:

- 100M tonne high-grade gold ore reserves with an average metal content of 0.17 oz gold per tonne ore, suitable for conventionally milling;
- 100M tonne low-grade ore with an average metal content of 0.05 oz gold per tonne ore, suitable for heap leaching; and,

- 300M tonne waste (sterile and sub-economic rock that must be mined to access the high-grade ore).

In this example the low-grade ore is exclusively “internal” ore that must be mined to access the high-grade ore. In a more real-world case there would be additional “external” ore that would enlarge the overall pit limits, and different economics would apply to those tons.

Assuming the following typical operating costs, which were taken for several recent projects in South America:

- average project-life gold price \$1,700/oz;
- milling (including crushing, grinding, metal recovery and tailings disposal) at \$15/tonne of ore processed;
- heap leaching (including crushing, stacking, leaching and metal recovery) at \$8/tonne of ore processed;
- mining at \$1/tonne of rock mined (all ore and waste);
- metal recovery in the mill of 90% for the average high-grade and 93% when that grade is increased; and,
- heap leach recovery of 65% for average low-grade and 68% when that grade is increased.

SOLUTION:

The mill-only option would process the 100M tonnes of high-grade ore and produce approximately 17M oz of gold for revenue of \$16,010M after capital and operating costs. Adding the heap leach circuit would add some capital and operating costs between the mill and the heap leach, but would double the reserve to 200M tonnes of ore resulting in approximately 22M oz of gold and an increase in revenue to \$23,020M. In this example, heap leaching increased the gold reserve by 30%. Most mining companies are publicly traded and total resource - ounces “in the ground” for gold miners - is a key factor in setting their stock price. Thus, simply adding heap leaching to a company’s technology portfolio does in fact significantly increase their market capitalization.

Of course, there are some limitations with heap leaching and not all gold or copper ores can or should be heap leached. Milling, for example, has better selectivity and most poly-metallic ores such as those with both gold and copper cannot be heap leached without giving up on one or the other metal. Primary sulfide copper ores (e.g., chalcopyrite, bornite) are very difficult to heap leach with economically viable recoveries, though bio-leaching technology is being commercialized and holds promise for huge resources of low-grade primary ores; the Escondida mine in Chile is the world’s largest such heap leach, with over 4 billion tonnes of primary sulfide resource, and the La Granja project in Peru, which is under study, has nearly twice that. For alkaline (gold and silver) leaching, the presence of sulfide minerals increases reagent consumption (and thus operating costs) and can reduce recovery, making gold and silver

sulfides much less amenable to heap leaching; bio-leaching technology is also emerging to make these ores heap leach amenable and the first commercial plant is in operation near Elko, Nevada.

HEAP LEACHING TECHNOLOGY

The basic principle behind heap leaching is relatively simple. The metal from the ore is extracted using physical contact with a solvent leaching solution to dissolve the target metal (or, in some cases, salt). The impregnated solution is collected and processed to remove most of the metal, the pH and solvent concentrations adjusted and the solution recirculated to the heap. To enhance metal recovery, modern processes often use one or more of several available upgrading methods including pregnant solution recycling (recirculation of lower tenor pregnant solutions to the heap before routing to the plant for metal recovery), bio-leaching (for sulphide copper and gold ores), air injection (an emerging technology for primary sulfide copper ores) and physical alteration of the ore (e.g., crushing, agglomeration). It should be noted that while these methods generally improve the metallurgical response of the ore, they can also change its geotechnical properties (Ulrich et. al., 2003) and, in the case of bio-leaching, those changes can be time dependent and difficult to predict.

Figure 1. Heap and pad schematic.

Typical modern heaps have fill heights (ore depths) typically on the order of 100 meters, with some of the highest exceeding 160 m; heaps exceeding 240 m with 4 MPa normal stresses are in planning (Lupo, 2010). Ore is usually crushed to about the gradation of road base, but in some cases is processed without crushing (so-called run-of-mine or ROM) or only with primary crushing (nominally passing 150 to 200 mm). Ore is stacked either with trucks (and sometimes loaders) or conveyor-stacking systems in lifts ranging from less than 5 m to greater than 15 m in thickness, with about 7m being typical. Each lift is leached and then either overlain or removed and replaced. In the case of oxide copper ores, which can have very high acid consumptions, a thin inter-lift liner is usually placed before the leached lift is overlain.

There are four types of heap leach pads:

1. **Conventional or ‘flat’ pads** – relatively flat, either graded smooth or terrain contouring on gentle alluvial fans in relatively thin lifts typically between 5 m and 15 m. The ore is stacked, leached, and then overlain in a multi-stacked or permanent heap;
2. **Dump leach pads** – similar to flat pads or can include rolling terrain. The term ‘dump’ usually means that the lifts are much thicker at around 50 m and the ore very low grade and processed ROM or primary crushed only;
3. **Valley leach pads (VLPs)** – as the name suggests, these systems incorporate leach pads designed in natural valleys using either a buttress dam at the bottom of the valley, or a leveling fill within the valley. Buttress dam can be as high as 100 m but more typically are around 20 m. VLPs can be impounding, with process solution stored within the heap, or free draining; and,
4. **Dynamic heaps or on/off pads** – these are hybrid leach systems. A relatively flat pad is built using a robust liner and overliner system. Then a single lift of ore, from 4 m to 10 m thick, is loaded and leached. At the end of the leach cycle the spent ore, or ‘ripios’ in most mining literature, is rinsed and removed for disposal. The pad is then recharged with fresh ore and the process repeated for 10 to 25 years. Usually loaded with conveyers and stackers. In some cases, especially for large operations, bucket wheel excavators are used in the unloading cycle, while in others, wheel loaders and trucks are used. For on/off pads, the critical design loads for the containment system come from the ore handling equipment, not the weight of the ore. Trucks and loaders can apply wheel loads of up to 53 tonnes, with 24 tonnes being common, with considerable horizontal loading caused by braking and turning.

While the civil and geotechnical design criteria for each of these will differ depending upon site-specific constraints and ore types, the following points are universal:

- The pad should be laid out to accommodate the loading method, ore production rate, leach cycle, ultimate tonnage to be processed, surface hydrology for higher rainfall sites, closure and local topography;
- Lift heights are set to optimize recovery and for ease of operations; thicker lifts result in lower stacking costs (per tonne of ore) but longer leach cycles and, in some cases, lower metal recovery or higher reagent consumption;
- Constituents of the leach solution - water, acid or alkali, cyanide, organics, and so forth - need to be conserved as much as practical and can constitute a full 50% of total operating costs. Further, in many arid sites such as Northern Chile and Southern Peru, water availability (or lack thereof) can limit production;
- Designs must recognize the need to avoid mingling of process solutions (where applicable) and to withstand a designated storm event as well as manage the dilution created by lesser storm events. That is, small storm events are, out of necessity, mixed with pregnant solutions but larger storm events should be isolated where practical;

- The heap must be stable for both static and dynamic conditions, and geotechnical properties must include the potential for physical, chemical and biological degradation inherent in the heap leaching process. For low permeability ores especially in tropical climates, static liquefaction due to rapid stacking of either the heap or the ripios dump (for on/off pads) can also be a critical design factor. The seismic risk of these sites is often underestimated by engineers and operators more familiar with North America. Common design PGAs in Northern Chile are around 0.40g and a recent tailings dam project used 1.25g as the design event.

LINER SYSTEM DESIGN

While heap leaching is important to the mining industry for the reasons already articulated, it's important to the geosynthetics community for other reasons. Conventional milling requires a tailings disposal facility, which is a complex and important geotechnical structure and most firms engaged in the civil and geotechnical design of heap leach projects are also design tailings facilities. In the copper industry, less than 1% of the area of tailings facilities are lined with geomembranes. For gold the number is larger and increasing, but remains well under 50%. On the other hand, essentially 100% of leach pads are lined with at least one geomembrane and the average leach pad now exceeds 1M m² in lined area.

Integral to the design of the heap leach facility is the geomembrane liner system, which provides a physical barrier between the facility and open environment to contain the leach solutions. The liner system also influences the design of the solution collection system and overall stability of the facility. Liner systems for modern heap leach facilities employ a range of geosynthetic products, such as geomembrane liners, geotextiles, GCLs, geogrids, geonets, and plastic pipes to achieve the desired performance for solution containment, solution collection, and heap stability. The design of the heap leach facility and liner system is tailored to suite the unique conditions at each mine site, ore characteristics, and leaching methodology. That said, the vast majority of pad liners are either HDPE or LLDPE of 1.5 or 2.0mm thickness, often with the bottom textured and with a low permeability foundation (clay, silt or GCL).

A heap leach liner system design must consider the following (from bottom to top):

1. Foundation Layer – the suitability of local conditions not only to withstand the intended dead and live loads with acceptable deformation and stability, but to be chemically resistant to the leaching solutions in the likely event of leakage (e.g., much of Atacama Desert of Northern Chile is covered with a few meters of soils with high soluble salt contents);
2. Subdrain – some heap leach pads incorporate subdrains due to subsurface ground water conditions. This is especially true in tropical or high Andean sites, and for all valley leach pads;
3. Low-permeability layer – either a compacted soil liner or (much less commonly) geosynthetic clay liner (GCL) is usually used;
4. Geomembrane liner – a flexible membrane to act as a composite liner with the underlying low-permeability layer. Double geomembrane liners are rare but

increasing, and in some cases are required either by industry standards (e.g., impounding VLP) or local laws (for all leach pads in certain jurisdictions);

5. Overliner materials – a drainage or protective layer to facilitate draining the heap and protecting the geomembrane liner. This layer also provides physical separation between the geomembrane and the stacking or unloading equipment; and
6. Solution collection and air injection piping – pipes are needed to increase the solution collection within the gravel overliner, as well as to inject air, if needed.

These liner system details are similar to landfills with some modifications for different processes and regulatory criteria. However, while environmental containment is a key driver, so is metal recovery and reagent conservation. One main difference is the solution flow; for example, the process flow rates are much higher for heap leaching than typical landfill leachate flows. Typical irrigation rates are 10 to 15 L/hr per m² of irrigation area. Required irrigation areas are dictated by the ore processing rate, and 100,000 to 300,000 m² are common on larger projects. This results in flows of 1,000 to nearly 5,000 m³/hr. Whereas typical landfill leachate flows are on the order of 2 to 20 m³/hr. These larger flows require better solution collection (tighter pipe spacing) or heads can build up and cause instability, increase reagent consumption, impede aeration and retard metal recovery. With burial depths of 140 m to 160 m, the pipes are pushed to - and often beyond - their limits and drainage system failures are becoming more common in the industry (see Figures 2 and 3).

Figure 2. Sink hole on top of the heap at the Cerro Verde copper mine, Central Peru, which developed directly over a collapsed drainage pipe. In part because of failures like this, the Cerro Verde heap has experienced dramatic increases in the water level, to over 20 m above the liner, and some local liquefaction failures (see Figure 3).

Figure 3. Local liquefaction failure at the Cerro Verde copper heap leach, triggered by high solution levels. For scale, the benches are separated vertically by 7 m.

While the most common method of heap leaching is to continuously stack new ore over leached ore, and allow the process solutions to flow through the underlying layers, there are cases where this is impractical. The most common being acid leaching of oxide ores, which continue to consume acid even after the target metal has been extracted. This is the case with uranium, oxide copper, and nickel laterites. In these cases, thin liners are installed between each lift of ore. These so-called inter-lift liners serve the purpose of intercepting pregnant solution after it has penetrated (typically) the upper most lift of fresh ore. Since the inter-lift liners do not serve an environmental protection function, they are typically relatively thin. A small amount of leakage is acceptable as the primary cost of leakage is the value of the additional acid consumption. The use of inter-lift liners became popularized in Chile about 15 years ago and now there are perhaps a dozen major operations using this technology. One of the earliest such operations used very thin low density polyethylene (not linear low or LLDPE) with the seams sewn in a “J” fashion like a geotextile. Seepage was estimated by measuring the cumulative flow reporting to the lower inter-lift liners and the base environmental liner, and averaged about 3% of the flow over the top-most inter-lift liner. Modern systems with better quality liners and proper seaming methods report much less than 1% bypass, and 1 to 2% is commonly used for process calculations (Smith, 1996 and Smith & Welkner, 1994).

Heap leaching has been successful for gold, silver, uranium and copper and is starting to take shape for nickel laterites. Nickel laterites have three major differences from the more traditional heap leach ores: (i) the ores are more soil-like than rock-like, (ii) the reagent (sulfuric acid) consumption is dramatically higher than for copper or uranium, and (iii) the process produces a significant quantity of plant filtrate (chemical tailings) that require aggressive management and containment. A typical nickel laterite ore will consume 500 kg of concentrated acid per tonne of ore, compared to well under 50 kg for most copper and uranium ores. This

high acid consumption also correlated to significant degradation of the physical properties of the ore, and nickel laterites can experience permeability reductions of several orders of magnitude during the leaching process. This makes heap leaching very challenging and while this application has been the subject of intensive research and pilot-scale testing over the past 15 years, there has only been one small-scale commercial operation (the Murin Murin mine in Northern Australia). On the other hand, the attraction of this technology is similar to gold and copper: heap leaching offers much lower capital costs as compared to the traditional processing methods of smelting or high pressure acid leaching (HPAL), and heap leaching is metallurgically-compatible with a wider range of ore types thus increasing resources for many projects. And while heap leaching has had a robust history of success for every mineral to which it's been applied, the primary hydrometallurgical process for nickel laterites, HPAL, has had more failures than successes, some of which spectacular; recent examples include the Ravensthorpe mine (owner: Australian miner BHP) in Western Australia, which resulted in a 90% write-off of the \$3.8 billion capital investment, and the Goro mine (owner: Brazilian miner Vale) in New Caledonia, which was built at total cost of over \$6 billion, versus the original estimate of \$1.8, and has little hope of ever recuperating that investment. It's no surprise, therefore, that every major nickel producer is currently studying heap leaching and large-scale pilot plants have or are operating in Australia, Turkey, Brazil, Colombia, China and the Philippines.

HEAP CONSTRUCTION

The construction or stacking of heaps involves placement of ore in controlled, loose and relatively dry lifts stacked with face angles at the natural angle-of-repose, with set-back benches between lifts to provide stable overall slopes as well as erosion control, as shown in Figure 3. Each lift is irrigated using drip emitters or, less commonly, sprinklers (either “wobblers” or “rain bird” style impact sprinklers). Leaching is generally conducted in a few months (gold, silver, uranium and oxide copper) to about 1-1/2 years (sulfide copper and nickel laterites) leach cycles. Irrigation solutions can be either recirculated leach solutions to upgrade the metal tenor, or fresh solvents (dilute high pH cyanide for gold and silver, weak sulfuric acid for uranium and copper, and strong sulfuric acid for nickel). The longer leach cycles require larger leach pad areas, stretching some facilities to dimensions in kilometers; as an example, the 2013 expansion of the Escondida copper bio-leach facility in Northern Chile will bring the leach pad's overall dimensions to 2 km x 5 km, or 10M m². This is one of three heap leach circuits plus a traditional mill and concentrator) at the Escondida complex.

The maximum rock particle size of ore ranges from ROM (cobble and boulder sizes) to the more common crushed sand and gravel sizes (most commonly, 90% passing, or P90, of 10 mm to 25 mm). The crusher operations often include agglomeration to provide a more efficient distribution and binding of fines for improved and more uniform permeability, reduced fines migration and, ultimately, better recovery of the target metals. The individual ore lifts are offset with benches along the exterior slope for stability, but also for operations. This “loose” stacking facilities solution application and desired permeability for leaching. The bench faces are not compacted, which is opposite for landfills. Landfills are compacted as dense as practical to maximize air space utilization, increase stability and reduce long-term settlement. This is another good example of the difference in drivers between heap leaching and municipal waste landfilling. A schematic section of the exterior ore heap slope is shown in Figure 4.

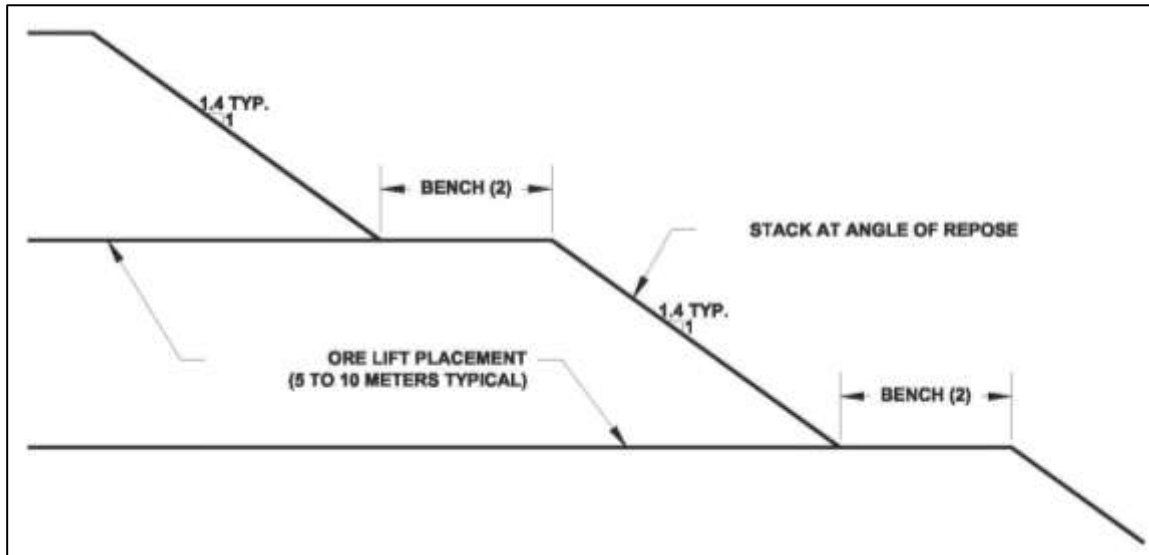

Figure 4. Typical cross section showing individual lifts and offset benches along exterior slope of heap leach pad to provide stability.

Ore is stacked a number of ways depending upon the shape of the leach pad, production rates and ore particle size. Transport to the edge of the pad can be by trucks or overland conveyor. For relatively low tonnage rate operations or those using very large particle sizes (either ROM or primary crush only, such as at Escondida), truck stacking is the most common approach. The larger the project, however, the more the economics tend towards conveyor distribution and stacking, as shown in Figure 5. This is also a less stressful way to place the ore and generally improves hydraulic performance. A method pioneered at the Mantoverde copper mine in Chile incorporates advancing the liner system at the same time as the heap is stacked, thus avoiding the need for a protective cover system to isolate the stacking equipment from the geomembrane (Figures 7 & 8). Drainage is accomplished by placing perforated pipes at relatively close spacing. This method is only suitable for well-drained ores of sufficiently fine gradation to not puncture the liner. This loose stacking of ore again facilitates the solution application by maintaining permeability of the ore without compacting it with repeated truck traffic. Pipe spacing might be as close as 2 m for higher irrigation rates or ores of modest permeability.

Figure 5. Portable stacking system consisting of tripper, grasshoppers, horizontal conveyors, and radial stacker.

Figure 6. View of heap leach pad being stacked with portable grasshopper conveyors.

Figure 7. Mantoverde-style liner deployment showing ore being stacked soon after liner is placed.

Figure 8. Solution collection system ready to be deployed in advance of ore stacking.

HISTORIC STABILITY PERFORMANCE

One of the earliest and best known large-scale geomembrane-related slope failures was the Kettleman Hills landfill slope failure in Northern California in 1988 (Mitchell et al. 1990). Several major landfill slope failures occurred between 1988 and 1997 in North America, Europe, Africa and South America (Koerner and Soong 1999). Several less known leach pad slope failures occurred at about the same time (1985 to 1993) at mine sites in North America, South America and Australia (Breitenbach 1997). The Northridge earthquake in Southern California in 1994 (Matasovic et al. 1995) and subsequent earthquakes in Chile and Peru in 1995 and 1996 gave some insight into the seismic behavior of high fills on geomembrane liner systems.

The historic performance of fills on geomembrane liner systems indicates that translational (lateral movement) wedge slip failures generally occur along the planar liner interface contact with soils or geosynthetic materials. However, heap failures differ from landfill failures in that the slope failure often occurs during the initial ore heap fill lift placement operations, rather than at the greater heights (Breitenbach, 2003; Smith & Giroud, 2000).

The known slope failures from weak foundation conditions beneath the liner system included a combination of one or more of the following: re-activating an existing landslide surface, thawing of frozen subgrade soils, overly wet subgrade (natural soils or underliner fills), subgrade subsidence in compressible natural soils or low density fills, and excavations at critical downgradient fill toe areas that caused unloading of toe support materials. The known slope failures from excessive hydraulic conditions above the liner system included a combination of one or more of the following: intense rain storm events, poor internal containment material drainage, excess solution application on the surface or injection into the heap (a method occasionally used for secondary recovery from low permeability ores), or solution pipeline breaks near exterior fill slopes and causing localized saturation. These high fill slope failure exceptions are rare in occurrence and can be eliminated or mitigated at the end of operations into closure. They also tend to be modest in terms of the damage they do, and rarely do they put the base liner system at risk.

For the non-miners, an interesting comparison of heap leach pads and landfills is discussed by Breitenbach & Thiel (2009).

LINER INTERFACE STRENGTHS

There is nothing particularly different in heap leach stability versus landfill stability; however, some important research has come out of heap leach design. With heaps pushing 160 meters in height and ore densities much greater than municipal solid wastes (bulk wet specific gravities of about 2.0), normal stresses on the liner system are generally much higher for leach pads than landfills. And with impounding VLPs, water levels and associated hydraulic heads on the liners can be much higher than landfills (up to 45 m).

Large-scale laboratory direct shear (LSDS) test results from studying the long-term liner performance under high loads indicate the geomembrane liner interface contact with underlying and overlying materials gains strength with time (Breitenbach and Swan 1999). The time-dependent increase in liner interface peak and residual shear strength is mainly due to two

conditions: 1) the apparent effect of high load deformations or dimpling on a micro scale in the planar geomembrane liner surface, and 2) a reduction in excess pore pressures in the low permeability base soils. The measured cohesion or apparent adhesion in the study decreased with time and were assumed to be negligible for conservative long-term liner strength conditions. Degradation of the overliner due to chemical attack can more than compensate for these increases and, thus, it's important for any testing program to consider this factor.

SEISMIC BEHAVIOR

Similar with landfills, leach pads are large earthen structures subject to an array of motions during a seismic event. Durkee, et. al. (2003) describe the seismic slope stability and deformation analyses for a heap leach facility. The performance is typically evaluated using analytical methods developed for earth embankments. In particular, pseudo-static slope stability and seismically-induced permanent deformation analyses are commonly employed. Since the anticipated time of construction and operation of a heap leach facility is relatively short at 10 to 20 years, and post-operational stability is generally less critical, pseudo-static methods are employed using the ground acceleration associated with the operational basis earthquake (OBE) to estimate the factor of safety during the working life of the heap leach. When post-operational (long-term) conditions are evaluated (e.g. reclamation, closure and post-closure), the design ground acceleration is often based on the maximum design earthquake (MDE). The higher acceleration associated with the MDE often produces pseudo-static factors of safety of less than one, therefore displacement analyses are often performed. Both the Newmark-type analysis developed by Makdisi and Seed (1978) and simplified Bray & Travasarou (2009) methods can be used to determine seismic displacements.

A case in point, with heap leach pads in high seismic areas such as Chile, Peru and Turkey, the intensity of the seismic shaking with PGAs of 0.35 (Chile, Peru) to 0.49 (Turkey) are high compared to the relatively modest values in California.

HEAP LEACHING ISSUES IN SOUTH AMERICA

Steep Terrain: Breitenbach and Smith (2012) identified some 26 valley leach pads (VLPs) in Latin America, and in the last decade 90% of those built in the world were in Latin America. VLPs, especially those with internal solution impoundments, present special design and operational considerations ranging from steep base slopes and challenging site grading to extreme ore depths (now exceeding 160m) and complex leach kinetics. The popularity of this technology stems in part from the mining boom, but it is also a result of the technology's success at projects like Barrick's Pierina gold mine in Peru (commissioned in 1998 and for the first few years of its life was the lowest cash cost gold producer in the world). There is now a blurring of the line between conventional leach pads (CLPs) and VLPs with flat pad designs now routinely incorporating steeper and variable slopes, terrain-contour grading, innovative overliner systems and other advancements pioneered on VLPs, pushing the importance of heap stability (Lupo, 2008). The identifying trait that distinguishes VLPs from CLPs is that two or three sides of the heap are contained by natural valley wall topography. This also tends to result in a relatively steep longitudinal slope (the axis of the valley), often in excess of 10% or even 20%. For this reason, VLPs commonly require a supporting buttress at the downstream toe, and this buttress can then be used to create an internal impoundment to store process solutions or extreme storm

events in the ore's available porosity. When internal ponds are used the resulting hydraulic heads can be extreme; in the case of Pierina, for example, the peak seasonal water level is about 45 m over the primary liner. In addition to increasing the leakage through the liner, this can also make the heap more vulnerable to liquefaction (static or dynamic). Leaching kinetics can also be affected, since a greater portion of the heap is saturated (or nearly saturated), and closure can be much more complex since heap rinsing and detoxification can require more time and effort, and ensuring long-term drainage a challenge (Breitenbach and Smith, 2012).

Crushing size: Metal recovery is related to crushing size, with finer particles generally allowing better recovery. With increasing metal prices the economic break-even point has moved to finer and finer particle sizes. But, finer gradations generally result in lower permeability and lower shear strength. For the same irrigation rate, lower permeability means higher degrees of saturation and, potentially, higher phreatic levels - decreasing stability and increasing the risk of liquefaction. It also means less air movement, which can retard leaching kinetics.

Liner systems: As projects are constructed in more challenging terrain, geosynthetic clay liners (GCLs) are becoming more popular, either to replace the clay underliner or to solve specific steep slope issues. Recent projects in Peru and Mexico have produced costs for compacted clay liners (CCLs) of up to \$15/m³, or \$6.00/m² for a 400mm-thick clay layer. The time to install a CCL can be on the critical path and, as any construction manager will attest, clay work is a high-risk task with cost over-runs and delays the norm. GCLs eliminate most budget and schedule risks while often providing superior leak prevention at similar costs. This is no news to landfill designers and operators, but is only recently becoming accepted in the mining industry.

Elevated temperatures: Most testing and design analyses for liner and drainage systems are performed at standard ambient temperatures of about 20°C. However, bio-leaching, the most common technology used for copper ores, can increase temperatures to at least 40°C. This increases the puncturing potential of geomembrane liners and makes polyethylene pipes more vulnerable to collapse. For example, standard dual-wall corrugated pipe behaves well under 140 m of burial at 23°C but collapses at 100 m depth when the temperature is increased to 50°C (Sinha & Smith, 2012).

Heap Drainage: The importance of heap drainage and controlling hydraulic head over the liner for heap stability cannot be overstated (Thiel & Christie, 2005). Overliner placement on steep slopes is often impractical or presents an unacceptable risk to either the liner integrity or worker safety. At other sites, suitable aggregate simply isn't available, a common problem at tropical and semi-tropical locations. In these projects an emerging technology to either replace or reduce the amount of high-quality gravel is the use of drainage geocomposites, which are cost competitive with a conventional gravel overliner. Where the stacking equipment is working on top of the active lift ("advance" stacking), a geocomposite can often completely replace the gravel overliner. For retreat stacking, where the stacker operates directly on the overliner, a geocomposite can be used for drainage and a lower-quality gravel (i.e., primary crushed ore) above that for physical separation. Cost comparisons on several projects have shown that the geocomposite system can be lower in cost to a conventional gravel overliner. This approach also

reduces construction time and lowers the risk of damage to the liner, most of which occurs when the gravel is placed (Smith & Li, 2012).

Limited Skilled Contractors: Countries with mining history (e.g., Chile) tend to have available skilled contractors for complex work items (clay, geomembrane, and dam construction). In countries with emerging mining industry, such as Argentina and Panama, this is a serious limitation that adversely affects an engineer's choice of technologies, construction schedule, and the project's success rate. Limited access to heavy earth moving equipment also slows production. During the construction of the VLP at Pierina (Peru, 1997-1998), the earthworks required five contractors and every available haul truck - 125 at peak construction. These delays strain owner schedules, increase the risk of cost overruns, delays and commissioning problems. The importance of schedules in mining is hard to overstate; the average production of a large copper mine is about 150,000 tonnes of copper annually. At current metal prices, the value of a lost day is now over \$3,000,000. And it's common for the construction manager to share in the delay-induced losses.

High Elevations: The typical copper or gold mine in Peru and Chile is at an elevation or around 4,000 m. The Pascua-Lama mine, currently under construction, straddles the Andes; the haul road exits the mine at an elevation of 5,100 m. Other than extreme weather, the issues at high altitude include (a) worker productivity, including mental clarity and increased propensity for errors, (b) worker safety and higher accident rates and the increase risk of fatalities; and (c) equipment productivity, as engines and motors require down-grading for horsepower at altitude, which means trucks move slower and pumps deliver less head, and consequently move less material. While some of this is easy to account for, such as engine and motor factoring, worker productivity and safety are often inadequately considered in planning, at considerable costs to owners, operators and contractors.

Extreme Weather: High rainfall and high altitude Andean sites add to the difficulty of construction as well as the need for design measures to divert severe peak events from inundating pads and ponds. Depending upon the site, the "dry" season may only provide a few months for construction and even then extreme events can create havoc. A case in point: one mine in Northern Sonora, Mexico, received over 490 mm of rainfall in July 2012, higher than the greatest annual rainfall on record. Such severities can cause delays in construction, damage constructed or under-construction areas, and even overtop the emergency ponds. They also increase the needed time to construct and commission in unpredictable ways. The high altitude, cold climate Andean sites offer another degree of difficulty requiring safety measures for workers and can slow productivity. Cold weather and wind can adversely affect access roads and create life-threatening conditions. Winds are stronger and more erratic at higher elevations; at Pascua-Lama winds in excess of 140 km/hr are common and the highest winds destroyed the recording station, literally ripping the station, tower and concrete footings out of the rock and tossing them down the mountain. Another Andean site had a gust of wind lift a geomembrane panel during placement, causing the technician standing on the liner to be thrown in the air and land on his head, compressing vertebrae in his neck.

Tropical and Andean projects can experience very high annual rainfall, with average annual precipitations from 1,000 mm to over 4,000 mm common. Storms can also be very intense, with peak rainfall of over 200 mm in a few hours, or 500 mm in a few days. The high

annual rainfall presents problems of surplus water, both in terms of water management, and making some construction activities very difficult or impossible (including operation of the stacking equipment as well as deploying liners). Intense storms can also damage agglomerated ore, creating impervious surfaces and zones of channeling within the heap and otherwise impede leaching. Average moisture content in the as-stacked ore can also be increased to the point of creating a risk of static liquefaction. One of the techniques almost universally used to manage high rainfall is the application of temporary geomembrane covers or “raincoats.” More specifically, a raincoat is placed over the heap to shed rainwater before it enters the process circuit. An industry review updated in 2008 found 34 heap leach projects that have used or are planning to use raincoats (Stemson, et al 2010).

Figure 9. Currently the largest use of raincoats is at the Lagunas Norte gold mine in northern Peru with approximately 30 ha installed (Sept. 2012).

Limited Knowledge: A lack of regulatory capacity in developing countries strains the local regulators faced with complex, modern projects. For example, the requirement for leak detection without the technology or what constitutes reasonable leakage rates is endemic in the developing world. Mexico allows shallow French drains, which are highly unreliable and give false confidence. Argentina, on the other hand, requires reasonably advanced leak detection (including, in some cases, double geomembrane liners) but has an expectation of zero leakage. Developing countries have limited resources and expertise for robust construction observation. Installation quality is often much lower than owner, regulator or community expectations. All of which results in higher leakage rates and corresponding higher metal loss, increased environmental risk and more regulatory intervention. The solution requires the design to

anticipate these potential shortcomings, and keep it as simple as possible. Ideally, a very high level of interaction with the affected stakeholders including in many cases educational outreach programs is required.

Remote Areas: Difficult access can affect equipment and contractor selection and can also affect recruiting for key positions, especially in a robust labor market. For example, Rio Tinto's La Granja site in Peru is only 220 km from Trujillo, a major city in Northern Peru, yet a 10 hour drive. In addition, the drug cartels have increased risks in Northern Mexico and Northern Peru and companies are placing restrictions on travel to these areas, thereby restricting experienced professionals from site visits. Many of the sites are adjacent to known drug cartels in Mexico and there are large areas in Peru and Colombia where any travel requires a military escort (on one of the authors' projects, the Peruvian military refused to provide escort!)

EMERGING TECHNOLOGIES

Electrical Leak Location (ELL): Well established in the North American landfill industry, this technology is only recently gaining traction in mining. There is already growing experience with leak testing in Peru, Argentina and Chile, and some jurisdictions are starting to make ELL surveys strongly recommended or even mandatory. Thiel, et al (2005) and Beck & Smith (2006) studied the economic benefits of this technology and found the ratio of benefit (reduced metal loss) to the cost of the surveys as high as 12 with very short payback periods. And this is before considering the harder to quantify but potentially much more important benefits of reduced environmental and social impacts.

While this technology is seeing a rapid growth in popularity among South American mining operations, a yet-to-be-tested benefit is the potential to perform routine verification of containment for on-off pads (dynamic heaps). With a conductive substrate (or a liner with a conductive bottom) and a little attention to detail, a leach pad could be surveyed for damage during each unloading cycle. It's only logical that the high benefit-cost ratio of ELL surveys on initial installations would accrue to the cyclic loading conditions of a dynamic heap. This is another way to increase profits, reduce the likelihood of failure, and improve the relationship between miners and stakeholders.

Thermal Covers: Seasonal low temperatures, especially at high altitudes, can retard leaching kinetics, extending leach cycles and reducing metal production. This is especially important for bio-leaching, where the effectiveness of the bacteria is much more susceptible to temperature than non-biological kinetics. Capturing solar radiation and reducing convection losses can add several degrees to the lowest seasonal temperatures, accelerating kinetics or adding weeks or months to the available leach time (or reducing the required leach time and thereby increasing production rates). Measurements at one pilot facility reported temperatures in the irrigation system immediately below the cover a full 35°C above ambient, which produced leach rates significantly faster than predicted from ambient temperature column tests. A large pilot test of thermal covers is currently underway in the Western United States and another is in planning in South America, both for bio-leach facilities.

Evaporative Covers: In many mining areas, including Northern Mexico, Southern Peru and much of Chile, water availability is a key issue and often a restriction. For example, in

Chile's copper district (Region 2), recent expansions at Escondida have required the construction of a large desalinization plant near Antofagasta and a 160 km pipeline - with a static head of 3,000 meters - to the mine site. Southern Peru Copper Co. is also considering desalinization for their increasing water needs. Total cost for water, including capital amortization and pumping, can exceed \$3.50/m³, and processing commonly uses 0.5 m³ or more of water per tonne of ore. Evaporation rates in the Chilean Atacama often exceed 3,000 mm/year, producing \$10.50/m² per year in the value of water lost to evaporation. Geomembrane covers can reduce evaporative losses to near zero and the payback period for these is often on the order of 1 to 2 years. There can also be considerable social benefit from taking aggressive and visible efforts to reduce water consumption in areas that have water shortages affecting agriculture and other key industries. Evaporative covers also have the benefit of reducing salt formation on top of the heaps, which can limit percolation and affect recoveries (see Figure 10).

(a) Without a raincoat

(b) With a raincoat

Figure 10. Nickel pilot heaps without and with raincoats, showing the reduction in evaporative salt formations. Such salts can significantly impair percolation and thereby leaching efficiencies. The salts also contain targeted metals, thus reducing recovery.

Evaporation control: Water supply is becoming one of the key areas limiting expansion of mining. In some areas, such as the Atacama and Namib deserts, water is so scarce that new projects are limited by their ability to either import (e.g., trans-national pipelines) or create (e.g., desalinization) fresh water. Limited water opens the door to spending a little money to reduce water demand in exchange for allowing higher mineral processing rates. Floating pond covers is the most obvious idea; with desert evaporation rates and high water costs, the economics pencil out even before considering other benefits like reagent consumption and reduced contamination in the final product (i.e., through dust and debris) as shown:

Floating cover installed cost: \$15 to 20/m²
Value of water savings: 3,000mm/m²/yr x \$3.50/m³ = \$10.50/m²/yr
Payback period = 17 to 23 months

Strong acid environments: Geomembrane properties are affected by strong acids, a long-known and long-avoided fact. Exactly how much the performance degrades is quite simply not well known but of course is of interest, especially with design lives now routinely exceeding 20 years and strong-acid agglomeration commonplace. Limited antidotal and even more limited laboratory data suggests some softening of HDPE & LLDPE and embrittlement of PVC and these affects are intensified at elevated temperatures. A recently completed and critically important study into this phenomenon carried out at Queen's University suggests that HDPE and LLDPE geomembranes perform well in acidic leach solutions, with OIT depletion rates slower than for MSW landfill leachates (Abdelaal, F. B., et al 2012).

ARD reduction and carbon credits: Mine wastes, including spent heap leach ore, are well known for their potential to produce acid rock drainage, a phenomenon related to the weathering of pyritic minerals and compounded by residual acids from the leach cycle. The acid then mobilizes heavy metals either in the same waste or present beneath the acid-producing wastes. The production of acid drainage requires oxygen, and unsaturated soil or clay covers do little to restrict air transport via barometric "pumping" from the top and exposed slopes. Geomembranes, on the other hand, can be excellent air barriers and installation of a geomembrane capping system can sufficiently reduce the availability of oxygen to prevent or significantly retard generation of acid. In addition to the obvious savings in long-term ARD treatment costs and the related reduction in environmental and social liabilities, for sites located in the developing world there may also be marketable carbon credits available since the neutralization of acid, whether naturally or via a treatment plant, releases vast quantities of CO₂. Consider a dump with an acid potential of 100 kg per tonne of waste; neutralization of that acid will produce carbon dioxide according to the following equation:

Thus, properly sealing the dump from oxygen and suppressing the acid reaction can produce 0.045 tonnes of carbon credits per tonne of waste. The European carbon market values these credits in the range of US\$20 to \$30 per tonne of CO₂, equating to \$0.88 to \$1.32 per tonne of waste. For a copper mine producing 25 to 100 million tonnes of spent ore annually, a fairly common range, this can make a meaningful impact to the bottom line.

CONCLUSIONS

This paper has shown the history and importance of heap leaching on the heavy metal mining industry, which in turn has shown the uses and importance of geosynthetics to mining. The heap leach projects are some of the largest users of geomembranes, by some estimates consuming 40% of all geomembrane produced, and continued uses are still being developed. The use of strong acids and bases, as well as extreme environments push the geosynthetics to their limits, but have shown to be an integral part of the mining industry's modern success.

GEOSYNTHETIC DESIGN METHODS USED IN ROADWAY APPLICATIONS

Robert M. Koerner
Geosynthetic Institute, Folsom, PA USA

ABSTRACT

From the very beginnings of geosynthetics roadways have been a major application area. Geotextiles were used successfully on soft subgrade soils for unpaved roads since the 1970's. Geotextiles for prevention of reflective cracking in asphalt overlays began in the 1980's. Geogrids within stone base aggregate for paved and unpaved roads, as well as railroads, began shortly thereafter. Considering the tremendous amount of roadways of all types, however, many feel (the author included) that the full potential of geotextiles and geogrids in roadway applications is largely unfulfilled. One reason is perhaps because the necessary design methodology is either unavailable or overlaps the various functions that may be simultaneously occurring, i.e., a specific design methodology for each mechanism is yet to be developed and moreover accepted by the owner/regulatory community.

This paper, essentially a review of available design methods for each mechanism, purposely distinguishes between four unique functions that geosynthetics provide in roadway applications. They are the following:

1. Geotextiles and/or geogrids used for reinforcement of soft soil subgrades for unpaved roads.
2. Geotextiles used for separation on firm soil subgrades for paved and unpaved roads
3. Geogrids used for reinforcement within stone base aggregates on firm subgrades for paved and unpaved roads
4. Geotextiles or geogrids used for waterproofing or reinforcement of reflective cracking in asphalt overlays of paved roads

The state-of-the-practice insofar as design is concerned will be presented in each of these four discrete areas. The perceived status of geosynthetics in roadways and recommendations going forward will be offered as well.

1.0 INTRODUCTION AND BACKGROUND

Stabilization of unsuitable subgrade soil for the purpose of constructing a pathway, aka a roadway, dates back to 3000 B.C. with the use of split-log *corduroy* roads over peat bogs (Dewar, 1962). The ridged surfaces were filled with available soils but the deterioration of the timber and particularly its lashing was an obvious problem. Many variations on this theme ensued including tar and bitumen surfaces and then concrete, but for the purposes of this paper, the paradigm change was made in 1926 by the South Carolina Highway Department (Beckham and Mills, 1935). A heavy cotton fabric was placed on a primed soil base, hot asphalt was applied to it and then a thin layer of sand used as the wearing surface. Eight field test sites of such unpaved roads were conducted. Until the cotton fabric deteriorated, the roads were in good

condition in that there was reduced cracking, raveling and backfill failures. This project was clearly the forerunner of the separation and reinforcement functions of polymeric geosynthetics as we know them today.

It is common knowledge that the amount of present roadways is enormous. Table 2 gives some statistics in this regard. Clearly, roads are vital to our way of life and an area in which geosynthetics have made some positive strides (as will be seen) but there is much more that can and should be done. This paper focuses on the main functions offered by geosynthetics used in roadway applications insofar as what has been accomplished over the past 25-years and where we might be venturing into the future. They are geotextiles and/or geogrids used for both unpaved and paved roads, for the functions of separation, reinforcement and waterproofing.

Table 1(a) - Roads in the USA in 2008 (Federal Highway Administration)

Type	Length (kilometers)	Length (miles)
unpaved	2,132,000	1,324,000
paved with asphalt	1,451,000	901,000
paved with concrete	84,000	52,000
paved but unspecified	2,867,000	1,781,000

Table 1(b) - Roads in Selected Countries in 2009
(World Road Statistics - International Road Federation)

Country	Major Roads (Paved ?)		Secondary Roads (Unpaved ?)	
	kilometers	miles	kilometers	miles
China	97,000	60,000	3,402,000	2,113,000
Japan	61,000	38,000	1,135,000	705,000
Germany	53,000	33,000	592,000	368,000
France	21,000	13,000	931,000	578,000
United Kingdom	53,000	33,000	367,000	228,000
United States	351,000	218,000	6,183,000	3,840,000

1.1 Overview of Geotextiles or Geogrids Used for Reinforcement of Soft Soil Subgrades for Unpaved Roads

Unpaved roads (also called secondary roads, farm-to-market roads, access roads and haul roads) represent a tremendous opportunity for geosynthetics, primarily geotextiles or geogrids. The situation generally focuses on soft soil subgrades which have the geotextile or geogrid placed directly on the ground surface even with the natural vegetation remaining in place. A stone base course (of varying types and thicknesses) is placed on the geosynthetic material. No permanent surfacing (i.e., concrete or asphalt pavement) is placed on the stone. At most, the road is surfaced with quarry crusher run or chip seal for reasonable ridability. At a later time, perhaps years after settlement takes place and ruts are backfilled, a permanent surfacing may be placed if the traffic warrants such an expenditure.

This particular application has triggered the high-volume use and acceptance of geotextiles in the 1970s followed thereafter by geogrids, since calculations can be made for the thickness of stone required both without a geosynthetic and then with a geosynthetic; the difference being the thickness of stone that is saved. By determining the cost of stone saved

versus the cost of the geosynthetic, the savings in using the geosynthetic is known immediately. The particular design process used in arriving at the respective thicknesses is obviously critical and will be described later.

That said, it is important to realize that the geosynthetic must have its tensile modulus or strength mobilized via deformation of the soil subgrade. The yielding of the soil subgrade is the triggering phenomenon, allowing for geosynthetic deformation and the mobilization of its tensile properties. How much deformation is necessary with regard to the vehicular loading, the particular geosynthetic, the time it takes for adequate strength mobilization, and so on, are all pressing questions, but the deformation of the soil subgrade is critical. A soft, yielding soil subgrade is needed to mobilize the geosynthetic's strength—but how soft? In light of the tremendous variety of assessments, most transportation engineers use a broad generality which is based on the California Bearing Ratio (CBR) of the soil subgrade. The CBR test is used throughout the world and standardized accordingly; e.g., see ASTM D1883. The CBR value is a comparison of the soil's resistance to the force of a 50 mm diameter plunger at a given deformation with that of a crushed stone-base material. It is actually a percentage value, although it is rarely expressed as such. The test on the soil subgrade can be performed either at the in-situ moisture content or the soil can be saturated for 24 hr and then tested. These two conditions give rise to unsoaked and soaked CBR values, respectively. Typical values are given in Table 2 where it is seen that soaked CBR values are generally lower than unsoaked values, but the difference greatly depends on the soil type.

Table 2 - Recommended Soil Subgrade CBR Values to Distinguish Different Geosynthetic Functions in Roadway Applications

Geosynthetic Function(s)	CBR - Value	
	Unsoaked	Soaked
Separation	≥ 8	≥ 3
Stabilization*	8-3	3-1
Reinforcement and Separation	≤ 3	≤ 1

*a frequently used but poorly defined transition term that always includes separation, some unknown amount of reinforcement, and often filtration as well.

Insofar as an approximate generalization as to when geotextiles or geogrids are used for unpaved roads as a function of unsoaked CBR values of the soil subgrade strength, see Figure 1. Clearly, base course thickness reduction factors increase as soil subgrade CBR's decrease. The figure also attempts to distinguish between different types of geotextiles and geogrids. That said, it does not attempt to distinguish between individual properties within each type of geosynthetic material. It is presented here only as a guide since the more analytic and product specific approaches are offered later in this paper.

Figure 1. Reduction of roadway base course thickness using various geosynthetics. (After van Gurp and van Leest [2002])

1.2 Overview Geotextiles Used for Separation on Firm Soil Subgrades for Paved and Unpaved Roads

Irrespective of whether the road surface is unpaved or paved, the stone base will be placed directly on the soil subgrade. Depending on the site-specific circumstances, most notably the soil's stiffness and moisture regime at this interface, a gradual movement of soil up into the gravel and the associated gravel down into the soil will occur. This is shown schematically in Figure 2. As indicated, the preservation of this original boundary is necessary in order to take advantage of the full-depth effect of the stone base course. Certainly, a geotextile placed at this interface so as to preserve the integrity of the interface is a worthwhile goal. In this case the geotextile is functioning as a separation fabric and has applicability to both paved and unpaved roadway systems.

(a) Mechanism of fine soils pumping into stone base voids and prevention using geotextiles

(b) Mechanism of stone base intrusion into fine soil subgrade and prevention using geotextiles

Figure 2. Different mechanisms involved in the use of geotextiles involved in the separation function (Koerner, 2012).

1.3 Overview of Geogrids Used for Reinforcement Within Stone Base Aggregates on Firm Subgrades for Paved and Unpaved Roads

Whenever geosynthetic usage in unpaved roads is discussed, the question of the material's use in paved roads on firm subgrades often follows. To address this properly, we must focus on the general characteristics of the situation. It is most important to recognize that if the road is to be paved with concrete or asphalt immediately (i.e., during initial construction), it cannot be placed on an excessively yielding soil subgrade. If the subgrade yields, the road section will deform and the surfacing will simply crack after a few load repetitions. Many agencies put the *lower limit* of acceptable unsoaked CBR values in the range 10 to 15. As just discussed, however, the geosynthetic must deform in order to mobilize its strength, and the *upper limit* of soil subgrade strength for such mobilization as suggested in Table 2 is an unsoaked CBR of 3 to 8. This contradiction begs the question of how the geosynthetic is to reinforce if it is not significantly deformed. Advocates of a reinforcement function in paved roads on firm soil subgrades will suggest that the geosynthetic deformation around the coarse-aggregate base course (when heavily rolled) is sufficient to mobilize the geosynthetic's strength. In this regard, emphasis shifts from savings in base course thickness to increased number of traffic repetitions. Thus the shifting of design method(s) will be done accordingly.

There is, however, another reason for using a geosynthetic within the stone base. Geogrids (and to a much lesser extent geotextiles) have been placed within the stone aggregate base course for providing lateral reinforcement. A properly designed geogrid inclusion prevents the stone from horizontal migration due to the dynamic loads produced by trucks and automobiles traveling on the asphalt or concrete wearing surface. Additional details on this mechanism will follow.

1.4 Overview of Geotextiles or Geogrids Used for Waterproofing or Reinforcement in Reflective Cracking of Asphalt Overlays of Paved Roads

This leads to the fourth category of this paper on geosynthetics in roadway applications which is the use of interlayers in asphalt overlays. The resurfacing of existing pavements which have excessive cracks in them represents an ongoing and expensive task for all federal, state, local, and private organizations that own and maintain roads. Such resurfacing is usually done with asphalt (bituminous) overlays ranging in thickness from 25 to 100 mm. Particularly exasperating to the road owners (and to the users and their automobiles, as well) is when the cracks in the original pavement reflect up through the new overlay earlier than anticipated. To combat this, thicker overlays than desirable are used but at the cost of added expense, lower curb heights, and excessive weight and thickness on the subgrade system. Due in part to the magnitude of this problem and the potential opportunities that it represents, the use of geotextiles to remedy the situation has been accomplished in a number of ways. In some instances strips of geotextile have been placed over the cracks, spanning it by 150 to 600 mm on each side, and the overlay placed above. Polyester, polypropylene, and fiberglass geotextiles, as well as geogrids, have all been used in this regard. By far the major use, however, has been to place full-width geotextile sheets over the entire pavement surface, which have been waterproofed with asphalt cement or asphalt emulsion, and then overlain with the final bituminous surfacing. The goal of such a process is to either decrease the thickness of the overlay while keeping a lifetime

equivalent to not using a geotextile, or increase the lifetime of the overlay while using the same thickness as without the use of the geotextile.

A very large market for geotextiles has developed as have the installation procedures. This is shown in the successive photographs of Figure 3 and is fully described in manufacturers literature, as well as in Koerner, 2012.

1.5 Overview of Paper

Using this introductory and background section of geosynthetics used in roadway applications we can readily visualize how the various mechanisms described are individually positioned within a roadway's cross section, see Figure 4. Of course, two or three areas can function simultaneously, but they will be treated separately so as to focus upon the idiosyncrasies of each.

Figure 4. The four areas of geosynthetic use in road applications to be described herein.

2.0 GEOTEXTILES OR GEOGRIDS USED FOR REINFORCEMENT OF SOFT SOIL SUBGRADES FOR UNPAVED ROADS

All of the major geotextile and geogrid manufacturers have an unpaved road design method for use with their particular geosynthetics. They usually show CBR (or other soil strength values) on the x-axis and the required stone thickness (with and without a geosynthetic) on the y-axis. All result in logical behavior, with the geosynthetic providing greater savings in stone aggregate as the soil subgrade becomes weaker. Since most manufacturers have a range of products available for the reinforcement of unpaved roads, it is also seen that the heavier and stronger geotextiles and geogrids result in greater stone savings than the lighter and weaker ones. Because each manufacturer's set of curves has its own background (based on theory, laboratory work, field observation, or empirical observation), it is nearly impossible to compare one manufacturer's procedure with another. Yet the design methods have served the industry well and generally with excellent success. Their use is certainly acceptable and if only one manufacturer's products are available, its method should continue to be used. If, however, a number of geotextiles and/or geogrids are available, a method that views them on the basis of a specific, well-defined property is needed. Such a property could well be the material's tensile modulus, which is the basis of design in the procedure to follow.

Giroud and Noiray [1981] use the geometric model shown in Figure 5 for a tire wheel load of pressure p_{ec} on a $B \times L$ area, which dissipates through h_o thickness of stone base without a geotextile and h thickness of stone base with a geotextile.

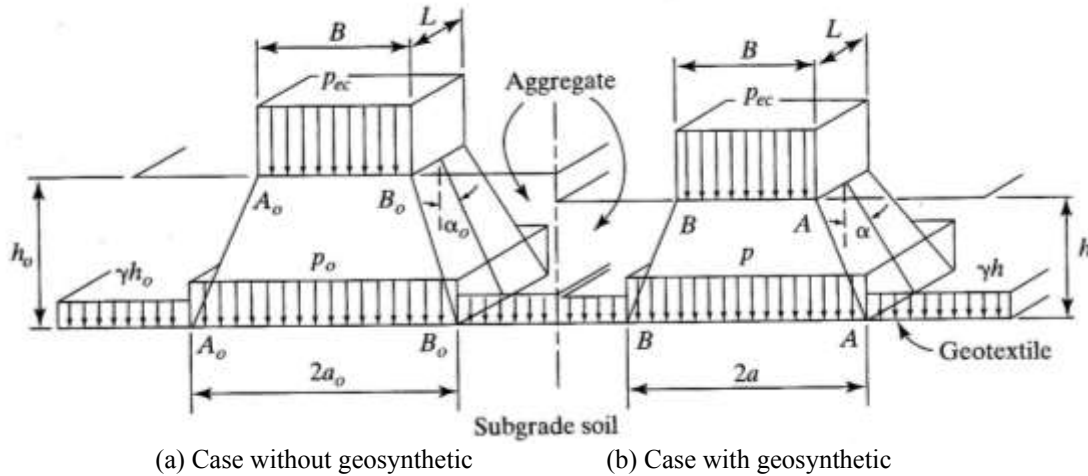

Figure 5. Load distribution by aggregate layer (after Giroud and Noiray [1981]).

This geometry results in stress on the soil subgrade of p_o (without geotextile) and p (with geotextile) as follows:

$$p_o = \frac{P}{2(B + 2h_o \tan \alpha_o)(L + 2h_o \tan \alpha_o)} + \gamma h_o \quad (1)$$

$$p = \frac{P}{2(B + 2h \tan \alpha)(L + 2h \tan \alpha)} + \gamma h \quad (2)$$

where

P = axle load, and

γ = unit weight of the stone base course aggregate.

Knowing the pressure exerted by the axle load through the aggregate and into the soil subgrade, shallow-foundation theory of geotechnical engineering can now be used. Assumed throughout the analysis that the soil is functioning in its undrained condition and thus its shear strength is represented completely by the cohesion (i.e., $\tau = c$). Thus the tacit assumption is that the soil subgrade consists of saturated fine-grained silt and clay soils. Critical in this design method are the assumptions that without the geotextile the maximum pressure that can be maintained corresponds to the elastic limit of the soil, that is,

$$p_o = \pi c + \gamma h_o \quad (3)$$

and that with the geotextile the limiting pressure can be increased to the ultimate bearing capacity of the soil, that is,

$$p^* = (\pi + 2)c + \gamma h \quad (4)$$

These assumptions reasonably agree with the earlier findings of Barenberg and Bender [1978] using small-scale laboratory tests, where on a deformation basis they found that large-scale ruts began at a $3.3c$ value with no geosynthetic reinforcement, versus a $6.0c$ value with geosynthetic (where c is the undrained soil shear strength).

Thus for the case of no geosynthetic reinforcement, Eqs. (1) and (3) can be solved to give Eq. (5), which results in the desired aggregate thickness response curve without the use of the geotextile or geogrid.

$$c = \frac{P}{2\pi \left(\sqrt{P/p_c} + 2h_o \tan \alpha_o \right) \left(\sqrt{P/2p_c} + 2h_o \tan \alpha_o \right)} \quad (5)$$

where

- c = soil cohesion,
- P = axle load,
- p_c = tire inflation pressure,
- h_o = aggregate thickness, and
- α_o = angle of load distribution ($\cong 26$ deg.).

For the case where geosynthetic reinforcement is used, p^* in equation (4) is replaced by ($p - p_g$), where p_g is a function of the tension in the geosynthetic; hence its elongation is significant. On the basis of the probable deflected shape of the geosynthetic-soil system,

$$p_g = \frac{E\varepsilon}{a\sqrt{1 + (a/2S)^2}} \quad (6)$$

where

- E = tension modulus of the geotextile or geogrid,
- ε = elongation (strain),
- a = geometric property, and
- S = settlement under the wheel.

Combining equations (2), (4), and (6) and using $p^* = p - p_g$, gives Eq. (7), where h is the unknown aggregate thickness with geosynthetic reinforcement. The geosynthetic reinforcement is represented by “E”, the tensile modulus of the specific geogrid or geotextile being considered per ASTM D4595, or equal.

$$(\pi + 2)c = \frac{P}{2(B + 2h \tan \alpha)(L + 2h \tan \alpha)} + \frac{E\varepsilon}{a\sqrt{1 + (a/2S)^2}} \quad (7)$$

With these two sets of equations, the design method is essentially complete, since both h_o (thickness without a geosynthetic) and h (thickness with a geosynthetic) can be calculated. From these two values $\Delta h = h_o - h$ can be obtained, which represents the savings in aggregate due to the presence of the geosynthetic. For convenience, however, the result can be read directly from Figure 6. This figure also considers the effects of traffic. In this case, the required thickness h' becomes $h' = h'_o - \Delta h$, which is obtainable from the curves by subtracting the two ordinate values of h'_o and Δh . Note that the effect of service lifetime takes the form of number of vehicle passages.

Figure 6. Design graphs for reducing aggregate thickness using a geosynthetic. Aggregate thickness h'_o without geotextile when traffic is taken into account and change in aggregate thickness (Δh) resulting from the use of geosynthetic rather than relying only on subgrade soil cohesion. (After Giroud and Noiray [1981])

It is important to recognize that in the previous design process the savings in stone aggregate can be directly compared to the cost of the geotextile or geogrid and the least costly alternative selected. Koerner (1982) presents a cost analysis of the alternatives with distance from the quarry and geosynthetic source being the major variables. This example problem and its solution follows.

Example: Given 1000 passages of a 80 kN single-axle-load vehicle with tire inflation pressure of 480 kPa; soft fine-grained soil CBR = 2.0; geosynthetic modulus $E = 170$ kN/m, and an allowable rut depth = 0.3 m. Determine the aggregate savings and do an economic analysis based on the distance the project is from the aggregate source and geosynthetic supplier, respectively, using the following data (the stone unit weight is 20 kN/m^3):

Distance (km)	Aggregate cost (dollars/kN)	Geosynthetic cost (dollars/m ²)
< 5	0.90	0.72
5-20	1.20	0.76
20-50	1.70	0.78
50-100	2.50	0.84
100-200	3.80	0.90

Solution: At CBR = 2.0 from Figure 6;

$$\begin{aligned}
 h'_o \text{ (without geotextile)} &= 300 \text{ mm} \\
 h' \text{ (with geotextile)} &= 205 \text{ mm} \\
 \Delta h \text{ (savings in stone)} &= 95 \text{ mm}
 \end{aligned}$$

Based on 20 kN/m^3 , this is a $0.020 \text{ kN/m}^2\text{-mm}$ stone thickness, which results in the following table. It is easily seen that the use of the geosynthetic reinforcement is very economical and becomes more so as the distance from the aggregate source to the project site becomes greater.

Distance from Source (km)	Aggregate total cost (dollars/kN)	Aggregate unit cost (dollars/m ² -mm)	Aggregate total cost (dollars/m ²)	Geosynthetic total cost (dollars/m ²)	Geosynthetic total savings (dollars/m ²)
<5	0.90	0.018	1.71	0.72	0.99
5-20	1.20	0.024	2.31	0.76	1.55
20-50	1.70	0.035	3/31	0.78	2.53
50-100	2.50	0.050	4/79	0.84	3.95
100-200	3.80	0.075	7.13	0.90	6.23

The Giroud and Noiray (1981) procedure just presented has been revised and upgraded for specific geogrids by Giroud and Han (2004, 2012) to include (i) an improved analytic formulation, (ii) a variable angle α_o in Figure 5, (iii) an increase in the bearing capacity factor for the reinforced case from 5.14 to 5.71, and (iv) a dimensionless parameter “k” which depends on contact area, base thickness, type of reinforcement and test method. Furthermore, k is defined as follows:

$$k = \tan \alpha_o \left(0.96 - 1.46J^2\right) \left(\frac{r}{h}\right)^{1.5} = 1.26 \left(0.96 - 1.46J^2\right) \left(\frac{r}{h}\right)^{1.5} \quad (8)$$

where

- α_o = stress distribution angle (see Figure 5)
- r = radius of tire contact angle
- h = base thickness after compaction
- J = aperture stability modulus of geogrids as determined by a laboratory test

The resulting design equation for the thickness of the aggregate base course “ h ” is as follows:

$$h = \frac{1.26(1 + k \log N)}{1 + 0.204(R_E - 1)} \left[\frac{\frac{P}{\pi r^2}}{\sqrt{\left(\frac{s}{f_s}\right) \left[1 - 0.9 \exp\left(-\left(\frac{r}{h}\right)^2\right)\right]} N_c c_u} - 1 \right] r \quad (9)$$

where

- N = number of axle passes
- R_e = modulus ratio of aggregate base to subgrade soil
- S = allowable rut depth
- f_s = reference rut depth (= 75 mm)
- N_c = bearing capacity factor
- c_u = undrained shear strength of subgrade soil
- P = individual wheel load
- k = see Eq. 8

This revised approach toward obtaining the required aggregate base thickness using geogrid reinforcement depends on “ k ”, which in-turn depends on “ J ”, the aperture stability modulus value that is obtained from a torsional rotation laboratory test. This test method, originated by Kinney (1998), has been standardized as GRI-GG9 (2004).

Some author’s commentary on this revised design procedure follows:

1. The original method used an elastic modulus as obtained from a standard wide-width tensile test which results in a stress-strain (or load-elongation) behavior of the candidate test specimen.
2. The revised method uses an elastic modulus as obtained from an in-plane torsional rotation method. As stated by Giroud and Han (2004, 2012) it is applicable to small deformation which they feel is more appropriate.
3. The modulus “ J ” in Eq. 8 generally has the dimension of “mm-kg/deg”, or equivalent, and this is used in Eq. 8 which has a constant in front of “ J ” and thus cancels the units out.

4. It should be noted that the torsional rotation method per GRI-GG9 has been used on all types of geogrids and data has been generated accordingly. The method has not been used for geotextiles although there is no reason why it could not be done in a similar manner.

Going forward, an alternative simulation test for the unpaved road application appears to the author to be the axisymmetric out-of-plane test. This test was developed by Shields, et al. (2005) for geogrids and then extended for geotextiles and geonets by Andrejack and Wartman, 2010, see Figure 7. This test has also been recently used by Wrigley, et al. (2011) who evaluated a number of geogrids and found remarkably good agreement with wide width tensile values at least up to about 2% strain. In using the above mentioned axi-symmetric out-of-plane tension test for high strength reinforcement materials failure is not likely achieved. In this regard, a modulus 2 to 4% strain is the limit depending on the strength of the geogrid or geotextile.

Figure 7. Axisymmetric out-of-plane tension test (after Andrejack and Wartman, 2010).

3.0 GEOTEXTILES USED FOR SEPARATION ON FIRM SOIL SUBGRADES FOR PAVED AND UNPAVED ROADS

As shown on Figure 4, geotextile separators are often placed directly on the soil subgrade in order to separate it from the overlying stone base aggregate. The twofold detrimental phenomena of loss of gravel and intrusion of soil subgrade was illustrated in Figure 2. The geotextiles being polymeric (presently the majority are polypropylene based) have sufficient durability properties such that degradation within pavement lifetime is not an issue. Of course, the geotextile must survive the installation process, but with adequate physical and mechanical properties (such as stipulated in the AASHTO M288 specification) this is readily accomplished.

Designing for separation itself, however, is elusive. Many manufacturers have guidance in that 25 to 100 mm of stone base aggregate are preserved over time by virtue of the inclusion of a geotextile separator. While this sounds reasonable to the author it is generally too subjective

for a cost-conscious and somewhat skeptical transportation engineer. That said, some limited empirical guidance is afforded by the U.S. Federal Highway Administration; see Figure 8 in this regard. Needed is either an analytic based design method or field justification based on actual long-term performance. That performance should show how long the pavement is serviceable both with and without the geotextile inclusion.

Figure 8. Reduction in stone base thickness when using a geotextile separator, adopted from FHWA (Jan. 1989).

To this end, four field sites have been prepared with and without geotextiles for an assessment over time, see Koerner (2000). These are full lane width paved road sites of approximately 100 m in length; see Figure 9. Furthermore, different geotextiles have been used at the sites to see if and how much longevity is associated with each geotextile as contrasted to the control sites at each end of the run with no geotextiles. Table 3 gives the relevant information, however, data on the performance is not yet available. It is felt to be essential to implement and evaluate as many such studies as possible in order to justify the widespread use of geotextiles as separators in paved road applications.

Table 3 – GSI Long-Term Benefit/Cost Separation Sites (Koerner, 2000)

Site	Location	Installed	Owner	Monitoring
1 a-b	Springfield, PA	June 1994	private	rut depth
2 a-f	Rt. 522, Orbisonia, PA	June 1998	PA-DOT	visual

Figure 9. Field sites in Pennsylvania under investigation to evaluate geotextile performance over time in the separation function.

Figure 11. Geogrid-reinforced aggregate base courses for roadways using geogrids, after Carroll, et al. (1987).

4.1 Use-What-Works

Use-what-works is not as foolish as it seems since this is precisely how unpaved road applications as just explained gained acceptance, particularly from contractors who verified the considerable saving in stone base using the geosynthetic. The fundamental difference with strong soil subgrades having $CBR_{US} \geq 8$ or $CBR_S \geq 3$, however, is that the base course is typically as thin as it can possibly be even without the geogrid inclusion. For example, stone base courses as thin as 100 to 150 mm are regularly used for asphalt paved roads and further reductions are simply not viable. Of course, for major roads and interstate highways the stone base courses become thicker. At any rate, a very different mindset is suggested for justification of the inclusion of the geogrid. This, the author and others believe, is better rideability (less rutting) and/or longer service lifetime (for direct cost savings). That said, this use-what-works approach toward selecting a geosynthetic is completely judgmental and is not felt to be a design method, per se.

4.2 The CBR Cover Design Method

The CBR Cover Design Method noted on Figure 10 is essentially for unpaved roads wherein separation, stabilization and reinforcement are the primary function and are related to the soil subgrade's CBR-value. Recall Table 2 in this regard. Again, however, the lower values of CBR are simply not viable when the base course is paved so the "unpaved road technique" is not applicable for this type of paved road situation.

4.3 The AASHTO Method

The AASHTO Method was based on a major experimental road test conducted in the 1960's resulting in the 1993 AASHTO Design Guide. The essence of the method is to calculate an overall structural number (SN) that is indicative of the required total pavement thickness for proper serviceability. It is solved using a nomograph based on the following equation.

$$\log W_{18} = Z_R \times S_O + 9.36 \times \log(SN + 1) - 0.2 + \frac{\log \frac{\Delta_{psi}}{2.7}}{0.4 + \frac{1094}{(SN + 1)^{5.19}}} + 2.32 \log M_R - 8.07 \quad (10)$$

where

- W_{18} = 18 kip design equivalent single axle loads (ESAL's)
- Z_R = standard reliability level
- S_O = standard deviation
- Δ_{psi} = allowable loss in serviceability
- M_R = resilient modulus for the geosynthetic being considered
- S_N = structural number as follows:

$$SN = (a \times d)_{hma} + (a \times d \times m)_{base} + (a \times d \times m)_{subbase} \quad (11)$$

where

- a = coefficient of relative strength
- d = thickness of each layer
- m = modifier for moisture in the system

In order to introduce geosynthetics into the above design process, there are two options. The *first option for increased W_{18} or EASL's* is based on a TBR-value as defined below, Berg, et al. (2000)

$$TBR = N_R / N_U, \text{ and} \quad (12)$$

$$W_{18-rein} = (TBR)(W_{18-unrein}) \quad (13)$$

where

- TBR = traffic benefit ratio
- N_R = load cycles to reach a given rut depth (reinforced)
- N_U = load cycles to reach the same rut depth (unreinforced)
- $W_{18-rein}$ = ESAL's for the reinforced case
- $W_{18-unrein}$ = ESAL's for the unreinforced case

Shukla (2002) suggests that TBR values are from 1.5 to 10 for geotextiles and 1.5 to 70 for geogrids. That said, the entire procedure is based on resilient modulus laboratory testing using a specific candidate geotextile or geogrid.

The *second option for reduced base course thickness* is based on a BCR-value defined as follows:

$$BCR = T_R / T_U \quad (14)$$

where

- BCR = base course reduction factor
- T_R = base course thickness for the reinforced case
- T_U = base course thickness for the unreinforced case

This value is then applied to the SN equation (but only on the base course layer), as shown below.

$$d_{base(R)} = \frac{SN_u - (a \times d)_{hma} - (a \times d \times m)_{subbase}}{BCR(a \times m)_{base}} \quad (15)$$

where

- $d_{base(R)}$ = reduced base course thickness due to the reinforcement
- SN_u = structural number corresponding to the unreinforced W_{18} value

There have been several field studies which have been focused on verification of the above procedure, particularly those of Abd El Halim, et al. (1983), Miura, et al. (1990) and Webster (1992). In general, BCR improvements are suggested to range from 20% to 40%, however, all assessments are specific to the reinforcement materials being considered and the resulting resilient modulus testing conditions.

4.4 The NCHRP Method

The NCHRP method is presently called the mechanistic-empirical (M-E) method and it attempts to incorporate geometry, all pavement materials (including the specific geosynthetic material), traffic climate and associated laboratory generated properties. Characterizing the candidate geosynthetic are its laboratory generated static and cyclic moduli. Different confidence levels can also be inferred in using the process which is diagrammatically shown in Figure 12.

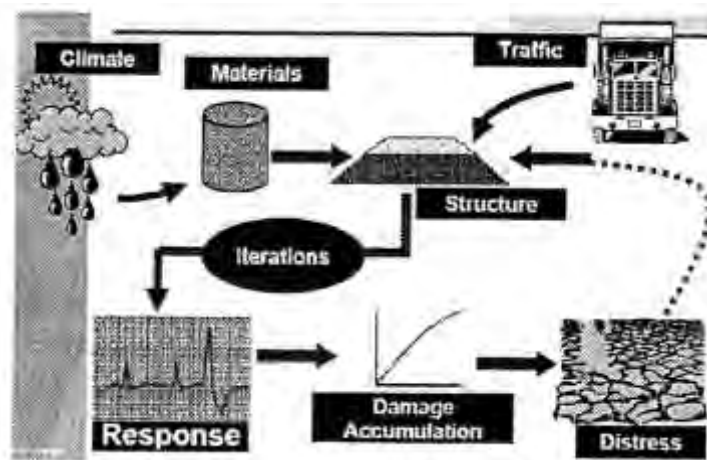

Figure 12. Flowchart for M-E Design (NCHRP 2004).

While some researchers feel that the M-E method is more appropriate than the AASHTO method (Al-Qadi, 2008), both rely heavily on measuring laboratory physical and mechanical properties. Even more importantly is the correlation of those laboratory evaluations to field performance which has been “spotty”, at least based on GSI’s unpublished field sites. In this regard it should be noted that small savings in aggregate thickness, as in paved roads, are very sensitive to laboratory test values. This is unlike the unpaved road aggregate savings situation which is less affected by changes in laboratory test values. The reader is referred to the NCHRP (2004) guide manual for details.

4.5 The Lateral Reinforcement Approach

As the name implies, the lateral reinforcement approach should be considered for assessing the pavement’s lifetime and service performance and also to assess the controlling mechanism involved. To the author, and others, longitudinal cracking of asphalt pavements is widespread in flat shoulder locations or those which are built-up fill areas; note the unsupported left side of Figure 4. Conversely, in areas which are in cut situations and have lateral restraint, as in the supported right side of Figure 4, such longitudinal cracks are at a minimum or altogether absent. Such observations strongly suggest to the author, and others, that the stone aggregate base course is laterally moving in a somewhat unrestricted manner in flat or unsupported fill shoulder situations. When the overlying bituminous pavement starts to lose its ductility (in as little as a few years), the movement of the original stone aggregate support results in such longitudinal pavement cracking as shown in Figure 13. It is shown in a more aggressive stage adjacent to a stream in Figure 14.

Figure 13. Longitudinal pavement cracking on unrestrained (left) pavement edge and none on curb retained (right) pavement edge.

Figure 14. Major longitudinal cracking causing traffic diversion.

Certainly, a properly aperture sized geogrid within the stone aggregate base course should prevent or minimize this occurrence. In addition to determining the tensile stress-strain properties of the geogrid (both static and dynamic), is the junction, or node, stiffness and/or strength. These concepts were first introduced by Kinney (1998) who showed the actual phenomenon by filming stone particle movement from a plexiglass bottomed box by a moving wheel load. In so doing the individual stone particles moved outward from the wheel load (as expected) and also moved slightly forward as well. The resulting elliptic spiral motion, which dissipated with distance from the wheel load, was greatly diminished by the inclusion of a geogrid.

Kinney then devised an in-plane torsional rotation test to quantify the geogrid's resistance to such applied torque values. The test is available as GRI-GG9 and is shown in plan and elevation as Figure 15. This concept of lateral reinforcement of the aggregate particles within the stone base course is considered by the author as being worthwhile to pursue (for firm soil subgrade situations) in the future.

Figure 15. Plan and elevation view of the test apparatus for in-plane torsional rigidity determination of bidirectional geogrid stiffness per Kinney (1998) and GRI-GG9 test method (2004).

5.0 GEOTEXTILES OR GEOGRIDS USED FOR WATERPROOFING OR REINFORCEMENT OF REFLECTIVE CRACKING OF ASPHALT OVERLAYS IN PAVED ROADS

The resurfacing of existing pavements that have excessive cracks in them represents an ongoing and expensive task for all federal, state, local, and private organizations that own and maintain roads. Such resurfacing is usually done with bituminous overlays ranging in thickness from 25 to 100 mm. Particularly exasperating to the road owners (and to the users and their automobiles as well) is when the cracks in the original pavement reflect up through the new overlay earlier than anticipated. To combat this, thicker overlays than desirable are used but at the cost of added expense, lower curb heights, and excessive weight and thickness on the subgrade system. Due in part to the magnitude of this problem and the potential market that it represents, the use of geosynthetics to remedy the situation has been attempted in a number of ways. In some instances strips of geotextile or geogrid have been placed over the cracks, spanning them by 150 to 600 mm on each side, and the overlay placed above. Polyester, polypropylene, and fiberglass geosynthetics have all been used in this regard. Alternatively, a major use has been with full-width geotextile sheets which have been waterproofed with asphalt cement or asphalt emulsion, over the entire pavement surface, and then overlaid with the final bituminous surfacing. In all cases, the goal is to either decrease the thickness of the overlay

while keeping a lifetime equivalent to not using a geosynthetic, or to increase the lifetime of the overlay while using the same thickness as without the use of the geosynthetic. It should be noted that this technique is used only for deteriorated existing bituminous pavements, not for cracked Portland-Cement concrete pavements. The significantly sharper edges of concrete would generally puncture and tear the geosynthetics used in this application.

That said, a clear-cut primary function is difficult to identify. It probably involves either the reinforcement from one side of the existing cracks to the other (via the geotextile's tensile strength), or moisture-proofing against water moving through the existing cracked pavement and into the subgrade via the impregnation of the geotextile with asphalt cement or asphalt emulsion. Since either function is possible; both design concepts will be described.

5.1 Full Lane Width Lightweight Geotextiles (or Geogrids) Using a Reinforced Based Design

The key to the reinforcement-based design of geotextiles and also geogrids in reflective crack prevention in bituminous pavement overlays is the effectiveness as determined by laboratory testing or by experience. Quantitatively, it is defined as follows:

$$FEF = \frac{N_r}{N_n} \quad (16)$$

where

- FEF = fabric effectiveness factor,
- N_r = number of load cycles to cause failure in the geotextile reinforced case, and
- N_n = number of load cycles to cause failure in the nonreinforced case.

Values of FEF vary widely when based on laboratory tests (as they usually are), the range being from 2.1 to 15.9; see Murray (1982). Upon having this value, however, design can be approached by a number of procedures. Majidzadeh, et al. (1982), use a mechanistic design procedure influenced by both rutting (distortion) and fatigue (cracking). Another approach, however, is merely to modify existing asphalt overlay design methods. In this regard the design traffic number (DTN), upon which overlay designs are based, can be modified as follows:

$$DTN_r = \frac{DTN_n}{FEF} \quad (17)$$

where

- DTN_r = design traffic number in the geotextile reinforced case,
- DTN_n = design traffic number in the nonreinforced case, and
- FEF = fabric effectiveness factor.

Using the Asphalt Institute's overlay design procedure (1977) the specifics are as follows:

1. Determine the soil subgrade strength value as represented by its CBR value.
2. Determine the initial traffic number (ITN). This is a combination of each vehicle's weight and respective number of load repetitions based on traffic counting.

3. Determine the adjustment factor for the desired design period and estimate traffic annual growth rate.
4. Multiply the ITN by the adjustment factor to obtain the design traffic number DTN for use in the thickness design chart.
5. Use Figure 16 (or equivalent) to determine the full-depth asphalt-to-pavement thickness, t_{An} , needed for the design subgrade strength value, the DTN , and the selected design period.
6. Determine the effective thickness, t_e , of the existing pavement.
7. The thickness of asphalt concrete overlay required, then, is equal to $t_{An} - t_e$.
8. This process is repeated for the geosynthetic-reinforced case using Eq. 17, which results in a thickness t_{Ar} .
9. The resulting two thicknesses (nonreinforced and geosynthetic-reinforced) are then compared ($t_{An} - t_{Ar}$) to note the savings in asphalt overlay thickness since the base thickness is the same in both cases. See Koerner (2012) for a numeric example using this method.

Figure 16. Thickness requirements for asphalt pavement structures using unsoaked subgrade soil CBR, after Asphalt Institute (1977). Arrows indicate a typical design wherein approximately 30 mm of overlay is saved using the reinforcing geosynthetic.

5.2 Full Lane Width Lightweight Geotextiles Using a Waterproofing Based Design

Again using the Asphalt Institute's techniques (1977), one can develop an alternate design procedure for geotextiles (this procedure only applies to geotextiles) used in asphalt overlay situations; this time using an approach based on a waterproofing hypothesis. This concept should not come as a surprise since adequate subgrade drainage of pavements has long been suspected as being the key factor for extending conventional pavement lifetimes. Cedegren (1989), clearly illustrates this type of improved pavement lifetime. The particular procedure to be used, adopted from Bell (1983-85), utilizes field-measured rebound deflections of the existing pavement system along with the design guide of Figure 17. The individual steps in the design are as follows:

Figure 17. Asphalt overlay thickness required to reduce pavement deflection from a measured to a design deflection value (a rebound test), after Asphalt Institute (1977). Arrows indicate a typical design wherein 30 mm of overlay is saved using the waterproofing geotextile.

1. Determine the representative rebound deflection.
2. Determine the initial traffic numbers (*ITN*). It is a combination of each vehicle's weight and respective number of load rejections based on traffic counting.
3. Determine the initial traffic number adjustment factor for the desired design period.
4. Multiply the *ITN* by the *ITN* adjustment factor to obtain the *DTN* for use in the overlay thickness chart.
5. Enter the overlay thickness chart at the representative rebound deflection and move down vertically to the curve representing the *DTN* (interpolate if necessary). Move horizontally to the overlay thickness scale and read the thickness of overlay required.

6. For the case of a geotextile included in the pavement cross-section and of it being suitably waterproofed, one can appropriately modify the representative rebound deflection (RRD) equation as follows:

$$RRD = (\bar{X} + 2s)fc \quad (18)$$

where

- \bar{X} = arithmetic mean of measured Benkelman beam deflection values,
- s = standard deviation,
- f = temperature adjustment, and
- c = critical period adjustment factor, which is largely influenced by moisture in the subgrade system.

7. The design process is then repeated as with the non-geotextile case, and the resulting two thicknesses are compared to note the savings in asphalt overlay using the geotextile. In this case it is again 30 mm (as with the reinforcement assumption). See Koerner (2012) for a numeric example using this method.

5.3 Commentary on Previous Two Subsections

This topic of crack reflection prevention in bituminous pavement overlays illustrates the dilemma of assessing the primary function that the geosynthetic serves. Using two completely different hypotheses (one based on reinforcement and the other based on waterproofing), two completely different designs can be developed. It simply begs the question of where the truth actually lies. For geotextiles it could be either, for geogrids it is reinforcement. For geotextiles, it might be a combination of the two phenomena working together! In general, however, it is felt that field reports are definitely on the positive side. Based on geotextile experiences to date, the following recommendations are offered:

- For those states that are using proprietary or competition-limiting specifications for geotextiles, the adaptation of Texas DOT specifications for use is encouraged.
- Prior to placement of a geotextile overlay system, the condition of the existing roadway should be documented. When an unstable roadway is suspected, deflection tests are recommended. While limiting deflection values have yet to be established for geotextile systems, it is important that data be obtained that could assist in their eventual evaluation.
- Since all geotextiles presently being marketed are not equivalent in physical properties, agencies should conduct the tests identified in the Texas DOT specification, including the asphalt retention test, so as to develop documentation that may be useful later in assessing relative geotextile performance.
- Rather than placing the geotextile on the cracked existing pavement, construct an asphalt leveling course first so as to provide a relatively unblemished surface for applying the tack coat and the geotextile. This will assure more complete and uniform impregnation of the geotextile by the tack coat and will also assist in determining the type of tack coat to be used and the proper application rate.

- For pavement rehabilitation projects that include pavement widening with new asphaltic concrete overlays, geotextiles placed longitudinally over the shoulder-pavement and/or widening joint should be considered. The Maine DOT (1994) has had success in this regard. Both longitudinal and transverse joints were retarded significantly when using a high strength geotextile directly spanning the cracks in question.
- Over jointed Portland-cement concrete pavements, no evidence has been provided to support placing a geotextile system across the full roadway width in a continuous mat. Instead, the use of heavy-duty geotextile materials in strips over transverse and pavement edge joints and cracks is presently recommended. A summary report by the U.S. Army Corps of Engineers (Alhrich, 1986) on this particular application of geotextiles has arrived at similar conclusions.

5.4 Use of High Strength Geotextiles or Geogrids Spanning Transverse and Longitudinal Pavement Cracks

The use of high strength geosynthetics to retard and minimize reflective cracking within old pavements from propagating through newly placed asphalt overlays is a related topic of great interest. Results of laboratory testing by Molenaar and Nods (1996) suggest the use of a power law to calculate the rate of crack propagation through the new overlay thickness:

$$\frac{dc}{dN} = AK^n \quad (19)$$

$\frac{dc}{dN}$ = crack propagation rate per number of load cycles,
 K = stress intensity factor, and
 A, n = experimentally obtained constants.

The following numeric example illustrates how Eq. 19 can be used in the prediction of overlay lifetime without, and then with, different types of geogrids and a geotextile.

Example: A 100 mm asphalt overlay is to be placed on top of a severely cracked pavement having a firm base. The DTN for the pavement is 100,000 load repetitions (cycles) per year. The combined overlay, existing asphalt layer and base profile, yields a design stress intensity factor (K) of 10 N/mm^{1.5} and constants A of 1.0×10^{-8} and n of 4.3. **(a)** Calculate the average rate of crack growth of the new asphalt overlay. At a full-propagation failure assumption, what is the lifetime (in terms of number of cycles and years) of the new asphalt overlay without reinforcement? **(b)** Redo the problem using the inclusion of various geosynthetic reinforcement materials with A values as follows:

nonwoven geotextile: $A_{GT} = 0.50$ ($A_{\text{non-reinf.}}$)—author estimate
polypropylene geogrid: $A_{PP} = 0.35$ ($A_{\text{non-reinf.}}$)—author estimate
polyester geogrid: $A_{PET} = 0.33$ ($A_{\text{non-reinf.}}$)—Molenaar and Nods (1996)
fiber glass geogrid: $A_{FG} = 0.25$ ($A_{\text{non-reinf.}}$)—author estimate

Solution: (a) Using the power law of Eq. (19), the crack propagation rate is calculated, from which the number of cycles and lifetime are obtained. The crack-propagation rate for the nonreinforced case is:

$$\begin{aligned} \frac{dc}{dN} &= AK^n \\ &= 1 \times 10^{-8} \times (10)^{4.3} \\ &= 0.0002 \text{ mm/cycle} \end{aligned}$$

from which the number of load cycles (non reinforced) is:

$$\begin{aligned} N &= \frac{T}{(dc/dN)} \\ &= \frac{100}{0.002} \\ &= 500,000 \text{ cycles or 5 years} \end{aligned}$$

(b) Using the various modified *A*-values for different types of geosynthetic reinforcement gives rise to the table below.

Reinforcement	Crack Growth Rate (mm/cycle)	Lifetime (cycles/years)
None	2.0×10^{-4}	500,000/5
Geotextile	1.0×10^{-4}	1,000,000/10
PP geogrid	0.7×10^{-4}	1,400,000/14
PET geogrid	6.6×10^{-5}	1,500,000/15
FG geogrid	5.0×10^{-5}	2,000,000/20

The technique is very intriguing and warrants additional research in this important roadway engineering application.

6.0 SUMMARY AND RECOMMENDATIONS

This retrospective paper on geotextiles and geogrids used in roadway applications has attempted to cover in as concise a manner as possible, the different geosynthetic functions applicable to typical roadway cross-sections. The main reason being that the overall status of roadway deterioration is so enormous and yet vastly undercapitalized upon from a geosynthetics perspective. The situation seems to be at a point where the relatively short lifetimes of pavement systems are unfortunately expected to be the norm. In the author's opinion, geotextiles and geogrids hold the key to longer pavement lifetimes as well as better serviceability of the roadway system itself. This is not meant to criticize the asphalt, concrete, or stone base courses being used, however, it is meant to criticize the nonuse of geosynthetic materials. Of course, the cost of the pavement system will somewhat increase, but the tradeoff of longer lifetimes and/or less stone base or asphalt surfacing will usually result in a net benefit/cost increase. Furthermore,

and in terms of sustainability, a large net saving of many tons of CO₂ per highway project will be realized, see Miner and Davis (2011) in this regard.

The paper is presented in four very discrete and independent sections while recognizing that interactions are present in some cases. This method of presentation is done in order to focus on specific design methodologies and field performances whenever available. The four different independent sections are summarized as follows; recall Figure 4:

In Section 2.0, geotextiles and/or geogrids are used for reinforcement when placed on soft soil subgrades of unpaved roads where the focus is on stone base aggregate saved by inclusion of the geosynthetic material.

It is felt that this topic has the best formulated analytic procedure of all that are treated in this paper. The Giroud-Noiray (1981) development is analytically viable using basic geotechnical engineering principles. The result is a design nomograph which can be readily used to determine the amount of stone base necessary without a geosynthetic and then with a geosynthetic. The difference is, of course, the thickness of stone base saved.

Important in using this procedure is that the specific geosynthetic to be used (geotextile or geogird) is represented by its elastic modulus obtained from a standardized wide-width tensile test resulting in a stress vs. strain, or load vs. elongation, test. Its applicability to all geotextiles and geogrids is an important feature.

Giroud-Han (2004, 2012) have revised this method to include improvements in the analytic equations resulting directly in the required stone base thicknesses. They also changed the test method for characterization of the geosynthetic being used. Now the recommended test method is an in-plane torsional rotation test and even further the available data is only valid for two specific types of manufactured biaxial geogrid. This particular test does not appear to the author to simulate the actual field behavior or the downward pyramidal force diagram upon which the method is based. Of course, the required modulus could be taken from a more representative test method. In this regard the author favors a large scale axisymmetric pressure test which is available and is currently being standardized.

In Section 3.0, geotextiles are placed directly on soil subgrades for the purpose of long-term separation of it and the overlying stone base course thus providing better rideability of the surface in both paved and unpaved roads.

Conceptually, stone base particles punching down into the subgrade soil and the subgrade soil migrating upward into the stone base is easy to visualize. The softer the subgrade soil, the more aggressive is the phenomenon. Both reduced stone base thickness and its loss of drainage capability are expected and often seen after excavation. Yet, to analytically formulate the situation remains for the future. It is indeed worthwhile since the low cost geotextile being used need only to replace about 25 mm of stone base to justify itself.

In Section 4.0, reinforcement geogrids are placed within the stone base aggregate of paved and unpaved roads on firm subgrade soils to either result in increased traffic or to

prevent the stone base aggregate from lateral movement thus preserving serviceability for longer lifetime.

There are numerous design methods that have been developed for this particular application. They are generally (not always) based on the increased number of equivalent single axle loads (ESAL's) that the reinforced stone base will provide over the nonreinforced stone base. Included are the CBR Cover Design Method, the AASHTO Method (1993), the NCHRP Method (2004), the M-E method (2004) and other related research efforts of which there are many.

For major highways with thick stone base courses, and even with subbase courses, the geogrid's inclusion can produce increased traffic repetitions or even save on stone base thickness. However, for the much more common roadways with only 100 to 200 mm of stone base overlain with 50 mm of asphalt, further reductions in stone base thicknesses are not likely in the author's opinion. Indeed, more traffic load repetitions are a worthwhile goal but to justify the increased cost of the geogrid reinforcement for this purpose is a difficult "sell" to many transportation engineers.

On the other hand, an analytic procedure for the *lateral reinforcement mechanism* has not been developed. Yet, there is ample field evidence that longitudinal cracking of asphalt paved roads is commonplace. Kinney, et al. (1998) have shown the behavior in laboratory demonstrations and in so doing developed the in-plane torsional rigidity test which is an excellent simulation. Needed are design methodologies indicating how a geogrid within the stone base restrains its lateral movement and subsequent distortion and cracking of the overlying asphalt pavement. Then the elastic modulus from the in-plane torsional rigidity test can be appropriately used.

In Section 5.0, geotextiles or geogrids used for waterproofing or reinforcement are placed on deteriorated asphalt roadway surfaces as a interlayer for subsequent asphalt resurfacing so as to provide lower cost or longer lifetime.

Whether the proper mechanism of reinforcement or waterproofing is more correct is uncertain, however, for this application both have a design methodology available for use. There are also many reports of field performance with excellent results in moderate and warm climates. There are, however, reported issues in cold climates. Many moderate and warm climate states use the application of full-width light weight geotextiles on a routine basis. It is indeed a worthwhile and mature application.

That said, other techniques of using high strength geotextiles or geogrids over transverse and longitudinal cracks as well as full width geogrids are still in the analytic development stage. Of course, at a higher unit cost than lightweight geotextiles the need for deterministic performance becomes more necessary.

In conclusion and in order to capture the author's thoughts and recommendations for these four geotextile and geogrid roadway applications, Table 4 is offered.

Table 4 – Status and Recommendations of Geosynthetic Use in Roadway Application

GS Location (see Figure 4)	GS Type	Function	Analytic Design Status	Field Verification Status	Owner Acceptability
Beneath Stone Base	GT or GG	Reinforcement	Excellent	Excellent	Excellent
Beneath Stone Base	GT	Separation	Poor	Good	Nominal
Within Stone Base • vertical stresses • horizontal stresses	GG GG	Reinforcement Reinforcement	Good Poor	Poor Good	Reasonable
Above Existing Pavement Surface	GT GG	Waterproofing Reinforcement	Good Emerging	Reasonable Good	Good

where GS = geosynthetic, GT = geotextile and GG = geogrid

Readily seen is that both analytic design and field verification need improvement before geotextile and geogrid use in roadway applications become standardized and fully accepted by the transportation community. An integrated analytic design **and** field performance verification is necessary for certain aspects of all four of the categories shown in Table 4. Only then can economic justification be relied upon which leads to confident acceptance. Since geotextile and geogrid potential is so great in pavement applications, such an integrated approach seems necessary and will, in due course, be implemented.

THE EVOLUTION OF GEOSYNTHETICS IN EROSION AND SEDIMENT CONTROL

C. Joel Sprague
TRI/Environmental, Inc., Greenville, SC

ABSTRACT

Much of the development of geosynthetics technology in environmental applications has been in response to government regulations. This is certainly true for geosynthetics used in erosion and sediment control. Geosynthetics continue to replace traditional materials such as soil and stone in performing important engineering functions in erosion and sediment control applications while simultaneously introducing greater versatility and cost-effectiveness. Geosynthetics are widely used as a “carrier” for degradable materials to the enhancement of vegetative establishment; as nondegradable materials to extend the erosion control limits of vegetation or soil; as primary slope or channel linings; as components in silt fences and turbidity curtains; and as a component in an ever growing array of sediment retention devices.

Along with the introduction of geosynthetics into this wide range of applications has come the need for industry-wide initiatives to promote their correct use and new test methods to characterize them. All of which, are a “work in progress”.

THE NEED FOR EROSION AND SEDIMENT CONTROLS

Much of the development of geosynthetics technology related to erosion and sediment control applications has been in response to government regulations. A progression of regulatory actions has brought a national focus on erosion and sediment control, including:

- Amendments to the Federal Water Pollution Control Act (1985) - eliminating discharge of any pollutant to navigable waters.
- The Clean Water Act (1987) - requiring National Pollution Discharge Elimination System (NPDES) Permits for large construction sites. More recently, NPDES regulation of construction activities on one or more disturbed acres of land became effective on February 16, 2012 . . . though numeric turbidity limits have been stayed!
- Intermodal Surface Transportation Efficiency Act (1991) - requiring erosion control guidelines for all federal-aid construction projects. This led to AASHTO’s “Erosion and Sediment Control in Highway Construction,” in Volume III, Highway Drainage Guidelines (1992). This has subsequently been made a regulatory document.
- Coastal Zone Act Reauthorization Amendments (1990) - requiring measures to control non-point sources of pollution in coastal areas.

The centerpiece of regulatory action has been the NPDES permitting process, which is required for construction activities. An NPDES permit requires a Storm Water Pollution Prevention Plan (SWPPP) that must include both the technical basis used to select the pollution control practices (a.k.a., best management practices or BMPs) to avoid increasing the historical amount of sediment in water and the maintenance of each sediment and erosion control measure.

Why Geosynthetics?

Geosynthetics have proven to be among the most versatile and cost-effective ground improvement materials. Their use provides the following advantages over traditional materials:

- *Lighter, Easier to Handle, More Durable* - Geosynthetics are comprised of plastic.
- *Verifiable Material Quality Control* - Geosynthetics are manufactured in controlled environments under standard operating conditions.
- *Easier Construction Quality Control* - Often the installation procedure for geosynthetics is as simple as rolling out and securing in place as opposed to concrete or rock being constructed in place and subject to variations caused by weather, handling and placement.
- *Real Cost Savings* - Geosynthetics are typically less costly to purchase, transport and install than are aggregates or subcontractor-dependent systems.
- *Technical Superiority* - Geosynthetics are engineered materials optimized for performance.
- *Easier Construction* - Geosynthetics can be installed quickly, providing the flexibility to construct during short construction seasons, breaks in inclement weather, or without the need to demobilize and remobilize the earthwork contractor.
- *Material Availability* - Numerous geosynthetic suppliers and ease of shipping insure competitive pricing and availability of materials.
- *Enhanced Sustainability* - Studies have shown significantly lower CO₂ generation than with natural soil or rock.

What do Geosynthetics do in Erosion and Sediment Control Applications?

Geosynthetics replace traditional materials such as soil and stone in performing important engineering functions, and thus can be selected via a “design-by-function” methodology as prescribed by Koerner (2012). While traditional applications of geosynthetics perform more common in-ground functions such as separation and filtration, geosynthetics used in erosion and sediment controls are used on the soil surface. As such, they introduce the following unique functions according to ASTM D5819:

- *Containment* - A geosynthetic provides containment when it encapsulates or surrounds materials such as sand, rock, and fresh concrete.
- *Dynamic Filtration* . . . A geosynthetic performs the dynamic filtration function when the equilibrium geotextile-to-soil system allows for adequate liquid flow with limited soil loss across the plane of the geotextile over a service lifetime compatible with dynamic flows.
- *Screening* . . . A geosynthetic, placed across the path of a flowing fluid (ground water, surface water, wind) carrying particles in suspension, provides screening when it retains some or all soil fine particles while allowing the fluid to pass through. After some period of time, particles accumulate against the screen, which requires that the screen be able to withstand pressures generated by the accumulated particles and the increasing pressure from accumulated fluid.
- *Surface Stabilization* . . . A geosynthetic, placed on a soil surface, provides surface stabilization when it restricts movement and prevents dispersion of surface soil particles subjected to erosion actions (rain, wind), often while allowing or promoting vegetative growth.

- *Vegetative Reinforcement* . . . A geosynthetic provides vegetative reinforcement when it extends the erosion control limits and performance of vegetation.

EROSION AND SEDIMENT CONTROL MATERIALS

Geosynthetics, as well as natural materials, are used extensively in erosion and sediment control systems such as:

- Temporary, degradable materials for the enhancement of vegetative establishment;
- Long-term, nondegradable materials to extend the erosion control limits of vegetation or soil;
- Primary slope or channel linings;
- Silt fences and turbidity curtains;
- Components in sediment retention devices.

A large construction site may have several different erosion and sediment control materials depending on location (i.e., slopes vs. channels), flow conditions (i.e., sheet vs. concentrated), and regulatory requirements.

Erosion Control Systems

There are two categories of erosion control systems: The first is termed temporary or degradable and the second is termed long-term or nondegradable. There are numerous types of materials within these categories according to Zoghi, et al, (2000). Temporary degradable systems include conventional loose mulches, as well as, hydraulic mulch geofibers (HMG), erosion control netting (ECN), open weave meshes (ECM), erosion control blankets (ECB), and fiber roving systems (FRS). The long-term systems include conventional sod and riprap, as well as, turf reinforcement mats (TRM), fabric formed revetments (FFR), geocellular confinement systems (GCS), gabions (G), and articulating concrete blocks (ACB). ECNs, ECMs, ECBs, and TRMs commonly contain geosynthetic components and are classified as rolled erosion control products, or RECPs. Other geosynthetic systems include FFRs and GCSs.

The advantages and disadvantages of the various systems are detailed in Tables 1 and 2. The relative performance of permanent systems is presented in Table 3, and the relative installed costs of the various erosion control systems is presented in Table 4. Following are brief descriptions of each system.

Hydraulic Mulch Geofibers (HGM) – Hydraulic mulch is commonly used as an alternative to loose straw mulch. It consists of short organic fibers, such as paper, straw, wood, coconut, or cotton, mixed with water in a tank (usually with seed) and sprayed over the bare soil. As it dries it forms a thin mulch layer, yet it is still susceptible to the wash and wind-blown problems associated with loose fiber mulches. A more stable matrix can be created by incorporating a tackifier or adhesive in the mixture that, after drying, is stable when re-wetted by rainfall.

Erosion Control Netting (ECN) – Erosion control netting is typically polyolefin biaxially-oriented process (BOP) mesh. ECNs are used for anchoring loose fiber mulches. They are rolled out over the seeded and mulched area and stapled or staked in place.

Open Weave Meshes (ECM) – Open weave meshes are woven of organic “twines” of jute or coir or polyolefin yarns. Organic ECMs typically are 0.25 to 0.50 in. thick and have 1 inch or larger square uniform openings. Polyolefin meshes are considerably thinner with smaller openings. All meshes are very flexible, promoting intimate ground cover, though they do not provide full ground coverage. Organic meshes also absorb water, which can help maintain soil moisture.

Figure 1 – ECM Applied Over Straw

Figure 2 – ECM on Hillside

Erosion Control Blankets (ECB) – Erosion control blankets are organic fiber filled “blankets” consisting of straw, wood (excelsior), or coconut fibers sewn to or between synthetic (or organic) nettings. ECBs provide a thick (up to 0.5 in.) full coverage of mulch which better absorbs rainfall impact and retains moisture. The nettings add strength to help ECBs resist erosive forces. Their useful life is limited to durability of the organic fibers.

Figure 3 – ECBs Come in Many Varieties

Figure 4 – ECB (left) vs. HMG (right)

Fiber Roving Systems (FRS) – Fiber roving systems use fibrillated, or split, yarns that are fed off spools and continuously fed from the spools through a special air gun and uniformly applied over a seeded soil surface. A randomly laid mat of continuous strands results and provides a high percentage of ground cover. A tackifier is then sprayed on top of the FRS to firmly anchor it to the soil. FRS can conform to almost any geometry.

Turf Reinforcement Mats (TRM) – TRMs are thick mattings composed of fused or stitched polymer nettings (often filled with polymeric fibers), randomly laid monofilaments, or yarns woven or tufted into an open, dimensionally stable mat. The dimensional stability produces a somewhat stiffer, but much stronger mat. These flexible, synthetic mats are designed to be used in conjunction with topsoil and seed or turf to create strong, durable and continuous soil-root-mat matrices which can provide more than twice the erosion protection of plain grass alone.

Figure 5 – TRMs are Polymer Structures

Figure 6 – TRMs are Used in Channels

Fabric Formed Revetments (FFR) – Fabric formed revetments take advantage of low-cost, durable, synthetic fabrics to produce three-dimensional forms for casting concrete slabs. By pumping a very fluid fine-aggregate grout into a fabric envelope consisting of two layers connected by tie-chords or by interweaving at points, a concrete mattress can be constructed in minutes. FFRs provide the durability of rigid linings, such as cast-in-place concrete or asphaltic concrete, and the flexibility and permeability of riprap or gabion systems.

Geocellular Confinement Systems (GCS) – Geocellular confinement systems, often called geocells, are made of strips of polymer sheet or geotextile connected at staggered points so that, when the strips are pulled apart, a large honey-comb mat is formed that can be filled with soil, rock or concrete. Geocell thickness (depth) typically ranges from 2 in. to 12 in. A GCS is effective at assuring that surface soil is retained on a slope.

Figure 7 – FFR Installed in Wave Zone

Figure 8 – GCS “Honeycomb” Structure

Gabions (G) – Gabions are compartmented rectangular containers made of galvanized steel hexagonal wire mesh and filled with hand-sized stone. In highly corrosive conditions a polyvinyl chloride coating is used over the galvanized wire. Gabions are more flexible, durable and permeable than rigid structures and more stable than loose rock.

Articulating Concrete Blocks (ACB) – Articulating concrete block (ACB) revetments are interlocking cellular concrete blocks, with varying amounts of open area within or between blocks, underlain by a filtration geotextile. The blocks can be assembled into mats either at the factory or on site with or without cables running through them. The blocks are held on the slope by anchors placed at the top of the slope and/or friction between the slope and the blocks. ACB revetments provide the porosity, flexibility, vegetation encouragement, habitat enhancement, and ease of installation of rolled RECPs and the nonerodibility, self-weight, and high shear resistance of rigid linings.

Table 1 – Some Potential Advantages and Disadvantages of Temporary, Degradable Erosion Control Systems

SYSTEM	POTENTIAL ADVANTAGES	POTENTIAL DISADVANTAGES
Loose Mulches	Lowest cost Well accepted High installation rate Moderate sediment yield Moderate vegetative density	Very temporary (< few weeks/months) No concentrated flows Dusty Requires anchoring (crimping, tackifier) May require noxious weed certification
Hydraulic Mulch Geofibers (HMG)	Low cost Well accepted High installation rate Moderate sediment yield Moderate vegetative density	Very temporary (< few weeks/months) Very low or no concentrated flows
Erosion Control Netting (ECN)*	More effective than tackifier (if properly anchored)	Temporary (1-2 yrs.) More costly than tackifier Netting may interfere w/ maintenance (if inadequately anchored)
Open Weave Meshes (ECM)*	Low to moderate cost Moderate sediment yields Moderate vegetative density Moderate moisture absorption	Temporary (1-2 yrs.) Low flows only Not complete ground cover Moderate moisture absorption
Erosion Control Blankets (ECB)*	Low to moderate cost Easy to install Good moisture absorption Very low sediment yield Very good vegetative density	Temporary (1-3 yrs.) Low to moderate flows Netting may interfere with maintenance (if improperly manufactured or inadequately anchored)
Fiber Roving Systems (FRS)*	Low to moderate cost High subgrade conformance Very low sediment yield Very good vegetative density	Temporary (1-2 yrs.) Low to moderate flows only Special equipment required

**Commonly composed partially or completely of geosynthetics.*

Table 2 – Some Potential Advantages and Disadvantages of Long-term, Nondegradable Erosion Control Systems

SYSTEM	POTENTIAL ADVANTAGES	POTENTIAL DISADVANTAGES
Sod	Immediate vegetation and its associated benefits	May need irrigation Risk of dying before establishment High costs Limited to turf grasses
Turf Reinforcement Mats (TRM)*	Moderate costs Long-term (indefinite) Moderate to high flows Encourages infiltration Mod. to high vegetative density Extends the limits of vegetation Flexible over differential settlement	Low to moderate sediment yields during unvegetated stage Requires vegetative establishment for effective long-term performance
Riprap	Long-term (maintenance req'd) Moderate to high flows Encourages infiltration Low to moderate sediment yield (when underlain by a geotextile)	Moderate to high cost Possible negative aesthetic/safety impact Difficult to install on steep slopes Low vegetative density Often unstable, especially w/o geotextile
Other Hard Armor Systems**	Long-term (indefinite) Moderate to very high flows Low to moderate waves Low to moderate sediment yields Range of fill materials Durable and low maintenance	High to very high costs None to delayed vegetation establishment None to low vegetation density May prevent infiltration Special deployment/equipment req'ts

**Commonly composed partially or completely of geosynthetics; **Including: Fabric Formed Revetments, Geocellular Confinement Systems, Gabions, Articulating Concrete Blocks*

Table 3 - Typical Erosion Control System Performance Limits

BMP	Limiting Shear (psf)
Mechanically or Hydraulically Applied Seeding	< 0.5
Mechanically or Hydraulically Applied Mulching	< 0.5
Meshes and Nets	0.5-1.5
E.C. Blankets	1.5-3.0
Fiber Roving	1.0-2.0
Natural Vegetation	up to 2.0
Sod	0.4-3.7
Turf Reinforcement	2.0-11.0
Geocellular Confinement	10
Fabric Formed Revetments	2.2-24
Riprap (6" to 18" thick)	2.5-5.0
Gabions (6" to 18" deep)	35
Interlocking Block Mats	4.4-25

Geosynthetics in bold. Conversions: ft/s = m/s x 3.28; psf x 47.88 = Pa

Table 4 - Costs of Erosion Control Systems

Erosion Control System*	Approx. Cost per Square Yard – Installed***
Dry-Blown and Hydraulic Mulching	\$0.50 - \$1.00
Meshes and Nets	\$0.50 - \$1.00
E.C. Blankets	\$1.00 - \$1.50
Fiber Roving	\$1.50 - \$3.00
Sod	\$2.00 - \$3.00
Turf Reinforcement	\$4.00 - \$7.00
Hard Systems**	\$15.00 - \$60.00

Geosynthetics in bold. * Excludes subgrade preparation, soil amendments and seeding operations.

** Includes Geocellular Confinement, Fabric Formed Revetments, Riprap, Gabions, Interlocking Block Mats.

*** Cost is very sensitive to freight and labor rates.

Sediment Control Systems

In general, the benefits of geosynthetic sediment control systems over traditional structures, such as rock checks and sediment traps, include: minimal labor required to install; low cost; highly efficient in removing sediment; very durable and sometimes reusable. The performance of sediment control systems typically depends on the proper selection and deployment of sediment retention devices (SRDs). SRDs, such as silt fences, typically cause the following to happen:

- The SRD initially screens silt and sand particles from runoff.
- A soil filter is formed adjacent to the upstream face and reduces the ability of water to flow through the fence.
- This leads to upstream ponding, which serves as a “stilling” basin to collect suspended soils from runoff water.

To perform satisfactorily as an SRD, the geotextile component must have properly sized openings, which initiate the formation of a soil filter. Also the strength and storage capacity of the SRD must be adequate to contain the volume of water and sediment anticipated during a major storm. Hydraulic loading during a storm event is commonly the primary loading considered.

Other SRDs include turbidity curtains and fiber rolls. Turbidity curtains are reusable floating panels of geotextile or geomembrane that prevent water-polluting sediment from shore-side construction or off-shore filling and dredging operations from moving off-site. The top edge of each curtain contains floats and weights are attached to the lower edge of the curtain to keep it vertical in the water. Fiber rolls are three-dimensional rolls of organic fibers contained within a tubular netting or geotextile structure. They are commonly used as ditch checks or slope interrupters.

Emerging Erosion and Sediment Control Technologies

Biotechnology – Probably the hottest topic in erosion control today is “biotechnology”, or the maximum use of vegetation. This technology appeals to environmentalists and engineers, alike, because it looks good and brings the many benefits of vegetation to bear on the problems of erosion and water quality. This is also why geosynthetic-containing RECPs are steadily gaining in popularity. RECPs nurture and support vegetation that, by itself, is often fragile, costly and labor-intensive to construct.

Geotextile Tubes and Containers – Very large geotextile containers filled with dredged material have re-gained popularity in the past decade because of their simple placement and construction, cost effectiveness and minimum impact on the environment. These containers are hydraulically or mechanically filled with a variety of dredged material types, including fine-grained materials. Containment of dredged material in geotextile tubes, bags or other large containers, filled in place or filled in large bottom dump hopper barges and dumped below water has helped solve several difficult construction problems. Dike construction using long, sometimes continuous, tubes in wetlands, subdivision and perimeter dikes in dredged material disposal areas, under

water stability berms, containment of contaminated materials, island construction, barrier island breach repair and structural scour protection are examples of projects that could not have been completed without use of geotextile containment systems.

Figure 13 – Biotechnology for Shoreline

Figure 14 – Geotextile Tube / Groin

Anchored Geotextiles and Geonets – An anchored geonet presents a good example of an emerging development in biotechnical stabilization, specifically for stabilization of sandy slopes and coastal landforms. The anchored geotextile or geonet is made of a fabric or net which is stretched over and pulled down tightly on the ground surface and is secured in place by means of anchors inserted through and fastened to the geotextile.

3D Cement/Fabric Composites – Unique 3-dimensional cement/fabric composites are replacing traditional concrete in some erosion control applications. Cement mix is trapped within a flexible 3D fabric structure. There may be a waterproof layer on one side. The composite can be hung vertically, laid in trenches, or cut and formed into shapes to create a durable layer of concrete, all without the need for molds or mixers. It can be installed in the rain and other wet conditions. The fabric is wetted to activate the cement, and within 24 hours, the product has cured to 80% strength. The fabric structure reinforces the concrete and reduces cracking, while using up to 95% less concrete than conventional methods.

Figure 16 – 3D Cement/Fabric Composite

INDUSTRY EFFORTS

The first attempts to promote the erosion and sediment control industry were by the International Erosion Control Association (IECA) in the 1980s. The IECA even set up a committee (Committee C) to look into test methods to characterize the ever expanding products being introduced. Within a few years, the IECA determined that because of liability issues surrounding the setting up of standards, the standardization effort was better undertaken by ASTM. As a result, members of Committee C became some of the strongest initiators of efforts to energize and formalize meetings of manufacturers to develop, draft, and standardize test methods. These efforts fueled two industry-wide initiatives:

- The Erosion Control Technology Council (ECTC), an industry group driven by manufacturers, and
- ASTM D18.25 and D35.05, Subcommittees on Erosion and Sediment Control, where other interest groups (i.e. engineers, regulators, researchers) where other industry partners could contribute to the standardization effort.

In 1994, the Erosion Control Technology Council (ECTC), an organization of rolled erosion control product (RECP), hydraulically applied erosion control product (HECP), and sediment retention fiber roll (SRFR) manufacturers commissioned a program to identify and establish a common terminology and to develop standardized index and performance tests for the characterization of erosion control and sediment retention products containing natural materials. In January 1997, a manual of common terminology and recommended index testing standards (*ECTC Technical Guidance Manual: TASC 00197*) was issued to the industry. Then, in the late 1990s, ECTC once again commissioned a new class of test – this time it was bench-scale performance tests – that focused on testing an erosion control product along with a default soil system under carefully controlled “standard” conditions. The project included the development of bench-scale (i.e. small-scale) laboratory tests for slope erosion, channel erosion, vegetation enhancement, and biodegradability.

Subsequent to each of these development efforts, there have been coordinated efforts to work through the ASTM International to achieve consensus standardization of both erosion control and sediment retention test procedures. This work continues within ASTM Subcommittee D18.25, “Erosion and Sediment Control Technology” and Committee D35, “Geosynthetics.” Over the past decade, ASTM has released several new standard test methods for turf reinforcement mats (TRMs) and erosion control blankets (ECBs) that have been eagerly adopted. New standard test methods for Sediment Retention Devices have also been released, though their adoption has been slower.

Though both ECTC and ASTM began their erosion control efforts with a primary focus on RECPs, the ASTM effort quickly evolved to include biotechnology, various hard armor systems, and sediment retention devices. The ECTC remained focused on RECPs until around 2006 when it, too, began addressing HECPs and then, more recently sediment retention fiber rolls (SRFRs).

ASTM has struggled to make significant progress in standardizing HECP test methods, though the effort continues. It appears proprietary interests make consensus building difficult.

Finally, it should be noted that the IECA has just in the last year re-initiated its effort to pursue erosion and sediment control standards. It has formed that Standards and Practices (S&P) Committee, including subcommittees focusing on terminology, sediment control testing, sediment control design, and turbidity testing. The IECA S&P Committee plans to funnel it's efforts into ASTM for eventual consensus standardization.

QUALITY CONTROL, QUALITY ASSURANCE AND PERFORMANCE TESTING

As noted in the previous section, the industry recognized early on that with so many new types of erosion control products (many incorporating geosynthetics), and their associated new applications, has come a need for new relevant tests to properly characterize them. Basic index tests are typically needed to assure manufacturing quality control. Not only are these tests useful for manufacturing quality control, but when used on the same materials deployed in bench-scale and large-scale performance tests, they serve to “bench-mark” the performance results to specific material properties. Not surprisingly, a variety of performance tests have been developed over the years to answer design questions regarding performance among different products and product categories.

Since 2003, the National Transportation Product Evaluation Program (NTPEP) has provided a program for independent testing of RECPs. The program has included both index tests and bench-scale “indexed performance” tests. The goal of the program is to minimize duplicative testing of erosion control products done by individual State Departments of Transportation (DOTs) by providing a process where manufacturers and suppliers submit their products to the NTPEP for independent index and bench-scale testing. The results of the testing are then shared with participating DOTs. The results of the testing may be used for assessing product conformance to material specifications. Further, the testing results provide quantitative material data necessary for placing specific products on, or removing specific products from a DOT's qualified products list (QPL). The NTPEP program is intended to serve as a nationwide quality assurance (QA) program for the DOTs.

Additionally, in 2009, NTPEP began offering independently verified large-scale erosion control performance testing to complement on-going index and bench-scale testing. NTPEP (2011) describes the purpose and rationale for exclusive use of standardized test procedures in the programs.

While standardized tests for geotextiles – which are used in many SRDs – have been available for decades, new tests have been needed for RECPs. The following section details the tests that have developed and are generally used to characterize RECPs and SRDs.

Index Testing

Index tests are standard tests that may be used for manufacturing quality control and to compare the relative material properties of several different RECPs. Quality Control tests are index tests which are performed on a production basis to evaluate product integrity, quality, continuity, and the impact of changes in production methodology on product properties. Quality

control test results can be reported with statistical relevance when they are run with sufficient frequency. Recently, ASTM D4354, “Standard Practice for Sampling of Geosynthetics for Testing”, has been revised to include appropriate sampling frequencies to achieve a 95% confidence level for RECP quality control, quality assurance, and conformance testing. Following are the index test methods used for RECPs:

- Mass per Unit Area: ASTM D 6475, “Standard Test Method for Measuring Mass per Unit Area of Erosion Control Blankets”;
- Mass per Unit Area: ASTM D 6566, “Standard Test Method for Measuring Mass per Unit Area of Turf Reinforcement Mats”.
- Thickness: ASTM D 6525, “Standard Test Method for Measuring Nominal Thickness of Permanent Rolled Erosion Control Products”.
- Tensile Strength: ASTM D 6818, “Standard Test Method for Ultimate Tensile Properties of Turf Reinforcement Mats”.
- Light Penetration: ASTM D 6567, “Standard Test Method for Measuring the Light Penetration of a Turf Reinforcement Mat (TRM)”.
- Water Absorption: ASTM D 1117 Section 5.4 and ECTC-TASC 00197, “Standard Guide for Evaluating Nonwoven Fabrics – Absorptive Capacity Test (for Larger Test Specimens)”.
- Specific Gravity: ASTM D 792, Method A, “Standard Test Methods for Density and Specific Gravity (Relative Density) of Plastics by Displacement”.

Following are index test methods used for SRDs:

- Mass per Unit Area: ASTM D 5261, “Standard Test Method for Measuring Mass per Unit Area of Geosynthetics”;
- Thickness: ASTM D 5199, “Standard Test Method for Measuring Thickness of Geosynthetics”. Note: Many SRDs are 3-dimensional products (i.e. wattles, bales, etc.), thus non-standard procedures are currently used to measure such things as density (or unit weight per length) and circumference.
- Tensile Strength: ASTM D 4595, “Standard Test Method for Measuring the Wide-width Tensile Strength of Geosynthetics”;
- Permittivity: ASTM D 4491, “Standard Test Methods for Water Permeability of Geotextiles by Permittivity”.
- Apparent Opening Size (AOS): ASTM D 4751, “Standard Test Method for Measuring the Apparent Opening Size of Geosynthetics”.
- Percent Open Area (POA): Corps of Engineers protocol CW02215.
- Ultraviolet Stability: ASTM D 4355, “Standard Test Method for Deterioration of Geotextiles by Exposure to Light, Moisture and Heat in a Xenon Arc Type Apparatus”. The exposed specimens are typically tested for retained strength in accordance with ASTM D 6818. Note: Since accelerated tests have not shown a consistent correlation to outdoor exposures, ASTM’s D 5970, Standard Test Method for Deterioration of Geotextiles from Outdoor Exposure is also used.

Bench-Scale Testing

Bench-scale “indexed” performance tests are a class of tests that have been developed to focus on testing the RECP/soil system or SRD/water system under carefully controlled “standard” conditions. Bench-scale tests have been developed for slope erosion, channel erosion, and vegetation enhancement for RECPs and for filtration efficiency and flow for SRDs. Bench-scale tests do not reflect product installation techniques or site conditions to which these materials are typically subjected. Therefore the results of these tests may not be indicative of a RECP’s or SRD’s actual field performance. Following are the bench-scale test methods used for RECPs:

- Slope Erosion and Runoff Reduction: ASTM D 7101, “Standard Index Test Method for Determination of Unvegetated Rolled Erosion Control Product (RECP) Ability to Protect Soil from Rain Splash and Associated Runoff under Bench-Scale Conditions”.
- Permissible Shear and Channel Erosion: ASTM D 7207, “Standard Test Method for Determination of Unvegetated Rolled Erosion Control Product (RECP) Ability to Protect Sand from Hydraulically-Induced Shear Stresses under Bench-Scale Conditions”.
- Germination/Vegetation Growth: ASTM D 7322, “Standard Test Method for Determination of Rolled Erosion Control Product (RECP) Ability to Encourage Seed Germination and Plant Growth under Bench-Scale Conditions”.

Following are the bench-scale test methods used for SRDs:

- Filtration Efficiency and Flow: ASTM D 5141, “Standard Test Method for Determining Filtering Efficiency and Flow Rate of the Filtration Component of a Sediment Retention Device Using Site-Specific Soil”.
- Horizontal Permeability: Many SRDs are three-dimensional, and therefore cannot be tested for clear water flow (a.k.a. permeability or flow rate) using standard procedures that have been developed for planar materials. To fill the gap, a “horizontal permeability” test has been developed that exposes the SRD to a constant head of clear water on one side.

Large-Scale Testing

Large-scale performance tests have been developed to simulate expected field conditions to report performance properties of “as installed” RECPs. Large-scale tests have been developed for slope erosion and channel erosion. The channel erosion test may be conducted un-vegetated or vegetated. Performance of RECPs relies not only on material properties but also on the installation techniques. Products are installed on the test slope or channel per manufacturer installation recommendations. The results of these tests are more indicative of actual field performance of RECPs and are acceptable for use in design calculations. Following are the large-scale test methods used for RECPs:

- Slope Erosion: ASTM D 6459, “Standard Test Method for Determination of Rolled Erosion Control Product (RECP) Performance in Protecting Hillslopes from Rainfall-Induced Erosion”.

- Channel Erosion: ASTM D 6460, “Standard Test Method for Determination of Rolled Erosion Control Product (RECP) Performance in Protecting Earthen Channels from Stormwater-Induced Erosion”.

The most unique thing about SRD’s is that, typically, for them to be very effective in retaining sediment they must also impound most of the runoff. Conversely, for them to freely pass runoff, they have to be allowed to pass a significant amount of sediment. Neither of these extremes is usually preferred, so the user has to determine the proper balance of retaining sediment while permitting seepage. Following are the large-scale test methods used for SRDs that are used to quantify the “balance” of retention and flow provided under standard conditions:

- ASTM D 7351, “Standard Test Method for Determination of Sediment Retention Device Effectiveness in Sheet Flow Applications”.
- ASTM D 7208, “Determination of Temporary Ditch Check Performance in Protecting Earthen Channels from Stormwater-Induced Erosion”.
- ASTM’s WK11340, is a derivation of ASTM D 6459, Large-scale Slope Erosion Testing, but permits a flatter slope and calls for a lighter rainfall.
- ASTM D 7351 can be modified to better simulate the runoff being more concentrated and potentially having a lower sediment load as may be applicable to inlet protection.
- Another modification to the D 7351 protocol that has been proposed is the Texas Transportation Institute’s (TTI) Sediment Control Device (SCD) performance testing facility to focus on evaluation of roadside SCDs.

Some of the unique standardized tests are shown in the following figures.

EXISTING INDEPENDENT DATA AND MATERIAL SPECIFICATIONS

Independent RECP and SRD Data

While relatively little independent data on SRDs exists, the opposite is true for RECPs. Thanks largely to the NTPEP program mentioned earlier, much independent data on a wide range of products is available at www.ntpep.org. Sprague and Sprague (2013) have summarized the available NTPEP data and proposed associated specifications.

Generic RECP and SRD Specifications

The most widely circulated “generic” specifications for RECPs are the categorizations presented by the ECTC (2006) and the Federal Highway Administration’s FP-03 (2003). These specifications include both temporary and permanent RECPs, and reflect different performance levels based on functional longevity, C-Factor, and Permissible Shear from large-scale testing. An update of the ECTC specification is expected in the coming months.

Unfortunately, there are no widely circulated “generic” specifications for SRDs. Thankfully, the IECA Committee on Standards and Practices is working toward developing specifications, but developing test methods is their initial focus.

CONCLUSIONS

Geosynthetics continue to replace traditional materials such as soil and stone in performing important engineering functions in erosion and sediment control applications while simultaneously introducing ever greater versatility and cost-effectiveness. Geosynthetics are commonly used along with temporary, degradable materials for the enhancement of vegetative establishment; as long-term, nondegradable materials to extend the erosion control limits of vegetation or soil; as primary slope or channel linings; and as components in silt fences and turbidity curtains and an ever growing array of sediment retention devices.

Industry-wide initiatives are well underway to promote the correct specification and use of geosynthetics in erosion and sediment control. This includes efforts to facilitate more

comprehensive quality systems in manufacturing and better measurements of performance via new and better test methods. All of this is indeed a “work in progress”.

THE INTERNATIONAL GEOSYNTHETICS SOCIETY (IGS): NO BORDERS FOR THE GOOD USE OF GEOSYNTHETICS

Jorge G. Zornberg, Ph.D., P.E.

Professor, The University of Texas at Austin, Austin, Texas, USA

President, International Geosynthetics Society (IGS)

ABSTRACT

Over its 30 years of existence, the International Geosynthetics Society (IGS) has grown enormously, both in the number of members and in the scope and impact of its activities. Today, the IGS has over 3,000 members, including over 150 corporate members and 350 student members. During this period, the IGS organized a remarkable number of international conferences and regional (continental) conferences as well as hundreds of national (chapter) conferences. In addition, it has formed chapters in 38 countries or groups of countries, and implemented numerous educational, technical and outreach programs. This paper provides an overview of the history of the IGS, its standing within the context of international learned societies, an overview of its chapters, of its conferences and of ongoing initiatives aimed at providing continued advancement of geosynthetics.

INTRODUCTION

2013 marks the 30th anniversary of the International Geosynthetics Society (IGS). Over its 30 years of existence, the IGS has grown remarkably. As of January 2013, the IGS consists of 3,135 members, including 2,620 individual members, 356 student members, and 159 corporate members. The IGS chapters, which are somewhat equivalent to the member societies of other international societies, were initiated with pioneer chapters in western Europe, North America and eastern Asia, but subsequently spread out to the rest of the world, including South America, Africa, and eastern Europe.

During this period, the IGS has accomplished the organization of seven international conferences, thirteen regional (continental) conferences, and hundreds of national (chapter) conferences. In addition, current counts show IGS chapters in 38 countries or group of countries, with several other countries currently in the process of establishing new chapters. The society has established awards programs with emphasis on rewarding technical excellence, it has implemented numerous educational programs, compiled educational material, prepared terminology documents in multiple languages, sponsored student programs, and organized numerous outreach programs, to name a few of its activities and achievements. To provide a context to the IGS trajectory in fostering the good use of geosynthetics worldwide, this paper provides an overview of the history of the IGS, its standing within the context of international learned societies, an overview of the chapters of the IGS and a summary of its successful conference series. In addition, the

paper provides an overview of the current structure of the IGS, its operating units and a few examples of ongoing initiatives.

The information in this paper is an updated and expanded version of information partially presented by the author as part of the “President’s Corner” series of articles published in *IGSNews*, the Newsletter of the IGS.

AN OVERVIEW OF THE THIRTY YEAR-HISTORY OF THE IGS

The organization of early international conferences on geosynthetics (or “fabrics” at the time) provided the forum for discussions on the formation of an international society. An early international conference on the use of “Fabrics” in geotechnics was held in Paris, France, in 1977. However, the concept of an international society, which will later become the IGS, was only formulated in 1980 (Giroud 2008). Subsequently, during the Second International Conference on Geotextiles held in Las Vegas, USA in 1982, the formation of the IGS was explicitly discussed. Finally, the “International Geotextile Society,” as it was named at the time, was officially founded on November 10, 1983 with Charles Schaerer (Switzerland) as its President. This founding of the society initiates the 30 year-timeline shown in Figure 1.

The timeline highlights **important milestones** in the history of the society (see Figure 1, in pink). At the time of the society’s founding in 1983, the “G” in the IGS acronym originally corresponded to “Geotextiles,” but the growth of the scope of the society activities was reflected in 1994 when the IGS Council approved changing the society’s name into the International “Geosynthetics” Society. As also shown among the milestones in the figure, access to the highly regarded “Geotextile & Geomembranes” technical journal was added as a benefit to the IGS membership early in the history of our society (in 1987), becoming the first official journal of the IGS. A second and equally prominent technical journal, “Geosynthetics International,” became an official IGS journal in 1994. The availability of two technical journals is good evidence of the high emphasis of the IGS on the dissemination of information. It is notable that these two journals have been consistently ranked among the best journals in the field of geotechnical engineering.

Outreach to young members in our discipline has received special focus throughout the history of the IGS, with key milestones being the establishment of student membership in 1990 and the implementation of unique student awards programs since 2000. A fresh and equally relevant milestone is the creation by the IGS Council of the its Young Members Committee in December 2012, which aims at facilitating and promoting the active participation of young members (under 35 years old) in technical geosynthetics activities and the operation of the IGS.

More recent milestones in the history of the IGS include the formation of the IGS Technical Committees (TCs), approved by the IGS Council in 2010 as well as the implementation of Council Operating Units that include not only IGS Council

Committees but also Council Task Forces. Also in 2010, the IGS Council approved a statement for the Core Purpose of the IGS, a 4-year operations plan, and a long-term Big Audacious Goal. In 2011, the office of the IGS Secretariat Manager was relocated to South Florida (in Jupiter, FL), after a long, productive operation of the IGS secretariat activities from Easley, South Carolina. Also in 2011, and following approval by the IGS Council, the IGS accepts invitation by the Federation of International Geo-Engineering Societies (FedIGS) to join this Federation as its first non-founding member. Finally, and on the verge of preparation of this article (January 2013), the total IGS membership exceeded the mark of 3,000 IGS members, which probably deserves a place as a milestone in the 30 year-timeline (approximately 100 members per year over the existence of the IGS).

Also shown in the timeline are the **international conferences** organized by the IGS (see Figure 1, in blue). As discussed subsequently in this paper, the international conferences, along with the regional and chapter conferences, are vital forums to discuss the continuous advancement and transfer of information regarding geosynthetics. Changes in the name of the international conferences reflect the growth of our discipline, from the first international conference (preceding the formation of the IGS) “on the Use of Fabrics,” to international conferences “on Geotextiles,” to international conferences on “Geotextiles, Geomembranes and Related Products,” to (since 1998) international conferences on “Geosynthetics.”

The international conferences also represent important landmarks in the affairs of the IGS as they are the setting of its quadrennial general assemblies, where change in the council and elected officers of the IGS occurs. The presidency of Schaerer, appointed by the first IGS Council in 1983, was followed by seven subsequent presidents which, following a procedure probably unique among international learned societies, were all elected by direct vote of each one of the IGS members. They include J.P. Giroud (USA, 1986-90), Kerry Rowe (Canada, 1990-94), Colin Jones (UK, 1994-98), Richard Bathurst (Canada, 1998-2002), Daniele Cazzuffi (Italy, 2002-04), Fumio Tatsuoka (Japan, 2004-10) and, as of May 2010, Jorge G. Zornberg (USA).

Finally, the timeline also shows a number of important **“first” occasions/events** in the history of the IGS (see Figure 1, in yellow), starting with the formation of the first IGS Council in 1983. The first issue of the IGS Newsletter (IGSNews) was published in 1985 and has been regularly published since then. The first of the current 38 chapters of the IGS was the Japanese chapter, approved by the IGS Council in 1985. With the increasing relevance of the geosynthetics discipline and of the activities of the IGS came the opportunity of recognizing excellence. Accordingly, as shown in the timeline, the first Honorary membership was awarded in 1989 (to Prof. Masami Fukuoka), the first series of IGS Awards was presented in 1990 (to J.E. Fluet and E.R. Steinle) as was the first Young IGS Member Achievement Award (to R. Jewell), the first Mercer Lecture was awarded in 1992 (to Prof. R.M. Koerner), the First Giroud Lecture (also awarded to Prof. R.M. Koerner) was presented in 1998, the first IGS Service Award (to Prof. D. Elton) was presented in 2001, and first IGS Achievement Awards were presented in 2006 in recognition to exemplary service to an IGS chapter.

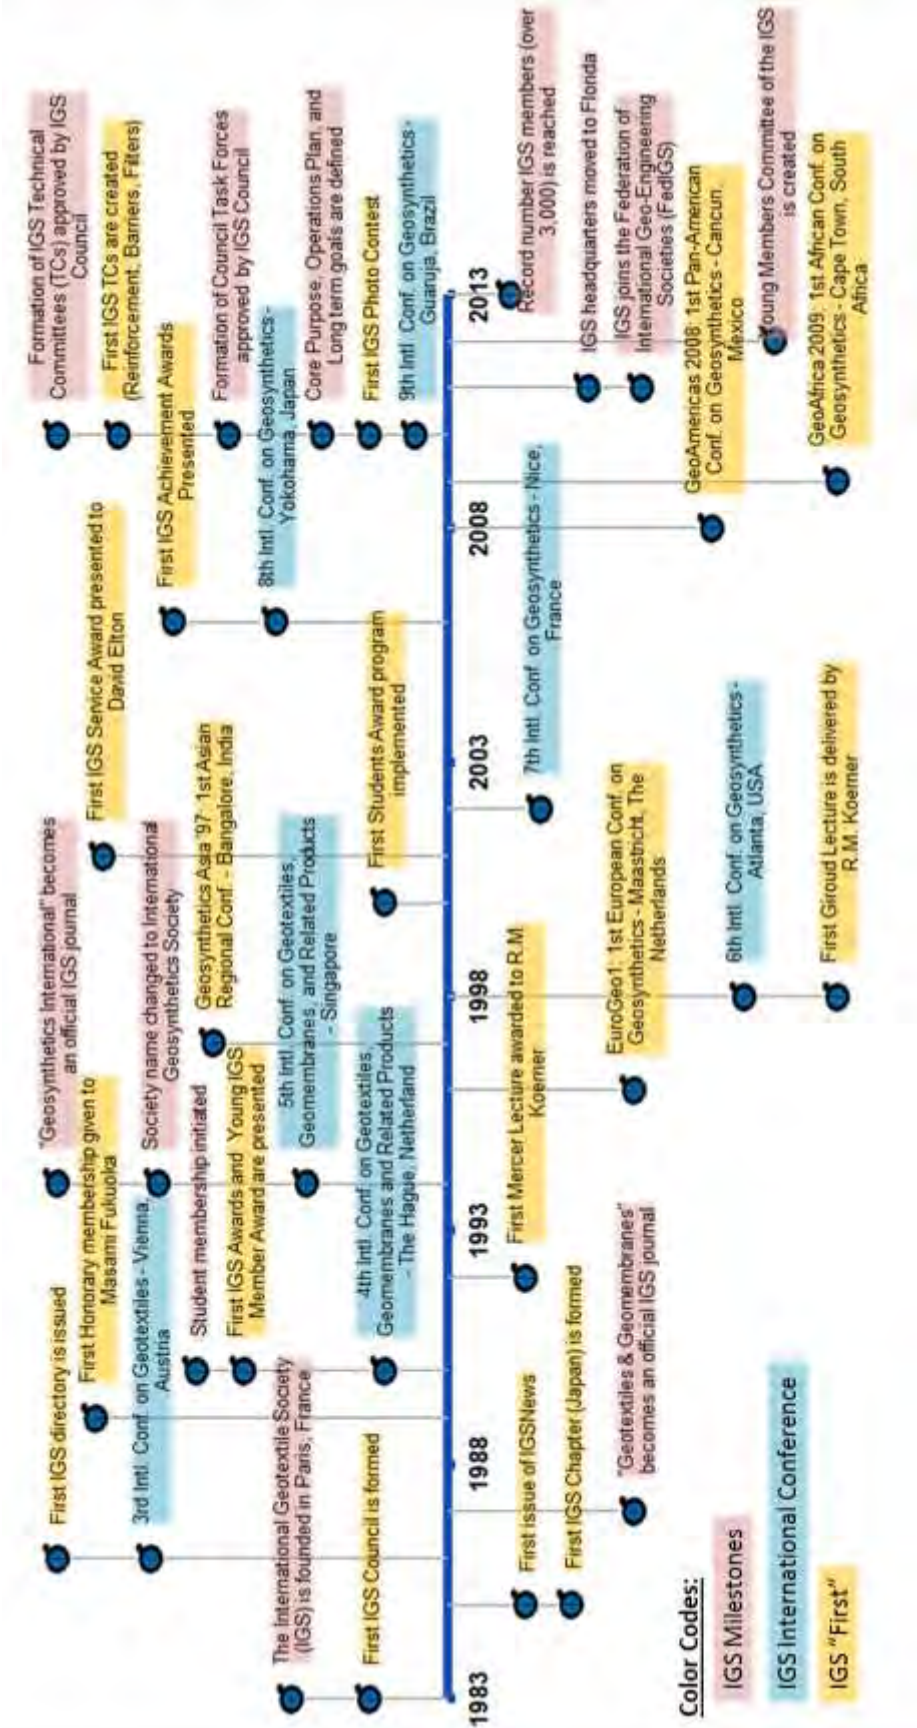

Figure 1: Overview of the thirty year-history of the IGS.

While the formation of the IGS was partly triggered by the forum of geosynthetic experts organizing international conferences (two of which preceded the creation of the IGS), it was the IGS that subsequently triggered the organization and successful implementation of other regional, specialty, and national geosynthetic conferences. Noteworthy among them are the series of IGS regional conferences, which are also organized also every four years (two years apart from the International Conferences). The European regional conferences (EuroGeo series) was launched in 1996 (Maastrich, the Netherlands), the first Asian Regional conference (Geosynthetics Asia series) was held in 1997 (Bangalore, India), the Pan-American Regional conferences (GeoAmericas series) were initiated in 2008 (Cancun, Mexico), and the African Regional conferences (GeoAfrica series) launched in 2009 (Cape Town, South Africa). A more recent IGS “first” also shown in Figure 1 includes the First IGS Photo Contest in 2010, which received over 140 entries of photos documenting the good use of geosynthetics worldwide. Finally, and also in 2010, the IGS Council approved the creation its first Technical Committees (TCs) on Soil Reinforcement, Barrier Systems and Filtration all initiated in 2010.

Throughout its 30 years of existence, the army of volunteers that have served the IGS Council, its chapters, its committees, and its conferences has and continues to make a significant difference towards an expanded, good use of geosynthetics worldwide.

THE IGS IN THE INTERNATIONAL ARENA

The IGS occupies a special place among the international learned societies with focus on Geotechnical, Environmental, and Hydraulic Engineering. A current initiative of the IGS is that of increasing the connection to international sister societies. Some important steps have been recently taken in this direction, which will enhance the coordination and collaboration of the IGS with four important International Sister Societies, namely:

- the International Society of Soil Mechanics and Geotechnical Engineering (ISSMGE),
- the International Society of Rock Mechanics (ISRM),
- the International Association for Engineering Geology and the Environment (IAEG), and
- the International Commission for Irrigation and Drainage (ICID)

The interaction with ISSMGE, ISRM, and IAEG is product of the recent decision of the IGS to accept the invitation to join the Federation of the International Geo-Engineering Societies, or FedIGS (Zornberg 2011). This Federation includes these three founding member societies and now the IGS as the very first non-founding member international society invited to join. Joining FedIGS will bolster the IGS objective of increased connections to sister international organizations. Specifically, the IGS now has a direct channel of communication with three of the most relevant International Geo-Societies.

Table 1 provides a comparison of the membership, as well as the number of chapters and technical committees, of the IGS with that of the ISSMGE, ISRM and IAEG as self-

reported by the various organizations in May 2012. The number of individual members of the IGS is an order of magnitude smaller than that of ISSMGE but on the same order of magnitude as the individual membership of the ISRM and IAEG. On the other hand, the IGS includes a healthy corporate membership, which exceeds (often significantly) the number of corporate members of our sister geo-societies. The table also compares the number of chapters (or member societies) among the different international sister societies. As shown in the table and discussed later in this paper, the presence of the IGS around the globe is increasing with the continued increase in its number of chapters. The IGS is now represented on all the continents with its 38 chapters, which is comparable to the number of national groups of international sister societies. In addition, the IGS has initiated the implementation of Technical Committees (TCs). While this number is comparatively small (TCs on Soil Reinforcement, Barrier Systems, and Filtration), the IGS TCs are expected to grow rapidly and to provide significant opportunities for collaboration with the ISSMGE and other sister societies.

Table 1. Number of chapters, committees and membership of the IGS and some International Sister Societies

	ISSMGE	ISRM	IAEG	IGS
Number of National Groups or Chapters	86	48	55	38
Number of Individual Members ^(*)	18,323	5,992	2,900	2,976
Number of Corporate Members	21	125	0	159
Number of Technical Committees	24	9	10	3

(*) Includes student members

Another important development involving the relationship of the IGS with International Sister Societies is the Memorandum of Understanding recently signed between the IGS and the International Commission for Irrigation and Drainage (ICID). The IGS Officers met with the Board of ICID in October 2010, and set the base for a process that ended in October 2011 with the signing of the Memorandum of Understanding. The International Commission on Irrigation and Drainage (ICID) was established in 1950 as a Scientific, Technical and Voluntary Not-for-profit Non-Governmental International Organization (NGO) with headquarters in New Delhi, India. The Commission is dedicated to “enhancing the worldwide supply of food and fiber for all people by improving water and land management and the productivity of irrigated and drained lands through appropriate management of water, environment and application of irrigation, drainage and flood management techniques.” ICID has a consultative status with the United Nations Economic and Social Council (ECOSOC), United Nations Educational, Scientific and Cultural Organization (UNESCO), and the World Meteorological Organization (WMO). Since the mission of ICID is to stimulate and promote the development of new technologies worldwide for achieving sustainable irrigation and drainage technologies, the cooperation with IGS is expected to lead to guidelines and policies that acknowledge the benefits of geosynthetics in important hydraulic projects.

In addition to these collaborative efforts with international sister societies, the IGS has formalized its relationship with standard organizations, including TC 221 of the

International Standards Organization (ISO) and TC 189 of the European Committee of Standardization (CEN). Collaborative efforts are currently being planned the various international sister societies and international standard organizations, which are expected to promote the advancement of geosynthetic technologies in multiple areas of engineering.

NO BORDERS FOR THE GOOD USE OF GEOSYNTHETICS I: THE IGS CHAPTERS

2012 was an active year regarding increasing the portfolio of chapters in the IGS, and by the time of its meeting on December 12, 2012 (12-12-12) in Bangkok the IGS Council concluded the year with the approval of four new chapters in four continents (Kazakhstan, Ghana, Iran, and Colombia). This represents an increase in the number of IGS chapters of over 10%. These new additions, which brought the total number of chapters in the Society to 38, provide good evidence of the healthy and continued growth of the IGS.

The addition of each new chapter provides the IGS with the opportunity not only to the newcomer by extending our ongoing technical activities into new geographic areas, but also to existing IGS chapters who receive additional stimulus to their ongoing activities. A good example is the recent opportunity to initiate a program aimed at providing educational material on geosynthetics to professors in the universities of some of our youngest chapters. The IGS response to this need is expected to lead to a broad initiative focused on undergraduate education on geosynthetics. This initiative will certainly benefit young and mature chapters alike.

The concept of IGS chapters developed soon after the founding of the IGS. During its 30 year-timeline, the number of IGS chapters has grown remarkably. Figure 2 shows the chronology of the formation of IGS chapters. As shown in the figure, the number of chapters has been increasing at a significantly high (and reasonably steady) rate of over one chapter per year; 1.25 chapters per year, to be more precise. As previously mentioned, Japan took the initiative of formalizing the very first chapter of the IGS in 1985. This initiative was soon followed by North America (NAGS) and the United Kingdom, which formed the first chapters in the Americas and Europe in 1986 and 1987, respectively. New chapters were continuously added to the IGS ranks and, by 1993 (the 10th anniversary of the IGS), a total of 10 chapters were already operating across Asia, Europe, and North America. By the end of the second decade in the life of the IGS, a total of 24 chapters had been formed (now in all continents). And by 2012, the number of IGS Chapters had reached 38 as a result of a continued focus on increasing the presence of the IGS and of geosynthetics to all regions.

Figure 2: Chronology of the formation of IGS Chapters.

Figure 3 shows the world presence of the IGS in the form of IGS Chapters. As mentioned, during the first decade of the IGS, chapters were created in western Europe, North America and eastern Asia (countries shown in red in Figure 3). They correspond to regions in the world where the geosynthetics market is now mature regarding the currently traditional applications involving geosynthetics. During the second decade of the IGS, new chapters spread out to the rest of the continents, including South America, Africa, and Oceania (countries shown in green in Figure 3). This second generation of chapters includes growing economies in the world where the geosynthetics industry is probably still finding its acceptance by governmental agencies but that now counts with a solid group of professionals educated on geosynthetics. Indeed, many of the most spectacular projects involving geosynthetics have been constructed in some of these countries. Finally, during the third decade of the IGS, new chapters have been formed in areas such as eastern Europe, central Asia, and Latin America (countries shown in purple in Figure 3). This third generation of chapters includes countries where the geosynthetics market is mostly in the emerging stage and where technology transfer, which should be sensitive to local practices and economic conditions, may lead to a significant increase of the geosynthetics market.

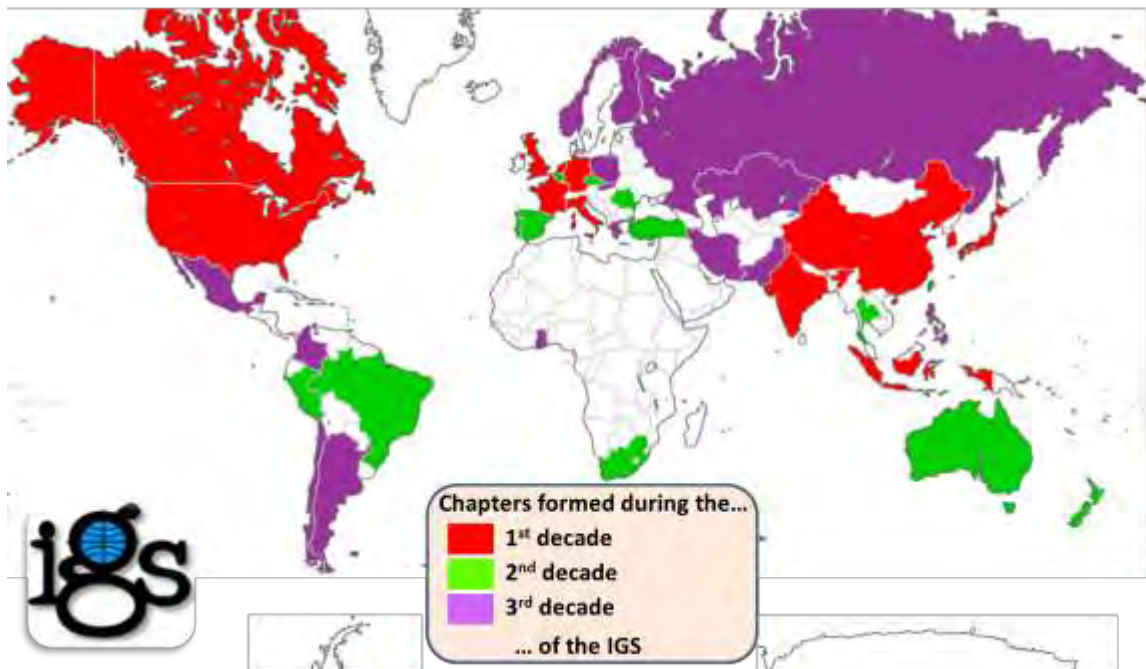

Figure 3: Chapters formed during the three decades-history of the IGS.

The number of technical activities conducted by the many IGS chapters is, simply, impressive. Starting in 2008, new guidelines were developed by the IGS to facilitate the communication and summary of the important chapter activities. The heart of this new approach is the completion by the IGS chapters of a new Standard Reporting Form. These reports have highlighted a truly impressive number of technical activities organized by the IGS chapters. These activities include, to name a few, multi-lingual national conferences, educational programs aimed at regulators, student initiatives and a healthy number of professional meetings. Ongoing initiatives being implemented at the IGS level to directly benefit the individual IGS Chapters include support to the development of online chapter membership web pages, nomination of chapter members in the various technical committees of the IGS, participation in the student awards program of the IGS, involvement in the technical program of the IGS Regional Conferences, and participation in the various ongoing educational initiatives of the IGS.

NO BORDERS FOR THE GOOD USE OF GEOSYNTHETICS II: THE IGS CONFERENCES

The Conferences of the IGS have played a remarkable role in the development of geosynthetic products and its applications. Much of the information on material properties, testing methods, applications and design approaches that we use in geosynthetics engineering has been vetted through these conferences. Of particular importance are the **International Conferences** of the IGS, which are held every four years. This series of conferences has been a premier outlet of, and in many cases has

indeed triggered, many of the advances in geosynthetics. Figure 4 illustrates the location of the various international conferences (see yellow stars, with the corresponding conference number). As illustrated in this figure, the international conferences of the IGS have been well distributed throughout the globe. The first International Conference was held in Paris (France), in 1977, and was followed by the 1982 conference in Las Vegas (USA), the 1986 conference in Vienna (Austria), the 1990 conference in The Hague (Netherlands), the 1994 conference in Singapore, the 1998 International Conference on Geosynthetics (ICG) in Atlanta (USA), the 2002 ICG in Nice (France), the 2006 ICG in Yokohama (Japan), and the most recent 9th ICG held in Guarujá (Brazil) in 2010.

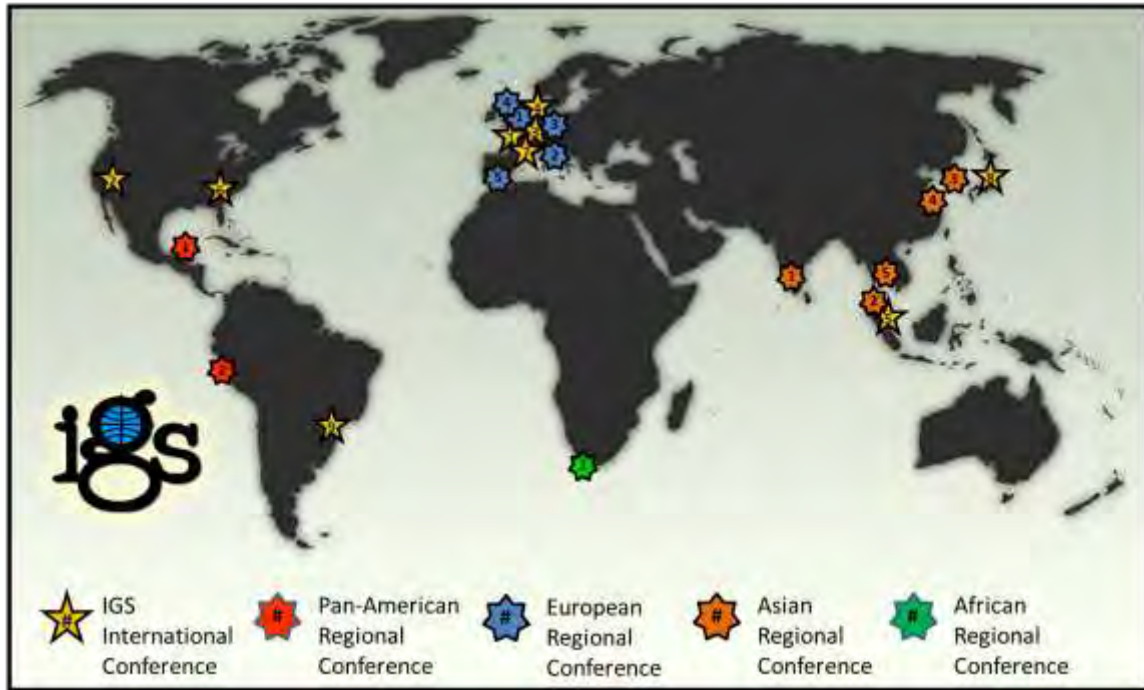

Figure 4: Past International and Regional Conferences of the IGS.

(Note: the number in each symbol corresponds to the sequence in each series of conferences)

In addition to the international conferences, **Regional Conferences** of the IGS have been organized in Europe, Asia, the Americas, and Africa. As with the international conferences, the series of IGS regional conferences are organized every four years, generally 2 years after the international conferences. Figure 4 also shows the location of the previous regional conferences of the IGS. The European Regional Conferences on Geosynthetics (“EuroGeo” series of conferences) include the 1996 EuroGeo1 in Maastricht (Netherlands), the 2000 EuroGeo2 in Bologna (Italy), the 2004 EuroGeo3 in Munich (Germany), the 2008 EuroGeo4 in Edinburgh (UK) and the 2012 EuroGeo5 in Valencia (Spain). The Asian Regional Conferences on Geosynthetics (“Geosynthetics Asia” series of conferences) include the 1997 conference in Bangalore (India), the 2000 conference in Kuala Lumpur (Malaysia), the 2004 conference in Seoul (South Korea), the 2008 conference in Shanghai (China), and the 2012 conference in Bangkok (Thailand). The Pan-American Regional Conferences on Geosynthetics (“GeoAmericas” series of conferences) started in 2008 with GeoAmericas 2008 in Cancún (Mexico), which was

followed by the recent 2012 Conference in Lima (Peru). Finally, the African Regional Conferences on Geosynthetics (“GeoAfrica” series of conferences) is the newest series of regional conferences of the IGS, having started in 2009 with GeoAfrica 2009, which was held in Cape Town (South Africa).

The venues for many of the **upcoming conferences** of the IGS have already been selected. Figure 5 shows the locations of the upcoming IGS International and Regional Conferences on Geosynthetics. The next of these conferences will be the much-anticipated Second African Conference on Geosynthetics, GeoAfrica 2013. The conference will take place in Accra, Ghana, on November 18-20, 2013. With important infrastructure needs in Africa and impressive projects address them in areas such as mining and transportation, we anticipate that major opportunities to the advancement of geosynthetics will spring from this important African event. As also shown in the figure, the next international conference, the 10th International Conference on Geosynthetics (10ICG) will be held in Berlin from 21 to 25 September 2014. The conference will take place in direct connection with the 33rd Baugrundtagung (German Soil Mechanics Conference). As the Baugrundtagung expects over 1,200 participants, great synergy and interaction is anticipated between these events, especially in the co-organized, co-located exhibition. The overlapping of lectures from both events will also attract many additional experts from the geotechnical and geosynthetics professions.

Figure 5: Upcoming International and Regional Conferences of the IGS.

(Note: the number in each symbol corresponds to the sequence in each series of conferences)

As noted, three of the conferences of the current cycle of IGS Regional Conferences took place in 2012, including the Second Pan-American Geosynthetics Conference

(GeoAmericas 2012), held in Lima, Peru, the Fifth European Geosynthetics Conference (EuroGeo5) held in 2012 in Valencia, Spain, and the Fifth Asian Geosynthetics Conference (Geosynthetics Asia 2012) held in Bangkok, Thailand. Each one of these conferences concluded with the announcement of the venues for the next series of conferences. The IGS is extremely pleased with the full suite of upcoming (2016) IGS Regional Conferences. As also shown in Figure 5, they are scheduled to take place in Miami, USA (GeoAmericas 2016, 11-13 April 2016), Istanbul, Turkey (EuroGeo6, 25-29 September 2016), and New Delhi, India (Geosynthetics Asia 2016, November 2016). Finally, the IGS Council in its meeting of 12-12-12 has already selected the venue for the subsequent (2018) International Conference on Geosynthetics (11ICG), which will be held in Seoul, South Korea in September 2018. Even though many IGS activities will take place until this event, we are looking forward to what will certainly become another landmark in the history of geosynthetic developments.

In addition to the series of International Conferences, and the multiple series of Regional Conferences organized under the umbrella of the IGS, the chapters of the IGS regularly organize **national conferences** on Geosynthetics. They attract significant local participation and provide a remarkable forum for transference of knowledge on geosynthetics. Inspection of the IGS calendar of events in the IGS website (www.geosyntheticssociety.org) includes the listing of many of these well-established events. For example, in this Spring 2013 the French Chapter of the IGS will be holding Rencontres Géosynthétiques 2013 (Dijon, France April 09-11, 2013). This will be the 9th conference of this series in France and corresponds to one of the many series of national conferences on geosynthetics organized regularly by the chapters of the IGS.

The organizing committees of each one of these upcoming IGS International, Regional, and National Conferences on geosynthetics are planning well-integrated technical programs that will include innovative technical sessions, discussion panels, and educational components. Each one of them will certainly provide unique opportunities to share experiences, knowledge, advances, and opportunities related to geosynthetics and affiliated technologies.

CURRENT STRUCTURE OF THE IGS OPERATING UNITS

The governing body of the IGS is its Council, a body of 24 representatives elected for the most part by direct vote of the IGS membership at large. The leadership of the IGS Council includes five IGS Officers: the IGS president, vice-president, and immediate past president, who are elected directly by the IGS members, as well as the IGS secretary and treasurer, who are appointed by the IGS Council. Considering the significance of communications and bold goals of the IGS, the IGS Council approved a new structure of Operating Units aimed at facilitating communications and implementing tasks effectively (Zornberg 2010). Figure 6 shows the structure of the current (2013) IGS Operating Units. Compared to the structure of previous IGS Councils, the new structure involves comparatively fewer Council Committees but it now includes a number of formal Task Forces. Under the new structure the Council Committees, which typically meet before the

meeting of the IGS Council, evaluate relevant issues and make recommendations for consideration by the Council. On the other hand, Task Forces involve a small number of members who will typically meet after the council with the objective of implementing the new council decisions. In addition, a new track of Technical Committees was approved by the IGS Council. Unlike the Council Committees and Council Task Forces, the schedule of the meetings of Technical Committees does not necessarily conform to that of the IGS Council.

The chairpersons selected by the IGS Council to lead each one of the Council Committees, Council Task Forces and Technical Committees are also shown (in parenthesis) in Figure 6. The group of Committee Chairs form an Operating Unit that meets regularly in order to facilitate implementation of activities that bridge across multiple committees. The Financial Committee, the only committee required by the IGS bylaws, provides advice on financial matters to the IGS council.

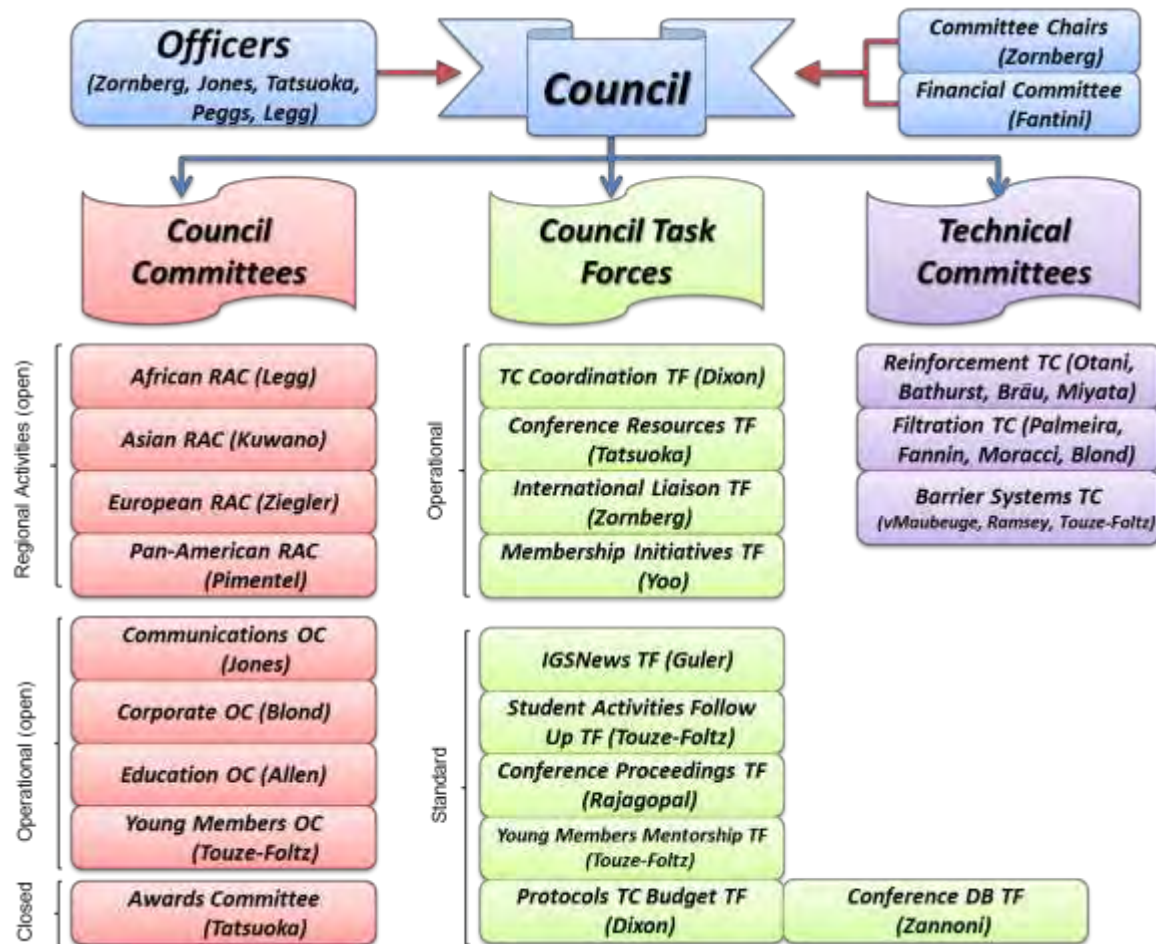

Figure 6: Structure of the Council Committees, Council Task Forces and Technical Committees of the IGS Council.

(Note: Chairpersons of the various Operating Units are shown in parenthesis)

The Council Committees of the IGS Council include a group of Regional Activities Committees, the charge of which includes promoting the activities and presence of the IGS in a given region, helping with the formation of new IGS Chapters, assisting in the organization of regional conferences of the IGS, and facilitating the distribution in the region of material to promote technical and educational events that will benefit the geosynthetics discipline. These are open committees, so representatives of the IGS chapters are encouraged to participate in the meetings and activities of these committees. Another group of committees involve the Operational Committees of the IGS Council, which are also open for participation by any IGS member. These include the Communications Committee, which is tasked among other activities to compile each issue of *IGSNews*, the Corporate Committee, which serves the needs of the corporate membership of our Society, the Education Committee, which has generated a wealth of educational documents at multiple levels and in multiple languages over the years, and the brand new Young Members Committee, which aims at facilitating the activities of the new generation of IGS members. Finally, the Awards Committee is a closed committee serving the IGS Council in identifying and recognizing the most deserving technical contributors to our industry.

While individual members of the IGS Council have diligently worked to accomplish a myriad of important activities, recent experiences have indicated that tasks are often implemented more effectively when the effort is organized under formal Task Forces of the IGS Council. A number of these Task Forces conduct continued operations. This includes the TC Coordination Task Force, which aims at organizing the new Technical Committees of the IGS, the Conference Resources Task Force, focused on consolidating the rich experience gained so far in IGS conferences, the International Liaison Task Force, which focuses on the interaction with our sister learned societies, and the Membership Initiatives Task Force, which aims at evaluating issues related to the characteristics and number of IGS members. In addition, a number of additional Task Forces are short-lived, with an expected completion of their activities in approximately one year. These include the Task Forces on *IGSNews*, Student Activities, Conference Proceedings, Young Members Mentorship, Budget Protocols, and Conference Database. These Operating Units have been assigned well-defined tasks, which are expected to be completed and delivered to the Council by the time of the next meeting of the IGS Council.

A new addition to the structure of Operating Units of the IGS Council is the set of Technical Committees (TCs) of the IGS. This includes three TCs: Soil Reinforcement, Filtration, and Barrier Systems. The leaders of these new TCs initiated their operation after having compiled proposals that were approved by the IGS council and outlined the possible activities of these TCs. These possible activities include interacting with conference organizers to lead technical sessions at upcoming conferences, with designers to produce technical documents, with academics to offer short courses, and with special emphasis on young professionals who are expected to stimulate the use of geosynthetics among the new generation of engineers.

INITIATIVES OF THE IGS

It is a daunting task to document the many initiatives of the IGS, as they are so many. Consequently, and for illustration purposes, this section summarizes two of these many initiatives. One of them is a well-established, continued effort. The second one is a new initiative.

One of the many **well-established initiatives** of the IGS relates to high-level dissemination of information on geosynthetics, which is a core mission of the IGS. This is well accomplished by the two official technical journals of the IGS: “*Geotextiles and Geomembranes*” and “*Geosynthetics International*.” “*Geotextiles and Geomembranes*” is published six times per year by Elsevier. Under the leadership of Kerry Rowe as Editor, the journal aims at increasing general awareness, prompting further research and assisting in the establishment of international codes and regulations about geosynthetics. “*Geosynthetics International*” is published six times per year by Thomas Telford. Under the leadership of Richard Bathurst as Editor and J.P. Giroud as chair of the Editorial Board, the journal covers research, behavior, performance analysis, testing, design, construction methods, case histories and field experience regarding geosynthetics. The IGS is very proud by the very high impact factor of its two journals, which constitute an excellent example of a well-established activity of the IGS that serves the IGS membership and the geosynthetics community at large. The editors and editorial boards of these two journals have been certainly driven by the same enthusiasm that has driven the rest of the IGS leadership. It should be emphasized that access to these two journals is free for IGS members with direct download available through the IGS website. This is among the most important direct benefits of the IGS membership.

A good example of one of the **new initiatives** of the IGS is the pilot program being initiated to address the educational needs in the country of one of our youngest chapters: Argentina. Specifically, the “Educate the Educator” (indeed, “Educando al Educador,” as the course will be in Spanish) will take place in Villa Carlos Paz, Argentina, from May 26 to 28, 2013. This is a good example of a joint effort between an IGS Chapter (IGS-Argentina in this case) and the IGS (through its Pan-American Activities and Education Committees). The focus of this program is on undergraduate education with the overall goal that every civil engineering student graduating from a civil engineering program in Argentina will have received a basic exposure to geosynthetics. The goal is perhaps a simple, one hour-long exposure class, but offered to every single civil engineering undergraduate student in the country. As part of this effort, 30 civil engineering professors will receive a fellowship that will cover expenses to participate in a premier training program on geosynthetics. This pilot program will benefit from the involvement of the Argentinean Council on Civil Engineering Curriculum (CODIC), an agency that has encouraged the development of this educational program. A terrific precedent of training civil engineering professors exists as a training program was previously implemented in North America over fifteen years ago (Elton 1996). After over 15 years since the excellent experience in North America, education on geosynthetics at the undergraduate level remains a current, worldwide need. The IGS is not alone in recognizing this important need. Indeed, the Geosynthetic Institute (GSI),

with its major educational arsenal on geosynthetics, and the Geosynthetic Materials Association (GMA), with its capability of mobilizing the geosynthetics industry, are equally engaged in promoting basic geosynthetic education. The opportunity exists for significant synergism in this undergraduate educational effort.

FINAL REMARKS

With the IGS now completing three decades of existence, the challenges and opportunities involving the dissemination of geosynthetics knowledge continue to be significant. Indeed, the role of the IGS in this dissemination is expected to continue to grow, and it is the intention of the IGS to tailor the assistance to the various geosynthetics interest groups according to their specific needs. A remarkable characteristic of the IGS has been its capability to evolve while, at the same time, always maintaining a clear aim at its core purpose, which is **“to provide the understanding and promote the appropriate use of geosynthetic technology throughout the world.”**

IFAI TURNS 101 WITH 33 YEARS OF GEOSYNTHETIC REPRESENTATION

Andrew Aho, Director, Technical Markets, IFAI

In 2013 the Industrial Fabrics Association International (IFAI) celebrates its 101st year. The association had humble beginnings when 14 members met at the Brown Palace Hotel in Denver on September 12, 1912. Today, IFAI, with 1800 member companies, is the largest trade association representing suppliers, end product manufacturers and service providers of industrial fabrics.

The association began as the National Tent & Awning Association representing the canvas and awning manufacturers in the central part of the United States. Today, IFAI represents 12 distinct special interest groups or market segments. These special interest groups include the original tent and awning markets and now extend into highly technical markets such as safety and geosynthetics.

At the start, the mission of the trade association was to set standard weights and pricing for products made of canvas. A mission like that today would likely end in criminal and civil prosecution of the trade association leadership. The initial group was formed to combat the price setting policies of the cotton mills that supplied the raw materials for the canvas manufacturing industry. Eventually, the association would expand to include the cotton suppliers.

The first president of the association was A.H. Rawitzer of the Scott-Rawitzer Manufacturing Company of Omaha, Nebraska. The association grew rapidly and by 1915 it needed an official office to coordinate its activities. It had elected as its second president W.K. Jacobs, who owned the Minnesota Tent & Awning Company in St. Paul, Minnesota. W.K. Jacobs sited the office of the association in the same building as his business. The association headquarters remained in downtown St. Paul until 1997 when moved into its current location in Roseville, Minnesota, a first ring suburb of St. Paul.

Also in 1915, the association started publishing the *National Tent and Awning Manufacturer's Review* which has morphed into today's IFAI's flagship publication *Specialty Fabrics Review*. The first employee of the association was James E. McGregor, hired as both the editor of the Review and the executive secretary of the association. He remained in those positions for 37 years. McGregor wrote an editorial in each issue he published. In the 1930s some of his editorials had nothing to do with the fabric industry. Some took aim at the rubber stamp congress, radicals and a subject current today, the federal deficit. By the 1950s McGregor's editorials seemed obsessed with communism, including Stalin and tips on how to spot a Communist.

During McGregor's tenure, the membership continued to grow. In 1936 the membership expanded to include the truck cover and boat cover manufacturers. However, in the 1940s synthetic fibers such as rayon and nylon challenged canvas in the marketplace. The association continued to be a canvas organization. In 1957, companies from Canada joined the association and the association added International to its name – Canvas Product Association International.

(Today, IFAI has members in more than 50 countries.) Polyester became part of the market in the 1960s. The association was no longer just for canvas manufacturers and in 1966 the Review changed its name to the Industrial Fabric Product Review. With the advent of polypropylene and acrylics in the 1970s and more synthetic based fibers in the 1980s the association remained stubborn and kept canvas in its name until 1981 when it was changed to Industrial Fabric Association International.

With the growth in synthetics, many market segments or divisions were formed at IFAI. In 1980 IFAI formed the Geotextile Division, representing the manufacturers of geotextiles. In 1982 IFAI organized the Second International Conference on Geotextiles in Las Vegas, Nevada. IFAI began publishing *GFR* magazine (now *Geosynthetics* magazine) with the first issue in the summer of 1983. Geosynthetics have been an important part of IFAI ever since. IFAI has organized or co-organized thirteen geosynthetic conferences since 1982 and published the conferences proceedings.

Demand for geomembranes has increase due to regulation of hazardous and solid wastes and the end of open dumping of waste in the United States in the late 1970s and early 1980s. The industry needed a place for trade association activities and in 1983 IFAI formed the Geomembrane Division. Activities of both the Geotextile and Geomembrane Divisions were related to the development of specifications and technical issues related to the materials. The Geotextile Division worked with the American Association of State Highway and Transportation Officials (AASHTO) and academic, state and federal representatives to develop and revise the AASHTO M288 geotextile specifications. The Geomembrane division focused on the new RCRA regulations and specifications for liners used in waste containment.

In 1997 the members of the two divisions voted to change the direction of the association to one of marketing geosynthetics and move away from the specification and technical issues. That year IFAI merged the Geotextile and Geomembrane Divisions to form the Geosynthetic Materials Association (GMA). Joe Luna of Colbond was the initial chairman of the GMA Executive Committee. Other members were Gary Willibey of Amoco Fabrics and Fibers Co., Marc Theisen with Synthetic Industries, Dave Clarke with TC Mirafi, Giovanni Capra of Tenax and Monte Thomas of TNS Advanced Technologies. IFAI assigned staffer Danette Fettig as the managing director. Ms. Fettig continued managing GMA until 2004.

By 1998 GMA had 37 members companies including producers of geogrids and geocells. That year GMA developed its first website www.gmanow.com. Maccaferri joined the GMA Executive Council later in 1998 and Massimo Ciarla proposed the development of GMA Mexico. Oscar Couttollenc was contracted to represent GMA Mexico from his office in Mexico City.

Even though the association looked to a move away from specifications and technical issues it remained embroiled in the development of specifications for geotextiles and geogrids. The AASHTO subcommittee on Materials Technical Section E4 Task Force on Geogrid/Geotextile Specifications requested that GMA help develop further a specification for Geotextiles and a separate specification for Geogrids. The issue was very controversial due to the proprietary nature of the brands and materials. The result was the development of a White Paper rather than

a specification. In July of 1998 GMA presented AASHTO with the White Paper: *Geosynthetics In Pavement Systems Applications*. A further attempt to move away from technical issues was unsuccessful when the same AASHTO committee requested the industry make another attempt to develop a specification for geogrids. Again the result was a report known as GMA White Paper II: *Geosynthetic Reinforcement of Aggregate Base/Subbase Course of Pavement Structures*, published in June 2000.

In 2000, *GFR* magazine became the official magazine of GMA and remains today with the new name *Geosynthetics*.

Term limits required GMA to replace Joe Luna as chairman of the GMA Executive Council. Giovanni Capra was elected chair in 2001 and for two two year terms ending in 2005. Under Giovanni Capra's guidance GMA continued to build on the membership growth enjoyed under Joe Luna. The membership was now at 45 and included the majority of manufacturers and large distributors of geosynthetics. The Executive Council grew to eight members by adding GSE represented by Ernie English. The market segments were represented by focus groups based on products. GMA continued to focus on market promotion and education. GMA contracted with TRI to develop a *Geosynthetics Handbook*.

There remained need for technical presence within GMA. In 2003 discussions with Dr. Bob Koerner began regarding becoming the "technical arm" of GMA.

By 2004 GMA had gained significant membership and an aggressive agenda. It was clear that GMA needed additional staff time from IFAI. IFAI made a commitment to provide additional staff expertise to GMA. At the same time, Chairman Capra began an initiative to develop a long term strategic plan for GMA. The plan identified the need to compete with traditional construction materials at a policy level within the U.S. government. It also recognized the need for more education regarding the proper use of geosynthetics. In 2005, Andrew Aho was hired as the managing director of GMA. During that year, Ernie English replaced Giovanni Capra as chairman. After a short time as chair, Ernie English resigned due to work commitments at GSE and John Henderson from TenCate was elected chairman.

GMA began a search for a lobbying firm that could help GMA affect government policy to help preserve and grow the geosynthetic market in the United States. GMA hired Kemp Partners and the Whitmer and Worrall lobbying firm to represent the industry in Washington, D. C. The Kemp Partners firm was led by Jack Kemp the former congressman and vice presidential candidate. For the first time, the industry had full time representation in Washington, D.C. along with a very high profile name associated with it.

The second need identified by GMA's strategic plan was more education regarding the proper use of geosynthetics. Technical information was very much needed in the market place. Since the GMA plan was to promote the industry and shy away from technical issues that had caused disruption in the membership, GMA looked to Dr. Bob Koerner and the Geosynthetic Institute and concluded the discussion begun in 2003 by contacting with them to provide technical assistance to the market place through the GMA Techline. After a slow start in 2005, the Techline has become a robust educational tool for anyone with technical questions regarding

geosynthetics. The Geosynthetic Institute team have fielded thousands of technical questions through gmatechline@ifai.com.

John Henderson led GMA from 2005 to June 2011. During his tenure GMA's government relations program matured. The successful efforts to get the Government Accountability Office (GAO) to complete a study of geosynthetics as an innovative material in transportation applications began at that time. The government relations activities were a very attractive recruiting tool and GMA's membership doubled by 2007 and now boasts 80 member companies. In addition, a major accomplishment during this time was the development of the AASHTO/NTPEP audit program for manufacturers of geotextiles used by state DOTs. The program also requires that the prime manufacturer's name or numerical I.D. is printed on the fabric.

Boyd Ramsey of GSE became chairman when Henderson's terms ended. Boyd Ramsey took the lead in fashioning GMA's position on coal ash waste, ensuring that geosynthetic liners in coal ash disposal sites were included in the two regulatory options put forth by the Environmental Protection Agency (EPA). GMA has been a strong supporter of the legislative solutions moving through congress regarding coal ash waste.

The GMA government relations program has been very successful at the federal level, with a list of congressional champions. GMA is now leveraging that success at the state and local level. The GMA State and Local initiative began in the fall of 2012. The initial target states are Tennessee, Ohio and Illinois. GMA members and lobbyists have been meeting with state DOTs to promote the AASHTO audit and printing program. GMA is also connecting with the Governors' offices and the road builder associations to promote the use of geosynthetics. Meetings are also held with the state EPAs to promote GMA's position regarding coal ash waste. Education and government relations will continue to be the focus of GMA's activities. All but a few manufacturers are members of GMA. GMA developed a program for distributors, and today a third of the members are distributors of geosynthetics. Membership also includes testing firms and equipment manufacturers. GMA has strong relationships with the Geosynthetic Institute, the International Geosynthetics Society (IGS), Fabricated Geomembrane Institute (FGI) and North American Geosynthetics Society (NAGS), and often invites those organizations to participate in GMA lobby days and presents a united front as we educate congress and federal agencies.

The geosynthetics industry will remain an important part of the business activities of IFAI. IFAI will continue its philosophy of hosting conferences with partners to expose related industries to geosynthetic materials. The Geosynthetics 2013 conference includes co-locating with the Southwest Geotechnical Engineers Conference and GRI 25. In 2015 IFAI will co-locate with International Erosion Control Association (IECA) in Portland, Oregon. The annual IFAI EXPO has included geosynthetics in its programming and has begun to draw both attendees and exhibitors to the EXPOs. IFAI's magazine *Geosynthetics*, and its associated website, is the premier source of case studies of geosynthetics applications, as well as the source of the array of geosynthetic products which are featured in the annual *Specifiers Guide*. GMA will continue to represent the industry to congress and federal regulatory agencies as well as at the state and local level.

30 YEARS OF THE MAGAZINE FORMERLY KNOWN AS *GFR*

Ronald W. Bygness

Geosynthetics magazine, Industrial Fabrics Association International, Roseville, Minn., USA

ABSTRACT

This article is on the formation and background of *Geosynthetics* magazine (formerly *GFR*) and reviews some of the many highlights over its 30-year history. It also sheds insights into its host institutions; the IFAI and GMA. Its success as the worldwide magazine of, and about, the geosynthetics industry is assured. Furthermore, it is well positioned to continue this leadership position well into the future.

INTRODUCTION

In 1915, the Industrial Fabric Association International's precursor—the National Tent & Awning Association—started publishing the *National Tent & Awning Manufacturer's Review*, which has morphed into the current IFAI flagship publication, *Specialty Fabrics Review*.

With the growth in the manufacturing and distribution of synthetic materials, additional market segments (divisions) were formed at IFAI. In 1980, IFAI established the Geotextile Division, representing the manufacturers of geotextiles. In 1982, IFAI organized the Second International Conference on Geotextiles in Las Vegas, Nevada. IFAI has organized or co-organized 13 geosynthetic conferences since 1982 and has published the conferences' proceedings.

IFAI began publishing the *Geotechnical Fabrics Report*—quickly referred to as simply *GFR* (now *Geosynthetics* magazine)—with its first quarterly issue in the summer of 1983. *Geosynthetics* have been an important part of IFAI ever since. The magazine is now celebrating its 30th anniversary.

Also in 1983, IFAI formed the Geomembrane Division. Activities of both the Geotextile and Geomembrane Divisions were related to the development of specifications and technical issues related to the materials. The Geotextile Division worked with the American Association of State Highway and Transportation Officials (AASHTO) and academic, state, and federal representatives to develop and revise the AASHTO M288 geotextile specifications. The Geomembrane Division focused on new regulations and specifications for liners used in waste containment as specified in 1976's [Resource Conservation and Recovery Act](#) (RCRA) plus several added RCRA amendments in the 1980s.

In 1997, IFAI merged the geomembrane and geotextiles divisions into the Geosynthetic Materials Association (GMA), and assigned former *GFR* editor Danette Fettig as the managing director. Fettig continued managing GMA until 2005.

In 2000, *GFR* magazine became the official magazine of the Geosynthetic Materials Association (GMA) and remains so today with the magazine's new name, *Geosynthetics*. *Geosynthetics* is also the official publication of the North American Geosynthetics Society (NAGS).

In mid-2005, Andrew Aho was hired as the managing director of GMA. Later that year, Ron Bygness was named the new editor of the magazine formerly known as *GFR*, with his first issue—February/March 2006—redesigned and retitled *Geosynthetics*.

GMA looked to Dr. Bob Koerner and the Geosynthetic Institute (GSI), and concluded discussions that had started in 2003, by contracting with them to provide technical assistance to the marketplace through the “GMA Techline.” After a slow start in 2005, the Techline has grown into a robust educational tool for anyone with technical questions regarding geosynthetic materials and their many applications. The GSI team has fielded thousands of technical questions through gmatechline@ifai.com, with selections of Techline Q-and-A regularly reprinted in *Geosynthetics* magazine.

Geosynthetics flourished following its name change and comprehensive redesign in 2006, growing from 36 pages in eight 2005 issues, to 56 pages per issue in five 2006 bimonthly magazines, and up to 64 pages per issue in 2010. The December/January issue continued each year as the annual *Specifier's Guide*.

The *Geosynthetics* magazine website launched in mid-2009, offering geosynthetics and geotechnical news, educational papers, print magazine content, feature stories, electronic archives, and association news from GMA, NAGS, GSI, and numerous other organizations and sources. IFAI's magazine, *Geosynthetics*, and its associated website, is today a premier source of case studies of geosynthetics applications, as well as the source of the array of geosynthetic products, applications, and services that are featured in the annual *Specifier's Guide*.

Five snapshots of the 30-year history of “The magazine formerly known as *GFR*” follow, with one of the five chronological segments featured in each of the 2013 issues of *Geosynthetics* magazine.

THE BEGINNINGS: 1983-1988

1983: The first issue of a new quarterly magazine called *Geotechnical Fabrics Report* is published by the St. Paul, Minn.-based Industrial Fabrics Association International (IFAI). The editor is Michael E. Coughlin ... Byline contributors in the premiere issue are Bruce Lamberton, J.P. Giroud, Robert Carroll Jr., and A.S. Balasubramaniam. The editor also recognizes industry experts as technical article reviewers: Dick Bell, Joe Fluet Jr., Bob Koerner, and Giroud ... Also in 1983, the Geomembrane Division is formed at IFAI.

1984: June 20-24—IFAI cosponsors the International Conference on Geomembranes in Denver, Colo. ... *GFR* notes that on Nov. 8, 1984, two days after his re-election, President Ronald Reagan signed H.R. 2867, The Hazardous and Solid Waste Amendments of 1984, amendments that mandate double liner systems in hazardous-waste landfills (Subtitle C).

1985: Joan R. Haglund is the new editor and *GFR* switches from a quarterly to a bimonthly publishing schedule ... June 4-5—The first geotechnical conference concentrating on both geotextiles and geomembranes is held in Cincinnati, Ohio ... In the November/December 1985 issue, *GFR* introduces the “Product Reference Guide & Directory” (later to become the “Specifier’s Guide”).

1986: The Austrian postal administration issues a stamp featuring a roll of light-brown nonwoven geotextile in commemorating the 3rd International Conference on Geotextiles (3ICG), held in Vienna ... *GFR* reports that Superfund amendments from the U.S. Congress change the size of the trust fund and how it is replenished as well as the criteria for selecting sites ... in January, the American Society on Geosynthetics (ASG) is formed ... Giroud is elected president of the International Geosynthetics Society (IGS) ... the Geosynthetic Research Institute (GRI) is founded and incorporated ... Koerner, the GRI director, publishes the first edition of *Designing With Geosynthetics*.

1987: *GFR* switches to a bimonthly, except monthly in November and December, with the December issue devoted to the “Product Reference Guide & Directory” ... The Geomembrane Division suggests changes for the EPA’s “Manual of Procedures and Criteria for Inspecting the Installation of Flexible Membrane Liners.”

1988: The Geotextile Division publishes a brochure featuring the history of the geosynthetics industry covering polymers, applications, and specifications ... *GFR* reports on the EPA releasing new regulations for the operation of municipal solid-waste landfills (Subtitle D) ... *GFR*’s Product Reference Guide is renamed the “Specifier’s Guide.”

AN INDUSTRY EVOLVING: 1989-1994

1989: *GFR* reports that EPA regulations now require leak-detection systems along with secondary containment linings... the September/October issue includes an IFAI marketing research article, “Geotextile Market Report: An Industry Evolving,” which charts annual production in millions of square yards: 1985 (210 msy), 1986 (235 msy), 1987 (264 msy), 1988 (297 msy), 1988 forecast (333 msy), and 1990 projected (369 msy).

1990: Danette Fettig begins a 16-year career at IFAI, starting as the *GFR* editor ... In an interview with *GFR*, newly elected IGS president R.Kerry Rowe challenges the industry to “disseminate knowledge concerning the benefit and correct use of geosynthetics to a broader range of potential uses and to encourage the development of new and innovative products and applications.”

1991: *GFR* notes the founding and incorporation of the Geosynthetic Institute (GSI) ... IFAI’s Geotextile Division starts a Washington Liaison Committee with a goal of expanding geotextile acceptance and use in federal projects.

1992: *GFR* reports that the Geotextile Division’s government relations Liaison Committee met with members of the U.S. House Public Works and Transportation Committee’s Surface

Transportation Subcommittee to promote the use and value of geotextile materials in maintaining the nation's infrastructure. Several representatives say they have never heard of geosynthetics.

1993: The magazine's 10th anniversary is marked with a cover makeover that highlights the letters *GFR* in red ... *GFR* now has 14,000 subscribers ... *GFR* writes about industry growth slowing as municipalities put off work on landfills after the EPA's ruling on Subtitle D is put on hold.

1994: *GFR*'s annual "Specifier's Guide" is available on disk for the first time ... 1994 is the first of five years for the Educate the Educators program—the "Professor Training Course for Geosynthetics" is the brainchild of Barry Christopher and courses are conducted during five summer sessions at Auburn (Alabama) University, from 1994 to 1998. Geosynthetics courses are offered today at more than 60 universities, up from only six in 1994.

ONWARD WITH A FEW BUMPS: 1995-2000

1995: *GFR* covers Geotextile Division's ongoing fight against the EPA's proposal to include geotextiles as a product that can be manufactured with recovered materials ... after five years as editor, Danette Fettig moves into a marketing position at IFAI and Dawn Sawvel is named *GFR* editor ... Austria-based Polyfelt (later acquired by Royal TenCate) ceases U.S. operations, leaving 75 people out of work and 5-6 million pounds of geotextiles stockpiled in its warehouse.

1996: After a year in IFAI marketing, Fettig returns to the geo world as the geosynthetics division's staff director as well as conference coordinator for Geosynthetics'97 in Long Beach and 6ICG (1998) in Atlanta, Georgia... GSI's Robert Koerner is awarded the 1996 Terzaghi Lectureship, presented by ASCE's Geo-Institute ... Two interesting items in the 1996 *GFR* calendar: Sept. 30–Oct. 2, the first EuroGeo conference—EuroGeo1 in Maastricht, Netherlands; and "Legal issues and the geosynthetics manufacturer"—a seminar held during the 1996 IFAI Expo in Atlanta.

1997: *GFR* reports that the American Association of Transportation Officials (AASHTO) is asking IFAI's geosynthetic's divisions to develop specifications for geosynthetics in pavement-subbase reinforcement.

1998: IFAI announces that its geotextile and geomembrane divisions are merging into a single Geosynthetic Materials Association (GMA)... With funding, sponsors, and attendees getting harder to arrange, the class of 1998 is the finale for the Educate the Educators program at Auburn University.

1999: *GFR* covers the EPA's accelerated plan for toxic contamination cleanup at facilities that generate, store, treat, or dispose of hazardous material—1999 projections are 200 cleanup sites per year until at least 2005 ... GMA is named the representative geosynthetic trade association to the National Transportation Product Evaluation Program (NTPEP) ... GMA opens an office in Mexico City.

2000: Maria de Lurdes Lopes from Portugal and GMA managing director Danette Fettig from the U.S. are the first women elected to the IGS Council ... *GFR* reports on the largest geomembrane footprint project in North America—301 acres at Florida gypsum stack site.

AN ANNIVERSARY AND A NEW DIRECTION: 2001-2005

2001: *GFR* notes that the U.S. Congress passed a \$32.9 billion bill for federal highway programs... An artificial reef is constructed with geotextile containers filled with sand to help slow erosion of Surfer's Paradise in Narrowneck, Australia on Australia's Gold Coast ... ASCE's 2001 "Report card for America's infrastructure" hands out below-average grades, specifically referencing *an aging bridge network* (five years before the I-35 bridge collapsed in Minneapolis).

2002: *GFR* reports that the American Society of Testing and Materials (ASTM) is changing its name to ASTM International ... *GFR* celebrates its 20th anniversary with a four-part history lesson by authors J.P. Giroud (June/July issue), Greg Richardson (August), Ian Peggs (September), and Robert Koerner (October/November) ... Daniele Cazzuffi elected IGS president at 7ICG in Nice, France.

2003: Former associate editor, Chris Kelsey, is named *GFR* managing editor ... in *GFR* industry news, NTPEP launches a new program to help state DOTs prequalify rolled erosion control products ... *GFR* publishes its third Spanish-language issue ... IFAI announces plans to partner with ASCE's Geo-Institute for its 2005 biennial geosynthetics conference—Geo-Frontiers-2005 in Austin, Texas.

2004: A March *GFR* article recaps the U.S. University Council on Geotechnical Education and Research workshop in Atlanta ... *GFR's* compilation, "Designer's Forum—Vol. 1 (1997-2003)" now available ... Geosynthetic Research Institute (GRI) approves two new standards—GT12b (nonwoven geotextiles as protection material) and GT13 (geotextiles as separation between subgrade soil and aggregate) ... A landmark article, "Lessons Learned from Failure: Landfill Covers" by Gregory Richardson and K.L. Pavlik, is published in the October/November issue of *GFR*.

2005: A watershed year for the geosynthetic industry's trade association and its magazine—Andrew Aho is hired as the new managing director of GMA, *GFR* undergoes vigorous internal redesign efforts with Vol.24, No.1 (February/March 2006), and Ron Bygness comes onboard as the new editor of *Geosynthetics* (née *GFR*) magazine ... Aho and Bygness are inaugurated at their first geosynthetics conference, NAGS 2005/GRI-19, Dec. 14-16, in Las Vegas, Nevada.

NEW DIRECTIONS: 2006-2012

2006: *GFR* officially becomes *Geosynthetics* with the publication of the February/March 2006 issue ... *Geosynthetics* reports on the Bowman Road bridge in Defiance County, Ohio—the first U.S. bridge to use the Geosynthetic Reinforced Soil / Integrated Bridge System promoted by the Federal Highway Administration (FHWA) ... *Geosynthetics* announces that GMA will offer a new level of membership for geosynthetics distributors.

2007: The year debuts with the Geosynthetics 2007 conference in Washington, D.C. and at the event, *Geosynthetics* highlights geosynthetic materials in expanding the infamous I-5/805 “Merge” in Southern California ... *Geosynthetics* reports on GMA’s contracting with a Washington, D.C. lobbying firm to implement the association’s government relations program.

2008: “In the Lab” returns as an occasional column in *Geosynthetics* ... *Geosynthetics* runs a classic case history, with Bill Hawkins of Fiberweb and GSI’s George Koerner unearthing a 1972 geotextile installation ... editor Bygness unleashes his “three-corner stool” program—trade association (GMA), publication (*Geosynthetics*), and industry conference management (IFAI’s biennial geosynthetics conferences since 1982)—in the magazine’s August editorial, “We are all in this together.”

2009: *Geosynthetics* wins gold and silver medals for Best Technical Article from the Minnesota Magazine and Publications Association ... J.P. Giroud elected to the National Academy of Engineering ... a new recurring column continues in *Geosynthetics*—featuring questions-and-answers from the GMA Techline.

2010: www.geosyntheticsmagazine.com gets support from the print magazine, with the “On the Web” column in every issue ... the December 2008 coal-ash disaster in Kingston, Tenn., continues to fuel nationwide discussions by the EPA for coal-ash containment with mandatory linings and groundwater monitoring ... a clarion call for the 20-teen years—“sustainability”—is spreading like wildfire as the GSI column asks, “Are We Missing the Sustainability Boat?”

2011: Boyd Ramsey elected chairman of GMA’s Executive Council, replacing two-term chair, John Henderson ... *Geosynthetics* launches its two-year Sustainability Series, with content provided by GRI-24 papers presented at GeoFrontiers-2011 in Dallas ... Old-timer Series—“Recalling early days of shear testing” by Allan Breitenbach—concludes with Part 3... GeoFrontiers-2011 hailed as the best geosynthetics conference since, well, since GeoFrontiers-2005 in Austin, Texas.

2012: IFAI’s Steve Warner steps down and is replaced as president/CEO by Mary Hennessy... “Giroud-Han design method” gets a two-part update and explanation by the well-known authors... It’s everywhere—“To frack or not to frack,” asks *Geosynthetics*’ August editorial—as controversial oil and gas recovery methods spread across North America.

CONCLUSION

As with the industry itself, *Geosynthetics* magazine has an interesting history, likewise with ups and downs, plenty of highlights along with a few forgettable lowlights during its 30-year publishing history. The magazine formerly known as *GFR* moves into its fourth decade with the ongoing objectives of serving, informing, educating, and learning from the geosynthetics community. It has been a good 30-year run. And the future of *Geosynthetics*—the industry and the magazine—look bright indeed.

ASTM INTERNATIONAL COMMITTEE D35 ON GEOSYNTHETICS – LOOKING BACK OVER 30 PLUS YEARS

L. David Suits
Executive Director, North American Geosynthetics Society

February 2014 will be the 30th anniversary of ASTM International Committee D35 on Geosynthetics. But it had its beginning in the Fall of 1977 when a group of seventy plus persons gathered in a crowded hotel room in New York City in response to a questionnaire to determine interest in test standardization for these new engineering materials then known as filter fabrics. That was just one of the commonly used names for geotextiles that included construction cloth, construction fabrics, stabilization fabrics, erosion control fabrics and many more names that described their intended use. The questionnaire was distributed to fabric manufacturers, DOT and other government agency engineering departments, civil and geotechnical engineering consulting firms, and the civil and geotechnical engineering departments at universities across the U.S. A. It was early in 1978 when, as a result of this meeting, ASTM organized subcommittee D13.61 on filter fabrics under Committee D13 on Textiles. Trudy Raumann from Monsanto deserves the credit for getting this group organized and setting it on its way.

When thinking of other persons involved in this initial effort, too many names come to mind to list all of them for fear of leaving some out. When the subcommittee was formed four subsections were set-up. In addition to section leaders and the subcommittee chairperson a subcommittee secretary was appointed. Those taking on these initial leadership positions were: Tudy Raumann (Monsanto), subcommittee chair; Paul Miller, subcommittee secretary (US Army Corps of Engineers); John Ball (University of Alabama), followed by L. David Suits (then of the NYSDOT), section on permeability and filtration chair; Dana Toups (Carthage Mills), followed by Robert G. Carroll Jr. (then of CFMC-Mirafi), section on endurance properties chair; Dick Van Scoy (DuPont), followed by Bennett Baird (DuPont) shortly after its formation, section on mechanical properties chair; and Marshall Silver (University of Illinois and STS Consultants), followed by Barry Christopher (then of STS Consultants), section on nomenclature chair.

In 1980 it was realized that there was limited participation from the geotechnical community in the work of subcommittee D13.61. To try and encourage more participation from this area a joint subcommittee between Committee D13 on Textiles and D18 on Soil and Rock was formed. The subcommittee carried the designation D13.61/D18.19 on Geotextiles and Related Products. Ballots on draft standards went through both subcommittees and both Main committees. Administering joint ballots and resolving negatives proved to be a nightmare. Following discussions with Committee D13, Committee D18, and ASTM Headquarters, and with agreement from all three, ASTM Committee D35 on Geotextiles and Related Products was officially formed in February of 1984 at the Town and Country Hotel in San Diego, CA. Barry Christopher, then of STS Consultants, was named chair. In 1985, after further discussion between D18 and D35, the geomembrane subcommittee under D18 was moved to D35.

As of the writing of this paper membership in Committee D35 has grown from those 70 plus persons meeting in New York City to 316 members.

In order to ensure continued participation from the geotechnical community, the D35 bylaws originally required that it meet for both of its semi-annual meetings in conjunction with the meetings of Committee D18. The bylaws have since been revised to require that only one of the semi-annual meetings be held with D18. However, the Committee still continues to hold both meetings the same week as D18.

Since the beginning in the crowded hotel room in 1977 there have been 70 meetings of Committee D35 and its predecessors. These have been held all over the US and Canada. They include: New York City (2); Philadelphia, PA (1); Washington, DC (1); Charlotte, NC (1); Atlanta, GA (7); Chicago, IL (1); Orlando, FL (3); Phoenix, AZ (3); Kansas City, KS (1); Kansas City, MO (1); Cincinnati, OH (1); St. Louis, MO (3); Louisville, KY (2); New Orleans, LA (3); Los Angeles, CA (1); San Diego, CA (4); San Francisco, CA (2); Ft. Lauderdale, FL (2); Coco Beach, FL (1); Tampa, FL (3); Albuquerque, NM (2); Toronto, Canada (3); Baltimore, MD (2); Denver, CO (4); San Antonio, TX (2); Montreal, Canada (1); Memphis, TN (1); Las Vegas, NV (1); Atlantic City, NJ (1); Seattle, WA (1); Reno, NV (2); Norfolk, VA (2); Dallas, TX (1); Salt Lake City, UT (1); Costa Mesa, CA (1); Vancouver, Canada (1); Anaheim, CA (1); Jacksonville, FL (1).

As the number of polymer products for geotechnical related applications grew, the scope of D35 encompassed many of these new materials and their testing technology. The D35 subcommittee on terminology developed a definition for the term “geosynthetic,” which received Committee approval. In 1989, D35 received ASTM approval to change its name to ASTM Committee D35 on Geosynthetics.

Realizing that in order to develop standards for the various test methods of interest there needed to be some guidance on how to sample these materials to ensure test results that were indicative of the materials. That is the test results needed to be statistically valid. The first standard to receive D35 approval was Practice D4354, Practice for the Sampling of Geotextiles for Testing. This has since been renamed to Practice for Sampling of Geosynthetics for Testing. Shortly after D4354 was approved Method D4355, Test Method for Deterioration of Geotextiles from Exposure to Ultraviolet Light and Water (Xenon-Arc Type Apparatus) was approved. These approvals took place in 1984 shortly after D35 became a Main Committee. In 1985 D35 activities were focused on diverse array of property tests; Suits, et al., 1985.

These included among others:

D35.01 - Mechanical Properties

Grab Tensile Strength

Wide Strip Tensile

Puncture Test

Trapezoid Tear

Diaphragm Bursting Strength Test Method

D35.02 – Endurance Properties

Abrasion Resistance
Creep Behavior
Chemical Resistance
On-Site Protection and Handling

D35.03 – Permeability and Hydraulic Conductivity

Apparent Opening Size
Gradient Ratio (Soil-Geotextile System Performance)
In-place Transmissivity (Underload)
Permittivity Underload
Thickness

As of the writing of this paper there are 155 approved D35 standards. They include test methods, guides, practices, and specifications. They appear in ASTM International Volume of Standards 4.13.

Many of the first standards that were being worked on were adaptations of existing ASTM Committee D13 textile standards. Revisions were made to incorporate the needs of the geotechnical community. They were primarily index property standards such as trapezoid tear, grab tensile, mass per unit area, thickness, and pin puncture. Standards that were directly related to the needs of the geotechnical community, yet still considered as index property tests included geotextile permittivity, the apparent opening size of geotextiles, unconfined tension creep of geosynthetics, mineral stabilizer content of bituminous geomembranes, and geonet breaking force among many.

As work progressed in developing the index property standards it was realized that there was a need to start developing standards which would help to evaluate the performance of the geosynthetics. While some of the following may be considered as quasi-performance, they are closer to performance than index properties. These include filtration efficiency of geotextiles, wide width tensile strength, pullout resistance, vertical compression of geocomposite pavement panel drains, geotextile clogging potential, long term creep, and interface shear, among many. One of the difficulties with performance tests is that they may require a long time to complete. An example is determining the long term creep characteristics of a geosynthetic. The method for accelerated compressive creep of geosynthetic materials based on time-temperature superposition using the stepped isothermal method allows the determination of the very long time creep characteristics (1000-10,000 hours) in a relatively short period of time.

To assist in the use of the test standards a number of guides and practices have also been developed by D35. Examples of these, besides the sampling one mentioned above, include practices for determining the 2% secant modulus for polyethylene geomembranes, evaluating the deterioration of geotextiles from outdoor exposure, quality control of geosynthetic clay liners, determining the specification conformance of geosynthetics and the installation of geocomposite pavement drains. Examples of guides which have been developed include selection of test

methods for prefabricated vertical drains, acceptance testing requirements for geonets and geonet drainage composites, the storage and handling of geosynthetic clay liners, the mechanical attachment of geomembranes to penetrations and structures, the identification, storage and handling of geosynthetic rolls and samples, and the use of expanded polystyrene geofoam in geotechnical projects, among several others.

The last area of standardization that the committee started to work in was the development of standard specifications for the various geosynthetic materials. While there was an initial resistance to move into this area it was realized that in order to complete the loop in standards development, this was a necessary step to take. Examples of specifications developed thus far include circular-knit geotextile for use in subsurface drainage applications, geocomposites for pavement edge drains and other high flow applications, prefabricated bituminous geomembranes used as canal and ditch liners, non-reinforced PVC geomembrane seams, non-reinforced PVC geomembranes used in buried applications, geosynthetic alternate daily covers, and rigid cellular polystyrene geofoam.

For those who may not be familiar with the ASTM International protocol for developing and approving standards a brief summary follows. In D35 each subcommittee has a number of task groups (TG) which work on individual standards. Once agreement has been reached in the TG, the draft is sent to a subcommittee ballot. Each individual member of the subcommittee receives a ballot and can vote on the draft. While each organization that is represented on the committee can have as many members on the committee as they want, only one member has the official vote. There must be a 60% return of official votes for the ballot to be valid. That said any negative vote or comment received from any individual member has to be addressed and resolved. Once all issues are addressed and resolved at the subcommittee level, the draft is sent to a Main Committee ballot. The same protocols rule at this level as at the subcommittee level. Due to space limitations this paper cannot go into the specifics of how resolution can be made, but in summary the following actions can be taken: 1) Agree with the voter and re-draft the standard and re-ballot; 2) After discussion with the negative voter explaining why the draft is written as it is, the voter may withdraw his/her negative vote; 3) The negative voter may be found non-persuasive for a valid technical reason. In this instance the recommendation must be upheld at the subcommittee and/or Main Committee; 4) The decision may be made that the issues are too numerous or complex and the draft withdrawn from consideration. While this may sound like a cumbersome procedure, it insures that all concerns are heard and addressed in a fair manner resulting in the best standard that can be developed at that time.

Since its very beginnings the activities of D35 and its predecessors have received excellent administrative support from ASTM staff at all levels. These include: Jim Thomas, current President of the Society, who served as the D13 Staff Manager when the activities first got underway; Ken Pearson, current Senior Vice President of Operations, served as the staff manager to D18 when D18 first was involved; Bob Morgan, the current Staff Manager to D18; Janet Bove, the first Staff Manager to D35; Jamie Kerr, past Staff Manager to D35; Bob Held, past Staff Manger to D35, Pat Picariello, past Staff Manager to D35; Christi Sierk, past Staff Manger to D35; and Katerina Koperna, current D35 Staff Manager.

Besides staff support, ASTM has assisted D35 in standards development through various one hour training workshops which are available to all ASTM International members. One particular training opportunity is a two day leadership workshop, while open to all ASTM International members, has assisted D35 members to become leaders within the Committee and their respective organizations.

One of the primary activities of the Committee beyond standards development has been technology transfer through informal workshops and formal symposia. The first years of D13.61 and D13.61/D18.19 were filled with workshops where technical and marketing people shared their activities and needs in the area of testing. These workshops have provided, and continue to provide, excellent exchange of practices and concepts. Since the establishment of Committee D35 there have been countless committee sponsored “workshops” focusing on specific geosynthetic issues. These workshops bring together interested D35 and non-D35 members to accelerate resolutions to difficult technical issues and advance the understanding of difficult methodologies in geosynthetic standards development.

Since its organization in 1984 D35 has sponsored ten formal symposia. Nine of these have resulted in a formal Standard Technical Publication (STP) of the papers presented. These symposia include:

1985 – Los Angeles, CA – Joseph Fluet, Organizer and STP Editor; “Geotextile Testing and the Design Engineer (STP 952 – 11 papers)

1989 – Orlando, FL – Ian Peggs, Organizer and STP Editor; “Geosynthetics: Microstructure and Performance (STP 1076 – 13 papers)

1990 – Las Vegas, NV – Robert M. Koerner, Organizer and STP Editor; “Geosynthetic Testing for Waste Containment” (STP 1081 – 26 papers)

1993 – San Antonio, TX – Robert G. Carroll, Jr. and Jonathon Cheng, Organizers and STP Editors; “Geosynthetic Soil Reinforcement Testing Procedures” (STP 1190 – 17 papers)

1995 – Denver, CO – Shobia Bhatia and L. David Suits, Organizers and STP Editors; “Geotextile Filters and Prefabricated Drainage Geocomposites” (STP 1281 – 15 papers)

1996 - Atlanta, GA – Larry Well, Organizer and STP Editor; “Testing and Acceptance Criteria for Geosynthetic Clay Liners (GCLs)” (STP 1308 – 18 papers)

1999 – Memphis, TN - Peter Stevenson, Organizer and STP Editor; “Grips, Clamps, and Strain Measurements” (STP 1379 – 12 papers)

1999 – Seattle, WA – Jim Goddard, John Baldwin, L. David Suits Organizers and STP Editors; “Testing and Performance of Geosynthetics in Subsurface Drainage,” jointly

sponsored by D35, D18 and the Transportation Research Board Committees on Subsurface Drainage, and Geosynthetics (STP 1390 – 9 papers)

2003 – Denver, CO - Robert Mackey and Kent Von Maubeuge, Organizers and STP Editors; “Advances in Geosynthetic Clay liner Technology: 2nd Symposium” (STP 1466 – 10 papers)

2012 – San Diego, CA – Kent Von Maubeuge, Organizer and STP Editor; “Current and Future Practices for the Testing of Multi-Component Geosynthetic Clay Liners” (There has been no STP number assigned as of the writing of this paper.)

The real progress of the D35 standards development has come from the many members who have taken on a personal objective to achieve the development of a standard. Some have accomplished this many times through the past three decades. The highest award given out by ASTM to recognize outstanding contributions to the Society is the Award of Merit. Committee D35 has had nine recipients of this award. They include: L. David Suits (1986), Robert Carroll (1987), Jack Hodge (1988), Barry Christopher (1990), Ronald Frobel (1992), Robert Koerner (1994), Robert Mackey (2003), James Goddard (2009), and Sam Allen (2010). Along with the award goes the title of Fellow of ASTM.

The Committee has recognized many others through Committee sponsored awards for their work in developing D35 standards. The names are too numerous to try and list here.

The current Committee Officers and Technical Subcommittee Chairs are:

Chairman – Robert Mackey

1st Vice Chairman – Tim Bauters

2nd Vice Chairman – James Goddard

Recording Secretary – Mark Wolschon

Membership Secretary – James Olsta

Subcommittee D35.01 on Mechanical Properties – Joel Sprague, chairman

Subcommittee D35.02 on Endurance Properties – George Koerner, chairman

Subcommittee D35.03 on Permeability and Filtration – Dave Suits, chairman

Subcommittee D35.04 on Geosynthetic Clay Liners – K. Von Maubeuge and J.P. Kline – co-chair

Subcommittee D35.05 on Erosion Control – Vacant as of the writing of this paper.

Subcommittee D35.10 On Geomembranes – Gary Kolbasuk – chairman

Past chairmen of D35 include: Barry Christopher (1984-1989); L. David Suits (1990-1995; 1998-2003); David Wyant (1996-1997); Sam Allen (2004-2009); Robert Mackey (2010-present).

In an effort to help people become familiar with the D35 standards the committee has been offering a one day short course highlighting many of our standards that are published in the ASTM International Book of Standards. These sessions have been offered over the last several years at the geosynthetics conferences held in North America.

The D35 Committee has been excellent doorway for those new to the geosynthetic field, allowing them to learn the latest technical knowledge and make professional contacts within geosynthetic organizations. Many of the current experts and leaders within the geosynthetic field have started their careers and found opportunities for growth and leadership through their involvement within D35.

In conclusion: As new geosynthetics and new applications are developed, the work of D35 will continue. However, it will not only continue in the development of new standards, but in maintaining the current standards to keep them relevant to the needs of the geosynthetics community. All ASTM International standards must be reviewed at least every five years, and actions taken to; 1) reapprove as is; 2) revise to bring them up to date with current practices at the time, or; 3) withdraw as no longer relevant.

ACKNOWLEDGEMENTS

The author wishes to thank Robert G. Carroll, Jr., Barry Christopher and Robert Mackey for providing reviews and suggestions for this paper.

THE GEOSYNTHETIC INSTITUTE'S BACKGROUND AND HISTORY

Robert M. Koerner
Geosynthetic Institute, Folsom, PA USA

ABSTRACT

Most histories of people, places and things (like organizations) are chronologically subdivided between watershed events. This history of the Geosynthetic Institute is written along similar lines. The very sporadic beginnings in the late 1970's until 1986 is the first section to be described. Indeed, the year 1986 was pivotal in a number of ways. The second period from 1987 to 1998 was most important in establishing ourselves as the premier geosynthetics research and development organization on a national and international basis specializing on all types of geosynthetics and in all of their myriad applications. The third period from 1999 to the present represents a segue from the institute being focused completely on R & D, to related activities such as broad-based information, professional education, laboratory accreditation, inspection certification, along with the requisite R & D projects.

Now after these 35-years we approach the fourth period which is indeed the future. In this regard we offer some "musings" as to what it might portend for GSI and by association for geosynthetics in general.

INTRODUCTION

This paper reviews about 35-years of involvement in the area now known as geosynthetics materials and applications in discrete stages. They are as follows:

- 1.0 The beginnings through 1986 which include personal events leading to the formation of the Geosynthetic Research Institute within Drexel University
- 2.0 The time from 1987 through 1998 in which we mainly performed federal agency (U.S. EPA and U.S. FHWA mainly) projects and established ourselves accordingly.
- 3.0 The time from 1999 to the present in which we reconfigured ourselves to a full-service institute servicing its membership to the maximum extent possible.
- 4.0 The future beyond 2013 which is, of course, conjecture but will likely bring about entirely new applications areas (using existing or yet-to-be-developed products and materials) and is indeed exciting. We will use our "crystal-ball" to anticipate such activities. Only the future will tell how close we come to these predictions.

1.0 BEGINNINGS THROUGH 1986

Bob Koerner having received his doctoral degree in Geotechnical Engineering from Duke University in 1968, at age 35, started his academic career at Drexel University later than most beginning assistant professors. The Dean of Engineering at Drexel at the time, George Dieter, more than suggested that he get his research activity in high-gear and without delay. This was done over the next approximately ten years working in multiple (but unconnected) areas of deep

foundations, powder metallurgy, pharmaceutical powders, coal briquetting, acoustic emission monitoring, soil grouting, ground penetrating radar, and eventually pond liners and filter fabrics. Bob published over a hundred technical papers in this ten-year period before geosynthetics (many with U.S. EPA sponsorship under John Brugger and many co-authored with physics colleague Art Lord) and rose through the academic ranks to full professor in 1975.

The last two items in the above list of project areas came about from several consulting projects; namely, an architectural pond liner and a clogged geotextile erosion control mattress. This latter situation eventually generated several papers on geosynthetics in the late 1970's. The activity also stimulated a small research collaboration with Frank Ko of the Philadelphia College of Textiles and Science which resulted in more technical papers and the development of some specialized laboratory testing equipment.

In this same time frame Bob was also inviting speakers to make classroom presentations and two were memorable; Bill Witherow of Carlisle Rubber Co. and Bill Regan of Mirafi, Inc. (now TenCate Geosynthetics Inc.). They both gave informative in-class presentations to his graduate foundations course and opened up in his mind the opportunities within the emerging technology.

The real break came, however, when a Wiley Book Company editor Dan Morris asked Joe Welsh, a grouting contractor colleague, to write a small nomograph on construction fabrics. Joe didn't have time but suggested that Bob did. Bob initially thought that there wasn't enough published information on the topic but shortly thereafter the proceedings of the 1977 Paris Conference on the "Use of Fabrics in Geotechnics" became available. Bob called Dan and said that we would indeed write such a book. Thus, the 1980 first book on the subject became available; see Figure 1. It was an instant success and the phone "simply never stopped ringing".

Figure 1. The first book on geosynthetics (Koerner and Welsh, 1980).

The impact of the book was so strong that all other research was halted and full concentration focused on this emerging area. Industrial contracts from Crown Zellerbach, Tensar, Mirafi and DuPont were the first of many and very soon a small research group was formed at Drexel. At this time the group was working out of the soils laboratory at Drexel which was well equipped soils-wise since Bob had developed a three-term graduate level soils laboratory sequence. As with all soils labs, they are inherently dirty and a somewhat clean area was desired for this new polymer related work. Also, there was no privacy and other facility and students had no inhibition of “borrowing” from our well-stocked equipment and hardware. In 1982, the small group moved into an enclosed room (about 30 by 20 feet) within the structures laboratory. The structures facility were not happy by this intrusion, but we had research money and were not to be denied; see Figure 2.

Yet, not all was smooth-sailing. Allen Halliburton of Oklahoma State University reviewed the book shown in Figure 1 with the awkward comment that “here is the salad, but where is the meat-and-potatoes”. Of course, this type of challenge led to a better and more comprehensive book which was stimulated by conversation with Dick Bell of Oregon State University and Jean-Pierre Giroud of Woodward-Clyde Consultants (now URS Corp.). In 1984, we had just finished team-teaching a course on what was now known as geosynthetics at the University of Wisconsin. The idea that was proposed was to put together a joint set of notes which would form the basis of a new book. As it turned out, Jean-Pierre was discouraged by his company and Dick was having difficulty in finishing his federal highway grant on geotextiles. Therefore, Bob persisted alone and in 1986 published the first edition of the meat and potatoes textbook, “Designing with Geosynthetics”. Four major items converged with its publication in 1986. First, in this pivotal year of 1986, Drexel’s President, William Gaither, called together the engineering faculty to encourage the faculty to develop centers and institutes, as opposed to doing independent consulting. Bob jumped on the opportunity and posed to him that we needed unique and automatous space (which was readily located) to which he countered that we weren’t to get him in trouble and no financial assistance was to be forthcoming from Drexel, i.e., we had to do it on our own!

Second, we moved from our one-room operation in the main engineering building to the West Wing of the Rush Building on Drexel’s campus, see Figure 3. The group consisted of Bob Koerner, Grace Hsuan (then an Assistant Professor of Civil Engineering and fortunately for us a polymer expert), Art Lord (a Professor of Physics and long-time faculty colleague), Marilyn Ashley (who started as Drexel’s civil engineering department secretary shortly after high school in 1973 and moved and then remained with us throughout our total experience), a new employee named Paula Koerner as a clerk/accountant, and a superb group of graduate research assistants including (most of all) George Koerner then working on his doctoral research.

Third, is that we incorporated as the Geosynthetic Research Inc. on August 12, 1986 (to be modified into Geosynthetic Research Institute on March 3, 1989 and eventually to the Geosynthetic Institute on December 16, 1991).

(c) The third floor hydraulics laboratory

Figure 3. Home of GRI in the West Wing of the Rush Building on Drexel's campus from 1986 to 1998.

Fourth, with the brand-new *Designing With Geosynthetics* book we “went on the road” teaching two-day courses. Manfred Hausmann of Australia was on sabbatical leave and handled the Drexel courses for Bob, and Paula did all of the logistics (books, slide trays, hotels, registration, lunches, breaks, etc., etc.) in the following cities.

1. September 4-5, 1986, Washington, DC
Sheraton, New Carrollton, MD
2. September 17-18, 1986, Atlanta, GA
Sheraton, Century Center I-85
3. September 23-24, 1986, Raleigh, NC
Sheraton, Crabtree, SC US 70W
4. October 8-9, 1986, Dallas, TX
Sheraton Grand at DFW Airport
5. October 14-15, 1986, Houston, TX
Sheraton Town & Country I-10
6. October 29-30, 1986, San Francisco, CA
Sheraton Airport, Burlingame
7. November 3-4, 6, Los Angeles, CA
Sheraton Industry Hills
8. November 19-20, 1986, Chicago, IL
Sheraton North Shore, Northbrook
9. November 24-25, 1986, St. Louis, MO
Sheraton Plaza I-270

All of these two-day courses were well attended and helped immeasurably in establishing GRI in the eyes of the fledgling geosynthetics communities. Most notable was the San Francisco course in which Bob Landreth of the U.S. Environmental Protection Agency and Henry Haxo of Metrecon Inc. were in attendance. This gave us not only credibility but also access to EPA funding. In turn, conducting the various projects brought involvement with the consulting and manufacturing communities with the eye of eventually forming a consortium of member companies.

By the end of 1986 all of the pieces of the institute were in place to be acted upon accordingly.

2.0 TIME FRAME FROM 1987 THROUGH 1998

This eleven-year period is subdivided accordingly to major activities undertaken as the Geosynthetic Research Institute, or GRI, functioning out of the West Wing of the Rush Building on Drexel University’s campus; recall Figure 3.

2.1 Formal Courses at Drexel

According to Drexel’s definitions, “centers” are focused on research only, while “institutes” perform research and also have an associated curriculum. Being an institute, we crafted a master’s degree program specializing in geosynthetics engineering. It consisted of ten, three-credit, term long courses in geosynthetics and it was complimented by electives and math

requirements. Additionally, theses on geosynthetics topics were often selected by the students as electives.

Table 1 – Master of Science in Civil Engineering – Special Program in Geosynthetics Engineering

Fall	Winter	Spring
1. Geosynthetic I (CIVE 650) (geosynthetics overview and geotextiles)	Geosynthetics II (CIVE 651) (geogrids, geonets and geomembranes)	Geosynthetics III (CIVE 652) (GCLs, geopipes and geocomposites)
2. Polymer Properties (CIVE 790) (physical, chemical and mechanical properties)	Polymer Processing (CIVE 791) (polymerization and processing of geosynthetics)	Polymer identification (CIVE 792) (chemical test methods and fingerprinting of geosynthetics)
3. Math Requirement	Math Requirement	Perspectives in Geosynthetics (CIVE 790-571)
4. Elective Sequence I	Elective Sequence I	Elective Sequence I
5. Elective Sequence II	Elective Sequence II	Elective Sequence II

Bob Koerner taught the Geosynthetics I, II, II and Perspectives courses while Grace Hsuan taught the three polymer related courses. The program was quite popular and many of the students taking this program have made their careers in geosynthetics, a fact of which we are very proud. Incidentally, Paula Koerner was given her nickname “GeoMom” from this group of students during this period of time.

2.2 Funded Research

Obviously, these students functioning as research assistants (or R.A.’s) needed financial sponsorship and we were fortunate in soliciting grants from several federal agencies (mainly the U.S. EPA) and others as well. Table 2 presents the main contracts in this regard.

Table 2 – Major Sponsored Research Projects

Sponsor	Topic	Date	Co-PIs with Bob	Amount
EPA	Geomembrane Lifetime	1983-86	A. E. Lord	\$ 190,000
EPA	Geosynthetics in Landfills	1987-92	A. E. Lord	450,000
EPA	Biological Clogging of Filters	1988-93	G. R. Koerner	600,000
EPA	Stress Cracking of HDPE	1989-93	Y. G. Hsuan	600,000
NCHRP	Performance of GS Drains	1990-93	G. R. Koerner	500,000
PaDOT	Geogrid Design Methods	1991-92	R. Wilson-Fahmy	50,000
EPA	QA/QC of Geosynthetics	1992-93	D. E. Daniel	80,000
EPA	Performance of Landfills	1993-00	D. E. Daniel and R. Bonaparte	1,000,000
NSF	Lifetime Prediction of GSs	1994-01	Y. G. Hsuan	170,000

The heavy funding from the U.S. Environmental Protection Agency is noteworthy in the previous table and it was due to our close association with Robert E. Landreth. Bob was the Chief of the Municipal Solid Waste and Residuals Management Branch of EPA located in Cincinnati, Ohio. Our association was very close since we represented the engineering counterpoint to Henry Haxo (a research chemist) who did all of the early research on

geomembranes and their compatibility to various leachates. After Henry retired, GRI “inherited” the bulk of EPA’s solid waste landfill research activity. In addition to the research, there were numerous EPA conferences and workshops in EPA’s headquarters in Cincinnati; all of which we had a heavy commitment. They included, but were not limited to, the following:

- Two conference workshops on geomembrane installation
- Two conference workshops on QA/QC of geosynthetics
- Three conference workshops on geosynthetic clay liners
- Two traveling seminars to all ten EPA Regions

Regarding this last item, some additional detail is warranted due to its importance in spreading the research and related technology to the regulatory community. The following description is taken from a paper by Greg Richardson (then with S & ME, Inc. and later a consulting engineer) entitled “GRI – The Beginnings” written and delivered at a 2004 Symposium Honoring the Research Achievements of Robert M. Koerner at Drexel University and published accordingly.

“After completion of the EPA design manual in the fall of ’87, Bob and Greg were asked to prepare a portion of a manual for a training course to be held in each of the EPA regions. These courses were free to attend and open to EPA staff, state regulators, engineers, owners, etc. The course format was quickly established: David Daniel of the University of Texas at Austin would present clay liner design and placement considerations, Bob Landreth would discuss chemical compatibility of liners, Greg would discuss liner design, final cover design, and liner inspection, while Bob discussed leachate collection and long-term considerations. During the summer of ’88, courses were held in San Francisco, Seattle, Dallas, Chicago, Denver, Kansas City, Philadelphia, Atlanta, New York, and Boston. With attendance ranging from 400 to over 600, we were overwhelmed with the response.

EPA monitored the effectiveness of the courses by having the audience rate the speakers and provide comments. While Dave, Bob, and Greg had comparable weighted averages for scores, Greg alone attracted the outliers. Each night, as we flew to the next course, Dave and Bob would read to our fellow passengers selected comments from the outliers regarding Greg. With such comments as “should not be allowed in public”, “a danger to the global environment”, etc., Greg relied on bourbon to counter the stares of fellow passengers. Comments too obscene to be read were passed from aisle to aisle; the lack of in-flight movies was not noticed by anyone except Greg.

Allowing two years for the dust to settle, Bob Landreth organized a second national course series focused of landfill closures. This was precipitated by the significant number of Superfund and CERCLA closures of sites contaminated by historic industrial/municipal actions. Paul Schroeder (of the U.S. Army Corps of Engineers) joined our team to discuss the HELP model but proved to be ineffective at deflecting the outliers from Greg. As we moved from Atlanta, Philadelphia, Boston, Dallas, Kansas City, Denver, Newark, Chicago, Seattle, and Oakland during the summer of 1990, Bob and Dave presented “Outliers – Part II” to the traveling public.

Approximately 10,000 people attended these two series of national EPA courses and for most this was their first exposure to geosynthetics and landfill design procedures. Even more than a decade later, it is rare to meet with a regulatory group regarding a landfill that someone in the group has not attended one of these courses.”

The importance of these two series of twenty lectures cannot be overstated. It put all of us speakers (and with it GRI) in the spotlight with respect to landfill, surface impoundment and waste pile design and construction. Figure 4 shows the group, but doesn’t nearly show the camaraderie and sheer joy we had being together and thus becoming life-long fiends.

2.3 Technical Research Publications

With extremely active and ongoing academic courses and research projects, the usual academic *publish or perish* mantra was very easy to embrace. We looked forward to spreading-the-word of this quite new field of geosynthetics. In order to form a contrast within the various time-frames of this paper we group the various publications accordingly; see the shaded portion of Table 3.

Here it is seen that the publications increased dramatically after the 1979-1986 time period in all of the different categories. Of course, almost everything was new and the various requests were abundant. After this intermediate period from 1987 to 1998, the activity remained strong, but a clear shifting from journal articles to proceedings papers is noted. People wanted the information as soon as possible and the peer-review scrutiny of journal articles simply took too long.

Table 3 – General Statistics on GRI/GSI Geosynthetic Publications

Type	1979-1986	1987-1998	1999-2012
Books, Proceedings, and Major Reports	2	32	38
Journal Papers and Keynote Papers	7	63	26
Conference Proceedings Papers	20	65	108
Major Articles and Proprietary Reports	10	62	112
TOTALS	39	222	284

Robert E. Landreth; U. S. EPA

Davie E. Daniel; Univ. Texas at Austin

Robert M. Koerner; Drexel Univ. & GRI

Gregory N. Richardson, S & ME, Inc.

Figure 4. Team of speakers at the 1988 and 1990 U. S. EPA region workshops on liner and cover systems.

2.4 Professional Courses

Since very few universities and colleges teach even a single course in geosynthetics (at its peak only 15 did so and considering that there are about 600 engineering universities and colleges in America that's only 3.3%), professional courses ranging from 4 hours to 3 days duration were regularly offered and invariably well received. Using the time increments described in this paper, the following table applies.

Table 4 – General Statistics on GRI/GSI Geosynthetics Professional Courses

Sponsor	1979-1986	1987-1998	1999-2012
Professional Organizations	14	21	4
Conference Organizations	2	6	6
GRI/GSI Hosted	4	45	66
Agencies	1	40	3
Universities	2	11	2
Companies	5	24	2
Others	2	1	2
TOTALS	30	148	85

The most active time period was from 1987-1998 when 148 geosynthetics courses were presented. Within this period only 45 of the 148 (30%) were offered at GRI since we were quite constrained space-wise. This changed dramatically in the next time period when we moved to new facilities with conference space and better all-around logistics. Also noted is that we were invited to speak at many state agencies, no doubt stemming from the U.S. EPA seminars mentioned earlier. Other than those estimated 10,000 people, a crude guess is that we reached an additional 5,000 participants with the above listed courses.

2.5 The GRI/GSI Consortium

Having such a close association with federal agencies like EPA, it was somewhat natural that the entire geosynthetics community would be interested in us. Thus, the idea of forming a consortium was discussed with, among others, Greg Richardson who greatly encouraged the idea. A visit to the Textile Research Institute at Princeton University gave the idea of creating a very broad institute including agencies, owners, designers, testing laboratories and manufacturers, and eventually resin/additive suppliers, and contractors/installers as well. While some of the generated data and research findings would not be to the liking of all groups, once decided upon everyone would be *onboard*. We decided to start beginning in 1987 with an initial membership fee of \$15,000 per year (\$10,000 per year afterward) and had an immediate response. Organizations joining in the first year were as follows:

1. Gundle (now GSE)
2. Soil and Materials, Inc.
3. U.S. EPA
4. Polyfelt (now TenCate)
5. Waste Management Inc.
6. Hoechst Fabrics Co.
7. Browning Ferris Ind. (now WMI)
8. Monsanto Inc.
9. E. I. duPont Co.
10. Golder Assoc.
11. Mirafi (now TenCate)
12. Tensar Inc.
13. U. S. FHWA

To date, we have had 119 member organizations (of which 53 have remained throughout) and an additional 18 associate members which are state or federal agency related. The latter are at the reduced membership rate of \$1,000 per year whereas membership is now at \$10,000 per year and has never been increased! A current listing of the membership is on our website at www.geosynthetic-institute.org. Needless to say, we are deeply appreciative of this past and ongoing member and associate member support.

In this time period from 1987 through 1998 considerable structure to the institute's operations was being formed:

- A home page was developed and maintained.
- Annual meetings were held.
- Focus groups of like-minded organizations were formed and held accordingly.
- GRI Standards for test methods, guides, practices and specifications were developed.
- Separate specification group meetings were held.
- Traveling seminars to member locations were regularly given.
- A quarterly Newsletter/Report was generated.
- An annual GRI conference was formed.

2.6 The GRI Conferences and Proceedings

Since research results should be available to the members as soon as possible, an annual research conference was initiated in 1986. For the first sixteen years it was held at a nearby Philadelphia hotel, but eventually it went to various locations-of-opportunity where other events were being held. Different from other conferences, the idea of having a specifically targeted conference theme was implemented. Thus, the GSI conferences have always been a tutorial-of-sorts, and included presentations from all member organizations, not only GRI personnel. Conferences to date and their themes have been as follows:

GRI-1 (1987)	“Soft Soil Stabilization Using Geosynthetics”
GRI-2 (1988)	“Durability and Aging of Geosynthetics”
GRI-3 (1989)	“The Seaming of Geosynthetics”
GRI-4 (1990)	“Landfill Closures: Geosynthetics, Interface Friction and New Developments”
GRI-5 (1991)	“Geosynthetics in Filtration, Drainage and Erosion Control”
GRI-6 (1992)	“MQC/MQA and CQC/CQA of Geosynthetics”
GRI-7 (1993)	“Geosynthetic Liner Systems: Innovations, Concerns and Designs”
GRI-8 (1994)	“Geosynthetic Resins, Formulations and Manufacturing”
GRI-9 (1995)	“Geosynthetics in Infrastructure, Enhancement and Remediation”
GRI-10 (1996)	“Field Performance of Geosynthetics and Geosynthetic Related Systems”
GRI-11 (1997)	“Field Installation of Geosynthetics”
GRI-12 (1998)	“Lessons Learned from Geosynthetic Case Histories”
GRI-13 (1999)	“Geosynthetics in the Future: Year 2000 and Beyond”
GRI-14 (2000)	“Hot Topics in Geosynthetics I: Bioreactors, GCLs, SRWs, Industry Issues”
GRI-15 (2001)	“Hot Topics in Geosynthetics II: Peak/Residual, RECMs, Installation, Concerns”

- GRI-16 (2002) “Hot Topics in Geosynthetics III: Probability, Landfill Uses, Poor Backfill, Concerns”
- GRI-17 (2003) “Hot Topics in Geosynthetics IV: MSE Properties, Geotextile Tubes, Challenges, Opportunities”
- GRI-18 (2004) “Geosynthetics Research and Development In-Progress”
- GRI-19 (2005) “Sessions on Low Permeability Backfill Soils, Heap Leach Systems and Various Hot Topics”
- GRI-20 (2007) “Use of Geosynthetics to Combat or Mitigate Acts of Terrorism and/or Natural Disasters”
- GRI-21 (2008) “Geosynthetics in Agriculture and Aquaculture”
- GRI-22 (2009) “It’s All in the Details”
- GRI-23 (2010) “Geosynthetic Materials Durability: Field and Laboratory Experiences”
- GRI-24 (2011) “Optimizing Sustainability Using Geosynthetics”
- GRI-25 (2013) “25-Year Retrospectives on the Geosynthetic Industry and Glimpses Into the Future”

The GRI Conferences (consisting mainly of GRI personnel and GRI member speakers) were always action-packed, informative, innovative and dynamic. The core group assembling and coordinating them are shown in Figure 5a. The conference proceedings form a data base of great value and, while not widely distributed, have us referencing the information on a regular basis. Among stand-out events were the hospitality sessions with the largest shrimps imaginable (thanks to National Seal Corp.) and the after-conference critique of all speakers with a grading system that sometimes boarded on *brutal*. The reviewers were invariably the best-in-the-business.

The brochure from the first GRI Conference in 1987 on “Soft Soil Stabilization Using Geosynthetics” follows, along with a photograph taken during the associated field trip.

Figure 5a. Bob Koerner, Paula Koerner, Grace Hsuan, Marilyn Ashley, Jamie Koerner, George Koerner and Te-Yang Soong taking a break from GRI conference organizing.

Very Soil Soil Stabilization Using High Strength Geosynthetics

Thursday, October 22, 1987

Friday, October 23, 1987

- 6:00 Registration**
Creeese Student Center, 32nd and Chestnut Streets, Philadelphia, PA
Lobby of Room 101
- 9:00 Welcoming Remarks**
- Dr. R. W. Schneider, VP Research, Drexel University
 - Dr. R. E. Woodring, Dean of Engineering, Drexel University
- 9:15 Session I - Design**
- J. Fowler, Corps of Engineers, Vicksburg, MS
"Overview and Perspectives"
 - R. M. Koerner, Drexel University, Philadelphia, PA
"Current Design Methods"
 - R. K. Rowe, University of Western Ontario, Ontario, Canada
"Finite Element Methods"
 - J. F. Beech, GeoServices Inc., Boynton Beach, FL
"Time-Dependent Strength Behavior"
 - Short Papers and Open Forum
- 12:30 Lunch**
- 1:30 Session II - Details**
- F. Ko, Drexel University, Philadelphia, PA
"Seaming and Joining Methods"
 - R. D. Holtz, Purdue University, W. Lafayette, IN
"Vertical Strip Drains"
 - A. E. Lord, Jr., Drexel University, Philadelphia, PA
"Centrifuge Methods"
 - G. N. Richardson, Soil and Material Engineers, Inc., Raleigh, NC
"Testing and Monitoring"
 - Short Papers and Open Forum
- 4:00 Actual Testing of High Strength Fabrics and GRI Open House**
- 7:30 Dinner**

- 8:00 Session III - Manufacture and Construction**
- P. Pisseeuw, Enka, b.v., Holland
 - G. Willibey, Nicolon Corp., Atlanta, GA
 - B. Myles, ICI, England
 - R. Mattox, Tensar Corp., Atlanta, GA
 - Short Papers and Open Forum
- 11:30 Session IV - Field Trip (with Box Lunch)**
- B. Ulbell, S. Fritzing, Corps of Engineers - Overview of Wilmington Harbor Project
- 12:15 Session IV - Field Trip**
- R. V. Locurcio, LTC Corps of Engineers, Philadelphia, PA
(Bus to Wilmington, Delaware to view installation of sewn 1500 lb/in (260 kN/m) fabric placed off a floating barge in 10' (3 m) deep water with a dike built on top of it. Project is 3.2 miles (5.2 km) long and 600' (180 m) wide with strip drains for accelerated consolidation. Truly a fantastic project! Return bus to Philadelphia International Airport or Sheraton Hotel.)

Figure 5b. Bao-Lin Hwu, John Bowders, Bob, COE Inspector and Jack Fowler at Wilmington Harbor field trip during the first GRI conference.

2.7 The GRI Proprietary Reports

In trying to attract and maintain members, we felt that something of proprietary value should be offered. In this regard R & D reports, which are only accessible on the password protected portion of our website, seemed worthwhile. These reports are purposely kept out of general circulation for at least two years and then only disseminated on a piecemeal basis. They are as follows:

1. March 20, 1988, "Environmental Stress Cracking of HDPE Geomembranes Seams and Related Studies"
2. December 7, 1988, "A Quantification and Assessment of Installation Damage to Geotextiles"
3. June 27, 1989, "Biological Clogging of Geotextiles Used as Landfill Filters"
4. June 21, 1990, "The Photo-Initiated Degradation of Seven Nonwoven Needle Punched Geotextiles"
5. October 1, 1990, "Finite Element Modeling of Soil-Geogrid Interaction with Application to the Behavior of Geogrids in Pullout Loading Condition"
6. June 18, 1992, "Parametric Evaluation of Primary Leachate Collection System Behavior Using the "HELP" Model"
7. December 9, 1992, "Geotextile Specifications for Transportation Applications: GRI's Second Survey"
8. December 9, 1992, "Stability Analysis of Multilined Slopes in Landfill Applications"
9. June 24, 1993, "Stress Cracking Behavior of HDPE Geomembranes and its Prevention"
10. July 27, 1993, "Experimental Puncture Behavior of HDPE Geomembranes Without, Then With, Various Protection Materials"
11. August 10, 1993, "A Survey of State Municipal Solid Waste (MSW) Liner and Cover Systems"
12. June 22, 1994, "FEM Behavior of Analysis of Plastic Pipe at High Normal Stresses"
13. September 26, 1994, "Design Methodology for Geomembrane Protection Materials"
14. February 3, 1995, "Drainage to Retaining Structures Using Geocomposite Sheet Drains: The State-of-the-Practice in the USA"
15. July 5, 1995, "Leachate Clogging Assessment of Geotextile and Soil Landfill Filters"
16. December 11, 1995, "Long Term Durability of HDPE Geomembranes Part I - Depletion of Antioxidants"
17. June 17, 1996, "Behavior of Waves in High Density Polyethylene Geomembranes"
18. December 9, 1996, "Cover Soil Slope Stability Involving Geosynthetic Interfaces"
19. June 17, 1997, "The Design of Drainage Systems Over Geosynthetically Lined Slopes"
20. June 18, 1998, "Earth Retaining Wall Costs in the USA"
21. December 7, 1998, "A Survey of Solid Waste Landfill Liner and Cover Regulations: Part I - USA Status"
22. December 18, 1998, "Analysis and Critique of Ten Large Solid Waste Landfill Failures"
23. March 30, 1999, "A Survey of Solid Waste Landfill Liner and Cover Regulations: Part II - World Wide Status"
24. July 30, 1999, "Geosynthetic Reinforced and Geocomposite Drained Retaining Walls Utilizing Low Permeability Backfill Soils"

25. December 20, 2000, "Installation Guide for Drainage Materials Associated With Segmental Retaining Walls (SRWs)"
26. August 1, 2001, "Field Monitoring and Laboratory Study of Geosynthetics in Reinforcement Applications"
27. January 9, 2002, "Internal Drainage of Low Permeability Backfill Soils of Geosynthetic Reinforced Earth Walls"
28. August 7, 2002, "A GRI White Paper on the Questionable Strategy of Soil-Only Landfill Covers" [Comment; white papers now form a core publication effort for the institute]
29. September 30, 2003, "Selected Papers on the Design Decision of Using Peak versus Residual Shear Strengths"
30. June 14, 2005, "Direct Shear Database of Geosynthetic-to-Geosynthetic and Geosynthetic-to-Soil Interfaces"
31. July 17, 2006, "Status of Adoption and Use of the AASHTO M288 Geotextile Specification Within U.S. State Departments of Transportation"
32. January 12, 2007, "GRI's Third Survey of Solid Waste Landfill Liner and Cover Systems: Part I - USA Status"
33. February 27, 2007, "Translational Failure Analysis of Solid Waste Landfills Including Seismicity"
34. October 24, 2007, "GRI's Third Survey of Solid Waste Landfill Liner and Cover Systems: Part II - Worldwide Status"
35. September 12, 2008, "Symposium Papers on Vegetated MSE Berms at Landfills"
36. October 15, 2008, "Inadequate Performance of Geotextile Filters Under Difficult and Challenging Field Conditions"
37. November 4, 2008, "Geosynthetic Supported Base Reinforcement Over Deep Foundations"
38. December 16, 2009, "A Data Base and Analysis of Geosynthetic Reinforced Wall Failures"
39. April 1, 2010, "Remediation of Excessively Deforming MSE Retaining Walls"
40. June 23, 2010, "On the Prevention of Failures of Geosynthetic Reinforced Mechanically Stabilized Earth (MSE) Walls and Recommendations Going Forward"
41. October 27, 2011, "Analysis and Critique of Twenty Large Solid Waste Landfill Failures"
42. January 3, 2012, "Lifetime Prediction of Laboratory UV Exposed Geomembranes: Part I - Using a Correlation Factor"

3.0 TIME FRAME FROM 1999 TO PRESENT

By 1999, the Geosynthetic Research Institute was well recognized nationally and internationally primarily as a research and development institute within, or associated with, an academic institution, namely Drexel University. However, the membership wanted more than R & D studies which invariably relied on students. Remember, the main goal of students is to finish and get on with their lives. The desirable *new dimensions* required a broadening of personnel and activities which brings into focus the third phase of this retrospective paper.

3.1 Legal Arrangements

Regarding various incorporations the following took place:

- August 12, 1986 “Geosynthetic Research Inc.” in Delaware (abandoned April 15, 2012)
- March 3, 1989 “Geosynthetic Research Institute” in Delaware
- December 16, 1991 “Geosynthetic Institute” in Delaware
- September 8, 1993 GSI Granted IRS 501 (C)(3) Status (i.e., we are a nonprofit tax-free organization)

In addition, trade (service) marks were acquired for the interrelated institutes now under a new configuration, i.e.,

- “Geosynthetic Research Institute”,
- “Geosynthetic Information Institute”,
- “Geosynthetic Education Institute”,
- “Geosynthetic Accreditation Institute”,
- “Geosynthetic Certification Institute”,

and, if ever needed, “The Journal of Geosynthetics”. This provided for the expanded structure of the institute as shown in Figure 6.

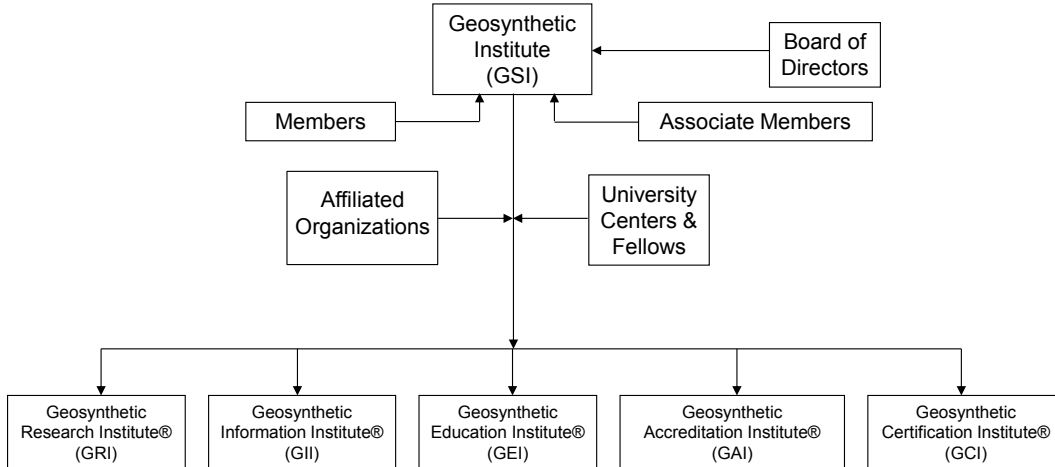

Figure 6. The organizational structure of the Geosynthetic Institute.

This organizational structure required a number of actions which took place immediately upon its formation. First, Bylaws were needed and they were developed and published on January 1, 1996. They have been slightly revised five times since then. Second, the Bylaws required a nine-person Board of Directors (BoD) which was selected on the basis of established focus groups plus acknowledgement of the growing international member organizations. Each BoD member serves for three years and the three groups of three are staggered annually. BoD members can repeat themselves. The names of the BoD members to date follow and we wish to gratefully acknowledge their service and guidance to the organization.

Third, the need and desirability of federal and state regulatory agencies was felt to be imperative. Discussions among the BoD eventually came to the conclusion that full membership at \$10,000 per year was not feasible, so a greatly reduced fee of \$1,000 was decided upon. To date, we have attracted six federal agencies, eleven state environmental agencies, four state transportation agencies and two city agencies. They are indeed welcome and their presence and collective inputs are very meaningful in every respect.

Fourth, it was recognized that geosynthetics are international (Geosynthetics-Without-Borders?) and that the institute's personnel and logistics are limited, so a special category of "Affiliated Organizations" was created. These are international government or academic institutes that are desirous of our information and wish to create a GSI-affiliated organization within their own country. Of course, all of our intellectual knowledge can be translated and used accordingly. To date, we have a GSI-Korea under the FITI Testing and Research Institute (Jeongyho Kim) and INHA University (Han-Yong Jeon), and also a GSI-Taiwan under the National Pingtung University of Science and Technology (C. Wayne Hsieh). Both are sincerely appreciated and very active.

Fifth, we have the ability to co-opt and coordinate activities with other universities on an as-required basis. To date, we have been involved with a research effort on plastic pipe with Drexel University (Grace Hsuan) a reinforced wall activity with the University of Delaware (Dov Leshchinsky) and a hydraulic structure waterproofing activity with the University of Texas at Austin (Jorge Zornberg). This activity is greatly augmented by the awarding of GSI Fellows which will be described later.

3.2 GSI's New Home

Operating from the West Wing of Drexel's Rush Building was not really suited for a rigorous plastics-related R & D institute and to the new activities which we planned; for example,

- it had erratic room air conditioners,
- it had no humidity control,
- it had regular squirrel-invasions,
- the security was poor (we had one burglary which Bao-Lin Hwu thwarted),
- it required lugging equipment up and down four flights of stairs,
- communications were difficult,
- there was no room for growth, and
- our rapidly growing neighbor, the College of Information Sciences, wanted us out!

It was really time for us to go and Jamie Koerner (George's wife) was perfect for finding us an off-campus home. Located beyond city limits and only four miles from the Philadelphia International Airport it was the former MRI center of a local hospital. Substantially built with a lot of potential laboratory space George Koerner reconfigured the entire building's 5000 sq. ft., single story building. The reception area for Marilyn Ashley was nicely configured as well as an adjacent area for Paula Koerner and Jamie Koerner. There is a perfect sized conference room capable of hosting up to 22-people and the final arrangements couldn't have been better if we had designed the building from scratch. It even has properly zoned space for expansion. Figure 7 shows photographs of our GSI home.

Figure 7. GSI's new home in Folsom, Pennsylvania.

3.3 Ongoing Research Activities at GSI

Research and development will always be a core activity of GSI and a number of projects have been carried-over to our new home. That said, our ideal research project is one which takes many, many years. Short term projects using standardized test methods are invariably shifted to the member consulting companies or testing laboratories. Research projects presently ongoing are the following. Note the estimated durations which are well beyond the time frame for graduating students.

- In-situ temperature monitoring of geomembrane liners and covers at both dry and wet landfills (15 years and ongoing).
- Flow behavior of leachate collection systems and fully degraded waste (7 years and recently concluded)
- Ultraviolet exposure of all types of geosynthetics in laboratory weathering devices (10 years and ongoing)
- Alkalinity between masonry blocks in MSE walls (7 years and ongoing)
- Forensic analysis of MSE wall failures and their remediation (12 years and ongoing)
- Forensic analysis of landfill failures (10 years and ongoing)
- Forensic analysis of geotextile filtration situations (15 years and ongoing)
- Forensic analysis of veneer slope slides (10 years and ongoing)
- Forensic analysis of all types of geosynthetic materials failures (30 years and ongoing)
- In-situ behavior of exposed geogrids of flexible faced MSE landfill berms (projected time is 50+-years)

An additional comment with respect to research has to do with the crafting of generic specifications for various classes of geosynthetics. This is a most difficult task since most companies seek conformance to their particular products while other groups seek ultimate safety against the unknowns. This middle ground balancing act has been reasonably successful with eleven complete specifications and another six in-progress. Those that have been adopted are available free on the institute's website. George Koerner describes details in a companion paper in these proceedings.

3.4 Ongoing Information Activities at GSI

From print-to-electronic formats, information generated from institute activities are split between that available to the general public and that available only to members. In fact, the institute's website (developed and maintained by Marilyn Ashley) is configured in this manner. Everyone (members and nonmembers) can access the open part at www.geosynthetic-institute.org, which has the following menu.

To go further one needs a members-only password. When you get into this section the following information is presented.

- GRI Standards (≈ 90)
- GRI Proprietary Reports (42)
- Citations of GRI Technical Papers (325)
- GSI Annual Meeting Notes
- Links to the Geosynthetics World
- Keyword Search for Literature
- Example Problems (from DwG book)
- Frequently Asked Questions (FAQs)

Note that the *links* section in the open part of the website is to GSI members, whereas the *links* section in the password protected section is to the entire geosynthetics world

The *Keywords Section* contains about 30,000 citations of the majority of the geosynthetics literature published in English. It's quite easy to use provided that you have a specific topic or area in mind. This is the section of the website that we (and others we are told) use the most used in our daily activities.

An interesting mechanism to broadcast information that is generally quite opinion-based is that of a *White Paper*. GSI has a special section of the home page devoted to this type of information outlet. There are presently twenty white papers, available to everyone, and they are of two types. One type is technical related (written by Bob and George Koerner) and the other is survey related (assembled by Jamie Koerner). These white papers are frequently visited and sometimes even referenced in technical papers which make us somewhat apprehensive. One has

to question the appropriateness of the action since many are opinion-based and all are without peer review. Nevertheless, they have served our needs as well as others quite nicely.

3.5 Ongoing Education Activities at GSI

Education, in its various forms is at the heart of all technologies and geosynthetics are no exception. That said, education has many forms. The 42-GRI Reports mentioned in Section 2.7 could easily be mentioned here as well. The 263 courses listed in Section 2.4 are directly related to education and now, more often than not, they are hosted at GSI where we can accommodate up to 22-people. Most are one-day long and having our laboratory in-house we (George and Bob) can go back-and-forth between lectures and related test demonstrations. It is a very effective format.

Obviously, power point presentations follow along with all projects and are shared with the membership. They number about 150 and most are about one hour in length. Some of the more current topics, like shale gas plays and coal combustion residuals, have short voice-overs on the individual slides.

All of these presentations are candidates for on-line webinars. Currently, eight are offered on a semiannual basis hosted by the American Society of Civil Engineers (ASCE). Their format is a noon to 1:00 PM presentation followed by 30 minutes of questions and answers. Some of these webinars have had as many as forty companies on line for the event.

Certainly the capstone of the institute’s education effort is embodied in the book titled “*Designing With Geosynthetics*”. Its sixth edition was published in 2012 and this latest version is available in hardback, or softbound and e-book. There is also a 1230 power point CD entitled “Instructors Guide”. The history of the various editions follows:

Table 6 – Publication History of the **Designing with Geosynthetics** 2012 Book

Edition	Published	Pages	Sales
First	1986	424	3197
Second	1990	652	2645
Third	1994	783	4686
Fourth	1998	761	5460
Fifth	2005	796	3500
Sixth	2012	914	?

Since 2008, GSI has been awarding graduate fellowships to students worldwide for conducting geosynthetics research. The criteria are as follows:

- Student must be pursuing a doctoral degree
- Student must be researching a geosynthetic topic
- Student must be approved by advisor or administrator

Table 7 gives the history of the program to date and many of the students have received second and third year funding as well.

Table 7 – GSI Graduate Student Fellowships

	Name	University	Advisor	Topic
<u>2008-2009 A.Y.</u>				
1-08	Michael McGuire	Virginia Tech University	George Filz	Reinforced pile supported embankments
2-08	Connie Wong	Drexel University	Grace Hsuan	Specification for corrugated HDPE pipe
3-08	Axel Ruiken	RWTH Aachen University	Martin Ziegler	Geogrid behavior in MSE systems
4-08	Elena Kapogianni	National Technical University of Athens	Michael Sakeilaniou	MSE slopes under seismic conditions
5-08	Xiaoming Yang	University of Kansas	Jie Han	Geocell behavior in aggregate bases
<u>2009-2010 A.Y.</u>				
1-09	Anil Bhandari	University of Kansas	Jie Han	Geogrids under dynamic loading
2-09	Brent Robinson	North Carolina State University	Mo Gabr	GT/GG behavior in lime stabilized soils
3-09	Ioanna Tzavara	University of Crete	Yiannis Tsompanakis	Seismic design for MSE reinforced walls
4-09	Majid Khabbazian	University of Delaware	Victor Kaliakin	GS reinforced stone columns
<u>2010-2011 A.Y.</u>				
1-10	Tanay Karademir	Georgia Tech	David Frost	Elevated temperature effects on strength
2-10	Jing Ni	University of Wollongong	Buddhima Indraratna	PVDs under cyclic loads
3-10	Bret Lingwall	University of Utah	Steven Bartlett	GS protection of buried pipes
4-10	Carmen Franks	University of Maryland	Ahmet Aydilek	GS filters for urban storm water runoff
<u>2011-2012 A.Y.</u>				
1-11	Ryan Corey	University of Kansas	Jie Han	GS protection of buried pipelines
2-11	G. Hossein Roodi	University of Texas at Austin	Jorge Zornberg	Pavement lifetime using field data
3-11	Felix Jacobs	RWTH Aachen University	Martin Ziegler	Geogrid reinforced soil behavior
4-11	Mahmound Khachan	Syracuse University	Shobba Bhatia	Deflocculants for geotextile tubes
<u>2012-2013 A.Y.</u>				
1-12	Chuangi Wang	University of Memphis	David Arellano	Properties of Recycled Expanded Polystyrene
2-12	Xunchang Fei	University of Michigan	Dimitrios Zekkos	Biodegradation of Geotextiles
3-12	Jitendra K. Thakur	University of Kansas	Jie Han	Recycled Asphalt Used in Geocells

3.6 Ongoing Accreditation Activities at GSI

The Geosynthetic Accreditation Institute-Laboratory Accreditation Program (GAI-LAP) was initiated following numerous requests to accredit the operations of testing laboratories within the geosynthetic community. The program is intended to monitor geosynthetic laboratory capability. The program goal is to accredit geosynthetic testing laboratories for performing consensus standardized test methods insofar as equipment, documentation and testing protocol. *It is important to note that this program is not meant to certify individual test results.*

The program was first requested by state and regional environmental regulators, during a series of courses taught nationally in 1988 (on liner systems) and again in 1990 (on cover systems). Subsequently, a survey of GSI member organizations listed the lack of geosynthetic laboratory accreditation as a severe shortcoming of the industry.

After a Pittsburgh meeting with a number of third-party testing laboratory owners on April 20, 1994, we framed the Geosynthetic Accreditation Institute-Laboratory Accreditation Program (GAI-LAP) around two international known standards; ISO 9000 and ISO 17025. Although the GAI-LAP models itself after these standards it does not profess to be affiliated with ISO or any other accreditation organization. Rather, the program is a hybrid one tailored to the immediate needs of the geosynthetic testing community.

It is felt that the GAI-LAP has a threefold effect on geosynthetic testing. *First*, it gives credibility to those laboratories that are properly equipped and prepared to do the respective tests. *Second*, by omission, it eliminates those laboratories that are not equipped to do specific tests. *Third*, as an ancillary benefit it requires laboratories to prepare a quality manual, write test-specific standard operating procedures and prepare test reports for each test method for which accreditation is desired.

The intent of the GAI-LAP is to prevent errors and inaccuracies by following an approved plan and utilizing standard procedures. By so doing, it is hoped that the funds expended in geosynthetic testing are being spent with clear objectives in mind. The intent of this endeavor is to have a system in place that will aid communication and be accompanied by a paper trail of documentation. The program is rigorous in comparison to the current state-of-the-practice in geosynthetics laboratory testing. It should be mentioned that despite its voluntary nature, competitive pressures may make accreditation seem like a necessity. This is particularly true for laboratories that do federally funded work or who are involved with international work.

The success of the program far exceeds our initial expectations. Driving home from the Pittsburgh meeting, Grace Hsuan, George Koerner and Bob Koerner anticipated about ten laboratories in the program and currently we have 49! They are 11-third party labs, 32-manufacturers quality control labs (which we never envisioned joining the program), four research institute labs, and two government labs. As shown in Figure 8, Synthetic Industries, Inc. was the first manufacturers quality control lab to join the program. There are a possible 280 geosynthetic test methods (ASTM, ISO and GRI Standards) that can be accredited and the average of the present 49 laboratories in the program is thirty.

Figure 8. Ceremony in 1996 at Synthetic Industries, Inc. plant for the first accredited manufacturing QC lab. (Ted Koerner, Leonard Chill and Bob)

The core of the program is to send samples to the accredited labs for specific tests to evaluate their proficiency in having results fall within two standard deviations ($\pm 2\sigma$) of the mean value (μ) of the material. The data base is kept by George Koerner who expertly directs the entire effort. Additionally, an on-site visit to each lab is required every five years and these visits have provided excellent training for the respective laboratories and their technicians. Additionally, one of the major outgrowths of the GAI-LAP program is the settling of “conflict resolution” issues between laboratories with different test results for the same tests. This issue occupies much of George Koerner’s time in reaching a consensus.

Needless to say, the program is an outstanding success and far beyond our initial expectations.

3.7 Ongoing Certification Activities at GSI

GSI now has two separate inspector certification programs. One (begun in 2006) focuses on QA/QC of field inspection of waste containment geosynthetics and compacted clay liners. The other (begun on Dec. 1, 2011) focuses on MSE Wall, Berm and Slope field inspection. They are both similar in that a perspective candidate must conform to the following:

- Be recommended by a professional engineer who knows, and can attest to, at least six months of acceptable experience performing CQA activities with either geosynthetic liner or cover systems or MSE walls, berms, or slopes using geosynthetic reinforcement.

- Submit a completed application and be approved by the Geosynthetic Certification Institute to take the exam.
- Must successfully pass a written examination (70% of the questions is the passing grade) proctored by GCI or a GCI designated organization and graded by the Geosynthetic Certification Institute to become a certified inspector.
- Must pay a one-time fee which covers a five-year period upon completion of the above items. The fee is \$500 for five-years of certification.

Program #1 - Inspection of Liner Systems for Waste Containment Facilities

This program now in its sixth year has been received, and in some cases required, by solid waste owners, state regulators, and design consultants for proper QCA in field installation of both geosynthetic materials and compacted clay liners. The statistics to date are as follows.

Table 8 – Inspection Certification Test Results - 2006-2012

Year	Geosynthetic Materials		Compacted Clay Liners		Commentary
	No. of people taking exam	No. of people failing exam	No. of people taking exam	No. of people failing exam	No. of people failing both exams
2006	141	5 (3%)	128	12 (9%)	2 (1.5%)
2007	82	11 (13%)	73	12 (16%)	7 (8.5%)
2008	95	25 (26%)	89	20 (22%)	13 (14%)
2009	36	7 (19%)	36	2 (5%)	2 (6%)
2010	59	12 (20%)	54	7 (13%)	5 (8%)
2011	54	6 (11%)	53	3 (6%)	1 (2%)
2012	34	5 (15%)	28	3 (11%)	3 (9%)
TOTAL	501	72 (25%)	461	59 (13%)	33 (7%)

The 5-year renewal period for those having taken the exam in 2006 is ongoing and about 60% have renewed accordingly. This is felt to be encouraging from our perspective.

Program #2 - Inspection of MSE Walls, Berms and Slopes

The official launch of this program was on December 1, 2012 with a course and the examination afterward. There are now thirty persons certified by GCI for the inspection of MSE Walls, Berms and Slopes.

While a field inspector cannot require proper design or instruct a contractor how to build the structure, flaws can be identified for possible design modification or mitigation action. Furthermore, and at minimum, construction practices can be observed and corrected if inadequate or improper. It will be interesting to see if this program has a positive impact in stemming the large number of MSE structure failures that we are presently confronted with.

4.0 MUSINGS ON GSI'S FUTURE

To accurately predict the future one must be both observant and lucky. Yet, the exercise is considered worthwhile by many organizations since in one's busy daily routine we rarely take time to project our thoughts forward. That said, the attempt will be made to suggest GSI's future in the context of research, information, education, accreditation and certification.

4.1 Future Research Activities

GSI's research has been, and will likely be in the future, decidedly "mission-oriented". As such, it is based on actual problems and related concerns. To do research for the sake of research itself or because a piece of laboratory equipment is idle is simply not justifiable in our opinion. There are simply too many meaningful field problems to be solved. Projects we envision to be ongoing or for the future are as follows;

- long-term field behavior of liner and cover systems,
- long-term field behavior of filtration and drainage systems,
- long-term field behavior of exposed geosynthetics,
- evaluation of long-term behavior of various infills within GCL's
- laboratory based lifetime prediction of exposed geosynthetics,
- evaluation of additive behavior (primarily antioxidants) in various geosynthetic material formulations
- evaluation of plasticizer and/or filler behavior in various geosynthetic material formulations
- evaluation of the use of recycled plastic in noncritical geosynthetic applications
- forensic analyses of all types of geosynthetic and geosynthetic-related system failures,
- effect of different alkalinity and oxidation levels on long-term behavior of geosynthetic materials,
- ongoing development and publication of GRI standards, test methods, guides, practices and specifications,
- development and initial test screening for new products developed by member organizations,
- developing data bases of inadequately performing geosynthetics and geosynthetic related systems, and
- other tasks and projects as suggested by the GSI member organizations.

4.2 Future Information Activities

Some commentary on the information value of conferences is in order. In the past, such conferences have been of major benefit for geosynthetics (and all other areas as well) in providing technical information, exhibits, networking among individuals, and opportunities for meetings of all types. Yet current economic and time constraints appear to be working against this mode of activity. Increased travel and lodging costs, high conferences and exhibit fees, solicitation of quality papers, time away from work, time away from family, etc., etc. all appear to be stressing the generic conference-type of activity. If this is a somewhat accurate

perspective, then what is available (now, or in the future) to provide a replacement for these traditional conferences?

Clearly, teleconferencing, and as an extension video teleconferencing, is how multi-national corporations are currently operating. This can be formatted for specific topics of technical orientation and even extended to business topics as well.

Somewhat related are company websites which are information-related vehicles that have also obviated print copy of brochures, leaflets, hand-outs, and related hard copy documents. Their ease of immediate updating is a tremendous asset. This trend will obviously continue and will (hopefully) be made more user-friendly and appealing. IT-people will very likely facilitate this in the near future.

The future status of technical articles of all types (including geosynthetics) is “dicey”. Clearly, hard copy is being greatly diminished. For example, the universally used and valued Journal of Mathematics by Elsevier Publishing Company costs university libraries \$23,000 per year! The geosynthetics industry currently has two excellent journals, one of which is completely electronic and the other moving in this direction. A users search for a particular article, however, is only as good as the keyword search engine can provide. That said, online reading (and understanding) of technical papers is, at the best, unwieldy in its reading and particularly its comprehension. However, there is simply no turning back in this regard.

This trend is now unnervingly moving into complete textbooks! The two volume sixth edition of “*Designing With Geosynthetics*” is now available as an e-book. It costs a paltry \$3.70 per volume (\$7.40 total). Incidentally, the previous 5th edition sells for \$300! Yet, to scroll from the index through the two volume 915-page book is tedious to say the least. If in the future, some voice command should be able to lead one directly to, for example, “axi-symmetric tension results of geogrids”, it would be a major breakthrough. Perhaps in the future?

4.3 Future Education Activities

Obviously we will continue to develop and provide power point presentations on all aspects of geosynthetics and geosynthetic related systems. Directly related is the offering of webinars which has just recently been started. We see a real future in this regard, not only for the education value, but also for the necessity of maintaining professional registration. While our offerings are currently on behalf of ASCE we envision many other possible hosts, IGS, NAGS, IFAI, GMA, ISSMGE, ASTM, ISO, etc. While interaction is not presently available, webinars are indeed cost-effective educational vehicles. In the future, however, an interaction feature will no doubt be available and perhaps even video.

This interactive feature will then allow our present one-day courses to be beamed live from GSI including laboratory demonstrations and actual test-by-test training. In this same regard, it is certainly possible to have every geosynthetic test method to be put on dedicated section of our website so as to illustrate proper laboratory procedures and training for laboratory technicians.

The national educational trend of distance learning is presently proliferating at a tremendous rate within all universities. Complete degree-granting curricula can be accessed and obtained on-line without ever going to the university campus, per se. This type of educational outreach is considered to be sufficient adaptable to present a geosynthetics course and it is only a matter of time for its development and implementation. In this regard, initial discussions are ongoing.

4.4 Future Accreditation Activities

The currently laboratory accreditation program of the institute has been extremely successful (thanks to George Koerner and the associated laboratories), but why should GSI stop at laboratory accreditation? Various segments of the geosynthetics industry which might be candidates for future accreditation are the following;

- manufacturing companies and technicians (currently provided by ISO 9000 or 14,000)
- installation companies and technicians (currently provided by the IAGI organization)
- design organizations (devoid of anything except the designers professional integrity)

This last item has been often requested in the past. Since so few civil engineering graduates have had any exposure to geosynthetics they are essentially all novices to the field. Note that there are 10,000 civil engineering graduates in America each year and like amount worldwide. Their lack of insight into the nuances of different geosynthetics and how they function can lead to naive and indeed dangerous designs, plans and specifications. GSI has often been challenged to develop a program of accrediting design consultants who are generating geosynthetic-related plans and specifications. By virtue of an interview and examination a professional engineering designation in “geosynthetic engineering” could be developed and implemented.

In a similar regard, we hope that the member organizations confide in us to the extent of peer-review of their information. Of course, this aspect of peer-review has been ongoing for project plans and specifications of many projects in the past. We hope this continues into the future. It is often surprising how a different set of eyes can pick out items which might become problematic or even disastrous. Of course this requires both confidence in us and rapid response. The institute will continue to provide such service as requested of its members.

4.5 Future certification activities

To “accredit” is one thing, to “certify” is quite another. At the least, certification implies complete compliance to what is claimed and, as such, carries both insurance and legal implications. In this regard, to certify products, designs, installations, etc., is beyond the institutional or financial capabilities of GSI.

On the other hand, to certify others to properly implement specific activities of their doing is felt to be reasonable. In this regard, two current GSI certification programs are ongoing and felt to serve a vital need; namely,

- inspectors certification for installation of geosynthetic and compacted clay liners for waste containment systems, and
- inspectors certification of geosynthetic reinforced mechanically stabilized earth walls, berms and slopes.

Other similar certification programs that could be developed in the future would focus on “waterproofing of hydraulic systems”, “geosynthetics in mining and minerals extraction technologies”, “geosynthetics in aquaculture and agriculture applications”, “geosynthetics in radioactive materials encapsulation”, and related (somewhat futuristic) applications.

4.6 Summary

Looking to the future, we hope that GSI is appropriately positioned for expansion and integration into various diverse activities. Not only are the materials themselves capable of transition and modification, but the systems utilization has the utmost flexibility to be directed toward new and challenging applications. As such, our present configuration seems to be flexible enough to provide a pathway into the future as is illustrated on Figure 9 following.

ACKNOWLEDGEMENTS

We sincerely thank all of our sponsoring organizations. Without them, GSI simply could never have happened nor prospered in the positive manner that it has done over these initial 25-years. This paper is a description of the activity that has been ongoing at the institute during this time period. The current GSI member organizations and their contact members are on the institute website at www.geosynthetic-institute.org. Board of Director members are identified accordingly.

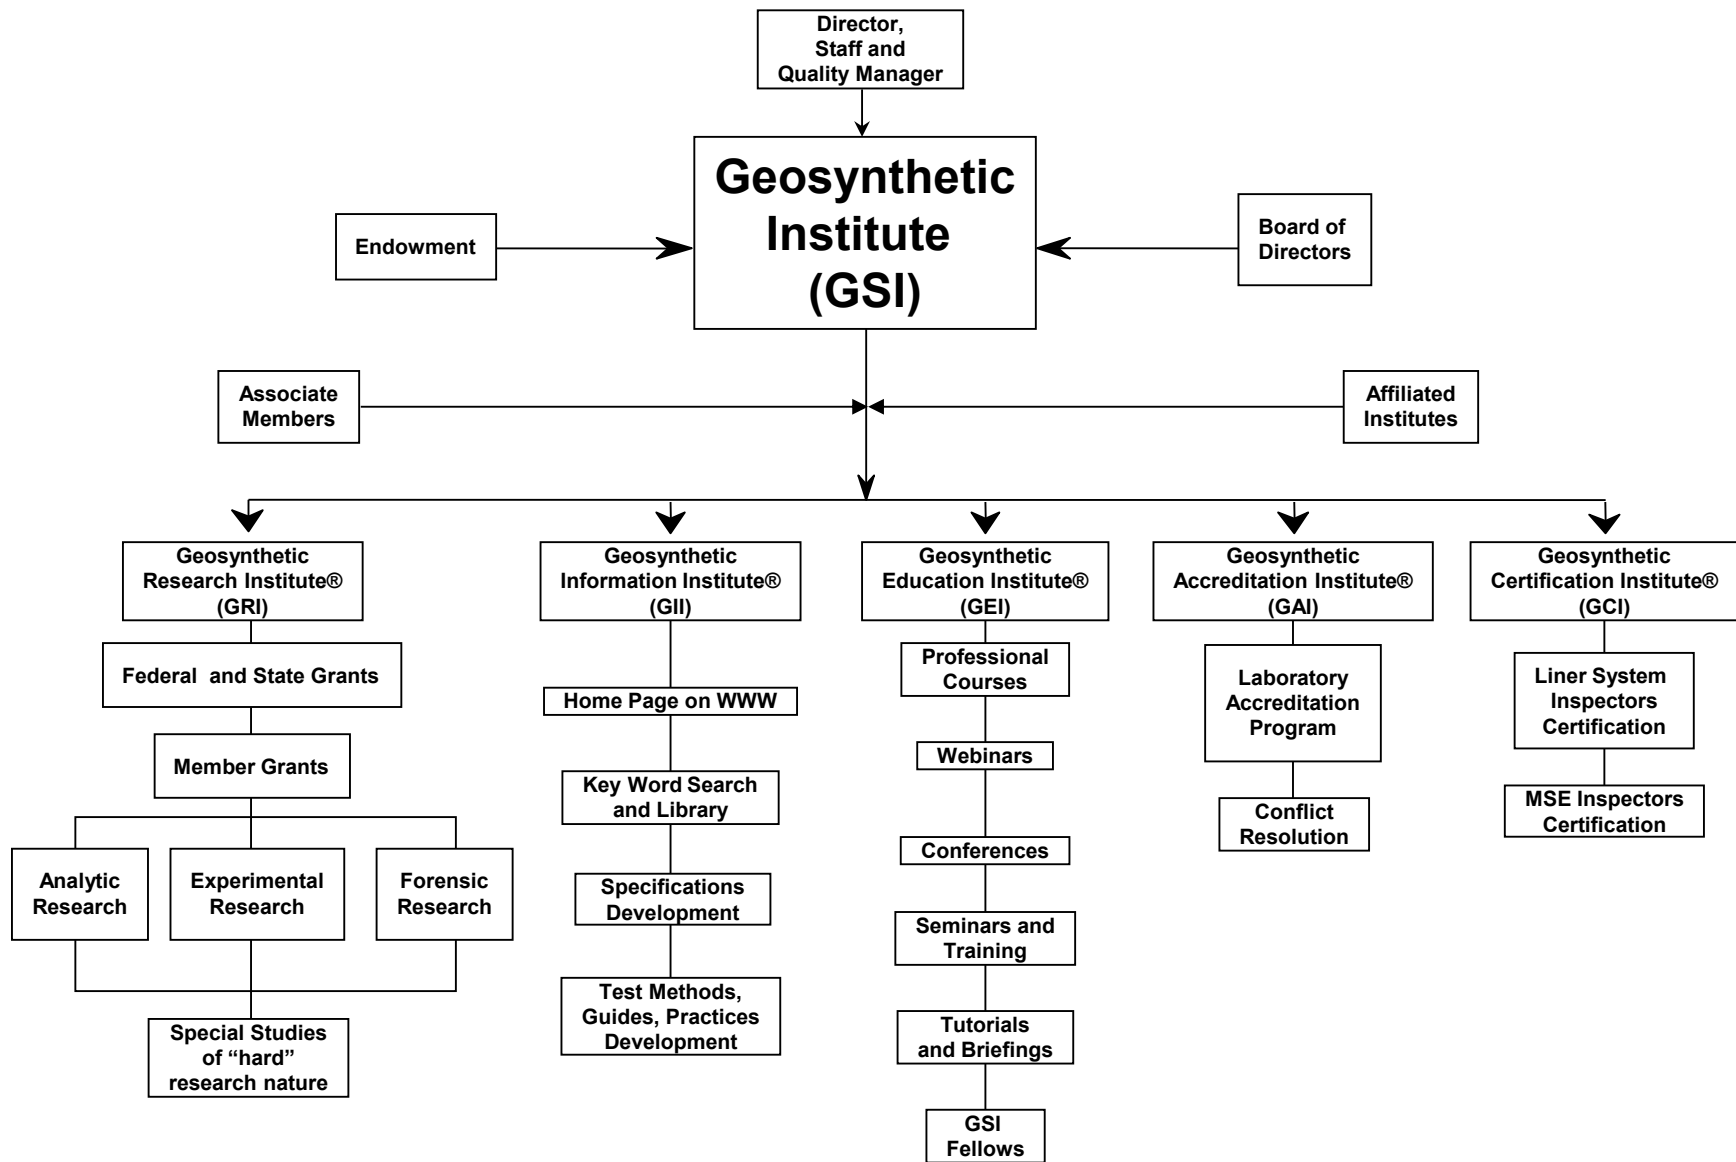

Figure 9 – Current structure of GSI with its operational capabilities

A Comparison of Landfill Closure Systems

David Beben, P.E., Project Engineer, HDR Engineering Inc., david.beben@hdrinc.com
Kanishka Perera, Ph.D., P.E., Project Manager, HDR Engineering Inc., kanishka.perera@hdrinc.com
Mark Roberts, P.E., Vice President, HDR Engineering Inc., mark.roberts@hdrinc.com

ABSTRACT

Each year thousands of acres of municipal solid waste (MSW) landfills are capped with a traditional USEPA Subtitle D landfill prescribed cover system comprised of a geomembrane liner, drainage layer and a protective and ballasting soil cover layer overlain with grass. However, alternatives to the traditional soil/geomembrane final cover are currently being designed, permitted and installed around the United States due to superior environmental performance, increased stability, secondary use applications and decreased cost. These innovative alternative cover systems also can offer lower construction cost, lower post-closure maintenance, ease of inspection, verification of performance, and low erosion. These aspects are compared and contrasted for three alternative MSW landfill cover systems: evapotranspiration (ET) covers, synthetic turf geomembrane covers and exposed geomembrane covers (EGCs). These cover systems are evaluated on the criteria of ease of permitting, infiltration rate, longevity, aesthetics, environmental impacts, regional suitability, construction and post-closure care costs, compatibility with on-site systems, and proposed end uses. HDR Engineering has utilized a performance-based approach to landfill cover system design and continues to successfully implement it for differing state regulatory frameworks in lieu of the Subtitle D-prescribed system. Using this approach to the USEPA's thirty-year post closure care period enables the regulatory community to rely less on prescriptive closures with a diminishing post-closure care fund over time to that of a performance based cap with sufficient funds available for repairs and even replacement based either on savings and/or secondary use revenue generation.

1. INTRODUCTION

Final cover systems are an essential component of a closed landfill's long-term environmental controls. Subtitle D of the Resource Conservation and Recovery Act requires that the final cover system must have an infiltration, or barrier, layer with a hydraulic conductivity equal to, or less than, that of the bottom liner system, a protective and ballasting layer comprised of 18-inches of soil fill to minimize infiltration, overlain with six-inches of topsoil to sustain vegetation, and a healthy stand of grass to reduce erosion. However, the USEPA also establishes in 62 FR 40710 that state administrators have the regulatory authority to approve alternative final cover designs that can meet or exceed specific engineering performance characteristics of the prescribed system. It explains that an alternative to the final cover can be approved if the permittee can show that the permeability of the infiltration layer can be met by an equivalent reduction in infiltration, and the protective cover layer can be replaced with a system that can be shown to reduce erosion and continues to protect the long-term performance of the infiltration layer. In modern landfill systems the infiltration layer is typically a geomembrane, a geosynthetic clay liner or a clay layer, and the protective cover layer often consists of soil and an underlying lateral drainage medium such as a geonet/geotextile or sand.

Landfill owners have researched alternatives to the prescriptive final cover system for a several reasons. One is that imported soil can be costly when a suitable soil source is not located near the project site. Second, the soil/geomembrane system can be prone to veneer-type failures, where the final cover system components slide down the sideslope. Final cover systems are particularly prone to veneer failures if the underlying drainage component between the protective cover and the impermeable geomembrane does not perform as designed for one or a combination of performance complications associated with Subtitle D closures. Third, the installation of a cover system cause greenhouse gas emissions, particularly from the soil borrow process, hauling vehicles and equipment pushing soil upslope at steep 4:1 or 3:1 slopes. Lastly, the maintenance operations during the post-closure care period of a Subtitle D prescribed cap typically require ongoing turf and soil maintenance for the entire system to perform as designed consisting of frequent mowing, water, fertilizer, top soil replacement, erosion control, and sedimentation basin maintenance.

Figure 1 Final Cover System Profiles

2. EVAPOTRANSPIRATION COVER

Evapotranspiration (ET) cover systems, also called water balance or monolithic covers, are designed to minimize infiltration of precipitation into waste by increasing surface runoff, soil moisture storage and evapotranspiration. The ET cover is comprised of a two to four foot soil cap supporting local plant species. Unlike the other alternative final cover options, the ET cover does not contain geosynthetics and is the only alternative considered for this analysis with an entirely vegetated cover. Additionally, ET covers rely on the water removal capabilities of uptake of moisture via plant transpiration and evaporation.

An ET cover is the most prevalent alternative to the Subtitle D landfill final cover system in western states with dry climates with low rainfall amounts. Texas, for instance, has several constructed ET cover systems. The Texas Commission of Environmental Quality (TCEQ) has published a guidance document (RG-494) which specifies less than 4 mm of percolation into the waste mass per year during the 30-year period of record. Currently, TCEQ plans to monitor three test site projects near Dallas, San Antonio and Houston to determine the appropriate approval mechanisms for ET covers. California has dozens of evapotranspiration covers in arid and semiarid regions of the state.

The following is listing of advantages and disadvantages of the ET cover compared with a prescribed Subtitle D cap and the other two alternate cover systems:

Advantages

- No geosynthetics are required.
- Landfill gas venting systems may not be necessary.
- This option has the lowest stormwater water runoff volume of the three alternatives.
- A low maintenance vegetated cover system that can be integrated with surrounding natural landscape.

Disadvantages

- Secondary uses may be limited such as solar power which would require rigid solar panels and frames, and concrete footings/slabs which could limit the ET cover performance features by affecting its evapotranspiration and water storage properties.
- Vegetation will experience an establishment period which can last several months to years and includes high landscaping maintenance activities that could include intense watering, fertilizer, erosion control, and re-seeding/planting . The cover system will be vulnerable to wind and rain erosion during this period.
- The post-closure care costs are higher than the synthetic turf and EGC alternatives due to the continued cover maintenance.
- Fertilizers and amendments are short-lived and will likely require re-applications.
- Significant soil quantities are required..
- Greenhouse gas emissions are the highest of the three alternative options.
- Unanticipated localized waste exposure is most likely to occur of the three alternative options.

3. SYNTHETIC TURF AND GEOMEMBRANE COVER SYSTEM

A recent addition to innovative final cover systems for landfills is synthetic turf which utilizes a studded LLDPE or HDPE geomembrane in conjunction with synthetic turf attached to woven geotextile. The synthetic turf system provides low maintenance costs and protection to the final cover geomembrane and underlying geotextile. The synthetic turf is typically green but can be manufactured in other colors. In contrast with an EGC, the synthetic turf does not require horizontal and vertical anchoring at discrete intervals and instead sand ballast is provided. The ballast is typically comprised of 1/2 to 1 inch thick sand layer (D_{50} approximately 0.6 mm) and assists with protection from long-term UV exposure, shear stress from light equipment and wind uplift. Synthetic turf was first installed as a landfill final cover system in 2008 in Louisiana. Since then, the system has been permitted and installed at landfills in Texas, California, Missouri, Pennsylvania, Florida and Georgia.

The following is listing of advantages and disadvantages of the ET cover compared with a prescribed Subtitle D cap and the other two alternate cover systems:

Advantages

- Less geosynthetic anchoring and/or pinning is required than typical exposed geomembrane cap (EGC) designs.
- A solar array comprised of rigid-type panels with concrete foundations is being installed in California.
- Post-closure maintenance costs (erosion, mowing, and fertilizer) are less than a Subtitle D or ET cover system.
- High interface friction and low chance for veneer stability issues when compared to a Subtitle D cover system.
- Less UV exposure of the geomembrane when compared to the EGC. Weatherometer ASTM G147(02) tests performed on the exposed portion of the yarn shows less than 10 percent tensile strength loss after 20 years. Additional UV exposure tests on the synthetics turf are ongoing.
- Conforms to various slopes and transitions and performs better than Subtitle D or ET on steep slopes
- Pro-rated 20+-year material warranty available

Disadvantages

- More stormwater runoff when compared to a Subtitle D or ET cover system.
- Erosion of ballast sand by wind and rain could make the cover system vulnerable against wind uplift under extreme conditions. Limited sand ballast and turf repair is expected in the post-closure period.
- Material creep could occur appearing like "loose carpet" and requiring specialized repairs
- Synthetic turf is currently a patented technology and therefore not competitively priced.
- Emergency gas vents in addition to passive vents or active wells are recommended.
- Sand ballast may be expensive if not locally available.
- Not yet authorized as a landfill final closure in most states.
- Unable to confirm the integrity of the barrier layer (geomembrane) with visual inspections.
- Slippery on steep slopes

4. EXPOSED GEOMEMBRANE COVER (EGC)

An exposed geomembrane cover system utilizes a single geomembrane layer over a prepared earthen subgrade. These cover systems contain no soil or vegetation and thus have a cost savings at closure and during the post-closure period of the landfill. EGC's have been utilized in the United States using HDPE, LLDPE, scrim-reinforced polypropylene, EPDM and other proprietary resin formulas for geomembranes. The EGC system does not have the potential for veneer slope-type failures (i.e. sliding of cover components) that can occur on a Subtitle D or synthetic turf cover systems. The EGC is anchored into the landfill utilizing trenches and/or pins designed to counter balance wind uplift forces.

EGC's have been permitted and installed as landfill closures in Louisiana, Florida, Delaware, Georgia, New York and Texas. The performance criteria of exposed geomembrane caps include UV resistance, seamability, seam durability, chemical resistance, puncture resistance, stress-strain characteristics, and interface friction. UV degradation has been noted as the most important property in exposed conditions. A multitude of UV exposure tests have been performed on geomembranes and the body of work and example projects are more extensive than synthetic turf. In research described in GRI's White Paper #6, HDPE geomembrane that has been exposed to accelerated aging via UV light has performed well. The study has estimated an HDPE lifetime of 36 years and testing at 70°C (158°F) is still ongoing. In other research, standard oxidative induction time and high pressure oxidative induction time tests have been performed to determine the antioxidant properties of the exposed HDPE and LLDPE geomembrane.

LLDPE rely on antioxidants (carbon black and other stabilizers) for their resistance to UV radiation. The nature of the LLDPE resin and its formulation is very similar to HDPE. Because LLDPE has a lower density, hence lower crystallinity, than HDPE, it has the effect of allowing oxygen to diffuse into the polymer structure more quickly and therefore reduce its lifetime when compared to HDPE (Koerner et. al, 2005). Past experience with exposed geomembranes in other industries and technical research has shown that polyethylene geomembranes that are manufactured with a sufficient level of stabilizers and antioxidants have excellent UV resistance and lifetimes much greater than the industry-standard time span of 20 years.

The following is a listing of advantages and disadvantages of the EGC cover compared with a prescribed Subtitle D cap and the other two alternate cover systems

Advantages

- Flexible solar panel arrays have been installed and are currently producing power. Fixed-frame solar arrays are possible similar to the synthetic turf solar panels.
- Accelerated aging tests indicate that HDPE manufactured per GRI-GM13 has a predicted lifetime greater than 36 years. GSE recently introduced a line of high-performance geomembranes that have superior endurance properties than typical 60-mil HDPE.
- HDPE geomembrane cost is competitively priced (based on resin prices) and commercially available.
- Post-closure costs (erosion, mowing, and fertilizer) are less than a Subtitle D or ET cover.
- Access to the landfill beneath the EGC is less cumbersome than the synthetic turf or Subtitle D cover systems.
- No veneer slope stability issues.
- Can confirm geomembrane integrity and make repairs relatively easily compared to synthetic turf or Subtitle D caps in which the barrier layer integrity cannot be confirmed and inspecting and repairing is difficult.
- UV exposure tests are indicating life-spans of greater than the standard 30-year Subtitle D post-closure care period.
- Not susceptible to shifting soils or erosion for long-term performance of ballast conditions or infiltration conditions
- Pro-rated 20+year material warranty available

Disadvantages

- Anchoring into the soil/waste is required increasing the capital cost and construction time. An alternative to anchor trenches are tension pins which are installed at discrete horizontal intervals and vertical depths. The EGC is connected to the pins to provide required counter balancing forces during wind uplift.
- More vulnerable to damage by hail, wind and other externalities than the other alternatives.
- Not yet authorized as a landfill final closure in most states.
- The most UV exposure to the geomembrane compared to other alternative final cover options.
- More stormwater runoff when compared to a Subtitle D or ET cover system.
- One landfill EGC final cover has been permitted and constructed in Louisiana. Regulatory approval for the EGC as final cover is pending in Texas and Georgia.
- Emergency gas vents in addition to passive vents or active wells are recommended similar to synthetic turf.

5. COST COMPARISON OF FINAL COVER SYSTEM ALTERNATIVES

Table 1 summarizes the costs of an example subject landfill located in West Texas – a region with arid climate conditions and in a state which has approved alternate final cover systems. This West Texas landfill has compared its currently permitted final cover system with each of the three alternatives presented above. These costs do not include engineering, permitting, quality assurance and certification that will occur during all installations. Additionally, the costs do not incorporate post-closure water quality monitoring, leachate management and general professional services.

Table 1. Budgetary Cost Comparison of Final Cover System Alternatives

	Permitted Subtitle D Cover System	Evapotrans- piration Cover (2.5-ft. Thick)	Closure Turf [®]	EGC
Closure Construction				
Construction Costs (\$/acre)	\$160,000 ¹	\$91,300 ¹	\$93,502 ²	\$75,000 ^{3,1}
Total Construction Cost (25- acre closure)	\$4,000,000	\$2,282,500	\$2,337,552	\$1,875,000
Post-Closure Final Cover Maintenance				
Vegetation Maintenance including fertilizer, mulch application, watering (\$/acre)	---	\$400	---	---
Stormwater System and Erosion Maintenance (\$/acre)	\$350	\$300	\$70	---
Geomembrane Maintenance (\$/acre)	\$25	---	\$100	\$150
General Inspections (\$/acre)	\$50	\$50	\$50	\$50
Total Annual Post-Closure Care (25-acre closure)	\$10,625	\$18,750	\$5,500	\$5,000
Total 30-Year Post-Closure Care (25-acre closure)	\$318,750	\$562,500	\$165,000	\$150,000

Notes:

1. Costs for permitted closure, EGC and ET cover systems are based on a unit cost of \$18 per cubic yard based on soils from an off-site borrow source approximately one mile from the site. Costs for gas vents (permit system), maintenance period (ET cover) and stormwater control are included.
2. Closure Turf construction cost is based on manufacturer's budgetary cost of \$2/square foot. Additional costs for gas vents, ballast sand and stormwater control are included the unit price.
3. EGC construction cost is based on a GSE's budgetary cost of \$0.55/square foot for green GSE High Performance Geomembrane. Additional cost for anchor trenches, gas vents, backfill soil and stormwater control are included the unit price.
4. Permitted closure system cost is based on geomembrane and geocomposite at \$0.50/sf and 0.55/sf, respectively.

6. SOLAR POWER GENERATION POTENTIAL

The development of solar power generating arrays on closed landfill final covers is an emerging technology. By generating renewable energy on closed sites, landfill owners are reclaiming land that would otherwise have limited post-closure use. Landfills with solar generating arrays will be able to accomplish a number of goals including post-closure period cost savings, the sale of renewable energy, lowering off-site energy purchases and providing an image of sustainability. The characteristics and costs of the two types of panel systems are discussed.

6.1 Photovoltaic Laminate (PVL) Solar Panels

Photovoltaic laminate (PVL) thin-film solar panels have been used in roofing, landfill EGC's and other applications. These panels are lightweight, flexible, easy to install and do not require an expensive concrete ballasting structure. The PVL's have been formulated to be exceptionally durable by encapsulation in UV-stabilized polymers. These panels have not been installed with synthetic turf or ET cover systems. As previously mentioned, a flexible solar array was constructed at the Tessman Road Landfill in San Antonio, Texas. Other EGC projects with flexible solar laminates have been installed in the country including a 1-MW array at the Hickory Ridge MSW Landfill in Atlanta, Georgia.

Construction cost and electrical revenue from a 250-kW solar panel array are discussed. A Xunlight XR36 PVL is selected with nameplate wattage of 300 watts per panel. Therefore, an array of 860 panels will provide 250 kW of direct current power. Based on previous EGC solar designs with a gentle slope and no liner penetrations, it is estimated that this array will require a 2.5-acre area of EGC. The kilowatt hours provided to the utility grid will vary in the field due to hours of sunlight, temperature, angle to the sun, and the efficiency of the conversion from direct current to alternating

current. Given these parameters, material and installation cost of a 250-kW array encompassing a 2.5-acre area will cost over \$1.2 million, produce 341 MWh of electricity in the first year and generate approximately \$27,000 of electrical revenue in the first year, assuming \$0.08/kWh electricity buy back cost.

6.2 Monocrystalline or Polycrystalline Solar Panels

Rigid solar panels (monocrystalline or polycrystalline) are most commonly installed on shallow (<5% grade) landfill slopes. In comparison to PVL's, the rigid panel have higher UV conversion efficiency, are more competitively priced and are able to be installed at an angle which maximizes incoming solar radiation. However, they are the heaviest and require a rigid frame mounting system.

A rigid-type solar array can be installed in conjunction with synthetic turf. A 1-MW system comprised of approximately 2,000 panels will soon be installed at the Crazy Horse Landfill in Salinas, California and another large array is planned in Connecticut. The rigid solar panels will be mounted on non-penetrating concrete footings and a metal frame will interconnect the panels to provide stability. The articulated frame is designed to prevent resistance to landfill differential settlement. Rigid-type solar panels can also be installed in EGC applications with racks welded directly to the geomembrane. A racking system welded directly to an EGC is used on a steep sideslope EGC at the Biosphere project in Arizona. If traditional ballasted racks are used in which concrete footings or foundations are incorporated in concert with an EGC, then the ballasted racks will require an isolation design that allows uplift conditions to occur without impacting the solar system.

A 250-kW array of rigid solar panels was also considered for comparison to a PVL array. Based on information from a similar landfill site, a 250-kW array will require 1.5 acres of landfill space, 40% of the footprint required by PVL's. A 250-kW array size was selected for comparison since it provides a good scale-able factor for expansion. A manufacturer provided a cost of \$5 to \$6/W for construction and installation which is greater than the cost for PVL's. The installation costs for crystalline solar panels can vary significantly and prices have recently declined due to competition from Chinese solar panel manufacturers. In the report "Tracking the Sun IV" by the Berkley National Laboratory, the PVL systems were slightly less expensive for systems >100 kW; however, the authors cautioned that there was a poor sampling of PVL systems. Given these parameters, a 250 kW area encompassing an 1.5-acre area will cost over \$1.5 million, produce 371 MWh of electricity in the first year, and generate approximately \$30,000 of electrical revenue in the first year, assuming \$0.08/kWh electricity buy back cost.

6.3 Solar Array Cost Comparisons

Table 2 is a summary table of the costs for a PVL versus a rigid-panel array. These costs are budgetary estimates based on project and will need to be re-visited for the site-specific conditions. We note that solar panel manufacturers will typically provide a guarantee of power generation over 20 years; for instance, Xunlight guarantees that their PVL product will retain 80% of its power-generating capacity after 25 years.

Table 2. Budgetary Cost Comparison of Solar Power Generating Arrays

	Photovoltaic Laminates	Rigid Solar Panels
Area of Final Cover Required for 250- kW Array	2.5 acres	1.5 acres
Electrical Generation from 250-kW Array for Initial Year	341 MWh	371 MWh
Electrical Revenue for the Initial Year	\$27,000	\$30,000
Capital Cost of 250-kW Array	\$1,200,000	\$1,500,000

Notes

1. Electrical generation was determined through the National Renewable Energy Laboratory's PVWatts calculator (<http://www.nrel.gov/rredc/pvwatts/>) and assuming a 0.705 DC/AC derate factor.
2. The capital costs of 250-kW arrays were from Xunlight and Closure Turf, LLC. Additional costs were added for contingency and electrical interconnection.
3. The revenue from a 250-kW array is based on a \$0.08/kWh buy back price. This price can be increased due to incentives from the local power authority and grants.

7. CONCLUSIONS

Three innovative alternative landfill cover systems were evaluated on the basis of ease of permitting, infiltration rate, longevity, aesthetics, environmental impacts, regional suitability, construction and post-closure care costs, compatibility with on-site systems, and proposed end uses. These systems if designed and installed properly have performance equal

to or greater than a prescribed USEPA Subtitle D landfill cover system. ET cover system provides advantages in arid and semiarid regions when soil is readily available and relatively inexpensive. EGC and synthetic turf systems provide advantages in less greenhouse gas emissions during construction, little to no soil and less post-closure care maintenance. A cost comparison among the traditional prescribed Subtitle D cover system and three alternatives indicate that the Subtitle D system is the most expensive, followed by the ET cover, the synthetic turf and the EGC systems. Each of the three alternative cover systems have the capability of installing solar power generating arrays to provide the closed site with a beneficial reuse option.

ABSTRACT

The 41-year-old Santa Ynez Reservoir in Pacific Palisades, CA was an open water reservoir until recently when the Los Angeles Department of Water and Power (LADWP) covered it to conserve water, decrease water contamination, and change from chlorine to chloramines. The reservoir is on 9 acres of land and is approximately 70 feet deep. When full it holds 117 million gallons of potable water and serves both Pacific Palisades and the Highlands. A unique aspect of this project was the requirement to develop a custom color to address the aesthetic requirements demanded by the local community. This paper outlines the development of this custom colored cover material and the details of manufacture, fabrication, and installation.

1. INTRODUCTION

1.1 Santa Ynez Reservoir

The Santa Ynez Reservoir is tucked between two mountains in the Topanga State Park just north of Santa Monica, CA. The reservoir is overlooked by thousands of homeowners in an upscale neighborhood. The surrounding community was very concerned with the change in the appearance of the reservoir as it is a visual focal point for most of them.

To meet the stringent visual requirements set forth by the community, the LADWP worked with the material supplier and the installer to find a custom material color that would blend in with the surroundings. The material supplier proposed the use of a Chlorosulphonated Polyethylene (CSPE) cover material in a special mottled green camouflage color. They produced several large samples in different color combinations. After a thorough review by the community council and the local homeowners a green/black camouflage color was chosen.

Figure 1: The completed reservoir blends nicely with its surroundings.

The Reservoir was completed in time to bring it back online for Southern California's fire season. The community expressed their approval of the final appearance of the project, and LADWP added another covered potable water reservoir to their portfolio.

1.2 Background

The approval process for this project started in 2002 with a floating cover originally proposed for installation in 2006. The upgrade to the reservoir was part of a response to the US Environmental Protection Agency's (USEPA) Stage 2 Disinfectants and Disinfection Byproducts Rule (S2DBPR 2006) and the Long Term 2 Enhanced Surface Water Treatment Rule (LT2ESWTR 2006). These two rules were delayed in their release until 2006, which in turn delayed the Santa Ynez project.

LADWP chose to address the S2DBPR rule by switching from chlorine disinfectant to a chloramine disinfectant. This change reduced undesirable disinfection by-products (DBPs). DBPs are also reduced by adding an opaque floating cover as sunlight can react with disinfection chemicals to form undesirable by-products. A floating cover also addressed the LT2ESWTR surface treatment rule as the cover effectively isolates the stored water from surface run-off and rainwater.

With the choice to add a floating cover made, the next steps were to choose a material and to obtain approval from the local community.

2. COVER SELECTION

2.1 Material Selection

Chlorosulphonated Polyethylene (CSPE) was originally chosen as the cover material. CSPE has been used successfully in municipal reservoir service for other covers in California and has shown excellent longevity and performance. CSPE was also available with a 30-year warranty against normal weathering. Finally, CSPE was available in a variety of colors, all with extended weathering resistance. This selection of colors would be the key to moving this project forward.

Geomembrane and floating cover materials are not known for their wide selection of colors. In order to achieve long term UV protection the standard color is usually black. Black pigments - the most common being carbon black - provide excellent UV protection to thermoplastic geomembrane and floating cover materials. As soon as you move away from black the UV resistance falls off rapidly. CSPE is unusual in that it is a thermoplastic at the time of manufacture but then crosslinks in service to become a thermoset rubber product. As the material crosslinks it becomes more resistant to chemical attack and more resistant to UV degradation. This means that CSPE can be stabilized in a range of colors much more easily than regular thermoplastic geomembrane and floating cover materials. The manufacturer of the CSPE had developed a wide range of colors in the roofing industry, and this color palette was brought in to satisfy the aesthetics of this job.

2.2 Aesthetics

For 41 years the reservoir provided a visual focal point in the hills across from the Pacific Palisades community. The community association was very sensitive to the reservoir's appearance and had participated in a number of aesthetic upgrades over the years. Some of these aesthetic upgrades included specific plantings above the reservoir and in the dam face to make the area appear more natural. The color of the service road had also been chosen to better blend with the surroundings.

Figure 2 and 3: Naturalized concrete slope above the reservoir. Construction (left) and finished slope (right).

One of the most unique aesthetic features was a protected slope area above the reservoir. Surface run-off from rainstorms and rainwater infiltrating under the graded slope had washed out a section of the slope. The damaged section of the slope was replaced with a compacted soil-cement fill. PVC pipe sub-drains were installed to remove infiltrating rainwater and concrete surface drains for run-off. Although the soil-cement slope face was effective, it did not meet with

the aesthetic requirements of the community association. The solution was to create a rockscape that closely matched the surrounding area (Figures 2 and 3). The construction of this rockscape occurred at the same time as the new floating cover installation.

2.3 Color Selection

Choosing a cover with the active participation of the local community association was a very different experience. The first success was identifying that a cover could be used at all. It is a credit to LADWP staff that they were able to make the case for a floating cover in the first place. The next step then was to choose a color.

Initially the CSPE manufacturer sent a selection of colors for review. From these initial color swatches a selection was chosen. From these initial colors selections 10-ft by 20-ft samples were prepared and arrayed on the slope behind the reservoir for the community to observe and rate. In reviewing these samples it was felt that a multi-color arrangement would be preferable to a solid color and that a dark green with a mottled appearance might work.

2.4 Multi-Color Membrane

The CSPE manufacturer had available a rubber calendaring operation that essentially allowed them to “hand-make” specific colors and materials. By adding pieces of different material colors into the rubber at the last stage of mixing they were able to create a material with random streaks of color in an overall uniform shade. This is very similar to the multi-color patterns seen in resilient vinyl flooring. If the color is added early in the mixing stages it will be uniform; by adding different colors late in the mixing stages a series of streaks can be prepared.

Samples of the multi-color material were prepared for the community association and finally, after many samples and extensive consultation, a dark green material with black streaks was chosen. In the July/August 2011 issue of Land and Water the manufacture was quoted as saying, “The floating cover has been constructed of CSPE geomembrane panels that have been produced with a one-of-a-kind mix of black and green coloring in each panel. The color mix creates a large-scale camouflage that helps the entire reservoir mimic the changing shades of the hills and vegetation.” (Roades, 2011)

3. CONSTRUCTION

After draining the reservoir between October 2009 and May 2010, the old inlet/outlet tower and pipeline were demolished, and the asphalt concrete liner, which had served the reservoir well, was repaved (Figure 4 and 5). New pipelines and appurtenances were then installed and the facility filled. Then, in October 2010 the reservoir was drained again to enable the last phase of reconstruction. This included installation of the floating cover (work which began in January 2011).

Figure 4 and 5: Original reservoir (left) and after removal of tower and new asphalt concrete lining (right). Note the original concrete faced slope at back.

4. COVER MANUFACTURE

The cover was truly a hand-crafted one-of-a-kind material. Manufacture starts with blending of the ingredients. These ingredients travel through a number of blenders until they are fully dispersed into a batch of material that has the approximate consistency of cookie dough. About 50 lbs of this rubber dough are put onto a two-roll mill where they are heated and blended into a soft semi-molten state. An operator manipulates the rubber on the mill for a pre-set period, folding the material back and forth, until the material is blended and the colors are smooth and well-dispersed. Then the rubber batch is dropped onto a table and taken to the next two-roll mill. This second mill makes sure that all the materials are up to temperature before being fed into the calendar.

In the manufacture of this unique cover material 50 lbs batches of dark green material were laid out onto a table after the first mill, and three pieces of black were placed onto the rough sheet. This was then rolled back up and then transferred

Figure 6 and 7: Feeding CSPE into the two-roll mills. Mill #1 on left, Mill #2 on right. Tan CSPE shown.

to the second mill. On the second mill the operator did not blend the material but let the black form streaks in the surface. When the streaks had reached the right consistency the rubber batch was dropped onto a table and taken to the calendar to be fed into the machine.

The calendar squeezes the rubber batch into a thin film and then presses it onto the support fabric. The 45-mil material made for this project consisted of a 17-mil coating on both sides of a support fabric. The final product maintained a consistent color throughout the project. If you look at the pictures of the reservoir you can see that the color did not vary considerably from batch to batch.

5. COVER FABRICATION

The custom material was shipped to the fabricator's facilities in El Cajon, California, which is near San Diego. It is up to the fabricator/installer to create the drawings and layout details that will convert the designer's intent into a finished floating cover.

There are two guidelines that are followed for the design of floating covers in California. The first is M25 Floating cover guideline (AWWA 2000). The second is the CA/NV Floating Cover Guideline (AWWA 1999). The fabricator/installer prepared the cover drawings for this project as seen in Figure 11.

Because this reservoir was lined with an asphalt concrete liner, a chafer strip was used to prevent wear on the underside of the cover. The chafer strip is made from the same material as the floating cover and extends about 2/3 of the way down the slope. As the cover moves up and down in response to water level

Figure 8: Installing a 35-ft-wide fabricated panel.

changes, the chafer strip prevents wear against the asphalt concrete.

The fabrication step allows specialty materials, such as this specially colored material, to be made into large panels, thus reducing the need for field welds. (Prefabricated panels are prepared in the controlled conditions of the factory, which eliminates weather risk on fabrication seams. By using prefabricated cover panels, field installation times are reduced and overall seam quality improves.)

This fabricator has a unique ability to make prefabricated panels up to 36 ft wide without folds using a specially designed 36-ft-wide winder. Eliminating folds in prefabricated panels reduces wrinkling for a smoother appearance. The chafer strip panels were folded and fabricated into smaller bundles; however, the cover panels used the wide roll technique to make panels 35 ft wide.

Prefabrication welding was accomplished using hot wedge welders. The welders are uniquely set up with 3-inch-wide wedges and adjusted so that there is no flap left on either the top or the bottom of the seam. Welding the seam down completely on both sides of the weld makes it easier to clean the cover when it is in service.

Panels were prefabricated according to a predetermined plan. Each fabricated panel was wrapped in a protective wrapper and numbered to match the installation plan.

6. COVER INSTALLATION

Cover layout is detailed in Figure 11. The cover design is a defined-sump style that follows the design outlined in US patent 3,991,900. In this design a series of floats and weights are attached to the surface of the cover and create channels to collect rainwater. Pumps in these channels remove the rainwater and pump it off the cover.

Cover installation began in January 2011 and was completed later that year. The first component installed was the chafer strip. This was placed on the asphalt liner and secured to the top of the slope using a small concrete wall and batten bars. Sand tubes and sand bags held the chafer strip in place against wind uplift until the cover was placed on top.

The cover material was then placed on top of the chafer strip and extended across the bottom of the reservoir. The cover material must be completely placed to reduce the risk of rain delays before proceeding with detail work. Once the cover material is placed and tested the detail work can begin. Details included the floats and weights that create the defined sumps, as well as hatches and vacuum relief vents.

Figure 9 and 10: Chafer strip installation (left). Cover panels being installed (right).

A defined sump floating cover uses a series of floats and weights to create channels in the surface so that water can be removed. The floats are made from expanded polyethylene foam. This foam is then protected from UV damage by wrapping with the same material as the floating cover. These float covers are laid out and welded to the surface of the cover after the cover is completed and tested. The floats are typically 9 ft long, 6" thick, and 12" wide on the floor and 3' long x 6" thick x 12" wide on the slopes.

The weights in the bottom of the sump channels are sand tubes. A doubled section of CSPE material is first welded down the middle of the channels where the sand tube will rest in service. This is the highest wear area of a floating cover. This is where dirt and debris will accumulate and it needs to be protected. Once this wear strip is placed a series of straps are welded to the cover; these hold the sand tubes in place. The sand tubes are 5 ft long and are 5 inches in diameter on the floor and 3 ft long by 5 inches in diameter on the slopes. The sand tubes are made from the same material as the floating cover. They are also perforated so that there is no air in the tube that will work against the weight of the sand.

The layout of the floats and weights is adjusted based on the final layout of the pond. Because the seams in the final cover may vary slightly from their planned positions on the drawings, the final layout of floats and weights must be adjusted to the as-built dimensions of the cover.

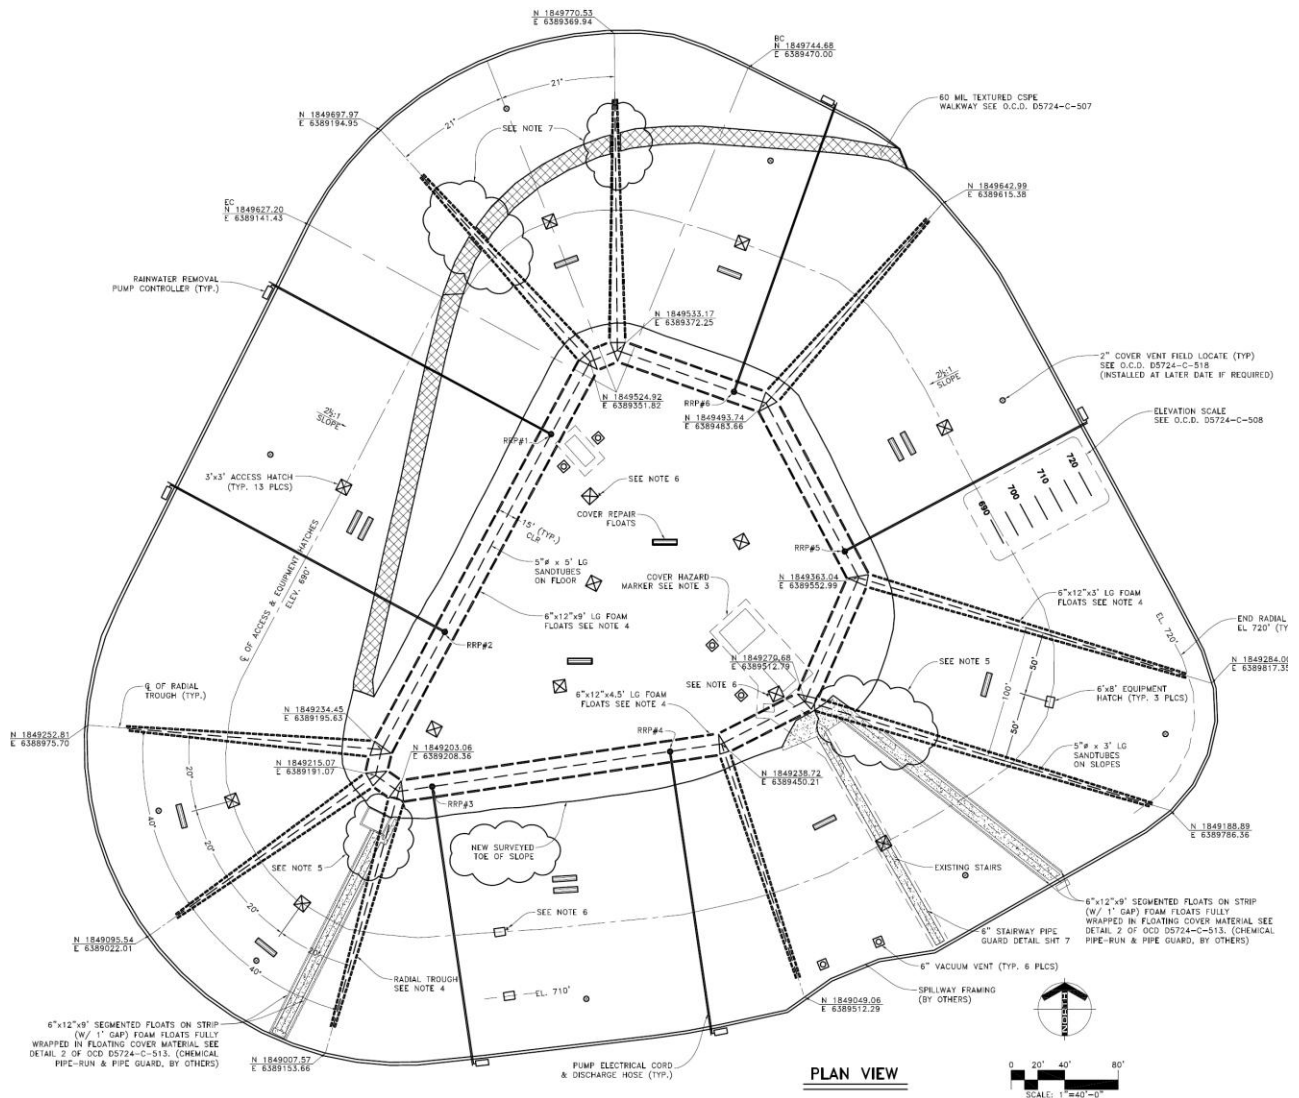

Figure 11: Layout design for the defined-sump floating cover.

The distance between float channels controls channel depths when the reservoir is full. On Figure 11 the distance between channels can be seen to be wider at the bottom of the reservoir and then tapering to the top of the reservoir. There is less slack to account for at the top of the reservoir so the channels are not as deep. This design has been worked out by experience and results in a smooth, flat cover at all operating levels.

Finally, there is an overflow spillway on the top of the reservoir that protects the cover against inadvertent overflows. This spillway was originally designed to have a stainless steel flap that would move out of the way during an overflow. The design was modified and the overflow flap constructed from CSPE material and sand tubes to minimize flap weight and

provide an efficient operation. A stainless steel frame was constructed and set into the concrete spillway. The chafer strip was then connected to the inside bottom of the frame while the cover was brought up over the frame and draped down the back. The draped section is then weighted with sand tubes to prevent the flap from opening unless there is an overflow.

Figure 12: View of the overflow swale.

7. CONCLUSION

The Santa Ynez floating cover project was an example of a standard cover that required non-standard attention to aesthetics and color. The final project is an attractive part of the local landscape while providing additional protection to drinking water in the area. The ability to select a “handmade” color on this project helped the local water department get the buy-in from the community they needed so that they could go ahead with the functional improvements needed. CSPE materials are one of the few geosynthetic barrier materials used for floating covers that has a broad color palette while maintaining long term UV resistance.

ABSTRACT

There are many critical applications where geomembranes can be subjected to abrasion, e.g., linings of tunnels, canals, reservoirs, pumped storage facilities, etc. In this sense abrasion is the ongoing process of scuffing, scratching or rubbing away of the surface exposed material. Abrasion can be intentionally imposed by an abrasive material in a controlled process or by abuse in an uncontrolled manner.

This paper reports on the abrasion resistance behavior of five commonly used geomembranes, i.e., HDPE, LLDPE, fPP, PVC and EPDM. The laboratory method used was the Taber abrasion device per ASTM D4060 wherein weight loss, strength retained and elongation retained were measured as a function of rotation cycles. Both dry and saturated conditions were evaluated.

In general the softer geomembranes, as measured by their durometer, abrade more readily than the stiffer ones. Thus, HDPE was the least abraded and EPDM the most. Regarding mass loss, the amount of abrasion under dry conditions was greater than under saturated conditions. This finding was reversed with strength retained and elongation retained in that the saturated conditions were slightly more severe than the dry conditions. This was unexpected and is puzzling yet the data is consistent in this regard. As anticipated, the coarser abrasion disk was more severe than the medium abrasion disk for all of the variables evaluated.

1. ABRASION TESTING

There are a large number of standardized abrasion test devices and procedures. Some of these are the following:

- Crockmeter Abrader
- Fully Abrasive Tester
- Sliding Block Abrader
- Transverse Abrader
- Gakushen Head Abrader
- Hexbr Flex Abrader
- Taber Abrasion Tester

All are designed as accelerated abrasion test devices but none are applicable to all materials and to different abrasion scenarios. In this regard, they are application specific; see Koerner and Bove (1989), Rigo and Cazzuffi (1991), Cancelli and Cazzuffi (1994), Mullen-Rochholz (1996), Alexander (1998), Ossa (2005) and Koerner (2012) who have evaluated abrasion of various geosynthetic materials. Of the above group, we have arbitrarily selected the Taber Abrasion Tester for evaluation of the geomembranes in this study. Perhaps the major reason for doing so is its adaptability for containing, positioning and evaluating smooth geomembrane surfaces.

Taber Abrasion is a test device and procedure to determine a selected material's resistance to abrasion. The abrasion phenomenon can be difficult to quantify and compare by itself that is why weight loss is often used to evaluate its effect. The original weight of a test specimen is measured, the test specimen is then placed in the abrasion tester; a load is placed on top of the abrader wheel and it is allowed to spin for a specified number of revolutions. The final weight is taken and the abrasion weight loss calculated. The load and abrading wheel can be adjusted for softer or harder materials. Abrasive damage is also judged numerically by the change in tensile properties of test specimens removed from the abraded material. Strength and elongation percentage retained between the abraded and unabraded specimen is measured via the appropriate tensile tests for the various geomembrane types. This ASTM test method (D4060) is similar to ISO 3537 and ANSI/SAE Z26.1, Test 17.

The Taber abrasion device used for this study is shown in Figure 1a. A schematic of the device during motion is shown in Figure 1b. Fundamental in conducting the tests are the applied weight on the rotating wheels and the type and texture of the abrasion wheels themselves. These are shown in Figures 1c and 1d, respectively. For the tests conducted in this study, we used a 1.0 kg weight throughout and used both CS-10 (medium) and CS-17 (coarse) abrasion disks.

2. DETAILS OF TABER ABRASION TESTING

To generate useful data, abrasion specimens must be flat. This is done one of two ways depending on the rigidity of the specimens. This is via a ring clamp specimen holder or threaded ring specimen holder. The threaded ring specimen holder was used in our case because all five geomembranes tested were rigid and tough enough to not undergo warping while being clamped and abraded in this manner. A neoprene rubber substrate served as the flexible material on the standard specimen platen with a 100 grit emory paper used in conjunction with the clamp ring. The neoprene substrate is standard procedure and the emory paper prevents any stretching and wrinkling.

Figures 1a and 1b show the test conditions in the “dry” condition. Thus a vacuum is applied continuously during the test. This is to prevent wheel surface change during the test that may become clogged due to the pick-up of plastic or other materials from test specimens. Such residue must be cleaned at frequent intervals. The abrasive effort cannot be subject to variation due to changes in the abrasive characteristics of the wheel during testing. Figure 2 shows a photograph of an abraded specimen with a stencil of how tensile specimens are cut from the abraded samples. As noted in Figure 1b, the abrasion simulates a skidding action about the specimen. With one wheel moving forward and the other in reverse as the specimen rotates on the platen in a counter clockwise manner. It is interesting to note that the track left on the specimen is somewhat wider than a wheel width.

Figure 2. Abraded specimen with tensile test outlines for strength and elongation retained properties.

A replicate set of all test specimens was also subjected to a saturated abrasion testing by equipping the Taber abrasion device with a rimmed specimen holder as seen in Figure 3. This is useful to determine the effect of absorbed and/or surface moisture on abrasion resistance of the test specimen. It should be made clear that saturating the samples during the abrasion exposure might be quite different than exposing them to flowing water.

Figure 3. Reconfigured specimen holder so as to provide for saturated conditions.

3. DETAILS OF GEOMEMBRANES TESTED

For this study we selected five different geomembranes that are commonly used in the applications listed in the abstract. They are high density polyethylene (HDPE), linear low density polyethylene (LLDPE), flexible polypropylene (fPP), Polyvinyl Chloride (PVC) and Ethylene Propylene Diene Monomer (EPDM). All were smooth surfaced and were about the same thickness between 0.75 and 1.20 mm. They conformed to international specification as first quality material. The corresponding specifications for each geomembrane are as follows;

- HDPE, GRI Test Method GM13, Standard Specification for Test Methods, Test Properties and Testing Frequency for High Density Polyethylene (HDPE) Smooth and Textured Geomembranes
- LLDPE, GRI Test Method GM17, Standard Specification for Test Methods, Test Properties and Testing Frequency for Linear Low Density Polyethylene (LLDPE) Smooth and Textured Geomembranes
- fPP, GRI Test Method GM22, Standard Specification for Test Methods, Test Properties and Testing Frequency for flexible polypropylene (fPP) Smooth and Textured Geomembranes
- PVC, ASTM D7176, Standard Specification for Non-Reinforced Polyvinyl Chloride (PVC) Geomembranes Used in Buried Applications

- EPDM, GRI Test Method GM23, Standard Specification for Test Methods, Test Properties and Testing Frequency for Ethylene Propylene Diene Monomer (EPDM) Geomembranes.

Each of the materials used in this investigation went through the complete set of physical, mechanical, and endurance tests cited in the respective specifications. The results of this testing are given in Table 1.

Table 1. Geomembranes evaluated in the abrasion testing of this study.

Geomembrane Type	Specification Designation	Nominal Thickness (mm)	Compounded Density (g/cc)	Durometer Shore Type D (hardness)	Comments
HDPE	GRI-GM13	1.0	0.942	50	passed all criteria
LLDPE	GRI-GM17	1.0	0.930	46	passed all criteria
fPP	GRI-GM22	0.75	0.949	33	passed all criteria
PVC	ASTM D7176	0.75	1.20	29	slightly low mol. wt. plasticizer
EPDM	GRI-GM23	1.15	1.32	27	passed all criteria

4. RESULTS OF THIS STUDY

The five geomembranes listed in Table 1 were all evaluated under dry and saturated conditions in the Taber abrasion device at cycles of 10, 100, 1000 and 5000 rotations with both the CS-10 (medium) and CS-17 (coarse) abrasion discs. Upon conclusion of the testing of each specimen, the following three properties were measured;

- mass (weight) loss in mg from the original test specimen's mass,
- strength retained as a percentage of the original strength, and
- elongation retained as a percentage of the original elongation.

Regarding strength and elongation testing, the ASTM test method used for the geomembranes was according to the designated specification. In this regard, HDPE, LLDPE and fPP used ASTM D6693, PVC used D882 and EPDM used D412. The results from this testing program are given in Tables 2a, b and c for the dry conditions and Tables 3a, b and c for the saturated conditions.

Table 2. Mass loss, strength retained and elongation retained for Taber abrasion testing in the "dry" condition.

(a) Dry mass loss (mg) Taber adhesion (ASTM D4060) results for five geomembranes under 1 kg load for various durations and abrasive disks

Cycles GM Type	Abrasion Disk CS-10 (Medium)				Abrasion Disk CS-17 (Coarse)			
	10	100	1000	5000	10	100	1000	5000
HDPE	0.4	0.8	10.4	33.0	0.2	2.8	4.3	46.2
LLDPE	0.3	1.4	14.3	32.1	1.2	1.4	6.5	42.0
PVC	0.7	6.1	26.0	58.8	0.6	5.6	29.3	69.2
fPP	0.3	0.5	14.8	60.5	0.8	2.9	8.7	68.2
EPDM	1.2	7.3	52.1	218.7	2.7	8.8	51.9	278.9

(b) Dry percent strength retained after Taber adhesion testing (ASTM D4060) for five geomembranes under 1 kg load for various durations and abrasive disks

Cycles GM Type	Abrasion Disk CS-10 (Medium)				Abrasion Disk CS-17 (Coarse)			
	10	100	1000	5000	10	100	1000	5000
HDPE	95	94	90	91	98	85	87	85

EPDM	100	88	86	74	92	83	85	76

5. DISCUSSION

Some general observations of the abrasion data shown in Table 2 (dry conditions) and Table 3 (saturated conditions) are that the data is reasonably “well behaved” insofar as the effect of number of abrading cycles. In this respect the dry condition mass loss shown in Table 2a increases exponentially going from 10 through 5000 cycles. In a like manner, the saturated condition mass loss in Table 3a is also exponentially increasing but significantly less so than with the dry specimens. Of course, this is logical to expect and was anticipated. Furthermore, since the applications envisioned invariably involve water, the saturated condition tests are probably closer to reality. Also seen in the comparisons of mass loss in Tables 2a and 3a, the CS-17 (coarse) abrasion disk is indeed more aggressive than the CS-10 (medium) abrasion disk by approximately 15 to 50%. Again this is an anticipated outcome. Clearly seen in this mass loss data is

that the ordering from lowest to highest is in direct proportion to the hardness of the various geomembranes. In this regard, recall the Shore hardness durometer values in Table 1. Perhaps the outlier in this uniformity is the EPDM geomembrane which is only slightly lower than PVC and fPP in durometer but is significantly higher in its mass loss at all cycles. This may be due to a change in the type of failure which was atypical in that small particles were being pulled from the gradually abrading surface. That said, the saturated mass losses are significantly lower than the dry mass losses and these, the saturated, values are probably more indicative of realistic geomembrane applications.

Regarding the strength retained values in Table 2b (dry conditions) and Table 3b (saturated conditions) the data shows a decrease with increasing number of abrasion cycles. However, the change is nowhere as drastic as with mass loss and is also somewhat less consistent. There also appears to be a relative sharp decrease in the 5000 cycle data over that of 1000 cycles. One other important feature of the strength retained data is that it was as great, or even greater, in the saturated tests than in the dry test. This finding was quite unexpected, but it occurred in most of the five geomembranes evaluated.

Finally, the elongation retained values of Tables 2c (dry conditions) and Table 3c (saturated conditions) trend extremely close to the strength retained values discussed previously. This comment refers to the elongation retained decreases being somewhat linearly decreasing with number of cycles rather than exponential as with the mass loss, but also with the close agreement of mass loss with decreasing durometer. Lastly, the fact that the elongation retained was lower under saturated conditions (Table 3c) than with dry conditions is again a surprise for which we have no answer. In this regard, the data must speak for itself.

6. SUMMARY AND CONCLUSIONS

The Taber abrasion device and testing protocol has been available for decades. In this regard it seems very well suited for testing geomembranes, yet there is a lack of experimentation in this regard. When abrasion of geomembranes are at issue, as in the applications mentioned in the abstract, it is felt that Taber abrasion should be a candidate test method. In fact, there is no generic specification that we know of which requires abrasion resistance. If this eventually occurs we recommend that the Taber device be specified and used accordingly. The test is, however, clearly an index test and the data is best considered when used in comparison to other like data.

In conclusion, five commonly used smooth surface geomembranes were evaluated in dry and saturated conditions. Under abrasion cycles from 10 to 5000 with two different abrasion disks (medium and coarse), the data obtained showed the following trends.

- Increasing cycles produced greater mass loss, less strength retained and less elongation retained.
- The mass loss data exhibited an exponential trend, whereas the strength and elongation retained were closer to a linear trend with increasing abrasion cycles.
- There was a clear trend of mass loss, strength retained and elongation retained with durometer of the five geomembranes evaluated; the harder the surface, the lower were the changes in values. In this regard the ordering from least-to-greatest changes was HDPE, LLDPE, PVC, fPP and EPDM.
- A major discrepancy in the anticipated trends, however, was when testing under dry conditions the mass loss was greater than when testing with saturated conditions, while with strength retained and elongation retained the wet conditions produced the greater changes. This was a most pronounced trend with both strength retained and elongation retained values being close to one another and mass loss being far greater in changes from as-received values and in the opposite direction.

An Innovative Use of Expanded Polystyrene Insulated Concrete Forms (ICF) for Geohazards

Bret N. Lingwall, PhD, PE, Kleinfelder, Inc, USA, blingwall@kleinfelder.com
Steven F. Bartlett, PhD, PEm University of Utah, USA, Bartlett@civil.utah.edu

ABSTRACT

Pipelines are damaged by permanent ground displacement (PGD) resulting from faulting, land-sliding, or liquefaction. Insulated concrete forms (ICFs), a product constructed of two slabs of rigid polystyrene foam, separated by plastic brackets, can be used in trenches as a compressible inclusion to reduce PGD pipeline damage. The initial rigidity and relative compressibility at large stress levels make ICFs a candidate for protecting underground pipelines undergoing PGD. The imposed pipe distress from PGD is reduced by lowering the resistance to pipe movement. ICFs, when placed in the trench, can perform this function; accommodating the horizontal movement between the pipe and the soil, reducing the imposed stress on the pipe. Full and bench scale tests were performed to define this interaction, soil-ICF-pipe non-linear springs required for pipeline design were developed. The results for the ICF-soil system shows a significant reduction in pipeline stress for the case where the pipeline undergoes PGD.

1. INTRODUCTION

The concept of using Expanded Polystyrene (EPS) Geofoam as a "compressible inclusion" between walls or foundation elements and a soil mass was conceptualized about 20 years ago (Horvath 1995, 2005). These publications explore this concept by simple numerical analyses and conceptual models for estimating the developed static earth pressures against buried structures using Geofoam inclusions. Yoshizaka and Sakanoue (2003) investigated Geofoam as a method to reduce lateral force-displacement relationships for buried pipelines. They found a 33 to 60% reduction in the lateral soil-pipe forces when Geofoam was used as light-weight trench backfill for pipe undergoing horizontal displacement. However, Yoshizaka and Sakanoue (2003) did not place Geofoam in the sidewalls of the trench, but used it as a light-weight cover to reduce vertical loads. More recently, Choo et al. (2007) explored the use of Geofoam as a cover system for buried steel pipelines subjected to vertical fault offset. They used centrifuge testing of scaled models to show the benefits of EPS as a light-weight material in reducing pipeline stresses undergoing vertical offset. Choo et al. (2007) demonstrated that the light-weight cover application of Geofoam can assist in reduction of pipeline damage, but they did not address the compressible inclusion effects of the Geofoam cover in reducing the stresses, particularly for horizontal offset problems.

Considerable work has been done for the case of rigid steel pipelines undergoing horizontal offset from strike-slip faults, liquefaction-induced lateral spread and slope failure. Newmark and Hall (1975), Wang and Yeh (1985), and Kennedy et al. (1979) developed solutions for the stresses and strains imposed on a steel pipeline by permanent ground displacements (PGD). For horizontal PGD and its impact to pipelines, ASCE (1984), MCEER (1999) and American Lifeline Alliance (ALA) (2005) recommend using the Newmark and Hall (1975), Kennedy et al. (1979) and Finite Element Method (FEM) approaches for evaluating vertical movements. ASCE, MCEER and ALA recommend that FEM and elastic methods are best suited for horizontal movements and are applicable to cases where the pipeline is buried sufficiently deep so as not to reach ground surface. In addition, ASCE, MCEER and ALA recommend using Trautmann and O'Rourke (1985) soil-pipe springs.

Perhaps numerical modeling offers the best method of evaluating complex soil/pipe interactions. FEM has been used extensively to model horizontal permanent ground deformations and their effects on buried steel pipelines (Takada, 2001 and Desmond et al., 1995). Recently, Karamitros et al. (2007) used the FEM to develop a strike-slip model for pipelines crossing active faults based on the earlier work of Wang and Yeh (1985) and Kennedy (1979). Trautmann and O'Rourke (1985) demonstrated that lateral and vertical movements of pipes through soil are essentially the same as for flat anchor plates undergoing lateral or vertical movements in soils. Their findings were confirmed by Cheuk et al. (2005). The objective of both Trautmann and O'Rourke and Cheuk et al. was to develop soil-pipe interaction Winkler springs for FEM modeling. The Winkler (1867) spring approach is based on developing relations that assume the soil and structure will interact as a non-damped uncoupled spring. Soil spring constants are generally dependent upon the sectional configuration and the dimensions of an underground structure, rigidity of soil deposits, direction of loading and boundary conditions (Matsubara and Hoshiya 2000). These springs are often non-linear, and research on Geofoam shows that soil-EPS-pipe interaction can be modeled with non-linear springs (Lingwall 2011).

Insulated Concrete Forms (ICFs) are proposed to be used as a compressible inclusion for laterally displacing pipes due to PGD. The compressible nature of the EPS foam material forming the slab sides of the ICF, coupled with the void between the slabs separated by only thin plastic clips, provide the potential to reduce the non-linear soil-pipe interaction spring stiffness and strength. This research develops the non-linear spring needed for pipeline design for PGD. The non-linear springs are developed through a combination of laboratory testing, bench scale pipe-ICF testing, and full scale pipe-ICF-soil testing with a laterally displacing pipe.

2. ICF FOAM MATERIAL

ICFs are constructed by separating two EPS slabs by a set of plastic clips. The plastic clips are spaced along plastic brackets, which are glued to the EPS slabs. The plastic clips separate the EPS slabs 152 to 304 mm depending on manufacturer and vendor. In this case, 152 mm long clips were used. The brackets are spaced 204 mm apart. The slabs are 304 mm in assembled thickness, and run 1.2 to 2.4 m in length. An ICF with two clips per bracket is shown in Figure 1. The edges of the EPS slabs have rabbited edges for stacking ICFs on top of one another for foundation wall construction.

Figure 1. ICF with 2 plastic clips in place on each bracket

Samples of the ICF foam material were trimmed using a hot wire cutter for specimen testing of the foam. Samples were trimmed to 2 mm cubes, matching the specimen size for Geofom in ASTM D6817. Specimens were measured to have a density of 24 kg/m³. This compares to the minimum specified density of EPS 22 from ASTM D6817 (22 kg/m³). 7 specimens were tested in uniaxial compression to approximately 80% vertical (axial) strain. The compressive resistance at 1% strain was found to be approximately 79 kPa, 5% strain of 132 kPa, and 10% strain of 144 kPa. These compressive resistances compare well to EPS 22 from ASTM D6817, as well as the specimen testing for EPS 22 from

Lingwall (2011). Figure 2 shows the compression test stress:strain curves for all 7 specimen tests as well as typical curve for EPS 22. It should be noted that the specimens were taken from 4 different ICFs from different production batches obtained from local ICF contractors. The foam material is shown to be variable, though the shape of the different stress:strain curves are similar for all specimens. The foam material shows extreme strain hardening after approximately 50% strain.

ICF Foam Material Compression Tests

Figure 2. Stress:Strain relationships for ICF foam material and comparison with EPS22

The strength of an ICF when placed against a laterally displacing pipe will be governed by the tensile strength of the foam slab. Lingwall (2011) showed that in pipe-EPS22 interaction Geofomo has tensile strengths of 95.7 to 191.5 kPa. ASTM D6817 specifies a minimum flexural strength of 239.4 kPa.

3. ICF-PIPE INTERACTION TESTS

Once the foam material was characterized, the next step in developing non-linear springs is bench scale testing. Bench scale testing performed involved placing a 406 mm long section of ICF against grade X60 rigid steel pipe. In this case, the pipe had an outer diameter of 89 mm (3.2 mm pipe wall thickness). The pipe and ICF were pushed together slowly, with forces and displacements measured. The resultant force-displacement relationship is the non-linear spring. This directly measured the complex behavior of the ICF as a system with foam, brackets, and clips interacting with the rigid pipe. The pipe was rigid in comparison with the ICF, though it did have some flexibility. The pipe is supported for 90 mm at the middle of its length. The top of the ICF was pushed by a 6.4 mm thick steel plate.

The ICF was pushed into the pipe in two configurations. The first configuration was pipe parallel to the plastic brackets and clips. This means that the resistance to pipe movement was completely dependent on foam slab rigidity and tensile strength. The second configuration was pipe perpendicular to the plastic brackets and clips. In this case, the resistance to pipe movement depended on both the rigidity of the foam slab and the stiffness and strength of the plastic clips.

Figure 3 shows the ICF and pipe at the end of interaction testing in a pipe parallel configuration, and that the foam slabs experience tensile failure at the point of pipe contact. Figure 4 shows the resultant force:displacement relationships for pipe-ICF interaction using 6, 8, or 10 plastic clips for the 304 mm wide, 406 mm long, section of ICF.

Figure 3. ICF after pipe interaction testing with rigid pipe

Figure 4 demonstrates that the pipe parallel condition produces almost no resistance to pipe movement. EPS22 resists movement many times more than the pipe parallel condition. This configuration is deemed too soft for realistic construction and pipe design. The results for the pipe perpendicular tests show less resistance to pipe movement than the EPS 22 block, but within a more reasonable range of resistances.

The resistance and stiffness shown in Figure 4 should not be used directly for design. The actual buried pipe system is backfilled with soil, and the ICF pushes against the compliant backfill and/or trench side wall. This introduces more complexity to the actual design non-linear spring. Also, construction and installation of an ICF trench system requires a separation material to keep backfill and debris from entering the void between the ICF slabs. If backfill or debris enters the void, the system could perform differently.

ICF-Pipe Interaction Tests

Figure 4. ICF pipe interaction test results showing forces at pipe displacements

4. FULL SCALE PIPE-ICF TEST

A test using a 171.5 mm OD pipe was conducted to obtain the force-displacement behavior (non-linear spring) for an ICF system with complete sand backfill. For this test, the pipe was pushed laterally in a trench box into an ICF, with sand surrounding the pipe and ICF. This test was done to explore the benefits of using ICFs as a compressible inclusion against a pipe undergoing horizontal displacement. The primary goal the research described in this section was to measure the reduction in stress on the pipe for the various cases and to later use this information for numerical modeling and design using the resultant non-linear spring information from testing. This full-scale experiment was conducted at the University of Utah's Department of Civil and Environmental Engineering in the fall of 2010.

4.1 Experimental Set-Up

A contained test system (i.e., trench box) was locally manufactured for the experimental program. This test system included a loading device, reaction system (i.e., box) for the load device, a test chamber for the soil-ICF-pipe interaction testing, and the necessary instrumentation for measurements.

The box's overall dimensions are: 5.33 m long, 1.83 m wide and 1.83 m high (Figure 6). The box was constructed of 6.4 mm thick steel plates. The horizontal load capacity of the box is approximately 112 kN. Both ends of the trench box were reinforced and braced with structural steel angle and channel sections to withstand the forces involved in the experiments. The end walls of the trench box were heavily reinforced to minimize the reaction deflections of the ram against the wall. A reinforced door was constructed on one end, which allowed side entry into the box. The top of the box was left open, this allowed for sand to be placed in the box from above.

Internally, the trench box is divided into two chambers by a rigid 10 mm steel partition wall. The first, or smaller, chamber houses the actuator and is 2.13 m long, as measured internally from the end wall to the partition wall. In the smaller chamber, the actuator reacts internally against the end wall of the steel box. Three struts extended from the actuator, through the partition wall, into the second chamber. Stiffeners were added to the struts to prevent any vertical

movement. Thus, the actuator imposes the purely horizontal force on the pipe via these steel struts that extend into the second chamber. Both chambers were 1.83 m wide.

The second, or larger, chamber is 3.2 m long and houses the pipe, geofoam and sand backfill used in the test program. It was filled with sand and/or EPS geofoam according to preselected configurations. In this chamber, the 171.5 mm O.D. steel pipe was welded onto the struts. This allowed sand to be placed around the pipe in the second chamber, and the pipe to be pushed laterally into the ICF and backfill system. The center of the pipe rests 457 mm above the bottom of the box, which produces a height to pipe diameter ratio (H/D) of 10. Sand backfill 1.7 m thick was placed above the pipe, giving the pipe a field stress condition.

The actuator used in this test program utilized a MTS electronic control and data acquisition system. The actuator has a maximum capacity of 445 kN with a maximum stroke of 150 mm. The maximum displacement rate for the ram is 3 m per minute. The ram is powered by a MTS pneumatic pump with computer controlled manifold and servo. Feedback for the system is through the displacement transducer and the tests were done as displacement controlled tests. (The system is capable of cyclic testing though this capability was not utilized in this test program.) Several types of measurements were taken during the test program. The total load applied to the pipe by the actuator was measured by a single load cell. The displacement of the actuator, as it pushed the pipe into the backfill material was measured with a displacement transducer. Vibrating wire and resistant base total earth pressure cells were placed in the backfill to measure the horizontal and vertical stresses that developed in the sand backfill mass. Both the load cell and the displacement transducer were calibrated prior to their use in the subsequent test program.

Sand was imported to the test for backfill. This clean sand was processed before delivery for a consistent gradation throughout the material. All fines were non-plastic, and the gradation is shown in Figure 5. Sand was used for backfill due to the low variability in its gradation, ease of placement, and consistent compaction. Sand was compacted in 304 mm loose lifts with a hand operated vibratory plate compactor to a dry unit weight of 15.7 kN/m³, (16.1 kN/m³ total unit weight). Compaction was tested on each lift with a nuclear density gauge.

Figure 5. Grain size distribution for sand backfill in full scale ICF-pipe test

In parallel with the full scale ICF-pipe interaction test, a baseline full-scale lateral pipe movement test was performed using only sand backfill. This baseline provides a comparison to the ICF test, and shows improvement over traditional backfill systems. The baseline case of sand only backfill was run first. Full details of the comparison baseline case are in Lingwall (2011).

The test procedure for both sand baseline and ICF backfill tests began with placing two layers of smooth plastic sheeting along the steel walls of the experimental box. Between the layers of plastic a friction reducing thin layer of silicon lubricant was applied. This lubricant, in conjunction with two layers of plastic, reduced edge effects, and better simulated a plane-strain situation. As such the data collected was interpreted as plane strain. This is similar to the approach used by Trautman and O'Rourke (1985) and Cheuk et al. (2005). The Trautmann and O'Rourke study is the basis for current design non-linear springs used in pipeline design for PGD. This test does not seek to revolutionize the pipeline design procedures, but update it with new information for a new backfill system. The ICF was then assembled as shown in Figure 1. The test was chosen to run in a pipe-perpendicular to plastic strut configuration based on the testing presented in section 3 of this paper. The ICF was wrapped in 2 layers of plastic to prevent sand backfill from flowing into the void between the foam slabs. The ICF was placed along side the pipe, and sand was backfilled around both.

After backfilling of the box, the actuator was displaced slowly (25 mm/min), with continuous data collection. The actuator was displaced until the threshold of 111 kN was reached on the load cell, or a maximum horizontal pipe displacement of 152 mm. After completion of displacement, the test is stopped. Data collection backed up, and the pipe retracted to its initial position. The box is then emptied, and the ICF exhumed for inspection and qualitative examination of its failure.

Figure 6. Full scale test apparatus schematic in Plan View

4.2 Full Scale Test Results

The force-displacement relationships measured during lateral pipe movement during both tests are shown in terms of force per unit length in Figure 7. The sand backfill test maximum pipe resistance was measured to be 50 kN/m at 57 mm of displacement. The curve is approximately linear until a measured load was reached of 10 kN/m at 0.4 mm of displacement. After that, the sand backfill test experienced a non-linear force:displacement relationship. The pipe resistance reduced after the peak to a residual value of 47 kN/m by 76 mm of pipe movement.

The measured peak force of the ICF backfill test was 29.5 kN/m at 21 mm of pipe movement. After this point, the plastic struts yielded in the test, at the same time the entire ICF began to push back into the sand backfill. A complex behavior occurred, with plastic struts and brackets bending, stretching, and yielding, with foam slabs failing in tension, with some compression of the material at the point of contact, while the entire ICF is pushed into the sand backfill. This behavior is similar to the behavior observed in the bench scale testing. This complex behavior is demonstrated in Figure 7 by the seemingly erratic behavior after yield. This complex behavior continued until the end of the test also seen in the exhumed ICF shown in Figure 9. The peak load of the ICF was 40% less than the loose sand backfill baseline, while the ICF also had softer system stiffness. This shows that the non-linear spring for an ICF backfill system is softer and less stiff than sand backfill system. This reduces potential pipe distress due to PGD. The results of the two full scale tests

were normalized as shown in Figure 8 by the depth below ground surface, unit weight of the surrounding backfill soil, and the projected contact area of the pipe. This unit-less presentation of the data is for easier comparison with the recommendations in ASCE, ALA, and MCEER as well as the original lateral pipe tests in loose sand from Trautmann and O'Rourke (1985). The required stiffness and strength for pipeline design can be taken from Figures 6 and 7.

Figure 7. ICF-Pipe full scale test results comparing with sand only backfill

After completion of the ICF backfill test, the ICF was exhumed from the sand backfill for examination. This exhumed ICF is shown in Figure 9. The pipe was loaded against the shown ICF foam slab down the center of the ICF. The displacing pipe loaded the ICF and caused it to crack down the middle as shown. The plastic struts and clips bent, yielded, but only in a few cases experienced ultimate failure. The foam material that was between the plastic struts and the pipe compressed significantly from an initial thickness of over three mm to a final thickness of less than 12.5 mm. Thus, the ICF foam slab experienced localized strains of 85% and greater. The foam slab opposite pipe contact showed little distress. The majority of the distress at that slab occurred at the plastic struts where the clips attached.

The results of the ICF test are dependent on the number of clips used between the foam slabs. If more clips are to be used in the ICF than used in this test (2 per bracket), then the results should be scaled similar to the difference in strength between the pipe perpendicular tests shown in Figure 4. The sand backfill was loose, and retesting with denser sands, different soils, and layered systems can result in differing non-linear springs. Site specific testing and design is recommended for situations where ICFs are proposed to protect pipelines in place from PGD.

Figure 8. Normalized ICF-Pipe full scale test results including comparison with sand only backfill

Figure 9. Exhumed ICF after full scale ICF-pipe test

5.1 Conclusions

The use of ICFs for geohazard reduction was investigated in this study by use of ICFs as compressible inclusions against pipelines undergoing permanent ground displacements from faulting, landslides, or lateral spreading. The foam material for the ICF was tested in compression for developing design non-linear springs for pipeline design with an ICF backfill. The foam material compared well to EPS 22, a grade of EPS Geofoam. Sections of ICF were then tested in direct contact with a displacing pipe, varying the number of clips and orientation of the pipe with respect to the plastic brackets that hold the separation clips in the assembled ICF. The pipe parallel bracket orientation was found to be too weak for reliable pipeline design. The number of clips used in ICF assembly affects the resistance to pipe movement. Full scale tests with a pipe and sand backfill in plane strain conditions were then conducted. The resultant full scale non-linear springs can be used for pipeline design. The loose sand only backfill baseline test compared well to previously published non-linear springs from the geotechnical literature. The ICF backfill test (with loose sand surrounding ICF and pipe) showed 40% less resistance to lateral pipeline displacement as well as a less stiff response. ICFs can thus be used for protection of pipelines at fault crossings or other areas of PGD. Site specific testing and design is recommended since these tests used only one grade of ICF from one manufacturer and used loose sand as the material through which the pipe was laid. Differing soils and ICFs, as well as differing geometries, can produce differing results.

ACKNOWLEDGEMENTS

The authors wish to thank Evert Lawton and Aurel Trandafir for their support of the full scale testing, and Kleinfelder Inc. for the use of its materials testing laboratory equipment and geotechnical instrumentation.

Analytical Approach of Junction Property Evaluation of Geogrids by Designing with Clamping System

H.Y. Jeon, Y Jin, Division of nanosystem engineering, Inha University, Korea(Rep.), hyjeon@inha.ac.kr

ABSTRACT

Geogrids are used as reinforcement materials with a significant mutual effect on the surrounding soil. This mutual effect can be explained by friction between the soil and geogrid surface, as well as the transfer of passive resistance of the cross direction rib to the geogrid machine direction rib via the junction to accommodate the load of the soil. Therefore, geogrids should have sufficient junction strength to maintain the mutual effect with the surrounding soil. In general, the junction strength is calculated using the conversion equation recommended in GRI GG-2. On the other hand, the GRI GG-2 test has inherent weakness in not being able to consider the scale effect of geogrid specimens. Recently, a newly developed multi-clamp was used to test the junction strength. This method gives the junction strength considerable scale efficiency in a better way. In this study, a range of test conditions including the junction number, strain rate and specimen length, were examined to determine their effect on the junction strength. The normalized geogrid junction strength was calculated. The data was used to assess the optimization conditions for the testing multi-junction strength. The results demonstrate the suitability of using the multi-junction strength test considering the scale effect.

1. INTRODUCTION

Textile geogrids are representative reinforcement materials consisting of connected parallel sets of intersecting ribs with an aperture of sufficient size to allow strike-through of the surrounding soil, stone or other geotechnical materials. Therefore, a geogrid is a matrix like material with large open spaces called apertures between the ribs, which are typically 10 to 100 mm, and are known as longitudinal and transverse ribs [1]. The network structure of a geogrid has a stronger interaction with the adjacent soil than other sheet type reinforcements. In general, the interaction between the soil and geogrid is divided into 3 terms; (a) friction between the geogrid and adjacent soil, (b) soil to soil friction in direct contact with apertures and (c) passive resistance of the cross direction ribs of geogrids. Geogrids impose loads due to friction of the cross direction rib surface to the soil and the transfer of passive resistance of the cross direction ribs through the junction with the mechanical direction rib. Therefore, adequate junction strength is needed to carry the induced force. GRI GG-2 with a "T" shaped specimen is used widely. This method can determine the single junction strength, junction efficiency, and geogrid junction strength. The initial values of the single-junction strength and junction efficiency are obtained directly from the test results. On the other hand, this method assumes a linear relationship between the junction strength and junction number. The geogrid junction strength is calculated using the conversion equation recommended in GRI GG-2 [2]. Most of the geosynthetics employed in civil engineering are used as tensile members, and are subject to an assessment of their tensile strength by taking a specimen of a wide width. Therefore, more reliable test methods that include the scale effect are needed. The current trend in the assessment of the tensile strength of geosynthetics involves tensile strength tests on a specimen with a width as wide as possible. This technique can provide more accurate and reliable test data, considering the scale effect of a specimen. This paper proposes a multi-junction test method to assess the geogrid junction strength by considering the aperture size scale effect.

2. EXPERIMENTAL

2.1 Preparation of Geogrid

Polyethylene-terephthalate (PET) filament woven and warp knitted geogrids with polyvinyl chloride (PVC) coating were used. Table 1 lists the specification and physical properties of geogrids.

Table 1. Specifications of the geogrids.

Geogrid	Raw Material /Coating Agent	Number of ribs (/m)	Mechanical properties	
			Ultimate Strength (ton/m)	Elongation at Break (%)
W-GG-1	PET/PVC	47	6	12
W-GG-2	PET/PVC	38	10	12
WK-GG-1	PET/PVC	42	6	12
WK-GG-2	PET/PVC	38	10	12

2.2 Single and Multi-Junction Tests

The testing apparatus shown in Fig. 1 (a) is used mainly for assessing the single junction strength of a geogrid according to the GRI GG-2. The test method uses a clamping fixture that grips the transverse ribs of the geogrid immediately adjacent to and on each side of the longitudinal rib. The lower portion of the longitudinal rib is gripped in a standard clamp. Each clamp is mounted in a tensile testing machine, where the test specimen is pulled apart.

Figure 1. Overview of the junction test clamp (a) single junction test clamps (b) old designed multi-junction clamp (c) newly designed multi-junction clamp

In this study, a single-junction test was carried out using multi-junction clamp device. From the test results, the geogrid junction strength and junction efficiency (standard) was calculated using the following equations (eq. 1~3).

$$J_{rib} = \sum_{i=1}^n J_i / n \quad (1)$$

$$J_{grid} = (J_{rib}) (n_{junction}) / w \quad (2)$$

$$E_{junction} = (J_{rib} / T_{rib}) \times 100 \quad (3)$$

where, J_{rib} =single-junction strength (average);
 J_i =single junction strength of each junction (experimental value);
 n = the total number of test specimens;
 J_{grid} = the geogrid junction strength per unit width;
 $n_{junction}$ = the number of junctions in a unit width; w = unit width (typically 1 m or 1 ft);
 $E_{junction}$ = the junction efficiency; and
 T_{rib} = the tensile strength of single rib (GRI GG-1).

Previous studies [3-4] employed an old designed multi-junction clamp to test the geogrid junction strength (Fig. 1 (b)). The basic concept for this equipment was to widen the single junction test clamp and the point-to-point length was

determined by the aperture size of the test conditions. For the old designed multi-junction test, the point-to-point length and width of the clamp was 25 mm and 280 mm, respectively. The upper clamp had 11 gripping points for the junctions and the lower clamp was a flat type with 11 gripping points. Using the modified method, the geogird junction strength should be more reasonable than that obtained from the single junction test. On the other hand, this type of clamp is only suitable for testing geogrids with an aperture size of 25 mm. A newly developed multi-clamp was used recently to test the junction strength. This is composed drawing a multi-junction grip. The clamp is composed of a set of single grips in parallel. The pitch of the clamp grips can be adjusted freely. The total number of restraining grips is 9. In the lower part, a normal type rib clamp was used. Fig. 2(c) shows the newly designed multi-junction clamp with 8 grips. The experimental results are reported in terms of the multi-junction strength per specific number of ribs. The geogrid junction strength per unit width was calculated using the following equations (Eq. 4~6):

$$J_{\text{multi-rib}} = \sum_{i=1}^n J_{i\text{-multi}}/n \quad (4)$$

$$J_{\text{grid}} = \frac{(J_{\text{multi-rib}})(n_{\text{junction}})}{(W)(n_{\text{test}})} \quad (5)$$

$$E_{\text{junction}} = (J_{\text{grid}} / T_{\text{wide-width}}) \times 100 \quad (6)$$

where $J_{\text{multi-rib}}$ = the junction strength of a specimen width with i number of junctions (average);
 $J_{i\text{-multi}}$ = the each junction's junction strength width with i number of junctions (experimental value);
 n = the total number of test specimens;
 J_{grid} = the geogird junction strength per unit width;
 n_{junction} = the number of geogird junction per unit width;
 W = the unit width (typically 1m or 1 ft);
 n_{test} = the number of junction in the tested specimen;
 T_{grid} = the geogrid tensile strength per unit width.

To evaluate the effectiveness of the newly developed multi-junction testing apparatus and test conditions (strain rate, specimen length and junction numbers), a multi-junction clamp was employed to determine the junction strength with a test speed of 20, 50 and 100 mm/min under ambient conditions. 1~8 rib specimens were gripped in the clamps and the gauge length was 50mm, 100mm and 150mm. The single junction test samples were prepared according to the GRI-GG 2 test method and the test process was performed according to the ASTM D4595 for the united test condition. Multi-junction tests have been used under the same testing conditions and procedures, as ASTM D4595 except for the clamp devices.

2.3 Single and Wide-width Tensile Tests

Single and wide-width tensile strength test conditions were used according to the ASTM D4595 test method. A roll grip clamp was used in this test. Table 2 lists the total test conditions. The test data was compared with those of the junction tests.

Table 2. Test condition

Properties	Single junction test	Multi- junction test	Single tensile test	Wide-width tensile test
Scale effect	Unconsidered	considered	Unconsidered	Considered
Strain rate (mm/min)	70 (20, 50, 100)	70 (20, 50, 100)	70	70
Specimen width	1 rib	1~8rib (200 mm)	1 rib	200 mm
Specimen length (mm)	300 (50, 100, 150)	300 (50, 100, 150)	300	300

3. RESULTS AND DISCUSSION

3.1 Optimization of Geogrids Multi-Junction Strength Evaluation

Table 3 lists the test results of the single junction strength classified according to the grip position. In the GRI GG-2 test method, the upper grip position is as close as possible to the vertical center rib. This newly developed test method recommends that the upper grip position be in the middle of the vertical center rib. The single junction strengths tested using the new developed methods were lower than those tested according to the GRI GG-2 for woven and warp knitted geogrid. The elongation values displayed an opposite trend to the strength. GRI GG-2 determines the specimen under ideal conditions to examine the maximum junction strength. On the other hand, in soil, the cross rib of the geogrids suffers from variable curvature ribbing, and the center bearing rib is at the peak of the curvature. Therefore, gripping the center of the cross rib is more appropriate for representing the actual utilizing conditions. Nevertheless, the junction test is an index test, not a performance text, even if it is adjusted from one junction to 8 junctions.

Table 3. Single-junction test results according to the grip position.

Geogrid	Value	20 mm/min		50 mm/min		100 mm/min	
		GRI	New	GRI	New	GRI	New
W-GG-1	J_{single} (kgf)	12.0	11.4	12.5	11.6	13.6	12.8
	Elongation (mm)	2.2	2.4	2.5	2.8	2.5	2.7
W-GG-2	J_{single} (kgf)	19.2	18.5	19.8	18.8	20.4	19.7
	Elongation (mm)	3.9	4.1	4.2	4.3	4.2	4.7
WK-GG-1	J_{single} (kgf)	28.2	27.1	30.1	27.5	28.5	27.7
	Elongation (mm)	6.1	6.3	5.8	6.7	5.9	6.3
WK-GG-2	J_{single} (kgf)	39.1	37.7	39	38	39.6	38
	Elongation (mm)	7.0	7.4	6.4	7.4	6.6	7.0

Similar to the single junction test, the mean junction strength per rib and the geogrid junction strength per unit width were also calculated using multi-junction test results. Firstly, geogrids with 1-8 junctions were tested and the curves of the junction strength to the number of junctions were plotted. Secondly, normalized values of the junction strength were calculated for each sample. Fig. 2 shows the junction strength plotted as a function of the number of junctions in different specimen lengths. The junction strength obtained at different lengths showed no change in junction strength at the rupture point because woven and warp knitted materials contained a PET filament. Therefore, to derive precise data, the same conditions except for the specimen length were summarized and analyzed.

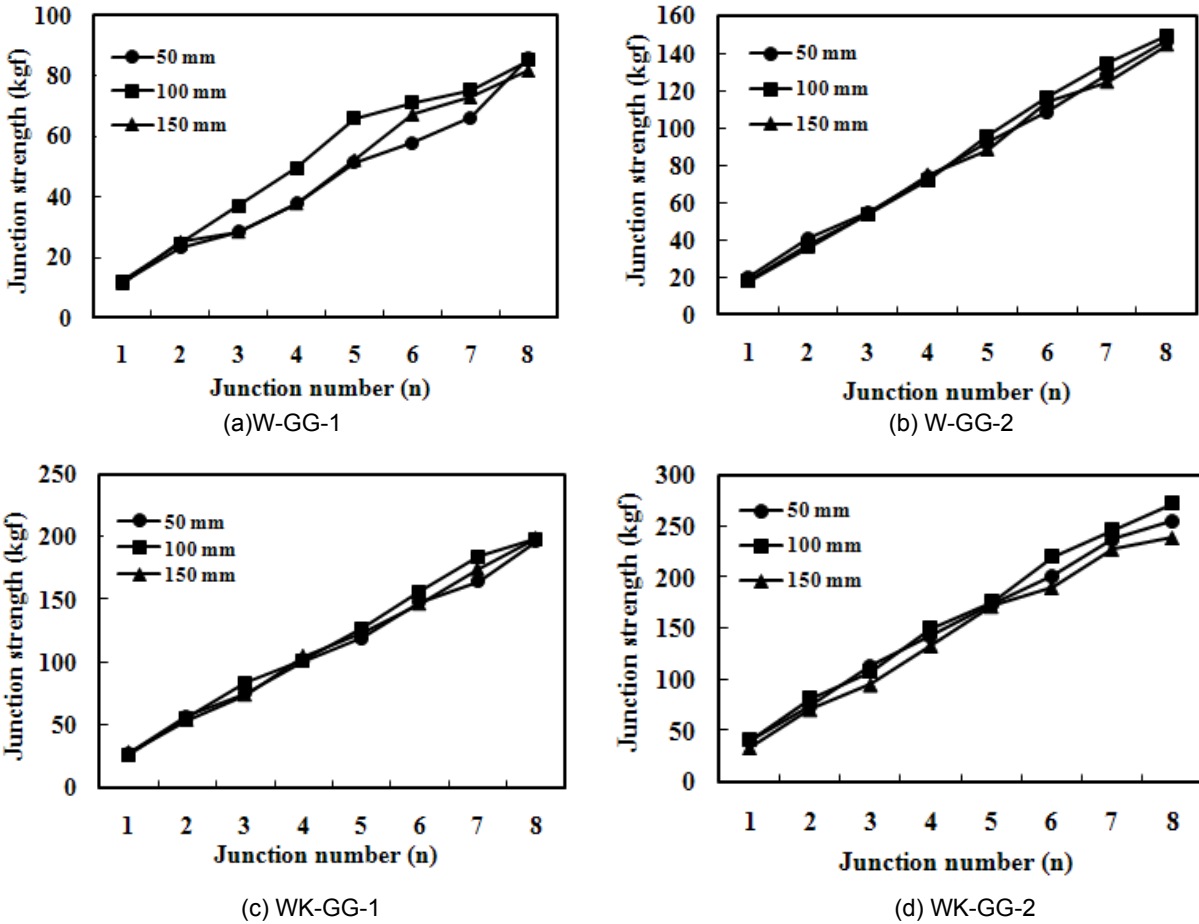

Figure 2. Regression analysis of the junction strength as a function of the number of junctions at different specimen lengths for geogrids.

Fig. 3 show the regression analysis results of the number of junctions as a function of the junction strength with the strain rate of geogrids. All the plots were divided uniformly and the curves showed a similar trend. Therefore, the data has good reliability. The junction strength increased linearly with the number of junctions. This difference was attributed to the scale effect and variation in the difference in manufactured products. Fig. 4 shows the relationship between the number of junctions and normalized junction strength with the strain rate of the geogrid. The woven geogrid junction strength depends strongly on the junction number, whereas the strength does not change significantly if the number of junctions is increased to three or more. Fig. 5 shows that the woven geogrids show residual strength over the peak strength. When the woven geogrid junctions were pulled out, the load-strain curve was just drawn by each member value mathematically, and the peak point appearance was not affected by any member over the peak strength. When the junction number was more than 3, their mutual-effect almost reached equilibrium and the data was stabilized. The woven geogrid junction strength increased with the strain rate due to a pulling-out mechanism. The abrasion force also increased with increasing strain rate. The multi-junction test indicated that a woven geogrid specimen with more than 3 junctions can provide reliable data of the junction strength with the scale effect taken into consideration. For warp knitted geogrids, each normalized value decreased lineally, whereas the junction number increased. This is because the warp knitted geogrid has no residual strength. Therefore, when the multi-junction strength was tested, the point peak can be determined provided at least one of the junctions is broken up. The strain rate had no effect on the warp knitted type. From this review, normalization of the junction strength is more reasonable with increasing number of junctions for a warp knit geogrid. Therefore, the junction width should be as wide as possible to consider the sufficient scale effect.

3.2 Analysis of Tensile Property and Junction Property for Geogrids

Table 4 lists the results of the multi-junction test proposed in this study. The mean and standard deviation of the test results were also calculated. The data deviation was uniform, and the maximum and minimum value have been selected and discarded to derive reliability data.

The results of the single and multi-junction tests were compared with those of the single and wide-width tensile tests. (Table 5). Equations 1, 2 and 3 were used to calculate the geogrid junction strength and junction efficiency (standard). These calculated values were compared with the values from the multi-junction strength test calculated from Equations 4, 5 and 6 (proposed). The multi-junction test values were lower than the single-junction test values due to the scale-effect. The scale-effect exists in both tensile and junction tests. On the other hand, a comparison of the results of the single tensile test and wide-width tensile test revealed a slight change because of the stable tensile strength and handling process. The scale effect in the junction test was much lower than the tensile test particularly the warp knitted geogrid. This was attributed to the single-junction strength data of the product distribution being more disordered than the single tensile test. Moreover, the multi-junction clamp has a greater tendency to error during handling. Therefore, multi-junction tests result in a large decrease in strength.

Table 4. Results of the multi-junction strength test.

Test no.	W-GG-1		W-GG-2		WK-GG-1		WK-GG-2	
	Strength (kgf)	Strain (%)	Strength (kgf)	Strain (%)	Strength (kgf)	Strain (%)	Strength (kgf)	Strain (%)
1	122	3.32	159	3.72	245	8.25	249	7.07

AVERAGE	115.7	3.5	166.3	4.0	273.6	8.9	253.3	7.3
SD ¹	5.68	0.40	6.72	0.29	9.1	0.49	6.61	0.38

¹SD is standard deviation.

Table 5. Results of the tensile and junction test.

Geogrid	$T_{\text{single-rib}}$ (T/m)	$T_{\text{wide-width}}$ (T/m)	$T_{\text{scale effect}}$	$J_{\text{single-rib}}$ (T/m)	$J_{\text{wide-width}}$ (T/m)	$J_{\text{scale effect}}$
W-GG-1	7.6	7.9	1.04	0.56	0.54	0.97
W-GG-2	13	12.8	0.98	0.86	0.79	0.92
WK-GG-1	8	7.8	0.97	1.43	1.29	0.9
WK-GG-2	12.8	13.1	1.02	1.52	1.2	0.79

Table 6. Junction efficiency of geogrids.

Value	Geogrid			
	W-GG-1	W-GG-2	WK-GG-1	WK-GG-2
E_{single}	7.4	6.6	17.9	11.9
$E_{\text{wide-width}}$	6.84	6.2	16.5	9.2

Table 6 lists the junction efficiency derived from Equations 3 and 6. The multi-junction test values were slightly lower than the single junction test values due to the scale effect of the multi-junction test, which is larger than wide-width tensile test. Moreover, the multi-junction test method can be more accurate in representing the junction efficiency than the single-junction test considering the scale effect.

4. CONCLUSION

Junction strength of warp knitted geogrid decreased with increasing number of junctions, whereas the woven geogrid had a similar value for 3~8 junctions except for a decrease of up to 3 junctions. The junction strength of woven geogrid increased with increasing strain rate, whereas the strain rate had no effect on the warp knitted geogrid. The specimen length did not affect the junction strength. Similar to the tensile test, the geogrid junction strength determined from the multi-junction test was lower than that from the single junction test due to the scale effect of the specimen. The geogrids junction strength and junction efficiency can be evaluated using the geogrids multi-junction test method considering the scale effect. The clamp width should be as wide as possible for a warp knitted geogrid to hold the maximum number of junctions, and a clamp width with a holding capacity of 3 junctions is needed for a woven geogrid.

ABSTRACT

High density polyethylene (HDPE) geomembranes (GMBs) play the primary role in composite liner systems used as hydraulic barriers. Performance of this function is contingent on how long the GMB remains intact without developing more than a limited number of holes during construction. The main source of long-term hole formation in liners is cracking that occurs after degradation of the polymer. This long-term effect will occur after the GMB has lost the protection of antioxidants and have become vulnerable to degradation (e.g., oxidation) and a consequent failure can occur even at low over burden stresses. The rate of antioxidant depletion and geomembrane degradation is a function of its compatibility with exposure media and this should be assessed for each type of exposure to ensure that there will be adequate liner durability and long-term performance. HDPE GMBs are now widely used in applications involving extremely high pH such as certain heap leach applications and mining ponds, the Bayer process, low-level radioactive waste and brine ponds. These applications involve the exposure of the liner to pH between 9.0 and 14.0. Although the durability of HDPE GMBs has been extensively investigated in the last two decades, there is a paucity of research into the performance of HDPE GMBs in these high pH solutions. To investigate the durability of HDPE GMBs in these environments with high pH, an extensive study was initiated looking at pH, GMB type, antioxidant package and GMB thickness on the service life of GMB in mining applications. In this paper, antioxidant depletion rates for geomembrane incubated in a solution with a pH = 13.5 are presented and a preliminary extrapolation to field temperature is provided. Results from standard OIT test are presented for a geomembrane without hindered amine light stabilizers (HALS).

1. INTRODUCTION

1.1 Geomembrane Durability

Geomembranes (GMB) are typically used in many environmental applications acting as a hydraulic barrier layer. High density polyethylene (HDPE) with density $\geq 0.941 \text{ g/cm}^3$ (ASTM D883) and linear low density polyethylene (LLDPE) with density between 0.919 and 0.925 g/cm^3 (ASTM D883) are the most commonly used PE GMBs in modern geoenvironmental applications. Typically GMBs are formulated from 94-98% PE resin, 2-3% carbon black, and 0.25-3% antioxidants and additives (Koerner et al. 2005). Chemical and environmental exposure of the GMB can cause various degradation mechanisms such as physical degradation, chemical degradation, biological degradation, ultraviolet degradation, degradation by swelling, degradation by extraction, oxidative degradation and thermal degradation (Haxo and Nelson 1984; Sangam and Rowe 2002). Performance of a GMB is contingent on how long the GMB remains intact without developing more than a limited number of holes during construction. The main source of long-term hole formation in liners is cracking that occurs after degradation of the polymer.

According to Hsuan and Koerner (1998), HDPE pass through three distinct stages during its service life. In Stage I; HDPE will start to lose its antioxidants either physically (due to volatilization and solvent extraction) or chemically consumed by free radicals. The depletion of antioxidant increase with time, reaching residual values that is not sufficient to protect the GMB. In the Stage II, the HDPE can resist degradation for some time after depletion of antioxidant (Stage I) without any measurable reduction in its physical properties. In the last stage (Stage III), degradation of the polymer takes place and a change in its physical properties is measurable. The end of the service life is defined when a specific property (e.g. tensile property per ASTM D5397; Melt index (MI) per ASTM D1238; stress crack resistance (SCR) per ASTM D5397) degrades with time to reach 50% of its initial (or specified) value.

1.2 Heap Leaching Applications

Heap leaching is a common geoenvironmental application for GMBs. Heap leaching is a mining technique where mineral ores (most commonly metallic) are crushed and staked in heaps on a lined pad. The heaps are usually irrigated with an acid or a base (based on the ore type and mineral) to extract the mineral from the ore in relatively short times. The leached solution which contains the dissolved mineral is called the pregnant leach solution (PLS). The PLS, which is characterized by its extreme pH and high metal concentration, is collected to be processed for mineral extraction.

Copper, uranium and nickel heap leaching are examples of acidic PLS where sulfuric acid is used in the irrigation of the heap. This results in an extremely low pH PLS that is in contact with the GMB. The pads are usually lined with a composite liner having, in addition to the GMB primary liner, a low hydraulic conductivity soil acting as a secondary liner such as compacted clay liner (CCL) or geosynthetic clay liner (GCL).

HDPE GMBs are now widely used in applications involving extremely high pH such as certain heap leach applications, mining ponds, the Bayer process and brine ponds. These applications involve the exposure of the liner to pH between 9.0 and 14.0. According to Kappes (2002) leaching gold and silver from their ores are similar where diluted sodium cyanide is used to dissolve the metals without dissolving other metals like copper and zinc. To reduce the mobilization of other minerals, the solution is maintained at pH of 9.5 to 11 by adding lime. In addition to mining applications, GMBs can be relied on to provide containment in stabilized hazardous solid waste landfills and low-level nuclear waste landfills. Low-level radioactive waste typically has a high pH in the range of 9-12.5 and has low concentrations of radioactive elements (Abdelaal et al. 2011).

Although the durability of HDPE GMBs has been extensively investigated in the last two decades, there is a paucity of research investigating the performance of HDPE GMBs in high pH solutions. Thus, to investigate the durability of HDPE GMBs in such environments with high pH, an extensive study was initiated looking at pH, GMB type, antioxidant package and GMB thickness effects on the service life of GMB in mining applications. The full test matrix together with the chemistry of the tested solutions is provided in Abdelaal et al. (2011). In this paper, antioxidant depletion rates for a 1.5 mm HDPE GMB incubated in a solution with a pH=13.5 are presented.

2. EXPERIMENTAL INVESTIGATION

GMB coupons (190 mm by 100 mm) were incubated in 4 liter glass containers separated with 5mm glass rods. The GMB tested is a 1.5mm HDPE (Table 1) where its additives package does not contain hindered amine light stabilizers (HALS) as previously indicated by Rowe et al. (2010b). GMB coupons are immersed in three different immersion solutions (Table 2) and incubated in forced air ovens at different temperatures. The temperatures used in this study are 75, 85, and 95°C allowing the accelerated ageing of the GMB in order to obtain antioxidant depletion times in convenient testing time frames. The use of the 95°C temperature was adopted after the findings of Rowe et al. (2010a) that showed consistent antioxidants depletion rates at 95°C together with the lower temperatures without changing in the depletion mechanism for both water and synthetic municipal solid waste (MSW) leachate.

Table 1. Index properties of the virgin geomembrane examined in this study.

Property	method	Values
Nominal thickness (mm)	ASTM D5199	1.5
Std-OIT (minutes)	ASTM D3895	100 ± 2.0 ¹
HP-OIT (minutes)	ASTM D5885	273 ± 16
Suspected HALS ²	--	No
Crystallinity (%)	ASTM E794	48
Density	ASTM D1505	0.947
Melt flow index (g/10min)	ASTM D1238	14.3 ± 0.8
Single point stress crack resistance (SCR) (hours)	ASTM D5397	840 ± 220 ⁵
Strength at yield MD ³ (kN/m)	ASTM D6693	27.0 ± 1
Strength at break MD (kN/m)	ASTM D6693	46.0 ± 5.0
Strain at yield MD(%)	ASTM D6693	24.0 ± 2
Strain at break MD (%)	ASTM D6693	825 ± 80
Strength at yield XD ⁴ (kN/m)	ASTM D6693	29.0 ± 0.5
Strength at break XD (kN/m)	ASTM D6693	44.0 ± 6.0
Strain at yield XD(%)	ASTM D6693	19.0 ± 0.4
Strain at break XD(%)	ASTM D6693	830 ± 95

¹Virgin OIT presented here differs from that reported in Rowe et al 2010 (a,&b) due to ageing of the roll in room temperature between the time of their tests and these tests;

²Hindered Amine light stabilizers;

³MD: Machine direction;

⁴XD: Cross machine direction;

⁵Based on a strength at yield in XD of 29kN/m. Additional replicates were tested since Abdelaal et al. (2011; 2012) resulting in a slightly higher average SCR reported here than in those earlier publications.

The chemical composition for the high pH solution presented in this study is simulating extreme pH of the PLS for gold, silver, aluminum heap leaching and low-level radioactive waste leachates. For safety reasons, both cyanide found in gold and silver PLS and radionuclides found in low-level radioactive waste leachate were excluded from the extreme high pH solution simulated in the current study. The selected chemistry of the high pH solution used (Table 2) represent the low metal concentrations found in the low-level radioactive waste to minimize the precipitation of the salts at such extremely high pH.

Table 2. Chemistry of the immersion solutions used in the current study

3. RESULTS AND DISCUSSIONS

3.1 Antioxidant Depletion Results

A differential scanning calorimeter (DSC) was used to obtain the standard oxidative induction time (Std-OIT) for the GMB specimens in accordance to ASTM D3895. Since the GMB presented in the current study does not have HALS, Std-OIT was solely used as an indicative tool for the antioxidant depletion stage. A first order exponential decay relationship (Hsuan and Koerner 1998) is used to depict antioxidant depletion rates in terms of Std-OIT depletion:

$$\text{Std-OIT}_t = (\text{Std-OIT}_o) e^{(-st)} \quad [1]$$

or, by taking the natural logarithm on both sides:

$$\ln(\text{Std-OIT}_t) = -st + \ln(\text{Std-OIT}_o) \quad [2]$$

where Std-OIT_t is the standard OIT remaining at any time t (min), Std-OIT_o is the initial standard OIT (min), s is the antioxidant depletion rate (month^{-1}), and t is the ageing time (month).

The variation of $\ln(\text{Std-OIT})$ with incubation time at 75, 85 and 95°C is presented in Figure 1 for a 1.5mm HDPE GMB (Table 1) in solution with pH = 13.5 (Table 2). The relation between $\ln(\text{Std-OIT})$ and time is fitted via linear regression, complying with the OIT depletion data previously presented in different immersion solutions for different GMBs by various investigators (Hsuan and Koerner 1998; Gulec et al. 2004; Rowe and Rimal 2008 a & b; Rowe et al. 2008; Rowe et al. 2009; Rowe et al. 2010 a, b & c; Abdelaal et al. 2011,2012). The slopes of the linear regressions, presented in Table 3, are the antioxidant depletion rates at different temperatures. For the incubation duration presented (4.5 months), full antioxidant depletion (to residual Std-OIT values) was achieved only at 95°C. Nevertheless, fitting the early data

obtained at 85 and 75°C would result in a conservative (shorter) estimate of antioxidant depletion time than fitting the data at the full depletion of antioxidants as demonstrated by Rimal and Rowe (2009). Consequently, predictions of antioxidant depletion stage at field temperatures presented in the next part, based on the conservative antioxidant depletion rates estimated at 75 and 85°C should result in shorter, hence more conservative, antioxidant depletion times at field temperatures. These estimates will be upgraded as more data comes available.

Figure 1. Antioxidant depletion rates (Std-OIT) for solution with pH=13.5 at three elevated temperatures.

Table 3. Antioxidant depletion rates for immersion in solution pH=13.5 at different temperatures.

Temperature (°C)	Antioxidant depletion rate (s) (month ⁻¹)
95	0.83
85	0.63
75	0.43

3.2 Antioxidant Depletion Predictions at Field Temperatures

A time temperature superposition technique (Arrhenius model) was used to extrapolate the antioxidant depletion rates at site specific temperatures. The Arrhenius equation, as presented by Hsuan and Koerner (1998) can be written as:

$$s = A \exp(-E_a / (RT)) \quad [3]$$

or, by taking the natural logarithm on both sides:

$$\ln s = \ln(A) - (E_a/R) (1/T) \quad [4]$$

where s = antioxidant depletion rate (month⁻¹), E_a = activation energy (J.mol⁻¹), R = universal gas constant (8.314 J.mol⁻¹.K⁻¹), T = absolute temperature (K), and A = a constant often called the collision factor.

The antioxidant depletion rate(s) at three elevated temperatures presented in Table 3 are used to establish the Arrhenius plot (Figure 2). Arrhenius equation for the HDPE GMB incubated in a solution of pH=13.5 is presented in Figure 2. Table 4 shows the predicted antioxidant depletion times at a potential range of field temperatures based on the Arrhenius equation presented in Figure 2. The antioxidant depletion stage is predicted to be 1.8 and 4.0 years at 60 and 40°C, respectively.

Figure 2. Arrhenius Plot of the antioxidant depletion for GMB immersed in solution pH=13.5

Table 4. Antioxidant depletion rates for immersion in solution pH=13.5 at different temperature.

Temperature (°C)	Antioxidant depletion time (years)
60	1.8
50	2.6
40	4.0

3.3 Antioxidant Depletion at Different Incubation Solutions

Figure 3 shows the antioxidant depletion at 85°C in solution with pH=13.5, water (Rowe et al. 2010a) and MSW synthetic leachate (Rowe et al. 2010b). The chemical compositions together with the pH of the three incubation solutions are presented in Table 2. It can be seen that the antioxidant depletion rates in MSW leachate is the fastest followed by solution with pH=13.5 then water. Table 5 shows the antioxidant depletion rates in different incubation solutions at 85°C. The depletion rate in MSW leachate and water is 1.8 and 0.4 times the depletion rate in solution with pH=13.5, respectively.

Figure 3. Std-OIT depletion for 1.5mm HDPE GMB in different immersion fluids at 85°C (data in water and MSW leachate are from Rowe et al. 2010a and Rowe et al. 2010b, respectively).

Table 5. Antioxidant depletion rates for immersion in solution pH=13.5 at different temperature (antioxidant depletion rates in water and MSW leachate are from Rowe et al. 2010a and Rowe et al. 2010b, respectively).

Incubation solution	Antioxidant depletion rate (s) (month ⁻¹)
Solution pH=13.5	0.63
Water	0.26
MSW leachate	1.11

4. CONCLUSIONS

Preliminary results were presented in this paper for antioxidant depletion from a 1.5mm high density polyethylene geomembrane in a solution with a pH = 13.5 representing extreme pH seen in some of heap leach pads applications, Bayer process, brine ponds and low-level radioactive waste landfills. The results are compared with those for immersion in water and synthetic municipal solid waste landfill leachate. Based on the testing duration presented in this paper, the following preliminary conclusions have been reached:

- The predicted antioxidant depletion times (Stage I of service life) was about 1.8 years at 60°C, 2.6 years at 50°C and 4.0 years at 40°C,
- The antioxidant depletion in solution with pH=13.5 was faster than water but slower than synthetic municipal solid waste landfill leachate. Antioxidant depletion rates in MSW leachate and water is 1.8 and 0.4 times the depletion rate in solution with pH=13.5, respectively, at 85°C.

The results presented in the current study only apply for the specific HDPE GMB without HALS tested in the immersion solutions presented. As indicated by Rowe and Rimal (2008b) and Rowe et al. (2010c), immersion testing is very extreme and the depletion rate in a real liner application is likely to be much slower (by a factor of 2.9-3.4 at various temperatures) than in the immersion tests. Also these times only represent the first stage of the ageing of the GMB and not the full service life. More testing is underway to investigate a wider range of pHs on different GMBs (LLDPE and HDPE) providing more indicative results on the compatibility of different GMBs in a range of solutions relevant to heap leaching, Bayer process, brine ponds and low-level radioactive waste applications. The full set of results will be published in a subsequent papers when they have been run a sufficient time to draw firm conclusions.

ACKNOWLEDGEMENTS

The research presented in this paper was funded by the Natural Science and Engineering Research Council of Canada (NSERC) and used equipment provided by funding from the Canada Foundation for Innovation (CFI) and Ontario Ministry of Research and Innovation. The authors are grateful to their industrial partners, Solmax International, Terrafix Geosynthetics Inc, Ontario Ministry of Environment, the Canadian Nuclear Safety Commission, AECOM, AMEC Earth and Environmental, Golder Associates Ltd., Knight-Piesold, and the CTT group for their participation in, and contributions to, the overarching project; however the opinions expressed in the paper are solely those of the authors. The authors are especially appreciative of the value of discussions with Rod McElroy, Senior Metallurgist AMEC Mining and Metals, Rick Thiel and Mark Smith.

ABSTRACT

This paper describes the use of Geotextile tubes for shoreline protection of a coastal town, to increase economical activities. The project was originated from serious erosion of an entire coastline, a situation which worsened in 2007 with the Cold Front #4, causing severe losses in buildings and major lagoons that represent an important aquaculture production source. From this event the authorities took emergency measures to stem the damage, by developing a first stage recovery in 2008 with the installation of Geotextile tubes to protect 300 linear meters of the coastline. In February 2012 was developed a second stage of more than 2,000 linear meters of Geotextile tubes.

Once this second stage was completed, the area faced strong winds and high waves of Tropical storm Ernesto in July 2012, where over the more than 2 km of protection, scour was observed only at the junction between two tubes. Due to the effective performance of this Technology in the present case, we conclude that the success in coastal protection and recovery of the beaches is related to the Geotube® Technology units manufacture processes, design characteristics and installation process.

1. INTRODUCTION

For centuries major storm events have battered shorelines and coastal areas. It is not only the size of the storm that leads to extensive damage, but the combination of sustained winds, rain, and flooding. Controlling and fighting the power of water is a daunting task, but geotextile containment technology is a proven, cost-effective method for a variety of shoreline protection and marine construction projects for defense against major storm events.

Geotextile tubes prevent storm damage and protect the environment through the building of custom marine structures. The installation of geotextile containers can be temporary or permanent, and in most cases the structures are invisible to the coastal environment. The technology involves the fabrication of a large container made of a specially engineered textile, which is filled with sand and buried within the shoreline. During installation, the geotextile container is filled to a specific design height that provides protection to adjacent coastal areas. The geotextile container holds the sand in place which prevents erosion and property damage during major storm events.

In Mexico these natural phenomena have caused serious damage in coastal areas, one of the regions with major erosion losses is the state of Tabasco, where Federal authorities have begun construction of several kilometers of sand dune core using geotextile tubes to prevent sand erosion and flooding of a small town, Sanchez Magallanes. The coastal area of Cardenas, Tabasco, has lost over a kilometer of beachfront due to the effects of climate change over the last 25 years.

The sand dune structure using geotextile tubes is designed to prevent further erosion along the shore, especially in summer when strong winds and large waves are particularly damaging to seaside communities. Many local residents have fled further inland due to the increasing erosion of shoreline.

2. LOCATION

The village of Andrés Sanchez Magallanes is a fishing port of 6200 inhabitants, located in the municipality of Cárdenas, in the Mexican State of Tabasco. It is located 137 km northwest of Villahermosa, the Statecapital and 87 km from the municipal seat, Cárdenas (Fig. 1).By its population and commercial activity, Sanchez Magallanes is the second population on importance of the municipality, only after the municipal seat, the city of Cárdenas.

The main economic activity in the community is fishing of oysters and crab, which is complemented with the livestock and tourist activity in holiday seasons. The system of lagoons "Carmen-Pajonal- La Machona" is where the main oyster's farms are located, which places the village as the main producer of oysters at the national level.Tourists come mostly from the municipal seat and the nearby state capital of Villahermosa. The main attractions of the town are the beaches of the bar of Santa Anna, the Spa "EnsueñodelTropico" (Dreams of the Tropic), the nearby lagoons system of El Carmen, La Machona and Pajonal, as well as the island El Pajal, where several species of birds nest.

Figure 1. Sanchez Magallanes location in the state of Tabasco, where were built 2 jetties and submerged breakwaters in the late 80's early 90's.

3. THE CHALLENGE

The villagefaces a serious problem of marine erosion. This problem has made many of its residents relocateto other areas.The marine erosion problem is caused by the effects of climate change, but also by the residents not maintaining thenatural barriers, mangrove and sand dunes, which are a major factor in coastal protection.

In this area of the coast of Tabasco, coastal current is predominantly from east to west, having an inversion of the littoral transport of short duration in the so-called "windy" season or "Nortes".

In the late 80's early 90's twojetties were built on the coast of Sanchez Magallanes. A structure like that placed on the coast,creates an obstacle to the current, and sand from the east side was intercepted by the east Jetty, being held in near-total form. The missing natural power of sand from the opposite side, since the waves and tide conditions remain the same, there is no compensation of the sand that is transported running down, or to the west, so the beach line recedes.

Proof of this is the fact that periodically the breakwater on the eastern side has required to be extended and on the opposite side has needed extends the built-in.Beach erosion that occurs immediately neighboring the west jetty of the port of Sanchez

Magallanes aside, even after building the four docks parallel to the coast, and the Jetty of close in the West end with Concrete bags elements, should not be viewed as something unusual. This because firstly by the fact that experience in other similar work carried out not only on the coasts of our country, but in other parts of the world, has shown that achieve a proper restitution of the original Beach line usually take awhile, between four to eight years.

Secondly, and this is the most important thing, is that prior to the construction of the jetties, initiated its construction by stages already for several decades, the regime of littoral drift of sand transported by the effect of currents generated by the action of the waves and tides was responsible for maintain a dynamic balance, being the sand carried by these currents removed in a certain place by the effect of the power at a certain given site, compensated by which was transported from upstream.

Because as described previously, the only way to avoid the occurring erosion on the part in question, while the work of the docks parallel to the coast retains the low volume of sand that manages to outflank the nose of the jetties, is resorting to a process of artificial feeding of restitution of the beach sand. Artificially supplied sand must be an almost total stop of the beach reverse process while the separate coastal jetties allow the deposit of sand carried naturally as a result of flanking the nose of the West jetty.

4. COASTAL PROTECTION AND RECOVERY OF THE BEACHES

4.1 Cold Front #4, October 2007.

In 2007, from October 20 to 23th 2007, the coast line of Sanchez Magallanes, suffered a strong involvement of the coastline by the action of the Cold Front #4 with gusts of up to 130 km/h and waves of up to 10m.

This event dramatically intensified the process of loss of sand in the West side, both due to the increase of the sea level, product of the tide, winds and the intense waves, being affected some buildings close to the beach as well as some other structures. During the visit to the site after this meteorological phenomenon was a setback in the almost uniform reduction of the coast line on the order of five meters approximately along three kilometers of the coast (fig. 2).

Figure 2. Heavy damage by erosion from the Cold Front #4 October 2007

The damages caused by the Cold Front #4 were not limited to the Sanchez Magallanes coast. The Cold Front #4 was also responsible for the flood of Villahermosa (the state capital) of that year, the biggest event of this type in decades. To solve

the emergency situation in Sanchez Magallanes the authorities decided to install 300m of Geotextile tubes to protect the central part of the town and stop erosion (fig. 3).

The installation took place in the month of January of 2008. Units of Geotextile tubes, with circumferences of 7.6m, lengths of 18m with mechanical ports (GP8) and conventional ends were used for the construction of a new sand dune 20m from the wet beach, almost at the footing of the remaining houses. The units were designed to achieve heights from 1.5m to 1.8 with a minimum safety factor of 3.4.

Figure 3. The units were covered with sand (from a nearby mine) to protect them against the traffic of villagers and visitors over them and vandalism.

The contractor (Control de Erosion) filled the units using sand pumps and the material used was taken from the ocean floor.

4.2 Sanchez Magallanes in 2008- 2011.

During this period, the wave action and the erosion destroyed almost 104 houses. The erosion along the Spa Ensueño del Tropicó demolished homes, businesses and public buildings.

Unfortunately for the local inhabitants, the tourist activity (locals and strangers) have to go to the nearby beach called Bahía Acapulquito, located in the Ejido San Rafael at the East part of the municipality far from Sanchez Magallanes.

Also the erosion created new challenges. Because of the destruction of the sand dunes the sea waves start getting very close and eventually (if nothing is done) will join lagoons El Alacrán and El Manatinero with the ocean; even mentioned that there is already evidence that that has happened in the past "windy season" in the Manatinero lagoon where sea water got into the lagoon.

Figure 4. Eventually sand has been deposited naturally favoring the beach recovery

In that regard, the local authorities emphasized that "we cannot allow that to happen because it puts at risk an entire ecosystem of the lagoon complex Carmen-Pajonal - La Machona by the effects of salinization of the water and that it would even extend to other areas of the municipality as "Costa Chica", to the detriment of fishing, the oysters, the agriculture and animal husbandry."

Therefore a new Coastal Line protection project became of vital importance not only for the inhabitants of the town and port of Sánchez Magallanes, San Rafael, El Alacrán and Sinaloa, among others that are located in the coast and whose properties are threatened by the advance of the Mexico Gulf.

The units installed in 2008 were under continue follow up by the local authorities and were proposed as the best method to protect the coastal line. During these 3 years the units withstand the forces of the ocean. Only one of the units was damaged by vandalism in the month of May of 2010. The remaining material of that unit was used by the local people to create small shelters and protection for their houses (fig. 4).

4.3 Sanchez Magallanes 2011-2012.

Figure 5. After 3 years Geotextile tubes installed in 2008 withstood the force of strong waves, by these Geotube® Technology were proposed as the best method to protect the coastal line.

In September 13 of 2011 the Direccion General de Puertos Mexicanos, the office of the Federal Government in charge of the ports and coastal structures started the bidding process LO-009000986-N34-2011, for the "Construction of the beach protection structures of Sanchez Magallanes". The project was designed to protect 2.1 km of the coast of Sanchez Magallanes from the jetty (called La Punta) to the local cemetery using Geotextile tubes (fig. 6).

The federal executives argued that the project is a rescue comprehensive since on the one hand is intended to revive the tourist, gastronomic and commercial activity in Sánchez Magallanes port, but also the protection certainly will prevent a sea join the lagoons because this complex Carmen-Pajonal - Machona Lagoon is the pillar of the oysters, activity of which depend on thousands of families. Also the protection of the beach will guarantee to the residents that their properties already will not be taken by the sea and therefore they regain their value.

Prior to this announcement, several meetings occurred between the engineers of Puertos Mexicanos and G&G, domestic representative of TenCate Geosynthetics in Mexico to analyze the problem and define the basis for the licitation. There were no doubts about the use of Geotextile tubes after the performance shown by these units at the site for several years.

Figure 6. There were installed 77 Geotextile tubes to attain the total longitude of 2,303.85 linear meters from the existing breakwater to the local cemetery along all the coastal line.

The characteristics of the Geotextile tubes designed for this project were:

- Textile Tube: 77 units of 27m each made of Geotextile tensile strength of a 180 x 180 kN/m accordingly to ASTM D 4595, polypropylene, sand color. Circumference: 7.6m. Also the units had Flat End® technology and mechanical (GP8®) ports.
- Scour Apron: made of Geotextile tensile strength of a 70 x 86.3 kN/m accordingly to ASTM D 4595, polypropylene, black, and 5.18m wide with one anchor tube of 1.2m of circumference. The scour aprons had to be attached to the units at the factory.

Due to the fact that some units would be laid on areas where house and other buildings existed before, a nonwoven needle punch Geotextile were considered as a protection. The fabric selected was Mirafi® 1100N CBR Puncture Strength 3.11kN accordingly to ASTM D 6241 (Fig. 7)

Mechanical Properties	Test Method	Geotextil Type 1	Geotextil Type 2
Wide Width tensile Strength (at ultimate) MD/ CD	ASTM D4595	78.8 / 109.4	1026 / 1026
Wide Width Tensile Elongation (%)	ASTM D4595	20	20
Factory Seam Strength KN/m	ASTM D4884	70	582
Apparent Opening Size (AOS) mm (US Sieve)	ASTM D4751	0.43 (40)	30 (0.60)
Water Flow Rate (l/min/m ²)	ASTM D4491	813	813
UV Resistance(% strength retained after 500hrs)	ASTM D4355	80	70
Mass/ Unit Area (g/m ²)	ASTM D5261	585	949

Figure 7. Characteristics of scour apron, anchor tube and geotextile tubes installed

The contract was awarded to Control de Erosion in December 2011 and the installation was set for the beginning of February 2012.

The installation project:

a) Demolition: Concrete structures were observed to demolish, being mostly of abandoned houses and remains of tourist restaurants and the Spa facilities. For the implementation of this concept pneumatic equipment such as a compressor of high pressure with a breaker hammer were used. The debris resulting of the process was moved to an authorized disposal site.

b) Cleaning and Leveling: Shall be carried out cleaning and leveling of the site through the use of mechanical equipment (backhoe or similar), to meet the lines and project levels. The place where the Geotextile tube units were placed will be aligned using metallic posts which placed default namespaces so that the tube will be laid in the places according to the blueprints. It should be noted that the area must be clean and free from any material with cutting edges, glass or any material that can affect damage materials (Fig. 8).

Figure 8. In the place, there was a lot of debris, resulting from the intense coastal erosion

c) Topobatismetrics of the work zone. There will be the work of topobatismetrics in the area of extraction of sand for the volumes of work and monitoring of the same, in order to correlate the project data with the data from the date of the construction of that work, likewise in the beach area will take place the lifting and topographic stroke to delimit levels and lines of project.

d) Protection Geotextile: It is fabricated according to measure indicating the project section, so local labor is used in combination with the workmanship specializing, work to run are as follows; (a) extends the roll of geotextile which is supplied with a width of 4 metres approximately, (b) is cut with extreme care to be attached through the use of a machine sand bag seamer, uses nylon cord and occur two seams to ensure that you do not remove, (c) sewing once the mantle of the geotextile is seam tube anchoring or ballast in accordance with draft which will be filled with sand hydraulically injected once they are already in the final project site. Once it is ready, they have to be rolled up and transported to the site of placement through the use of unskilled labor.

e) Installation and filling the units. Once the surface where the unit is going to be laid, the Textile tube with its scour apron is placed and aligned in the desired place. The process is executed in two stages. The first one uses a Toyo Pump of 30 HP. The pump fills most of the volume of the unit at high pressure. Sand is taken from the ocean floor. A diver in the ocean moves the nozzle of the pump like and extracts the sand. In the second stage or "finishing" the unit a Toyo Pump of 7.5HP is used to fill the last part of the units. The volume of each unit is approximately 117.8m³. The process to fill each unit takes 3.5 hours in average (Fig. 9)

f) Backfilling of the void between the Geotextile tubes units and the sand dune. The process was executed using the Toyo Pumps. Care should be taken in order to prevent erosion in the footing of the units where no scour protection exists.

Figure 9. Installation and filling of Geotextile tubes

5. RESULTS

In early August 2012 the coast of Sanchez Magallanes suffered the effects of Hurricane Ernesto. This phenomena crossed the Yucatan Peninsula from the Mexican Caribbean where were observed maximum sustained winds of 110 km /h with gusts of 120 km /h. It was observed that along the more than 2,000 linear meters of Geotextile tubes installed on the coastal line, only in one zone was observed scour between the joint of 2 units.

This scour has seen before when wave driven water overtopped the Geotextile containers and in returning to the ocean accumulated at one point undermining the tube and scour apron which resulted in erosion of the sand to a depth equal to the tube height. To solve the problem, a new tube of the same circumference, length and height as the original structure must be installed with a scour apron under the location of the new tube.

Despite this event of strong marine erosion along all Geotextile tubes line, it was clearly observed the retention of sand over the structure, which propitiates the beach recuperation and protection against future events of natural phenomena.

ACKNOWLEDGEMENTS

We are grateful to Eng. Mauricio Porraz of Erosion Control Company responsible of the geotextil tubes installation for the information shared. Also to Eng. Celso Morales and Arq.Arturo Perez Castro from the Federal Coordination of Ports and Merchant Marine in México.

Bending Stiffness of Geosynthetic-reinforced Soil (GRS) Platform

Christopher M. Gemperline, P.E., U.S. Bureau of Reclamation, USA, cgemperline@usbr.gov

ABSTRACT

Understanding the homogenous bending stiffness of geosynthetic reinforced soil (GRS) beams and platforms can aid in the design of civil structures that span unstable or compressible soil and subsurface pipe conduits. Despite the increasing use of GRS, GRS beams and platforms bending behavior has received little attention. GRS beams and platforms are typically composed of alternating layers of geosynthetic reinforcement and soil, resting on soft or unstable soil, and are competently supported on either end. This investigation evaluates composite or "homogenized" mass bending stiffness resulting from the inclusion of geosynthetic reinforcement in GRS. Analyses are performed using the two dimensional FEM and the Winkler foundation model. The research consists of two primary analyses. The first was a parametric study to ascertain the influential parameters contributing to the bending stiffness. The second investigated the effect of reinforcement spacing and the number of layers on the GRS stiffness. The research concludes that bending resistance is best gained by decreasing the spacing between reinforcement layers and using higher strength soils. Increasing reinforcement tensile strength also increases bending resistance, but the affect was ancillary to the spacing and soil stiffness. The GRS beams numerically modeled for this study exhibited similar displacement behavior to the Winkler foundation model, indicating that the bending behavior of GRS beams can be analyzed using methods that apply to fundamental concepts of beam bending theory.

1. INTRODUCTION

Geosynthetic-Reinforced Soil (GRS) is a soil mass that is reinforced by compacting layers of soil between horizontal layers of geosynthetic sheets. Over the past two decades, GRS has been employed in the construction of many types of earth structures, including retaining walls, bridge abutments, embankments, slopes, roadway, and shallow foundations. GRS structures have many distinct advantages over their conventional counterparts. GRS structures are typically more ductile, more flexible (hence more tolerant to differential settlement), more adaptable to low quality backfill, easier to construct, require less over-excavation, and are more economical. Among the various applications of GRS, the GRS platform has received little attention. A GRS platform is typically composed of alternating layers of geosynthetic reinforcement resting on soft or unstable soil and competently supported on either end. A GRS is a soil mass that is strengthened to restrain the development of tensile strain in the direction of bending. Since soil is weak in tension, suppression of tensile strain is an effective means to increase the bending stiffness of soil that will otherwise develop significant tensile strain. The inclusion of geosynthetic reinforcement therefore effectively improves the engineering behavior of the composite mass, or in other words improves the material properties. Civil engineering structures constructed on soft or unstable soils are likely to experience considerable settlement. Minimal displacements for most civil engineering applications are desired to maintain stability, structural integrity, serviceability, and durability. Design of structures such as roadways, railways, tanks, walls, slopes, pipelines, and buildings, on soft soils where the structure will impose a significant load over a large area, have employed a variety of techniques to minimize displacement. Traditional measures can be environmentally unsound, as well as cost, labor, and schedule prohibitive. Over the past decade the use of geosynthetic-reinforced soil (GRS) platforms to improve resistance of the underlying foundation soil against the applied loads or to transfer structural loads to more competent soils has gained popularity. A better understanding of GRS bending stiffness can be applied to design of civil works that require spanning undesirable soils. Bending stiffness is an important consideration for projects that have a small tolerance for movement such as rail roads, and pipelines. GRS platforms have also been extensively used to bridge over unstable soils and have also been effectively used to bridge areas that are susceptible to settlement when subsurface ice lenses melt following placement of fill soils. The ability to estimate the improved bending stiffness of GRS platforms will provide valuable insight in the design of GRS structures subjected to bending. This research investigated the improved bending stiffness of a GRS platform foundation using the Finite Element Method (FEM) and the Winkler foundation model. The objectives, method of research implemented for this study, a summary of results, and a proposed relationship to more conveniently estimate bending stiffness of GRS platforms are discussed.

1.1 Objectives

This study investigated the bending stiffness of a GRS platform using the Winkler Foundation model with two primary objectives. The first objective was to investigate effects of various parameters of a GRS platform on the bending stiffness of the GRS composite and the applicability of beam theory. The second objective was to develop a preliminary relationship for estimating the bending stiffness of GRS platforms.

Both objectives utilize numerical modeling to investigate the composite bending behavior of GRS beams. The Winkler Foundation model was used in this study to verify the FEM used to determine the vertical displacement at the base of GRS beams and then used again to estimate the composite bending stiffness of GRS beams. The first objective instituted a parametric study to analyze the effects that the amount of geosynthetic reinforcement, the tensile modulus of geosynthetic reinforcement, and the modulus of elasticity of soil used to construct GRS beams (E_b) have on composite bending stiffness. The second objective examined the relationship between the bending stiffness of a composite GRS beam and reinforcement spacing. This was achieved by varying the number of layers, which changes the geometric moment of inertia. Classical elastic bending theory establishes that the bending stiffness remains constant with added layers i.e. E_b multiplied by moment of inertia remains constant. The bending deflections determined from the FEM were compared to the bending deflections determined using the Winkler Foundation analytical model with known moduli of elasticity to estimate a composite bending modulus of elasticity for a GRS beam. A preliminary relationship between geosynthetic reinforcement spacing and bending modulus of elasticity is proposed.

1.2 Method of Research

This study examines GRS beams in pure bending where normal stresses in the GRS member remain below the yield strength and Hook's law applies. In other words, herein the GRS beam is treated as a uniform composite elastic material. Deformations of an elastic beam are caused by the bending moment measured by the curvature of the neutral surface. Curvature is defined as the reciprocal of the radius of curvature ρ , and has been shown to be related to the bending moment (M), modulus of elasticity (E), and moment of inertia (I) by equation 1 in the elastic range.

$$\frac{1}{\rho} = \frac{M}{EI} \quad [1]$$

Equation 1 defines bending stiffness or resistance to bending as being dependent on modulus of elasticity (E) and the moment of inertia (I). (EI) is commonly referred to as the bending stiffness. Classical bending theory suggests the deformed shape of a loaded beam remains constant as reinforcement layers are added to a beam such that EI remains constant. This study reveals that GRS generally follow this concept when applied to the Winkler Foundation model.

Numerical models of a simply supported geosynthetic-reinforced soil beam on an elastic foundation were created and analyzed using a FEM program. The models developed for the parametric study, the first portion of this study, evaluated the effects of geosynthetic reinforcement tensile modulus, soil modulus of elasticity, and the reinforcement spacing on the bending stiffness of GRS beams and platforms with the assumption of elasticity. Models developed in the second portion of this study evaluated the GRS beams and platforms bending stiffness with varying geometric moment of inertia to reinforcement spacing. A simply supported beam on an elastic half space was chosen for this study because, the widely used Winkler foundation analytical solution can be used to facilitate verification of the numerical model and provide a convenient way to estimate bending stiffness in a graphical manner. The Winkler foundation treats beams and platforms as flexible and the soil upon which they rest as a bed of springs. An elastic constant of the springs is referred to as the coefficient of subgrade reaction (k_f). A Winkler solution is appropriate because this study is limited to two dimensional bending and displacements. The Winkler model is further discussed in subsequent sections. The two dimensional modeling implies a unit platform or beam width. Because this study is concerned with the composite or "improved material" bending behavior of GRS beams or platforms, the geometric moment of inertia was determined using rectangular cross-sections with a unit width. A FEM software program that features a boundary condition that can be defined by a spring constant, which is a fundamental principal used by the Winkler foundation model, was selected.

2. FINITE ELEMENT MODEL AND VERIFICATION OF MODEL

A two dimensional FEM was used for modeling a beam composed of soil and geosynthetic reinforcement. The model was verified by comparing it to the analytical solution developed from the Winkler model. This section briefly describes the Winkler foundation and justifies the material parameters used in this analysis.

This study directly compares a GRS finite element beam to the Winkler foundation model which is a widely used analytical solution to an elastic beam on an elastic foundation. The displacements resulting from the loading conditions in this study are assumed to be small enough that shear, tensile and compression failure will not develop, therefore the FEM modeling conducted in this investigation assumes perfectly elastic soil properties. This is a simplification of true field condition because soil is not linear elastic and for intents and purposes does not resist tension; however, this assumption allows for direct comparison to the Winkler foundation model which although not precise, provides an accurate portrayal of the effect geosynthetic reinforcement has on soil beams. Future work could perhaps involve laboratory and field study in conjunction with FEM modeling to develop a more precise GRS beam analytical solution.

A two dimensional FEM model was used to model beams composed of soil and geosynthetic reinforcement. The FEM model was verified by comparing it to the analytical solution developed from the Winkler model. The verification process is described in subsequent sections of this paper. A plane-strain, FEM model was created to represent a simply supported beam on soft soil. The soft soil was modeled as equally spaced springs that resist load vertically, but not vertical. A 3-meter long 1/2-m thick non-reinforced beam was modeled using elastic parameters. GRS beam models developed for analysis were composed of linear elastic elements with structural beam elements interbedded at pre-determined horizontal spacing. The range of GRS beam geometry was selected to be similar to that used in a case study investigating the performance of a geosynthetic reinforced pile supported highway embankment presented by Liu (Liu, et al., 2007).

Finite elements were 2.5 cm by 2.5 cm quadrilaterals with 4 nodes. This analysis did not incorporate any type of staged construction or self-weight effects; therefore the incorporation of unit weight was not necessary. The bottom beam elements were connected to a bed of "springs," which are defined by a spring constant (k_s) equivalent to what is known as the modulus of subgrade reaction (k_f) when used to represent soil. One spring was located at the corner of each of the bottom row of elements of the beam. The beams analyzed in this study were subjected to a 250 kPa uniformly distributed vertically applied load across the full length of the beam as depicted in Figure 1. This loading was chosen because it resulted in discernible displacements near the beam midpoint making it easy to use graphical techniques described later and also because it avoids large deformations that would typically be associated with shear failure.

Figure 1. Two Dimensional Finite Element Model.

2.1 Winkler Foundation Model for Beams on an Elastic Foundation

Many models have been proposed to represent the half space response beneath structures (Scott, 1981) however, the spring model first suggested by Euler and further developed and used by Winkler is the most widely used and is commonly referred to as the Winkler foundation. The Winkler Foundation model was used in this study to verify the FEM model used to determine the vertical displacement at the base of GRS beam and then used again to estimate the composite or "improved material" bending stiffness of GRS beams. Many mathematical relationships have been pre-determined for a variety of Winkler foundation conditions and, conveniently presented by a number of authors (Young, 1989). The relationship between the vertical pressure (P) acting on a solid surface, and the vertical deflection (y) is given by the equation:

$$P = k_f y \quad [2]$$

k_f has been referred to by many names such as the coefficient of subgrade reaction, the subgrade modulus, and the modulus of subgrade reaction, but it is fundamentally the foundation soil stiffness. The Winkler solution models foundation soils as vertical springs with a single value (k_f). The Fem models the foundation as an elastic half-space defined by two constants, such as modulus of elasticity (E) and poisons ratio (ν). Obtaining precise comparisons between the one parameter Winkler model and a two parameter FEM model is difficult. Variations or improvements on the spring model have been suggested however, the complexity of the analysis increases rapidly for foundation models that incorporate more variables and features than those represented in the Winkler model. A soil subgrade is generally neither homogeneous nor isotropic. Even if the same soil is uniform for a considerable depth, the increasing overburden pressure with depth causes the soil to stiffen with depth. For this reason it seems reasonable to represent the foundation soil with something more suitable than the Winkler model. However, many other attempts at more precise mathematical solutions of a beam on elastic foundations become very complex and remain open to significant debate of accuracy. The Winkler model was utilized in this study for its convenience and history of successful use and for that reason a spring

boundary condition was implemented as the beam foundation in the numerical modeling. By selecting a foundation composed of vertical springs in the FEM model, direct comparisons of the results could be made to solutions of the Winkler model solved for known stiffness. The general solution to deflection of a flexible beam on a Winkler foundation is

$$w = C_1 \cos \beta x + C_2 \sin \beta x e^{\beta x} + (C_3 \cos \beta x + C_4 \sin \beta x) e^{-\beta x} \quad [3]$$

Where C_1 through C_4 are constants determined by the end and loading conditions and the parameter β has the dimensions length $(L)^{-1}$ and includes the properties of the foundation soil and the beam. The general solution describes the deflected shape of the beam between loading points and end constraints. The coefficients (C_1 , C_2 , C_3 , and C_4) are determined based on the end constraints and loading conditions or the “boundary conditions”. Specific solutions have been solved for many end conditions and loading schemes and tabulated for implementation in spreadsheets (Young, 1989). Deflection along the length of the beam is determined by using the method of super-position. A simple supported uniformly distributed load across the entire length of a beam was selected for this analysis because it was considered an idealized representation of a beam supported on the ends and soft soil between.

2.2 Material Properties

This section discusses the material properties that were selected to define the properties of elements in the FEM models. These values are considered realistic based on typical soil and geosynthetic properties used for GRS. The material properties presented in this section are considered the “base properties” and used for the majority of the models developed for this study; however, they were varied in the parametric study portion of the investigation to better understand which properties have the most influence on the bending stiffness of GRS beams.

Poisson’s ratio (ν) is defined as the ratio of the horizontal strain (ϵ_h) to the vertical strain (ϵ_v). Typical values of ν for silts and sands range from 0.2 for loose materials to 0.4 for dense material. Values for saturated clays vary from about 0.4 to 0.5. The theoretical maximum value for saturated clay undergoing no volume change when stressed is 0.5. For the purposes of this study variation of Poisson’s ratio is expected to have negligible influence and was assumed to be 0.3 for both the foundation and beam soils.

The purpose of this study focuses on the deflection of a beam composed of soil and geosynthetic reinforcement, therefore the mechanism occurring between the beam and the soft soil was not considered in significant detail. Consequently, the soil foundation material was modeled in a simplified way by vertical springs so that the beam deflection could be directly compared to the Winkler model. The stiffness of the foundation soil (k_f) depends on the compressibility of the soft soil and links the settlement (y) to the vertical stress. If a foundation of width B is subjected to a load per unit area of (p) it will undergo a settlement. From Equation 2 it can be seen that the units of k_f is Force (F)/Length $(L)^{-3}$. The value of the coefficient of subgrade reaction is not constant for a given soil, but rather depends on several factors, such as the length and width of the foundation, and also the depth of embedment, modulus of elasticity of the soil, poisson’s ration, and thickness of the soil unit. Since the modulus of the elasticity of the composite reinforced beam is unknown for this analysis an estimation of k_f with minimal beam properties was needed. Vlasov and Leontiev proposed the following relationship for a plane stress condition (Scott, 1981):

$$k_f = \frac{E_f}{(1 - \nu_f^2)} \frac{\nu B}{2} \quad [4]$$

The only beam property is width. ν has the dimensions L^{-1} and expresses the rate at which vertical displacement decays with depth. For most practical purposes ν can be assumed to be equal to one. The U.S. Bureau of Reclamation has published compression characteristics for various re-compacted soil types classified by the unified soil classification system (U.S. Bureau of Reclamation, 1998). This resource was used for selecting reasonable estimations for E_f to be used in Equation 4. Low plastic soils (CL) range from 4.6 to 2.8 percent compression at 100 psi. A value of 3.5 percent strain at 100 psi was selected as a representative value for the foundation soil. Since $E = \sigma/\epsilon$, then $E_f = 100 \text{ psi} / 3.5\% \cong 20,000 \text{ kPa}$. Assuming a ν_f of 0.3 and $B = 1 \text{ m}$ for a two dimensional plain strain analysis, then substituting E_f of 20,000 kPa into Equation 4 gives $k_f \cong 10,000 \text{ kN/m}^3$.

The FEM model consists of a beam resting on a bed of springs as shown on Figure 1, which requires a spring constant (k_s) for the springs that, exerts a constant reactionary force to the bottom of the beam and that is equivalent to the modulus of subgrade reaction. k_f is defined by the units of F/L and the k_s is defined with units of F/m³ therefore, the equivalent k_s for a given k_f can be found by using the area of the bottom of the plain strain finite element. For this study elements were 0.025 m long and the beam was assumed to be 1m in width for the plain strain condition. The k_s value is then found to be $10,000 \text{ kN/m}^3 (0.05 \text{ m}^2) = 500 \text{ kN/m}$

Silty sand with gravel (GM-SM) soils are typically recommended for use when constructing a geosynthetic soil mass and therefore, used to estimate reasonable FEM input parameters for the soil platform matrix. A linear elastic model was

chosen for the soil elements in this study for its direct correlation with the analytical Winkler Foundation model. For a linear-elastic model, there is no yield value defined. Using the U.S. Bureau of Reclamation published compression characteristics, for various soil types. The median value of 1.2 percent strain at 100 psi was selected as a representative value for the foundation soil. Since $E = \sigma/\epsilon$, $E_b = 100 \text{ psi} / 1.1\% \cong 57,000 \text{ kPa}$.

Beam elements were used to simulate geosynthetic tensile reinforcement. The beam element used in the FEM software for this study was formulated using the conventional Bernoulli beam theory. This beam element requires the slope, as well as the lateral displacement, to be continuous within the element. Each node associated with a beam element is given a rotational degree-of-freedom in addition to the two displacement degrees-of-freedom. The tensile modulus selected for this analysis is based on values for commonly used material published by a reputable geogrid manufacture. The tensile modulus at 1 percent strain is 547 kN/m in the machine direction and 773 kN/m in the cross machine direction. The cross machine value was chosen as the base value assuming the strongest direction would be oriented across the beam span. The structural member used to model reinforcement was selected to resist tension and the interface with the soil was fully bonded. The baseline material parameters are summarized Table 2

Table 2. Model Verification Input Parameters Summary Table.

	Winkler Model	Finite Element Model
Modulus of subgrade reaction (k_f)	10,000 kN/m ³	N/A ²
Spring Constant (k_s)	N/A	250 kN/m
Modulus of elasticity (E_b)	57,000 kPa	57,000 kPa
Poisson's ratio of the beam soil (u_b)	N/A	0.3
Beam Length (L)	3m	3m
Beam Thickness (h)	0.5m	0.5m
Soil Behavior Model	Linear Elastic ¹	Linear Elastic
Support Condition	Simply Supported	Simply Supported

Notes: 1) Assumption of the Winkler Method
2) N/A denotes not applicable to the method

A graphical comparison between the Winkler model and the FEM model was made. The calculated deflection at the bottom of the FEM model aligns very closely with the calculated deflection of the Winkler model at the bottom of a beam. This verification indicates that the FEM models developed to include geosynthetic reinforcement can reasonably be compared to the results of the Winkler model and used to better understand the GRS bending behavior.

2.3 Graphical Estimation of GRS beam composite Modulus of Elasticity

Several vertical displacement curves were developed with the analytical Winkler model using various moduli of elasticity for the beam. The results of the FEM simulation program were then compared to the Winkler model results to estimate an equivalent modulus of elasticity. Figure 2 illustrates how this was done. The vertical displacement measured in the FEM model is plotted with square points along with several gray Winkler model vertical displacements that were calculated using the same geometric shape as the FEM model beam but representing various moduli of elasticity. Symmetry is assumed between the ends of the beam and therefore only half of the beam deflections are shown here, this allows for an expanded view of the plots enabling a more precise estimation of composite modulus of elasticity. The FEM model vertical displacement results could then be compared to the graphical solutions of Winkler foundation to estimate a composite modulus of elasticity of the FEM GRS model. For the example presented in Figure 2 the FEM curve falls where it is anticipated the Winkler curve representing a modulus of elasticity equal to 150,000 kPa would be located. Hence, 150,000 KPa is selected to be a comparable representation of the modulus of elasticity for the GRS.

The FEM model boundary conditions at the ends of the platform are a little different from those used for the Winkler model. The Winkler model assumes a simple support whereas the FEM constrains lateral movement of the reinforcement. Restraining the lateral movement of the reinforcement prevents the ends of the beam from tipping inward, as is characteristic of simply supported beams Figure 3. For this reason the vertical displacement of the GRS FEM model does not match exactly to the simply supported Winkler. This deviation is most notable near the support where the FEM curve has a flatter shape. Even though, the end conditions modify the beam somewhat, a simply supported Winkler end condition still provides a good fit to the FEM as illustrated in Figure 2 by the good agreement with the vertical displacement determined at the bottom of the beam. This deviation from the Winkler solution represents a deviation from common beam theory. In this example, and in subsequent comparisons, the modulus of elasticity is estimated by best fitting predicted FEM and Winkler displacements at the midpoint and one third of the beam span length. It should be noted that this catenary effect is an added benefit that improves the performance of GRS beams and platforms and support structures.

Figure 2. Example of how composite GRS beam modulus of elasticity was estimated

Simply Supported Beam on Elastic Foundation Two Dimensional Winkler Model Reinforced Deformation Sketch

Figure 3. Sketch illustrating difference in end conditions for a GRS beam compared to a non-reinforced simply supported beam. The dashed end lines indicate the “tipped in ends” that are characteristic of simply supported beams. The solid end lines restrained by the boundary condition illustrate how the reinforcement restrains this movement

3. PARAMETRIC STUDY

The first objective of this study was to conduct a parametric in which modulus of elasticity, geosynthetic reinforcement and the number of layers geosynthetic reinforcement was varied to observe the effect each parameter has on the composite bending stiffness of a GRS platform. The Winkler model was used for estimating the lateral displacement of the flexible GRS beams on soil. It is important to remember that the Winkler foundation model makes the simplifying assumptions, that the platform is linear elastic and the foundation soil reacts as vertical springs.

The moment of inertia was kept constant in the parametric study while the geosynthetic reinforcement stiffness, soil modulus of elasticity, and the vertical spacing of reinforcement were varied as summarized in Table 3. The composite

modulus of elasticity for the trials was estimated using the graphical method described previously. A summary of the parametric testing program and the estimated moduli of elasticity is summarized in Table 3.

Table 3. Parametric FEM Modeling Program and Results Summary

Trial Number	Modulus of Elasticity x cross-sectional area of the geosynthetic reinforcement (EA)	Modulus of Elasticity of the beam Soil (E_b)	Number of Equally Spaced geosynthetic Reinforcement Layers at	Beam Length (m)	Estimated Modulus of Elasticity (kPa)
1	750 kPa	57,000 kPa	4	3.0	300,000
2	375 kPa	57,000 kPa	4	3.0	300,000
3	1500 kPa	57,000 kPa	4	3.0	340,000
4	750 kPa	37,000 kPa	4	3.0	200,000
5	750 kPa	77,000 kPa	4	3.0	375,000
6	750 kPa	57,000 kPa	2	3.0	250,000
7	750 kPa	57,000 kPa	8	3.0	375,000
8*	N/A	57,000 kPa	N/A	3.0	57,000

N/A denotes not applicable

*Note: Trial 8 was not modeled with reinforcement; rather it was used for verification of the FEM and comparison

The results presented in Table 3 of the parametric study show that reinforcement in general has a significant influence in GRS beam and platform bending stiffness. This is indicated by obvious difference in vertical displacement between Trial 8 which is un-reinforced versus the other trials. The results indicate that modulus of elasticity of the soil and the reinforcement spacing significantly influence in GRS beam. Increasing and decreasing the modulus of elasticity of the soil 10,000 kPa changed the composite modulus of elasticity 75,000 kPa and 100,000 kPa respectively. Increasing and decreasing the number of layers by two layers changed the composite modulus of elasticity 75,000 kPa and 50,000 kPa respectively. Fabric tensile stiffness had the least effect on the composite bending modulus of elasticity. Increasing and decreasing the fabric tensile modulus by factors of two changes the GRS beam modulus of elasticity 40,000 kPa and zero.

Some deviation from the Winkler solution is caused by the catenary boundary condition selected for the FEM model as discussed previously. The particular solution to the Winkler model represents a simple support at the beam ends. Unlike this, the FEM restrained the fabric layers from horizontal movement at the beam end. This resulted in slight differences in Winkler and FEM deflected shapes, especially near the support. Another effect that may have caused the variance from the Winkler model is that the structural members used to model the geosynthetic reinforcement were only allowed to resist tension and not compression, therefore, the composite E is not likely uniform from top to bottom of beam and the location of the neutral axis is dependent on the internal stresses developed from bending, which changes with beam location. These conditions do not constitute a variation from beam theory, but they do challenge creation of a closed-form analytical solution. Furthermore, because numerical modeling is complicated and time consuming, a simplified approach is justified.

4. STUDY OF MODULUS OF ELASTICITY IN RELATION TO MOMENT OF INERTIA

The second objective of this study was to examine the bending stiffness of GRS beams by analyzing the relationship between modulus of elasticity determined by the graphical method describe in Section 3 and the geometric moment of inertia of the beam. GRS beams of consistent spacing and material properties were modeled with varying moments of inertia. The moment of inertia was varied by addition of alternating layers of soil and geosynthetic reinforcement, which subsequently increased the cross-sectional height. Figure 4 presents sketches that illustrate the cross sectional areas of the beam configurations modeled for this portion of the study. The geometric rectangular moment of inertia of a GRS cross-section is defined by equation 5.

$$I = \frac{bh^3}{12} \quad [5]$$

Base (b) was assumed to be equal to 1-meter reflecting a two dimensional finite element analysis and use of the metric system of units. Height (h) was varied with the number of equally spaced GRS layers. Geometric modulus of elasticity was determined using the same graphical method described in section 3 and does not account for the varying stiffness of the soil and reinforcement.

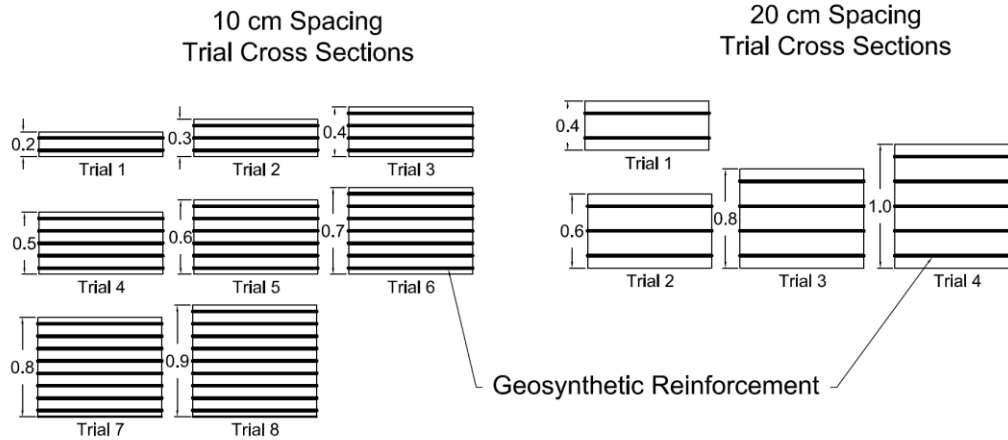

Figure 4. Sketch illustrating the cross sections of the varied FEM modeling program using varied moments of Inertia

The FEM model results for the GRS beam sections in Figure 4 are plotted with a set of Winkler beam solutions for a similar homogenous beam to graphically determine a modulus of elasticity for the GRS beam using the methods presented in Section 3. The modulus of elasticity was determined for three conditions 1) matching deflection at 1/3 the beam length, 2) matching deflection at midpoint (1/2 the beam length) and 3) visually best fitting the entire deflected shape of the FEM model to a Winkler solution.

It is evident from the results that beams with smaller geometric moments of inertia have larger differences between the estimates of modulus of elasticity at 1/2 and 1/3 of the beam length. For this reason, there is less confidence when estimating modulus of elasticity for beams with moments of inertia less than 0.005 m^4 using the graphical method applied in this study. There is less variation in the estimated moduli of elasticity for moments of inertia greater than 0.005 m^4 . This effect may be an indication that GRS beams require a minimum number of layers to develop a composite effect.

A Winkler platform exactly conforms to conventional pure beam bending mechanics so the deformed shape of the beam would be the same for all combinations of E and I having a constant product (C) ($EI=C$), all other parameters being equal. Hence, for pure beam bending, a linear relationship is expected for $1/E$ and I ($I=C(1/E)$). Taking the log of both sides of this relationship and rearranging, the pure bending relationship between I and E can be expressed as a linear relation between logarithms of I and E [$\log(I) = -\log(E) + C2$]. However, it is observed in Figure 6 that the relationship that develops from the FEM models is not linear, but rather log-linear. This is not a reflection of the FEM failing to comply with beam theory, rather, it is a consequence of not estimating the conventional moment of inertia of composite beams sections i.e. by implementing the parallel axis theorem on a transformed section. This was done so that a relationship could be developed to estimate a composite material stiffness enhancement. Some deviation from the Winkler solution is evident by the slight differences in the deformed shapes of the Winkler solution and the GRS Beam FEM. The reasons for these differences have been discussed.

Simplification of the calculation of the modulus was necessary to develop a useful relationship between modulus of elasticity and geometric moment of inertia for GRS beams with moments of Inertia greater than 0.005 m^4 or beam thicknesses of 0.4 m. Discussion of the relationship and restrictions follow.

Figure 5 a) and b) show the estimated moduli of elasticity versus geometric moment of inertia for the trials conducted. Moments of inertia greater than 0.005 m^4 were modeled for GRS beams having 10 cm and 20 cm reinforcement spacing respectively. Beam spans of 3.0 m and 3.5 m are presented separately with a best fit line.

The moduli of elasticity for the different beam spans appear to converge with increasing moments of inertia indicating beam span has less of an effect for GRS beams with larger moments of inertia or higher cross sections. This is intuitively understandable since thick short beams bend less and the effect of beam stiffness would become less significant.

As expected from the observations made in the parametric, study reducing the spacing of reinforcement layers provides an increase in modulus of elasticity as indicated in Figure 6 a) and b). This also, is intuitively explained since the beam becomes stiffer with addition of reinforcement. Figure 6 a) and b) show how the 10 cm reinforcement spacing improves the modulus of elasticity and consequently bending stiffness for both span distances modeled for this study. Once again, this effect appears to diminish somewhat with an increase in beam thickness therefore the benefit of closely spaced reinforcement increases with greater spans.

Figure 5. Estimated moduli of elasticity versus moment of inertia for the trails conducted with moments of inertia greater than 0.005m⁴. Figures a) and b) are the results of the 10cm and 20 cm reinforcement spacing. Lines were best fit to 3.0 m and 3.5 m span data.

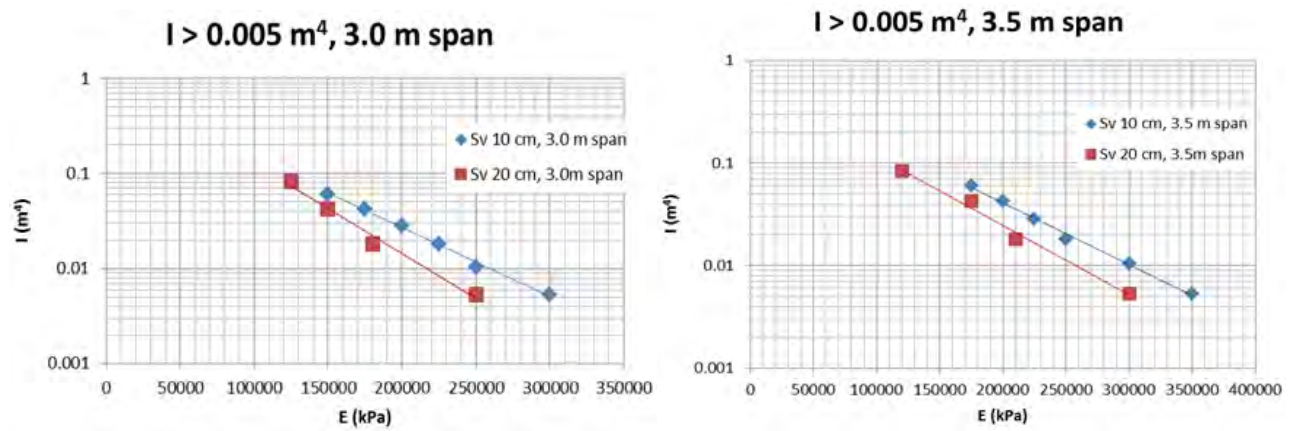

Figure 6. Estimated moduli of elasticity of versus moment of inertia for the trails conducted with moments of inertia greater than 0.005m⁴. Figures a) and b) compare the results of 10cm and 20 cm reinforcement spacing to the different span lengths modeled for this study.

The results from this portion of the study verify that the bending stiffness of GRS beams is largely a function of reinforcement spacing and geometric moment of inertia. The results also indicate that the span to beam height ratio has an ancillary effect. The beam span to length ratio is not evaluated further in this study, however it should be considered for future study.

4.1 Proposed S_v Composite E Relationship

A relationship between geosynthetic reinforcement spacing and the modulus of elasticity is developed here using the data above. A relationship to estimate modulus of elasticity for a given spacing is proposed based on the observation that E increases with I and converges to a single point. The relationship is presented in equations 6, 7, and 8.

$$E = \frac{\log(I) - b}{m} \quad [6]$$

$$m = -1 \times 10^{-7} S_v - 5 \times 10^{-6} \quad [7]$$

$$b = \log(I') - m E' \quad [8]$$

Where E is in units of kPa; S_v is to be the units of centimeters; and I' and E' are the moment of inertia and modulus of elasticity converge and have the units of m^4 and kPa respectively. For the GRS beam modeled in this portion of the study the I' and E' values were found to be $0.27329 m^4$ and $44,444 kPa$ respectively. Based on the results of the parametric study, I' and E' are expected to be a function of the material properties. The parametric study results demonstrate that the geosynthetic reinforcement tensile strength has a minimal effect on the bending stiffness. For this reason, the modulus of elasticity of the soil matrix is anticipated to have the most influence on I' and E' . Additional study could develop a relationship between the I' and E' making the relationship presented in this study applicable to additional soil types.

5. SUMMARY AND CONCLUSIONS

Geosynthetic-Reinforced Soil (GRS) is a soil mass that is reinforced by incorporating horizontal layers of geosynthetic sheets. A better understanding of GRS bending stiffness is expected to improve GRS design and application related to embankments on soft foundations, or negative batter GRS walls. This study investigated the bending stiffness of a GRS platform on a Winkler foundation with two primary objectives. The first objective was to investigate effects of various parameters of a GRS platform on the bending stiffness of the GRS composite and evaluate the applicability of beam theory. The analysis indicated that bending resistance is best gained by decreasing the spacing between reinforcement layers and using higher strength soils. Increasing reinforcement tensile strength had some effect upon bending resistance, but its affect ancillary to the spacing and soil modulus of elasticity parameters.

Some deviation from the Winkler solution is caused by the different boundary condition selected for the FEM model. Unlike a simply supported beam that the Winkler Model is based upon, the FEM restrained the fabric layers from horizontal movement at the beam end. This resulted in slight differences in Winkler and FEM deflected shapes, especially near the support. Another effect that may have caused the variance from the Winkler model is that the structural members used to model the geosynthetic reinforcement were only allowed to resist tension and not compression, therefore the composite E is not likely uniform from top to bottom of the beam and the location of the neutral axis is dependent on the internal stresses developed from bending, which changes with beam location. These conditions do not constitute a variation from beam theory, but they do challenge creation of a closed-form analytical solution. Furthermore, because numerical modeling is complicated and time consuming, A method of approximating the improved bending stiffness based on key parameters was the second objective. The relationships among geosynthetic reinforcement spacing, modulus of elasticity and geometric moment of inertia were examined. Based on limited analyses, the relationship appears to be functional for estimating a composite bending stiffness of GRS platforms with properties and dimensions within the ranges used for this study.

ACKNOWLEDGEMENTS

ABSTRACT

The hydraulic conductivity of Geosynthetic Clay Liners for the confinement of waste disposal facilities, mainly depends on the hydraulic conductivity of the core bentonite clay encased between the two geotextiles. Sodium bentonite clays are widely used for Geosynthetic Clay Liners due to their low hydraulic conductivity to water. Calcium bentonites are low cost and readily available. On the other hand, the hydraulic conductivity of calcium bentonites is higher compared to that of sodium bentonites. This study compares the impact of the treatment of calcium bentonite with an anionic polymer, Sodium Carboxymethyl Cellulose (Na-CMC) with HYPER clay technology, to the standard sodium activation treatment of calcium bentonites. The swelling ability and the hydraulic conductivity of a calcium bentonite to CaCl_2 solutions was compared to the hydraulic conductivity of sodium activated bentonite and polymer treated bentonite. Test results showed the beneficial effect of the anionic-polymer treatment on the swelling and hydraulic performance of the clay analyzed.

1. INTRODUCTION

Leachate from landfills may contain harmful substances for the environment and for the human health. The spread of these substances is prevented by the use of hydraulic barriers such as Compacted Clay Liners (CCLs) and Geosynthetic Clay Liners (GCLs). GCLs are factory – manufactured clay liners consisting of a thin layer of bentonite encased by geotextiles or glued to a geomembrane, may be mechanically held together by needling, stitching, or chemical adhesives. High quality bentonites, like sodium bentonite, are used in GCLs. Sodium bentonite clays are widely used because of their low hydraulic conductivity to water and favorable swelling properties (Mitchell, 1993; Shackelford et al., 2000; Egloffstein, 2001; Bouazza, 2001). However, these type of clay may be not readily available, expensive and prone to cation exchange in the long term. For these reasons there is a tendency to prefer low quality, less expensive and readily available calcium bentonite clays enhanced by treatment with sodium activation. However, exposure to high concentrations of organic or inorganic compounds, largely present in landfill leachates, can change the clay fabric, of natural-sodium or sodium-activated bentonites, increasing their hydraulic conductivity (Norrish, 1954; Mitchell, 1993). Another critical disadvantage of the sodium activation is the consequent formation of calcium carbonate precipitates into the soil. This calcium carbonate may re-dissolve during contact with a dilute permeant, releasing calcium ions that exchange with sodium in the clay (Guyonnet et al., 2005). This exchange leads to obliteration of the beneficial low permeability, and to the development of a more permeable clay.

To overcome these problems, modified clays have been recently introduced in barrier applications to improve their chemical resistance to aggressive permeants (Kondo, 1996; Onikata et al., 1996, 1999; Flynn and Carter, 1998; Schroeder et al., 2001; Ashmawy et al, 2002; Simon and Müller, 2005; Lorenzetti et al., 2005; Filippi et al., 2007; Betega de Paiva et al., 2008; Mazzieri et al., 2010; Katsumi et al., 2008; Di Emidio, 2010a&b; Bohnhoff & Shackelford, 2010; Palomino, 2010; Scalia et al., 2011; Malusis et al., 2011). In view of pollutant containment applications, it is of great interest to evaluate the potential benefits of these treated clays, by analyzing their hydraulic behaviour, investigating the mechanisms through which the amendments can improve the sealing capacity of a clay, to highlight the more suitable treatment technique and to further investigate the weaknesses of the available treatments with the aim of future advancements and improvements.

2. MATERIALS

In this study three materials are compared: a natural calcium bentonite (CaB), the same CaB sodium activated (SA CaB) and the same CaB treated with the HYPER clay technology (HCaB). The latter treatment method consists of mixing the base clay with a polymeric solution (containing 8% - by weight of clay - of Sodium Carboxymethyl Cellulose, Na-CMC) with a mechanical stirrer for 30 minutes. This slurry is then oven dried at 105° C for 16 hours. After drying, the HYPER (CaB) clay is ground first manually using a mortar and pestle and then mechanically using a Retsch Mortar Grinder RM 200. This treatment method can also be applied to other types of clay with different polymer dosages (Di Emidio, 2010b).

Some properties of the materials tested here are listed in Table 1.

The electrolyte solutions used in this investigation are deionized water, KCl and CaCl₂ solutions with different concentrations. The deionised water was used as base solution for the HYPER clay and electrolyte solutions preparation. The deionized water was produced using a water purification system PURELAB Option-R 7/15. The electrical conductivity of the deionized water was EC=0.0039 mS/cm, the pH = 7.57, and the redox potential was Eh=293 mV. The electrolyte solutions were used to test the swelling and the hydraulic conductivity of the materials. The solutions were prepared by dissolving different concentrations of KCl and CaCl₂·2H₂O (>99.7% pure) in deionised water. Some properties of the solutions are listed in Table 2.

Table 1. Characteristics of tested soils (CaB=calcium bentonite; SA CaB=sodium activated calcium bentonite; HCaB=HYPER CaB clay).

Characteristics	CaB	SA CaB	HCaB
Swell index (ml/2g)	12	19	42

	0.1	18.540	11	6.77	260

3. METHODS

The tests performed on the three samples were: (1) swell index test using various electrolyte concentrations and valence; (2) the swell pressure test and (3) the hydraulic conductivity test using a 5 mM Calcium Chloride solution. The swell index tests were performed to have a qualitative evaluation of the impact of various electrolyte solutions with different concentrations (0.0001 M up to 0.5 M) and valences (K⁺¹ and Ca⁺²). The swell pressure tests were executed to prepare the samples for the hydraulic conductivity test and also to overcome some limitations of the swell index test for the qualitative evaluation. These limitations can be caused by turbidity of the solutions during the experiment and/or macropores formation that could false the results (see Fig. 2 in Section 4).

3.1 Swelling Tests

Swell index tests were performed on the untreated CaB calcium bentonite clay, the sodium activated clay and the HYPER clay following the ASTM D5890. The bentonites were oven dried at 105° C. After drying, the bentonites were ground using a mortar and pestle until 100% passed the #200 mesh U.S. standard sieve. 90 ml of the testing solutions were poured into a 100 ml graduated cylinder. Two grams of sieved bentonite were poured in the aqueous solutions in 0.1 g increments. After the 2 g were added, the remaining 10 ml solution was poured to fill the cylinder to the 100 ml. This additional solution was also used to rinse any particle of bentonite adhered to the internal sides of the cylinder. After 16 hours of hydration period, the final temperature and the volume of swollen bentonite were measured.

Swell pressure tests were also performed on the untreated CaB, the sodium activated clay and the HYPER clay. The swelling pressure test apparatus used consists of a stainless steel ring (7.1 cm diameter) accommodated in a one-dimensional cell (similar to a standard oedometer cell) located in a frame provided with a load cell connected to a computer. The specimen was prepared by spreading a thin layer of dry clay (0.45 g dry bentonite/cm²) into the stainless steel ring placed into the oedometer cell. The aim of this procedure was to obtain samples that represent the bentonite core of a standard GCL with typical dry bentonite per unit area of 0.45 g/cm². After assembling the sample was inundated with the testing solution (CaCl₂ 5 mM). For these powder samples a fixed height (h=0,665 cm) was chosen to obtain a similar initial porosity (with a dry unit weight of 6.65 kN/m³) for all samples. The swelling pressure was measured by the load cell keeping the height of the sample constant. The achievement of a steady maximum swelling pressure was chosen as termination criteria. The CaB sample was dismantled from the swell pressure setup after 7 days, the Sa CaB sample after 10.5 days and the H CaB sample after 5 days.

3.2 Hydraulic Conductivity Test

As mentioned above, thin clay specimens were prepared for the hydraulic conductivity tests in the swell pressure setup, with the purpose of simulating the bentonite core of a standard GCL hydrated with the testing solution (CaCl₂ 5 mM) in order to test the hydraulic efficiency of non pre-hydrated samples. The hydraulic conductivity tests were performed in flexible wall permeameters. The tests were executed with a hydraulic gradient of about 55 and an average effective stress of 30 kPa. This effective stress was chosen in order to simulate an extreme condition, such as the lowest effective stress expected in a landfill cover. In case the effective stress is increased (to represent, for instance, a landfill base liner), the hydraulic conductivity will decrease accordingly (Petrov and Rowe, 1997).

The samples chosen for the hydraulic conductivity tests were: the calcium bentonite as base material, the sodium activated bentonite and the HYPER clay calcium bentonite, in order to compare the beneficial effects of the two treatments. A 5 mM CaCl₂ permeant solution was chosen in order to study the effect of cation exchange on the hydraulic conductivity of the clays analyzed.

4. RESULTS

This section shows the results of the experimental work on the calcium clay treated with two enhancement methods: the standard sodium activation and the novel HYPER clay technology that consists, as seen above, in a treatment with an anionic polymer. First, the swell index test results will be shown to have a qualitative indication of the impact on the treated and untreated clays of various electrolyte solutions with different concentrations and valences. There is, in fact, a well-known inverse relationship between the swell index and the hydraulic conductivity of bentonite clays (Jo et al., 2001), therefore it can give an idea of the potential hydraulic behavior of a soil. Then swell pressure test results will be shown, these tests were useful to overcome some limitations encountered in the swell index tests (e.g. due to macropore formation) and to prepare the samples from a powder to a simulated GCL disc, for the hydraulic conductivity test. Finally the results of these hydraulic conductivity tests will also be illustrated. The samples for the hydraulic conductivity tests were first hydrated with the permeant solution in the swell pressure setup to represent the worst case scenario (direct permeation with electrolyte solution without pre-hydration with water).

Figure 1 shows the swell index of the materials versus concentration of the KCl and CaCl₂ solutions used. As shown in the figure, the swell index of the treated clays was higher compared to that of the untreated calcium bentonite clay. The HYPER clay showed a higher swell index compared to both the untreated clay and the sodium activated clay for KCl solutions 0.0001 M up to 0.5 M. For CaCl₂ solutions from 0.0001 M up to 0.01 M (which is similar to a typical maximum pore water content that may be expected, Lin & Benson, 2005) the HYPER clay showed a higher swell index compared to the untreated clay. For concentrations of CaCl₂ higher than 0.05 M the swell index of the three clays was comparable. This result indicates that the HYPER clay treatment could potentially perform better compared to the sodium activation. For concentrations of CaCl₂ between 0.005 M and 0.01 M it was observed an unusual behavior for the sodium activated clay: a card house structure with marked macropores was detected (Figure 2-left); this behavior was highlighted with a letter "M" in Figures 1 and 2-right on the columns that showed this phenomenon. The card house structure with marked macropores evidently produced false measurements of the swell index of the sodium activated clay within that range of concentrations. To overcome this limitation and to represent the actual swelling performance of the clays, a one-dimensional swell pressure test was performed using a 0.005 M CaCl₂ solution. The swell pressure test, in fact, is not expected to be affected by this type of macropores formation, because of the mechanisms that govern the swell pressure phenomenon: when hydrated, the bentonite clay adsorbs a large amount of water molecules and ions; as a consequence a swell stress is raised by this water entering the pores among montmorillonite particles and the interstitial layers in individual montmorillonite crystals, leading to an increase in volume and manifested as a stress on the surrounding materials. On the other hand, the macropores formation, in the swell index test, leads to an increase in volume (due to the structure and the presence of macropores), but do not raise the interstitial stress between clay layers and on the surrounding materials. The results of the swell pressure are given in Figure 2 and 3. The swell pressure of the HYPER

clay is higher compared to that of the sodium activated clay in the 0.005 M CaCl_2 solution, in contradiction with the misleading swell index test results that showed an apparent opposite behavior due to the macropore formation (Figure 2-right). Figure 3 clearly shows the variation of the swell pressure for the three clays with time. As expected, both treated clays showed a higher swell pressure compared to the untreated calcium clay. As shown in the Figure 2-right, the swell pressure of the HYPER clay was higher compared to that of the sodium activated clay, overcoming the technical limitations of the swell index test observed and suggesting the potential higher hydraulic performance of the HYPER clay.

Figure 4 shows the hydraulic conductivity of the three clays vs. time. As expected, the hydraulic conductivity of both treated clays were lower than that of the untreated clay due to the typical thinner diffuse double layer between clay platelets in the calcium bentonite. Besides, Figure 4 also shows that the hydraulic conductivity of the HYPER clay was lower than that of the sodium activated clay, indicating a higher performance of the HYPER clay not only in terms of swelling ability (as seen above) but also in terms of hydraulic conductivity. These results were in good agreement with swelling tests results. As expected, the higher the swell pressure, the lower the hydraulic conductivity of the materials tested. The reference hydraulic conductivity to deionized water of a natural sodium-bentonite is of the order of $6.4\text{E-}12$ m/s (see Di Emidio, 2010a). The hydraulic conductivity to CaCl_2 5mM of the HYPER clay shown in Figure 4 is of the same order ($7.8\text{E-}12$ m/s after 1,5 Pore Volumes of flow) whereas the hydraulic conductivity to CaCl_2 5mM of the sodium activated clay was half order of magnitude higher ($3.04\text{E-}11$ m/s after 5 Pore Volumes, PV). The hydraulic conductivity of the calcium clay after 25 PV of flow is $1.52\text{E-}10$ m/s. The lower hydraulic conductivity of the HYPER clay is due to its thicker diffuse double layer (DDL) that is maintained in the long term due to the irreversible adsorption of the polymer into the clay (Di Emido, 2010b). The polymer, in fact, intercalates between the clay particles maintaining the interlayer open and adsorbing lots of immobile water molecules and ions. This phenomenon restricts the pore space available for the flow and causes tortuous flow pathways, which is typical of dispersed structured low permeable clays. Given that the thickness of the adsorbed layer is inversely related to the ions concentration and valence, bentonites are particularly sensitive to changes in the composition of the pore fluid. In particular, electrolyte solutions with high valence (such as the CaCl_2 solution used in this work) cause the thickness of the diffuse double layer to collapse and therefore the hydraulic conductivity to increase.

5. DISCUSSION SECTION

The swelling ability of the treated clays was quantified by means of standard swell index test and swelling pressure tests. Both showed that the treatment with the anionic polymer studied here improved the swelling ability of the untreated clay compared to the sodium activation method. The swell index test of the sodium activated clay showed some limitations in its accuracy due to the macropore structure of the clay in contact with CaCl₂ solutions. The macropores formed lead to a card house structure with an apparent high swell index. On the other hand, the swell pressure test was not affected by this phenomenon. Therefore, the swell pressure provided more reliable information on the swelling ability of the clays. Hydraulic conductivity tests were conducted on untreated calcium bentonite clay, sodium activated clay and polymer treated clay. As expected, the hydraulic conductivity of the untreated clay was the highest due to a compressed double layer thickness. The hydraulic conductivity of the HYPER clay was the lowest. The low hydraulic conductivity of the HYPER clay is due to its thick diffuse double layer (DDL) which is maintained in the long term. Further research is in progress to confirm these results for higher concentrations of the permeant solution (such as CaCl₂ 10 mM and 100 mM).

Benefit-Cost Analysis of Using Geosynthetics in Water Resources

M. Goldenberg, P.E., CETCO, USA, mgold@amcol.com

ABSTRACT

Increased water main breaks, leaking water reservoirs, and a lack of investment in infrastructure has left America's network of water systems in disrepair, warranting a D-minus grade from the American Society of Civil Engineers (ASCE, 2009). As certain regions of the United States, particularly the southwest, face water shortages, the need to rebuild the nation's water infrastructure is becoming increasingly important. This paper will present a cost-benefit analysis of constructing a composite liner system (geomembrane in combination with a GCL) to the expected savings in dollars from water saved. To evaluate their effectiveness in limiting water leakage, liner systems with and without an underlying GCL will be evaluated using tools commonly used in the landfill industry. Discount cash flow calculations indicate that the cost to construct a more robust liner will result in a net savings compared to the projected price of water lost over time from deteriorating reservoirs or those designed without a supporting low permeability secondary barrier.

1. INTRODUCTION

Funds for infrastructure are often seen as discretionary, especially during difficult economic times. Unfortunately, this lack of funding leads to deteriorating roads and bridges, water main breaks, leaking reservoirs, and so forth. This not only causes inconveniences in terms of roadway congestion, it can be more devastating in terms of a faulty bridge or a failed water reservoir. A lack of investment in the maintenance of current infrastructure can result in much greater costs in the future when the road, bridge, or water containment structure fails altogether. The importance of America's infrastructure is often understated - in terms of current and future economic investment, safety, and in the case of fresh drinking water, preserving a valuable limited resource.

According to the World Water Organization, the world's water consumption rate is doubling every 20 years, which is twice the rate of population growth (WWO, 2010). Further, it is projected that by the year 2025 water demand will exceed supply by 56% (WWO, 2010). The agriculture industry consumes between 75 and 90 percent of a region's available water supply (WWO, 2010). According to the Natural Resources Defense Council (NRDC), climate change will also have a significant impact on the sustainability of water supply in the coming decades (NRDC, 2010). A study by Tetra Tech for the NRDC found that more than 1,100 countries will face higher risks of water shortages by 2050 as a result of global warming. And more than 400 of these countries will face extremely high risks of water shortages (NRDC, 2010).

Economics would indicate that the price of water would increase in the coming years as the supply of fresh drinking water decreases. It is important to note that the current price of water in the United States is much less than several other developed countries, and this price is likely to increase in the coming years to cover the expenses necessary to repair the current water infrastructure and develop new infrastructure to sustain the resource. For example, Germany is currently paying \$1.91 for a cubic meter of drinking water. The United States is paying just \$0.51 for the same amount. Using tools that are commonly used in the landfill industry with reasonable assumptions, the total amount of water lost through compacted clay and geosynthetic lined systems can be approximated. From this methodology, the total cost of water lost can be calculated, and a cost-benefit analysis of installing a more robust geosynthetic system will be evaluated.

Figure 1. Fresh water price comparison in developed countries in U.S. dollar per m³ (American Water Works Company, September 2011).

Several options are available for lining water containment structures, including natural soil barriers and manufactured geosynthetics. For the purposes of this study, the following liner systems will be reviewed: traditional compacted clay liners, geosynthetics such as geomembranes and geosynthetic clay liners (GCLs), and composite liners, which include the combination of a geomembrane and an underlying soil layer or a GCL. Cost/benefit analysis on concrete liners were evaluated in the past (Zornberg and Webber, 2003). The study concluded that a geomembrane-concrete composite liner was more effective at reducing seepage as compared to concrete alone, 95% reduction as compared to 70% reduction. For the purposes of this paper, the goal is to maximize performance while minimizing cost. Accordingly, concrete will not be discussed further due to its significantly higher price in materials, hauling, and labor, as compared to soil and geosynthetic lined systems. The goal of this evaluation is to demonstrate a cost-benefit analysis of a properly installed geosynthetic system as compared to the price of lost water.

2. COMPACTED CLAY LINERS AND GEOSYNTHETICS

Compacted clay liners have been historically used to minimize infiltration in several applications, including water and wastewater reservoirs, landfills, and mining sites. Off-site borrow sources of clay or silt soils are often required to construct a low-permeability compacted soil liner. Significant upfront investigation is necessary to properly characterize the extent and the quality of the soil at the borrow source. In the landfill industry, the standard for a clay liner requires a hydraulic conductivity of 1×10^{-7} cm/sec and a thickness of 0.6 meters (2 ft) for sufficient performance. Depending on the availability of quality soil, the cost of excavating and hauling clay can be substantial, especially if distances are significant. Further, compacted clay can be difficult to install, with considerable variability in quality, which can lead to preferential flow pathways through the clay matrix (Rogowski, A.S., USEPA, 1990). Additionally, compacted clay liners can be susceptible to freeze-thaw cycling, with evidence of increased permeability due to its effects (LaPlante and Zimmie, 1992). For these reasons, a compacted clay liner would typically be installed in combination with a separate overlying geomembrane.

Because the topic of this paper is related to water containment, the geosynthetics that contribute to reducing water infiltration include geomembranes and Geosynthetic Clay Liners (GCLs). Drainage geocomposites can be used as well, often as leak detection layers in a double lined system. Several options exist for geomembranes, with the most popular being HDPE, LLDPE, PP and PVC. Each type of geomembrane has its own advantages and disadvantages, which are outside the scope of this paper and should be evaluated on a site-specific basis. Geomembranes are practically impermeable when intact; however, they are also prone to punctures due to installation damage. Giroud and Bonaparte (1989) presented field data on defect sizes and frequencies that were obtained from construction quality assurance and control (CQA and CQC) programs and forensic analysis for landfills and surface impoundments. They found that typical causes of defects in geomembranes include discontinuous seams, seam failures, damage from construction equipment, and puncturing by stones found in the adjacent soil. Although certain geomembranes may be more prone to punctures than others, it is reasonable and conservative to assume that at least some defects will occur with even the most stringent quality assurance and quality control program. Giroud and Bonaparte (1989) recommend using a frequency of one defect for every 4,000 m² of geomembrane and a defect area of 1 cm² for design purposes. Although these recommendations were based on landfill applications, it is reasonable to assume similar conditions for water containment structures utilizing geomembrane liners.

Various types of GCLs exist on the market. The most frequently specified are needle-punched reinforced GCLs - where the fibers from the cover geotextile are needlepunched through a layer of sodium bentonite clay to the opposite base geotextile. Geosynthetic clay liners that contain sodium bentonite between two geotextiles are typically characterized as “standard” GCLs, and are certified to maximum hydraulic conductivity values of 5×10^{-9} cm/sec, when tested in accordance with ASTM D 5887. The low GCL permeability is attributed to the low hydraulic conductivity of the sodium bentonite clay. As the bentonite hydrates, it swells and creates a tortuous flow path for water. Because standard GCLs are thin, typically 0.7 cm, increased water depths would result in high hydraulic gradients, which would translate into higher flow rates through the liner. Because of this, standard GCLs would not be recommended as standalone liners for liquid depths greater than 30 cm (1 ft). In these cases, the GCL should be used as a part of a composite liner (with an overlying geomembrane), or a composite GCL (geomembrane-laminated) can be considered as well. Geomembrane-laminated GCLs can be used as stand-alone liners in ponds or smaller water reservoirs. These types of GCLs are typically recommended for water depths that are less than 5 meters (16 ft). Because the seams of a geomembrane-backed GCL are simply overlapped, high water pressure can exacerbate the flow rate through the seams. A separate welded geomembrane overlying a standard GCL typically results in optimal hydraulic performance.

3. COMPOSITE LINERS

Geomembranes have been successfully used in countless liquid containment applications. Nonetheless, because of their thin structure they are susceptible to damage. While an intact geomembrane is virtually impermeable, minor damage can lead to a high leakage rate, especially when high hydraulic heads are being contained, and the underlying subgrade is porous. Much research has been devoted to measuring and minimizing leakage due to geomembrane defects (Weber CT, 2008; Giroud, 1997). Weber and Zornberg (2005) studied the application of geomembranes in dam construction. The study concluded that one should not expect the geomembrane to be fully impervious. This was attributed to a geomembrane being susceptible to installation damage and long-term service. Thorough construction quality control (CQA) can limit the number and size of geomembrane defects. However, even the most stringent CQA would not find the smallest punctures, which can lead to increased water losses. Nosko and Touze-Foltz (2000) used an electrical damage detection system to evaluate geomembrane damage during installation for over 300 landfill sites totaling more than 3,250,000 m². The study resulted in 4,194 defects detected, or approximately one defect per 800 m². It should be noted that defects can also occur post construction. During filling operations, as pressure increases, stones in the underlying subgrade can puncture a geomembrane.

Fukuoka (1986) and Brown et al. (1987) also investigated leakage through geomembrane defects. Fukuoka (1986) conducted large-scale permeameter tests to investigate leakage through defects in a reservoir liner for heads up to 40 m. Brown et al. (1987) conducted smaller scale permeameter tests to measure leakage through defects in liners for heads up to 1 m. Both authors concluded that a gap between the underlying soil and geomembrane contributed to significant increases in leakage where defects in the geomembrane occurred. Flow would occur laterally along the interface between the soil and geomembrane, as well as into the underlying soil layer. This research provided an initial understanding that the quality of contact between the geomembrane and the underlying soil or GCL can have a significant outcome on the overall leakage rate.

Further research by Giroud (1997) led to empirical equations for calculating leakage through composite liners with geomembrane defects. The equations are derived based on the understanding that the flow through a composite liner system (where a geomembrane overlies a low permeability soil or GCL) will depend on size of the geomembrane defect, the hydraulic head on top of the liner system, the hydraulic conductivity of the underlying soil or GCL, the thickness of the underlying soil or GCL, and the quality of contact between the geomembrane and the underlying low permeability soil or GCL layer, as shown in Figure 2. According to Giroud (1997) “in the case of a GCL, good contact conditions may be assumed because GCLs are usually installed flat, and because the bentonite slurry that may exude from a hydrated GCL contributes to establishing a close contact between the geomembrane and the GCL, provided sufficient compressive stress is applied.” Touze-Foltz and Giroud (2003) refined these empirical equations to more accurately predict liner leakage for three types of defects (circular defects, defects of circular length, and damaged wrinkles) and three types

Figure 2. Variables in Giroud's Equation (Giroud, 1997).

of contact conditions (excellent, good, and poor). The Touze-Foltz and Giroud equations only apply to relatively low hydraulic heads of less than 3 meters.

Weber (2008) conducted a series of hydraulic conductivity tests for geomembrane-only liners, geomembrane-compacted clay liners, and geomembrane-GCL liners under high hydraulic heads – up to 45 meters. Using existing equations by Giroud (1997) and Touze-Foltz and Giroud (2003), Webber (2008) developed equations for calculating leakage through geomembrane-compacted clay and geomembrane-GCL liners under high hydraulic heads. To evaluate the accuracy of existing equations used to predict leakage through geomembrane-only liners, Webber conducted geomembrane-only hydraulic conductivity tests, with a high permeability sand layer beneath the geomembrane. These results were evaluated using Bernoulli's equation for flow through an orifice, as recommended by Giroud and Bonaparte (1989). Webber (2008) concluded that these equations are valid for estimating flow through a geomembrane defect over a sand layer; however, the accuracy of the equation depended on the coefficient C, which can vary with the hydraulic head. The results of Webber's testing program are shown in Figure 3. The geomembrane-GCL and geomembrane-compacted clay liners performed very similarly as would be expected when quality clay (with an average hydraulic conductivity of 8×10^{-7} cm/sec in this case) is placed beneath a geomembrane. The geomembrane-only tests had leakage rates that were several orders of magnitude greater than the geomembrane/GCL and the geomembrane/CCL liners, which is consistent with the calculations in this study.

Figure 3. Results from experimental program by Webber, 2008.

4. BENEFIT/COST ANALYSIS FOR LINERS

To limit additional variability, Giroud's equations (Giroud, 1997) were used to calculate the leakage rate for the composite liner systems in this study. These equations are used regularly in the landfill industry, and are proven in their accuracy. As mentioned above, a drawback of using Giroud's equations for this study is the limited hydraulic head of 3 meters. Although this hydraulic head is not representative of field conditions, which are well over 100 meters in some instances, the end result is believed to be similar when comparing the effectiveness of one liner system to another. Darcy's Law was used to calculate the leakage through the compacted clay liner.

For the calculations in these analyses, the soil subgrades were assumed to be 0.3 meters (1 foot) thick at the specified hydraulic conductivities. The soil hydraulic conductivities ranged between 1×10^{-5} m/sec and 1×10^{-7} m/sec, with a most likely value of 1×10^{-6} m/sec. Because these hydraulic conductivity values are high (several orders of magnitude higher than the controlling liner component – the geomembrane) the end result would be the same considering greater soil thicknesses. The compacted clay component was assumed to be 0.6 meters thick with hydraulic conductivity values ranging between 1×10^{-9} m/sec and 1×10^{-7} m/sec due to the expected field variability of clay liners (Rogowski, USEPA, 1990). The GCL hydraulic conductivity values ranged between 3×10^{-11} m/sec and 1×10^{-10} m/sec, conservatively. The geomembrane defect diameters ranged from 0.0016 m to 0.05 m for each composite liner option. The number of defects in the geomembrane ranged between 2.5 to 25 per hectare for the GCL option and between 5 and 50 per hectare for the geomembrane-only option. This assumption is reasonable because the GCL acts as a geomembrane cushion in addition to a low permeability barrier. The contact coefficient

between the geomembrane and the GCL was 0.21, while the contact coefficient between the geomembrane and the soil was 1.15, as recommended by Giroud (1997). According to a study on dams titled Mission 2012 - Clean Water by the Massachusetts Institute of Technology, the average life of a dam is 50 years. The calculations in this study assume an interest rate of 10% over the 50 year period. As discussed in the introduction, the price of water can also vary. These calculations used a range between \$0.51/m³ (current price of water in the United States) and \$1.91/m³ (highest current price in developed countries), with a most likely value of \$0.92 (the average price in developed countries). The price may increase in time, which would work in favor of a potentially more expensive liner system that minimizes water losses.

Many of the parameters used to calculate the value of a composite liner system are highly variable. For this reason, a statistical approach was taken to find the probability that the benefit-to-cost ratio of constructing various liner systems was greater than one. The technical and economic effectiveness of the three liner systems were compared by comparing ratios of the net present or discounted life-cycle costs (e.g., NPV_{clay}/NPV_{GM/GCL} and NPV_{GM/soil}/NPV_{GM/GCL}). Using the method in Duncan (2000), the ratios were calculated for the most likely values (MLV), MLV plus one standard deviation, and the MLV minus one standard deviation. The values used for this study are shown in Table 1. Assuming a normal distribution, the probability that the discounted cost ratio would be greater than one was calculated. The results of these calculations found that, in most cases, it would be economically beneficial to construct a geosynthetic composite (GM/GCL) liner in lieu of compacted clay or a geomembrane-only liner. The probability that the discounted cost of a geomembrane-only liner would exceed the discounted cost of a geosynthetic composite liner is 100% when the underlying soil has a hydraulic conductivity of 1x10⁻⁶ m/sec. When the hydraulic conductivity of the underlying soil is an order of magnitude less permeable (1x10⁻⁷ m/sec), the probability decreases slightly to 93%. Comparing the discounted cost of a compacted clay liner to the discounted cost of a geosynthetic composite liner, the probability decreases to 82%. These calculations indicate that although geosynthetic liner systems may initially require a higher capital cost to construct, these costs are most likely offset by the improved performance (i.e., reduced leakage and saved water). Table 1 shows the range and most likely values of the variables used.

Table 1. Variable Input Parameters.

Variable	Units	HCV	MLV	LCV	σ
Head	m	3	3	3	
Defect Diameter	m	0.05	0.01	0.0016	0.008
Price of Water	\$/m ³	\$1.91	\$0.92	\$0.51	\$0.233

Installed Cost of GM/GCL	\$/ha	\$148,326	\$114,097	\$79,868	\$11,410
Cost of Recoverable Water Lost	\$/ha/yr	\$683	\$73	\$4	

Notes:

All costs in US\$

MLV = Most Likely Value, LCV = Lowest Conceivable Value, HCV = Highest Conceivable Value

σ = Standard Deviation. In general, standard deviations were calculated using $\sigma = (HCV - LCV)/6$, as recommended by Duncan (2000). In selected cases, such as the infiltration rates through the ET cap, this method resulted in a negative value for $MLV - \sigma$, indicating a skewed distribution. In these cases, two standard deviation values were used: for the lower bound, σ_1 was calculated using $0.68 \times \mu$ (Harr, 1987); for the upper bound, σ_2 was calculated using Duncan (2000).

5. SENSITIVITY ANALYSIS

The chosen values for hydraulic conductivities, number of defects, sizes of defects, and installed material costs were taken from historical research and CETCO's database. Although these values are believed to represent typical field conditions as accurately as possible, they are highly variable and should be evaluated on a site by site basis. For instance, the above calculations assume an interest rate of 10%. Increasing the rate to 12% will result in a decreased probability of 70% for the geomembrane/GCL liner to have a lower discounted cost than the compacted clay liner. The clay and underlying soil hydraulic conductivities are significant variables that can affect the outcome of these calculations. For instance, if the clay is assumed to be ideal, with little or no long-term deterioration, with hydraulic conductivity values of 1×10^{-9} m/s (MLV), 1×10^{-10} m/s (LCV), and 1×10^{-8} m/s (HCV), and leave all the other variables unchanged, the compacted clay liner becomes much more favorable, with a probability of 94% of having a lower discounted cost than the geosynthetic composite liner. Conversely, using the Benson (2007) data, which shows significant deterioration over time, with hydraulic conductivity values of 1×10^{-7} m/s (MLV), 1×10^{-8} m/s (LCV), and 1×10^{-6} m/s (HCV), and leave all the other variables unchanged, the geosynthetic composite liner becomes much more favorable, with a probability of having a lower discounted cost than the compacted clay of 100%. The same would apply to the geomembrane-only liner – if the underlying subgrade is naturally low permeability soil, the geomembrane-only option would be more favorable. These are just a few examples of the parameters specific to each liner system that can affect the calculated discounted cost ratios. Accordingly, it is recommended that when evaluating different liner options, the analysis above, as described by Duncan (2000), be performed using site-specific values to ensure that the option with truly the best technical and economic value (i.e., lowest discounted cost) is selected.

6. SUMMARY AND CONCLUSIONS

As certain regions in the United States and elsewhere face water shortages, the need for a sustainable solution increases. One aspect of this solution should include more robust liner systems to preserve the fresh water that is currently available. Several liner options are available – including concrete, compacted clay, geosynthetics, and combinations of these. This study evaluated a composite liner with a geomembrane in combination with an underlying GCL, a geomembrane by itself (over a porous soil), and a compacted clay liner. Example calculations found that in most cases it would be economically beneficial to construct a geosynthetic composite liner in lieu of a compacted clay liner or a geomembrane-only liner, despite the potentially greater short term material cost. As the price of water increases, this conclusion is further validated because of the decreased water loss with a more robust liner. Based on the calculations presented in this paper, the probability that the discounted cost of a geomembrane-only liner would exceed that of a geomembrane-GCL composite liner is between 93% and 100%, depending on the permeability of the soil beneath the geomembrane. The probability that the discounted cost of a compacted clay liner would exceed that of a geomembrane-GCL liner is 82%. These results support the use of a more robust, potentially more costly liner system to decrease long-term water leakage rates. It is recommended that this type of analysis be performed for site specific projects, as certain variables can greatly affect the performance of various liner systems.

It is also important to note that additional costs not taken into consideration in this study include those associated with obtaining additional fresh water where the existing water may be lost. For instance, the cost to locate, pump, and treat fresh water can be substantial. Countries such as Israel, India, Aruba, Australia, and several others are already forced to produce at least some fresh water via desalination, a process that is significantly more expensive than typical water treatment methods, generally more than twice as much (NY Times, July 2012). The energy required to desalinate water is substantial, and many environmentalists object to the method, which they say greatly contributes to global warming. The power needed to remove the salt from seawater accounts for 60 to 70 percent of the cost of desalination (NY Times, July 2012).

ABSTRACT

A large container and bulk cargo terminal is being constructed in the Port of Santos, Brazil. When completed the terminal will be the largest private owned port facility in Brazil with over 600,000 m² dedicated to container storage. To development the site, large quantities of imported fill would be required in addition to dredging and disposal off site of large volumes of contaminated sediments. In total this was a significant cost to develop the site. Allonda and TenCate engineers developed an alternative solution based on using the dredged contaminated sediments to be dewatered and contained on site in large geotextile tubes. This material would be environmentally secured permanently within the geotextile tubes over which the container storage yard would be constructed. Additionally, this solution would eliminate 600,000 m³ of imported fill and disposal offsite of the same volume of contaminated sediments. The alternative design greatly reduced the construction cost.

1. INTRODUCTION

Empresa Brasileira de Terminal Portuarios S.A. (Embraport) is an 848,000 m² container and bulk port terminal, being constructed in the Port of Santos, Brazil. This is an undertaking of Odebrecht Transportation in partnership with Dubai World Ports and Coimex. When completed, the Embraport terminal facility will not only be the largest private owned port facility in Brazil with over 600,000 m² dedicated to container storage, but it will be the largest in South America. Also, the terminal will be able to turn over 20 million TEU (units equivalent to a 20' containers) and 2 billion liters of bulk liquids per year. Total investment when completed will be \$1.15 billion/USD. The terminal is located on the north shore of the Estuario de Santos opposite the City of Santos in the State of Sao Paulo in an area that is primarily within a tidal flat zone.

To construct the terminal bulk and container storage area, more than 1.5 million m³ of fill would be required to be imported to achieve a platform level of +3.5 meters. The import of fill represented a major financial impact for the Embraport owners. In addition, 600,000 m³ of contaminated sediments was required to be, dredged from the entrance channel and turning basin of the terminal, dewatered, and disposed in an offsite facility, adding to the major cost of the site development. In total this put at risk the financial model for the project.

Allonda, the TenCate representative in Brazil, and TenCate engineers developed an alternative solution based on beneficial use of the contaminated dredged sediments. The solution was to use large (36.5m) circumference geotextile tube units to contain and dewater the contaminated sediments within onsite dewatering cells. The dewatering cells would be under the proposed container storage area, over which final fill and pavement section would be placed. The implementation of this solution would be to environmentally secure and contain the dewatered contaminated sediments within the fill section of the terminal, and reduce by 30% the required import of offsite fill material. The result would be to greatly reduce the construction cost and salvage the project financial model.

To proceed, major design considerations must be overcome. These included; 1) the ability of the geotextile tube system to contain and dewater contaminated sediments in a secure environment, 2) to treat all of the effluent and to return this effluent back to the native environment without any impact, 3) to provide a stable platform on which to store ocean containers stacked up to 7 layers high, and 4) to construct a site with a 40 plus year design life

This paper will address the design, modeling, field instrumentation, geotextile tube installation and dewatering operation, and effluent treatment required for the project. In addition this paper will present the economic impact of the beneficial use of contaminated dredged sediments for this project.

2. BACKGROUND

In 2007 Embraport was granted a Brazilian federal license to develop the site for the terminal and port facility. The initial survey and soil borings indicated that more than 50% of the site was in the tidal flats with an elevation between -1.0 and

+1.0. (See Fig. 1) All of the proposed terminal area was located over approximately 22 to 25 meters soft to medium sandy silt. To achieve the design platform elevation of 3.5m and to account for anticipated settlement, it was calculated that 1.5 million m³ of select fill must be imported to achieve the design platform elevation. Additionally, the environmental impact study identified more than 600,000 m³ of contaminated sediments were overlaying the sandy area of turning basin and entrance channel. As a condition of the construction license, it would be required that Emraport would remove and dispose in an upland secure facility all of the contaminated sediments that must be removed. Given the cost of these two requirements, the owners of Emraport contacted Allonda and TenCate engineers to submit a conceptual design incorporating geotextile tube technology to determine if this could be employed to help reduce some of the site development cost.

Figure 1 Location of Emraport Terminal

3. CONCEPT OF OPTIONAL DESIGN

Engineers proposed a conceptual design that consisted of impermeable berms to be installed around the perimeter of the site to an elevation of +4.5m with internal berms installed to an elevation of +2.5m to divide the site into several areas to act as geotextile tube dewatering cells. A woven geotextile separator would be placed on the mud surface within the cells over which a 0.5 m thick layer of gravel would be placed to act as a drainage blanket to convey the effluent from the geotextile tube to an internal channel. (See Figure 2)

Figure 2 Geotextile Tube with Internal Berm

Large geotextile tube units (36.5m cir. X 65m long) of a high strength woven monofilament by fibrillated tape woven engineered textile would be installed. (See Table 1 for the Geotextile Tube Mechanical and Hydraulic Properties) The 600,000 m³ of contaminated sediments from the turning basin and entrance channel would be hydraulically dredged and pumped to the geotextile tubes. In-line, an organic polymer would be injected to flocculent the solids and binding the contaminants to the soil particles. The effluent would be filtered thru the pores of the geotextile tube, collected in the

perimeter channels, and pumped to an onsite water treatment plant for secondary treatment to precipitate any heavy metals or other solids, to neutralize to a pH of 7 and then to release back to the natural environment.

Table 1 Geotextile Tube Mechanical and Physical Properties

Mechanical Properties	Test Method	Unit	Minimum Average Roll Value	
			MD	CD
Wide Width Tensile Strength (at ultimate)	ASTM D4595	kN/m (lbs/in)	78.8 (450)	109.4 (625)
Wide Width Tensile Elongation	ASTM D4595	%	20 (max.)	20 (max.)
Factory Seam Strength	ASTM D4884	kN/m (lbs/in)	70 (400)	
CBR Puncture Strength	ASTM D6241	N (lbs)	8900 (2000)	
Apparent Opening Size (AOS)	ASTM D4751	mm (U.S. Sieve)	0.43 (40)	
Water Flow Rate	ASTM D4491	l/min/m ² (gpm/ft ²)	813 (20)	
UV Resistance (% strength retained after 500 hrs)	ASTM D4355	%	80	

Filtration Properties	Test Method	Unit	Typical Value
Pore Size Distribution (O ₅₀)	ASTM D6767	Micron	80
Pore Size Distribution (O ₉₅)	ASTM D6767	Micron	195

Once all of the geotextile tubes within each cell have been filled, an overburden of up to 8 ton/m² would be applied to facilitate settlement. The settlement would be monitored and when stability the overburden would be removed and placed on the adjoining cell to repeat the process. (See Figure 3.)

By adopting this design, it was estimated that the cost of the site development could be reduced by 20% to 30%. Thus it was attractive to the owner who agreed to fund site testing to validate assumptions of the Concept of the Optional Design.

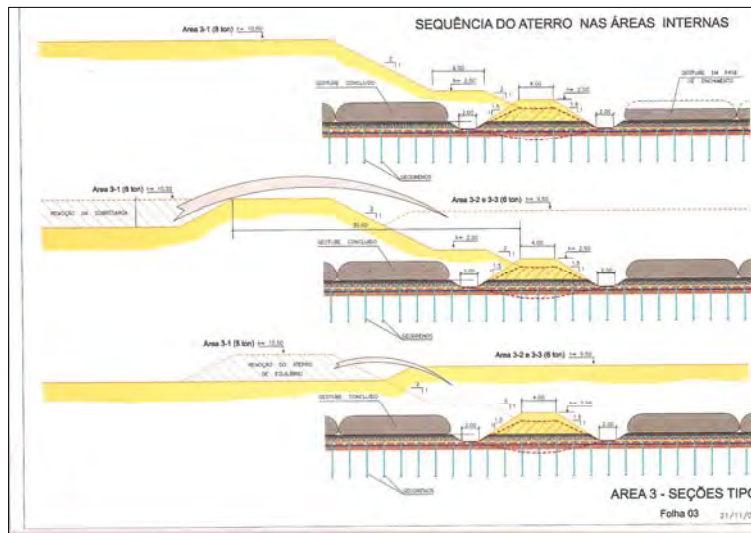

Figure 3 Geotextile Tube Overburden Placement Sequence

4. SITE TESTING AND MODELING

The first major questions that had to be answered were the settlement amount the rate of settlement. This would be based on the amount of fill that had to be placed over specific areas for container and bulk storage to achieve the design platform elevation. In some areas the fill would be as much as 4.5m thick. In 2008, to accurately forecast the settlement amounts and rates, a 150m by 75m test section was constructed at the most forward location of the fill section. (See Figure 4.) Different areas of the test section were loaded with the different overburden amounts that duplicate actual designed overburden amounts for the areas of the container and bulk storage. The settlement of each section was monitored over time to develop a curve that can be expected during the site construction.

Figure 4 Field Settlement Test Conducted in 2008

The second question that had to be answered was the consolidation that could be achieved when the contaminated sediments were contained and dewatered inside the geotextile tubes. To answer this question, a number of GDT model test were conducted using samples of the contaminated sediments taken from the ship berth area, the turning basin, and from the entrance channel. These test determined that 65% dewatered solids could be achieved within the geotextile tubes within 30 days after completing the geotextile tube filling. The GDT model testing also provided the information to select the type of polymer for the contaminated sediments, the dosage of polymer required to maintain the optimum dewatering performance, and to forecast the quality of the effluent that could be obtained during the dewatering phase.

5. CONSTRUCTION

Following the site and model testing, the final design was performed and construction started in 2010. The perimeter berm and internal dewatering cells were completed in 2011 and the first of 280 geotextile tubes 36.5m cir. X 65m long were installation and dredging started. Dredging was conducted using a 45 cm cutter head pumping to the geotextile tube units at a rate of 1,400 m³/hr. The dewatering contractor designed and managed the geotextile tube dewatering operation including the dredge manifold system, the automated polymer make down and injection system, and the effluent water treatment plant. Each geotextile tube was filled multiple times to a height of 2.2 m and allowed to dewater. The final dewatered height for all tubes was approximately 1.8 m. Each geotextile tube contained approximately 2,145 m³ after dewatering.

The effluent water from the geotextile tube units drained into a collection basin from which it was pumped to a water treatment basin. The pH of the effluent water was raised to precipitate dissolved solids. Next the water was transferred to a second basin where the water was naturalized, filtered thru activated carbon filters then released back into the environment.

After the geotextile tube units within each cell reached 65% solids following dewatering, a gravel drainage media was placed over the top of the tubes and then the overburden up to 8 ton/m² was placed over the gravel (See figure 5).

Figure 5 Drainage Layer and Overburden Placement March 2012

When all of the 600,000 m³ of contaminated sediments have been dredged into the geotextile tubes and the overburden consolidation phase completed, the container storage area paved section will be installed. (See Figure 6)

Figure 6 Pavement design

Figure 7 provides a rendition of the site when pavement has been completed in the winter of 2013.

Figure 7 Project When Completed 2013

6. CONCLUSION

The Embraport project is still under construction and will not be completed until late 2013. However, the dredging and dewatering of 600,000 m³ of contaminated dredging has been completed. The actual field results of the percent solids achieved and volume reduction correlate to the GDT modeling that was conducted prior to the start of dredging. The drainage blanket and overburden placed over the dewatered geotextile tubes has been completed and settlement of the site after placement of the overburden is consistent with the settlement results of the test section installed in 2008. Effluent from the geotextile tubes was maintained during and after the dewatering phase. The treatment and discharge back into the natural environment was monitored for the entire time of the process. The returned water was well below the standards required by the environmental permit. The reduction of importing 600,000 m³ of fill material to achieve the designed platform elevation has been achieved by the use of the dredged contaminated sediments from the turning basin and entry canal.

Therefore, it can be concluded that the beneficial use of contaminated sediments using geotextile tubes can be achieved, that modeling tools are available that can accurately forecast the results of the use of geotextile tubes, and total project savings are achievable when utilizing this technology.

Biofilm-enhanced Treatment for Arctic Wastewater Stabilization Ponds Using Geotextile Substrate

Evan Bridson-Pateman, Graduate Student, Dalhousie University, Canada, evan.bp@dal.ca
Rob Jamieson, PhD, P.Eng, Dalhousie University, Canada, jamiesrc@dal.ca
Craig Lake, PhD, P.Eng, Dalhousie University, Canada, craig.lake@dal.ca

ABSTRACT

Communities of the territory of Nunavut, Canada are facing potential changes to their wastewater discharge standards, as is the rest of the country. Remoteness and low populations create issues in implementing conventional treatment systems in these communities. Wastewater stabilization ponds are the most common treatment method, but berms constructed from thawed, coarse-grained local till result in continuous wastewater exfiltration. This study examines the potential for a geotextile biofilter retrofit to existing berms to treat wastewater as it exfiltrates.

Previous research suggests the suitability of geotextiles as a substrate for biological growth and filtration, however the effects of cold temperature on these biofilters is not fully understood. This study found that at 10°C, removal efficiencies were 40-80% for biological oxygen demand, 80% for total suspended solids, and 1-log for *Escherichia coli*. Maximum treatment performance was achieved fastest under the condition where large volumes of wastewater have passed through the filter.

1. INTRODUCTION

New wastewater treatment regulations from the federal government of Canada will have an impact on many Canadian municipalities, but those in remote areas of northern Canada face unique challenges. The entire territory of Nunavut, Canada has only 25 communities outside its capital city, with an average population of approximately 1,050. Some consist of as few as 130 people (Government of Nunavut, 2011). Communities in the Northern Territories of Canada also have small tax bases to fund infrastructure projects and must find innovative ways to meet wastewater treatment regulations imposed by the federal government. Even more challenging in terms of infrastructure development is that these communities are only serviced by air or sea transportation linkages. As such, deliveries of construction materials and machinery can only occur in optimum weather conditions, at high cost.

The most common form of wastewater treatment in these northern communities is the use of wastewater stabilization ponds (WSP) constructed from local till, and are often designed to rely on frozen soil berms to retain the wastewater. WSPs have been shown to effectively reduce effluent concentrations of biological oxygen demand (BOD₅), total suspended solids (TSS) (Saqqar and Pescod, 1995), and ammonia nitrogen (NH₄-N) (Pano and Middlebrooks, 1982). Furthermore, a 2-log reduction in fecal coliform bacteria is common (Polprasert et al., 1983). Many of the berms used to construct WSPs in these northern areas exhibit excessive seepage and low retention times due to the use of local sandy till in berm construction (Bölter, et al. 2006). The low retention times can diminish treatment (Meron et al., 1965) which may create challenges in complying with water quality regulations. Environment Canada's *Wastewater Systems Effluent Regulations* were released in 2012 and require maximum effluent concentrations of 25 mg/L for TSS and BOD₅, and less than 1.25 mg/L of NH₄-N (Environment Canada, 2012a). Bacterial discharge limits are typically evaluated on a case-by case basis.

The treatment performance of exfiltrating WSPs could be improved by a retrofit in two ways: (i) reducing the seepage through the berms, and (ii) providing a further polishing step to the exfiltrating water. One economical way to retrofit existing WSPs is through the use of geosynthetics such as geotextiles, since reconstructing the lagoons with imported clay material is economically impractical. Geotextiles can provide a medium for biofilm growth and hence provide potential biofiltration treatment. Although geotextiles are traditionally used in drainage filtration, research has shown their potential in wastewater treatment applications. In South Carolina, hanging-bag geotextile filtration of fresh liquid manure and lagoon sludge was used to accomplish 60 to 90% removal of TSS and 26 to 65% removal of NH₄-N (Baker et al. 2002). In Philadelphia, bench-scale experimentation with two-filter geotextile columns removed 91 to 97% of TSS and BOD₅, and 90% of NH₄-N in septic tank effluent (Yaman et al., 2005). This was confirmed at full-scale by Hu and Gagnon (2006), showing that using geotextile filters in recirculating biofilters resulted in 77% removal of TSS, 95% removal of BOD₅, 96% removal of NH₄-N, as well as 2.2 log removal of fecal coliforms. In addition to their use as direct filters of wastewater, there is evidence that geotextiles can be used as effective filters when used as baffles in sedimentation tanks. Municipal wastewater (with commercial, industrial and residential sources) was filtered using a tank with geotextile baffles and resulted in average removal efficiencies of 95% for TSS, 92% for

BOD₅, and 97% for NH₄-N (Korkut et al., 2006). If used within a WSP berm the biofilm that forms on the geotextile could also provide a reduction in hydraulic conductivity, which will result in increased retention times in the WSP. Palmeira et al. (2008) have shown hydraulic conductivity decreases in geotextiles by up to 4 orders of magnitude in 90 days via biological clogging.

Unfortunately, the effect of temperature on this type of treatment process is unknown, as all of these experiments were conducted at room temperature. In the arctic study area for this research, depending on latitude, communities have only 2 to 3 months per year with temperatures above 0°C, and average temperatures between -3°C and 11°C for those months (Environment Canada, 2012b). Studies on other types of biological filters have showed that biomat development was retarded at lower temperatures (Ratkowsky et al. 1982) and that treatment performance was reduced (Moll et al., 1999). Presumably, biological activity on the geotextile will be similarly affected by temperature.

The objective of this research is to examine the influence of temperature on the treatment of WSP effluent with geotextiles. This work is part of a larger study examining the temporal development of biofilm on geotextile biofilters within the time and temperature constraints of an arctic summer.

2. MATERIALS AND METHODS

2.1. Wastewater

The wastewater used within all experiments was collected from the outlet of the primary treatment unit of the Timberlea Wastewater Treatment Plant near Halifax, Nova Scotia. The effluent quality at this location is similar to the quality of effluent for an arctic WSP during the summer treatment season (Krkosek et al. 2012). During the experiments, wastewater was collected on a weekly basis and transported to Dalhousie University. Table 1 shows the average, and typical range of parameter values within the raw wastewater used in the experiments described below. Although it has undergone primary sedimentation, this water does not yet meet Environment Canada's regulations.

Table 1. Quality of influent wastewater

	a) Trial 1			
	NH ₄ -N (mg/L)	BOD ₅ (mg/L)	TSS (mg/L)	<i>E. coli</i> (CFU/100mL)
Mean	33.0	61.4	52.7	2.63E+05
Min	13.1	18.8	23.0	7.78E+02

	b) Trial 2			
	NH ₄ -N (mg/L)	BOD ₅ (mg/L)	TSS (mg/L)	<i>E. coli</i> (CFU/100mL)
Mean	40.0	61.2	69.3	2.87E+05
Min	27.7	0.0	52.0	6.67E+03
Max	49.4	103.3	109.6	6.46E+05
St. Dev	6.8	29.4	18.2	2.29E+05

2.2. Geotextile Biofiltration Columns

Acrylic columns were designed to examine the filtration of wastewater by the geotextiles. The columns employed the approximate dimensions specified in ASTM D1987 – 07. The split column secures a 10 cm diameter geotextile coupon over gravel, simulating a geotextile placed over a lagoon berm. An O-ring provided the seal to prevent leakage. A dimensioned drawing of the column is shown in Figure 1.

Figure 1. Geotextile Biofiltration Column

The experimental setup (see Figure 2) involved creating a “distributor” tank at a static height to keep a constant head of wastewater above the columns. Overflowing “receptacle” tanks were placed at adjustable heights to keep a constant head of water below the columns. This setup allowed for constant head hydraulic conductivity testing of the geotextile at various times during the biofiltration experiments. The apparatus was constructed in a refrigerated room at Dalhousie University. Temperature in this room was kept constant at 10°C to reflect the maximum average air temperature of an arctic summer.

Figure 2. Experimental Set-up

2.3. Geotextiles

Several different nonwoven, continuous filament geotextiles were chosen as the substrate for biofiltration. Yaman et al. (2005) showed that nonwoven, continuous filament geotextiles resulted in more biomass growth per unit area than both woven and stapled nonwoven geotextiles. This was confirmed by Korkut et al. (2005), with nonwoven continuous filament growing the most biomass.

Two nonwoven continuous filament geotextiles were supplied by Terrafix®. The first (product number 400R) was labeled with a ‘4,’ had an apparent opening size (AoS) of 0.212 mm, and a dry weight of 23.7 g/cm². The second (product number 600R) was labeled with a ‘6,’ had an AoS of 0.15 mm, and a dry weight of 33.9 g/cm². The geotextiles were installed in the columns above a 10 cm bed of 6 mm minus gravel. In total, six columns were used: ‘4A’ and ‘4B’ (duplicates of 0.212 mm AoS geotextile); ‘6A’ and ‘6B’ (duplicates of 0.15 mm AoS geotextile); and ‘gA’ and ‘gB’ (duplicates without geotextile, using gravel bed only)

2.4. Trial 1: Semi-Stagnant Condition

Influent wastewater was sampled and analyzed for a suite of water quality parameters. The wastewater was placed into each experimental column for one week (under no flow conditions), then drained through the geotextile where the leachate was analyzed for the same water quality parameters. After draining, the hydraulic conductivity of the geotextile was measured by allowing raw wastewater through the filter in accordance with the constant head procedure outlined in ASTM D1987 – 07. New raw wastewater was then added to the column and procedure was repeated. Trial 1 was run for three months; the approximate length of an arctic summer.

2.5. Trial 2: Continuous Permeation

For the second trial, a scenario where wastewater continuously permeates from the WSP was simulated. First, water quality parameters of the influent wastewater were measured, followed by permeation of the raw wastewater through each column at a rate of 1 to 2 mL/s. After 1.5L of raw water flowed through each geotextile (the equivalent volume of the column), the leachate parameters were again measured to discern any change that occurred across the geotextile.

After wastewater quality analysis, hydraulic conductivity was measured by allowing raw wastewater through the filter in accordance with the constant head procedure outlined in ASTM D1987 – 07. Finally, raw wastewater was again allowed to flow through the geotextile at a rate of 1-2 mL/s until a total of approximately 10L passed each column every week. Measurement of water quality parameters and hydraulic conductivity occurred once per week for three months. Due to space limitations, hydraulic conductivity test results are not reported in this paper.

2.6. Sample Analysis and Data Processing

All samples were analyzed at Dalhousie University following procedures from *Standard Methods for the Examination of Water and Wastewater* (Clesceri et al. 1998). Water quality parameters analyzed included BOD₅ (Std. Method 5210B) and TSS (Std. Method 2540D). NH₄-N concentrations were determined with TNT 832 kits from HACH Canada. In addition, samples were analyzed for *Escherichia coli* (*E. coli*) using membrane filtration onto m-ColiBlue24 culture media from HACH Canada.

Paired *t*-tests were performed to compare water quality before and after passing through the column. Paired *t*-tests were also performed to compare the average of the two duplicates of each geotextile (0.212mm, 0.15mm) with the average of the "gravel only" (gA + gB) columns.

3. RESULTS AND DISCUSSION

3.1. NH₄-N

Average effluent NH₄-N concentrations and percent reductions during Trial 1 are shown in Table 2. It could not be shown with statistical significance that there was any reduction in NH₄-N concentrations between the influent and effluent in any of the columns. There were also no apparent temporal trends in treatment performance. Similarly, in Trial 2, there was no statistically significant difference between influent and effluent NH₄-N concentrations, and no change in performance over time. Average effluent NH₄-N concentrations and percent reductions during Trial 2 are shown in Table 2. Effluent NH₄-N concentrations exceeded regulatory values for the entirety of both experiments.

Note: *n* = number of samples

Negligible changes in ammonium concentrations are most likely attributed to less nitrifying bacteria growth at low temperatures (Hwang & Oleszkiewicz, 2007). However, ammonia oxidation by these bacteria may have been impeded by another factor. Water with high BOD₅ sitting stagnant for seven days in a column (Trial 1) will create an anoxic environment, leaving less dissolved oxygen available to nitrifiers.

3.2. BOD₅

Average effluent BOD₅ concentrations and percent reductions during Trial 1 are shown in Table 3. All columns from Trial 1 produced a statistically significant reduction in BOD₅ concentrations between the influent and effluent. However, t-tests confirmed only the 0.212mm AoS geotextile removed more BOD₅ than the gravel layer alone. BOD₅ removal rates in Trial 1 did not change markedly with time.

Table 3. Average effluent biological oxygen demand concentrations (mg/L) and percent reductions

	Trial 1					
	4A <i>n</i> = 8	4B <i>n</i> = 8	6A <i>n</i> = 8	6B <i>n</i> = 8	gA <i>n</i> = 8	gB <i>n</i> = 8

% Reduction	40%	35%	31%	17%	48%	50%

Note: *n* = number of samples

Similarly, in Trial 2, effluent water quality was significantly better than influent, as shown by the % reductions in Table 3. Again, it could not be shown with confidence that either geotextile removed more BOD₅ than the gravel layer alone. However, BOD₅ removal rate was observed to increase in all columns over time, as shown in Figure 3. This may be due to increased clogging of the gravel, either by physical filtration of solids (section 3.3), or by biological growth. Although average BOD₅ concentrations only exceed the regulatory limits by <10 mg/L, after 80L had flowed through the filters, effluent BOD₅ concentrations were consistently below 25 mg/L.

Figure 3. Trial 2 percent reduction in biological oxygen demand concentration over time

3.3. TSS

Average effluent TSS concentrations and percent reductions during Trial 1 are shown in Table 4. All columns showed a statistically significant reduction in TSS concentrations between the influent and effluent. Both the 0.212mm and 0.15mm AoS geotextiles removed significantly more solids than the gravel layer alone. TSS removal rate improved with time, to a maximum of 80% after week 9, as shown in Figure 4. Average effluent concentrations for all geotextile columns were below the regulatory limit of 25 mg/L with the exception of one 6A replicate. The gravel columns exceeded regulations on average.

Table 4. Average effluent total suspended solid concentrations (mg/L) and percent reductions

% Reduction	60%	61%	61%	62%	48%	53%

Note: *n* = number of samples

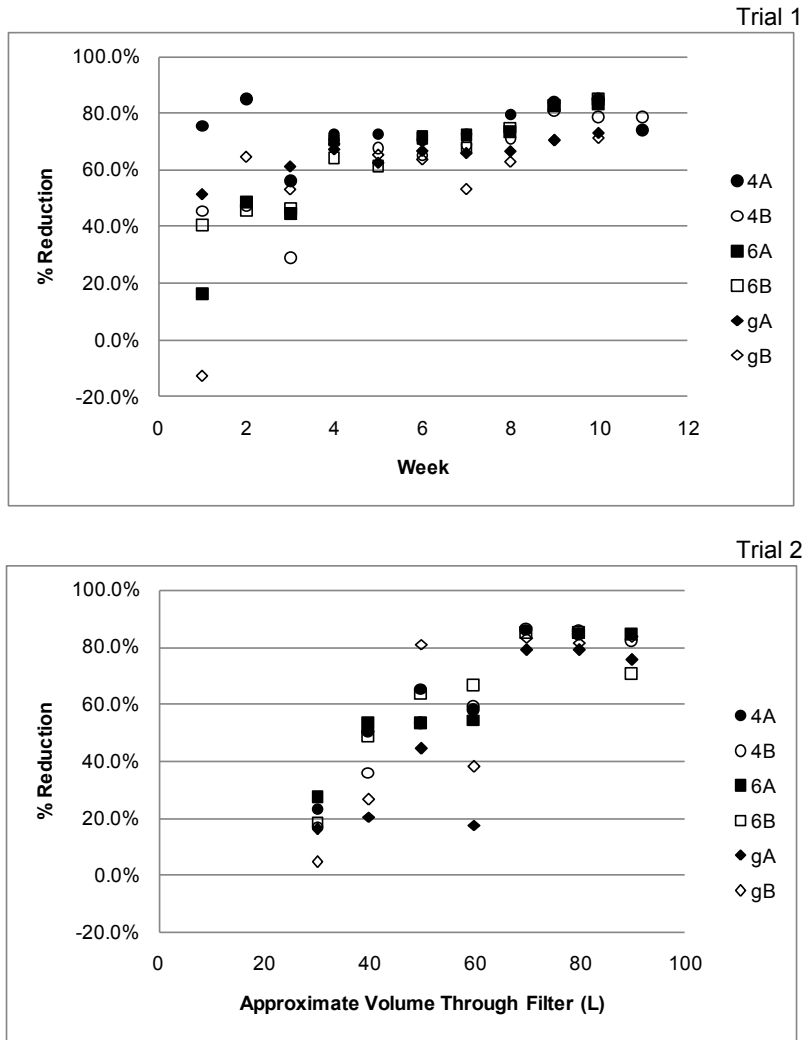

Figure 4. Percent reduction in total suspended solid concentration over time

Percent reduction of TSS concentrations in Trial 2 also improved with time, reaching a stable 80%, as shown in Figure 4. This happened at week five, and is likely due to the larger volumes of water passing through the filter, causing channels through the geotextile to constrict faster. Like Trial 1, all columns showed a statistically significant reduction in TSS concentrations between the influent and effluent. Effluent from all columns met Environment Canada's regulations.

It was also shown with 95% confidence that the geotextiles outperformed the gravel. However, removal of TSS in the gravel columns approached that of the geotextile columns as time progressed. This is likely due to biomat growth on the gravel in both types of columns gaining a more prominent effect by the end of the trials. Effluent concentrations and percent reductions are shown in Table 4.

3.4. *Escherichia coli*

Average effluent *E. coli* concentrations in Trial 1 are shown in Table 5. All columns showed a statistically significant reduction in *E. coli* concentrations between the influent and effluent. Only the 0.212mm AoS geotextiles removed significantly more bacteria than the gravel layer alone. *E. coli* removal rate in all columns was approximately one order of magnitude over the 12 week experiment for Trial 1.

Note: *n* = number of samples

By contrast, in Trial 2, no statistically significant differences between influent and effluent were observed. This is likely due to less time in the column (2.5 min vs. 1 week) for *E. coli* die-off to occur. The low log-reduction is shown in Table 5. Additionally, no significant differences were observed between the geotextile and “gravel only” columns.

4. SUMMARY AND CONCLUSIONS

To evaluate the applicability of geotextile as a biofilter substrate addition to wastewater stabilization ponds in the arctic, two scenarios were considered. Trial 1 simulated water contained in the WSPs for a one week period. Trial 2 simulated spring thaw followed by continuous exfiltration of water through the WSP berms. Both cases considered geotextiles without any existing biofilm prior to testing. Residential wastewater that had undergone sedimentation was used as raw influent to simulate the water quality in WSPs of Nunavut.

Two nonwoven, continuous filament geotextiles were tested, with apparent opening sizes (AoS) of 0.212mm and 0.15mm. In Trial 1, significantly better BOD₅, TSS, and *E. coli* removal was observed by these two geotextiles than tests on gravel alone. Of the two, the 0.212mm AoS geotextile outperformed gravel alone on more occasions than the 0.15mm AoS. The reason for this is unknown, as the two geotextiles performed similarly in Trial 2. With further study, it is anticipated that more corroborating evidence will be observed showing little difference between the two AoSs. Trial 2, significantly better treatment by the geotextile alone was observed.

In terms of TSS removal, efficiencies of up to 80% were observed in both trials. However, this removal rate was reached quicker for Trial 2 when more water passed through the filters per week. From the start of Trial 1, BOD₅ removal reached its average value of 42%, and remained relatively constant over the course of the study. In comparison, for Trial 2 BOD₅ removal improved with time, starting low, but ultimately reaching values between 60% and 80%. Limited results were observed from both ammonia and bacteria removal. No significant ammonia treatment was observed in either trial. Minor *E. coli* removal was observed in Trial 1 only.

Overall, the geotextiles provided the final polishing necessary to reduce TSS concentrations below the 25 mg/L maximum. Additionally, the gravel itself appears to contribute to the polishing effect, reducing effluent BOD₅ concentrations below 25 mg/L, after biomat growth and clogging occurs. However, effluent NH₄-N concentrations never fell below regulatory maximums. Further treatment for ammonia is necessary to avoid non-compliance.

Although some polishing effect by the geotextile was observed, it is important to note that this study was performed at 10°C. As previously noted, temperature has a considerable effect on biological activity (Ratkowsky et al. 1982, Moll et al., 1999). As such further study should be conducted at the overall summer average (5°C) and summer minimum average (1°C) air temperatures of a Nunavut summer (Environment Canada, 2012b). It should be also noted that

future studies by the authors are considering the influence of existing biomat formation on the geotextiles for a variety of potential operating conditions. Before recommending geotextile implementation in WSPs, the authors need the results of field-scale studies planned in a controlled environment at Dalhousie University.

ACKNOWLEDGEMENTS

Funding for this research was provided by the Government of Nunavut and NSERC. A special thanks to Brian Kennedy and Ray Dubé at Dalhousie University for their technical assistance in constructing and maintaining the columns and apparatus, and Rick Lowe at Halifax Water.

Biological Clogging Resistance of Tubular Drainage Geocomposites in Leachate Collection Layers

ABSTRACT

Although drainage geocomposites are frequently used for rainwater drainage or gas collection system in landfill covers, their application in leachate collection layers is rather limited. The authors believe that a key limitation to their use in leachate collection is a lack of knowledge of their sensitivity to biological clogging, and its consequence on the capacity of the Leachate collection layer (LCL) to meet landfill regulations prevailing in the US and Canada. In the first section of this document, a literature review was conducted of the actual drainage needs applicable to the LCL. This review led to the conclusion that leachate flow potentially reaching the LCL over the lifespan of a “dry tomb” landfill is significantly lower than what is required in the early stages of its life. This observation allowed for a larger tolerance to biological clogging of a drainage geocomposite if combined with a granular drainage layer meeting reasonable requirements with respect to biological clogging resistance. In the second section of this paper, the long term performance of tubular drainage geocomposites was investigated. Fresh leachate originating from a class 2, non-hazardous landfill located in the center of France, was circulated through a tubular drainage geocomposite during an eighteen months’ time period under anaerobic conditions, without any observation of clogging. In the third section of this paper, the results are analyzed and interpreted. Based on this research and analysis, it is suggested that the tested tubular drainage geocomposite could replace a fraction of the granular drainage layer of a Leachate Collection System (LCS) in a dry tomb landfill.

1. INTRODUCTION

Drainage geocomposites are used with an increasing frequency by landfill designers to substitute granular materials, especially in landfill covers. However, drainage geocomposite installations on the base of the landfill as a drainage component of the Leachate Collection System (LCS) are rather limited. The authors believe that a key limitation to their use on this particular location is a lack of knowledge of their sensitivity to biological clogging, among other fears and design challenges associated to the relatively harsh operating conditions at this location (i.e., high stress combined with potentially aggressive leachate). However, redesigning the drainage layer in order to permit partial replacement of the granular by a drainage geocomposite could represent a significant cost saving of high quality granular drainage materials, which can be expensive when they must be hauled in from distant quarries to the landfill, and also voluminous when compared to drainage geocomposites. Using geocomposites would therefore increase the waste storage capacity of the landfill and reduce the number of trucks, thus decreasing the carbon footprint of the landfill. Therefore, the installation of drainage geocomposites as a component of LCS in landfills is an alternative approach with both economic and environmental benefits.

The primary objective of the study was to validate that a tubular drainage geocomposite would not clog within 18 months, while exposed to fresh circulating leachate in a condition similar to what would be experienced in-situ and could therefore be used as a partial replacement of gravel in the design of leachate collection layer (LCS) at the bottom of landfills. The secondary objective was to assess landfill regulations in the US and Canada to determine if replacement of a fraction of the drainage layer by this tubular drainage geocomposite (Figure 1) would meet regulatory requirements.

Figure 1. Typical and Proposed LCS Design cross section

2. PERFORMANCE REQUIREMENTS

2.1 Regulatory Requirements

The head of leachate on the lining system and the thickness of the drainage layer are the two requirements which are commonly described in the various regulations prevailing throughout North-America.

In the vast majority of the cases, LCS must be designed to maintain the leachate head on the liner to 0.3 m or less. Landfills in EPA-approved jurisdictions must have a state or tribe approved performance design (EPA 1993). In the EPA-approved solid waste program in the State of California, a blanket LCS is required for a Class II municipal solid waste landfill, which the LCS must ensure no buildup of hydraulic head on the liner, but the thickness of the LCS is not specified (Title 27, California Code of Regulations).

In Canada, landfill regulations are mandated by provinces or territories, not the federal government. In some jurisdictions (i.e. Alberta), leachate head must be monitored, but there is no specified limit or design requirements for LCS thickness, thus no regulatory limits on the use of geocomposites in the LCS (Government of Alberta 2010). In Newfoundland, the LCS must be a minimum of 0.3 m in thickness plus a 0.375 m cushion layer between the LCS and the waste, with a maximum leachate head of 0.3 m (Government of Newfoundland and Labrador 2010). In the province of Ontario, the combination of the primary LCS and the cover must maintain leachate head on the liner at 0.3 m or less for a service life of 100 years and the infiltration rate through the final cover is required to be equal to or greater than 0.15 m/year (Ontario Regulation 232/98). This forced infiltration means that there will be leachate generation long after installation of the final cover, thus a continued potential for leachate generation, and therefore biological clogging.

As a consequence, the potential replacement of a fraction of the granular drainage layer by a geocomposite with sufficient hydraulic performances can be considered to be feasible for landfills located in jurisdictions which do not prescribe a minimum thickness of the drainage layer. Another factor that could potentially present some restrictions to this design is the prescribed design life of the LCL, i.e. under the Ontario regulation, which could require further investigations.

In order to assess that the hydraulic capacity of the drainage layer (0.30 m of gravel including the drainage geocomposite) will be sufficient to meet the performance requirement (maximum head of leachate of 0.30 m), it is necessary to:

- Identify the required capacity of the drainage layer; and
- Predict the long term behavior of the drainage layer (i.e. creep and clogging).

2.2 Hydraulic Requirements - Review of the Quantity of Leachate Predicted in the Literature

The key hydraulic design criteria for LCS systems are that the head on the liner needs to be smaller than the prescribed value (typically 0.3 m) and that the liquid thickness in the LCS be less than the thickness of the drainage layer thickness throughout the entire design life of the landfill. Typically the McEnroe equations are used to determine the liquid supply rate in the LCS system. The majority of the North American designers probably use the HELP model which uses the McEnroe equations as well. The more recent literature recommended double-checking the HELP model calculations with approximate solutions with Giroud's Equation (1992, 1995).

As an alternative design approach to predict leachate generation rates, Bellenfant (2009) states that there are two stages to consider; while the cell is being filled (~1 to 5 years), and after the final cover is installed (10's to 100's of years).

During the first stage, the quantity of leachate which is generated is the greatest, because there is no final cover and all the rainfall reaches the waste. Additional parameters have been identified as influencing the volume of leachate collected from the LCS:

- More evaporation will take place when there is thicker waste, therefore reducing the quantity of leachate reaching the LCS (Bellenfant, 2009);
- Techniques used in the operation of the landfill will change the quantity of water penetrating the waste, and also the leachate generated (i.e., type of daily covers, slopes).

The LCA model (SITA, Creed, EIA, 1998) provides an estimation of the quantity of leachate collected from the LCS relative to the precipitation, considering the number years that a cell has been in operation and the presence – or not – of a cover:

- 0 to 18 months with no cover, 20% of the precipitation quantity;

- 18 months to 5 years with no cover, 6.6% of the precipitation quantity;
- 5 to 10 years with no cover, 6.5% of the precipitation quantity;
- 10 years + with a geomembrane cover: 0.2% of the precipitation quantity.

Although the amount of water collected from the LCS is almost as much as the precipitation during the first weeks or months of operation when there is little or no waste in the cell, it rapidly decreases after only 18 months. Moreover, once a low permeability cover has been installed, the quantity of leachate to be drained by the leachate collection layer will be an insignificant fraction of what it was during its first weeks of operation. As a consequence, it is reasonable to consider that the LCS is a critical component of the lining system during only the first few years that the landfill is in operation if the landfill final cover is designed to allow only a nominal amount of precipitation to enter the landfill.

It is thus possible to state that even if the performance of a drainage layer designed to absorb the rainfall in a given area is reduced to 20% of its initial capacity after 18 months, it will still fulfill its function and meet regulatory requirements as a LCL when the landfill is operated in the conditions considered in the LCA model. The same approach can be used to state that a sufficient performance would be offered by a LCL presenting as little as 0.2% of its initial capacity following installation of a geomembrane final cover.

These numbers appear promising considering the observations reported by Rowe (2005), which suggest that clogging of the gravel layer can occur after a period of time that can vary between a decade to a century, depending on the design of the LCS and the properties of the leachate.

2.3 Long Term Performance of Geocomposite Drainage Layers

Among the issues which have to be considered in the design of LCS, creep, and biological/chemical clogging are among the key factors as outlined by GRI GC8, which is widely used in North America for the design of drainage geocomposites.

$$FS = \frac{\theta_{allow}}{\theta_{req'd}} \quad (1)$$

With

$$\theta_{allow} = \frac{\theta_{100}}{RF_{CR} \cdot RF_{CC} \cdot RF_{BC}} \quad (2)$$

where θ_{100} is the transmissivity measured in accordance with ASTM D4716 (after 100 hours seating time with in-situ conditions), and the RF are Reduction Factors addressing:

- RF_{CR} = creep deformation;
- RF_{CC} = chemical clogging;
- RF_{BC} = biological clogging.

Besides the creep, chemical, and biological clogging potential, the GRI GC8 approach also indirectly includes other limiting factors such as geotextile intrusion by requiring consideration as a reference value the transmissivity measured after 100 hours under in-situ conditions which reproduces geotextile intrusion.

However, the reduction-factor approach developed in GRI GC8 focuses solely on the drainage geocomposite itself and its long term performance, not as a component of a LCS. Issues such as the length of the design life used to determine these reduction factors are not clearly defined in the GRI GC8 standard, and could generate divergent interpretation of their significance. Moreover, it was not possible for the authors to identify any published scientific justifications for these proposed values in the GRI-GC8 standard, which have been discussed in-depth by several authors including Zhao et al. (2012).

Although the preferred approach to the design of drainage geocomposites may vary depending on the application and assumptions considered, there is a broad acceptance regarding the fact that creep and biological / chemical clogging are the key factors affecting the performance of drainage geocomposite used in LCS and that an improvement of existing design guidance would be welcomed.

Although biological and chemical clogging are likely to occur in every type of product, one of the strengths of tubular drainage geocomposites is the shape of the core and its ability to resist very high stresses while confined in soil. Saunier et al. (2010) have observed that the transmissivity of tubular drainage geocomposites was not affected by normal load or

creep up to normal stresses as high as 2500 kPa and test durations up to 100 hours. It was concluded that the creep reduction factor in GRI GC8 can be neglected as long as the product is confined in soil. As a consequence, it is suggested that biological and chemical clogging can be considered to be the only factors which are likely to affect the performance of tubular drainage geocomposites.

2.4 Leachate Composition

Several landfill leachate characteristics should be considered for proper evaluation of the performance of any product in contact with leachate. The nature of waste may change tremendously depending on local regulations, existence of recycling programs, wealth of the community and other factors. As a consequence, observations made on a given landfill may be applicable only to very similar landfills, but cannot be generalized to any type of landfill.

- Leachate composition;
- Age of the leachate;
- Temperature, which influences the growth of biomass; and
- Anaerobic conditions to reflect the conditions prevailing in the bottom of a landfill.

The leachate characteristics considered here is located in Section 3.2, Experimental Set-Up.

3. INVESTIGATION

3.1 Scope

The study was conducted on a landfill identified as 'class 2' under the French designation, which describes sites designed to receive municipal solid wastes and non-hazardous industrial wastes. For this type of landfill, the waste includes a significant fraction of organic matter resulting of normal human activity and is thus known to develop biologically active leachate.

3.2 Experimental Set-Up

Two tubular drainage geocomposites were tested, and compared to gravel. These consist of a series of 25 mm diameter perforated corrugated pipes sandwiched between two layers of non-woven polypropylene geotextiles (Figure 2). The upper geotextile (in contact with the granular drainage layer above), is composed of special fibers made with silver ions acting as a biocide agent (ACB filter).

Figure 2. Tested tubular drainage geocomposite

Issues related to leachate composition outlined above have been taken into account in the experimental design. Transportation to a laboratory to run a laboratory-controlled experiment was not considered to be a realistic option as the change of properties of the leachate would be too significant; it was thus decided to bring the experimental setup to the landfill. The test temperature was controlled within a range of 20 to 30°C considering that only the first two years of

service are of interest to the authors. Although it is known that the temperature at the bottom of landfills can exceed this value after several years of service (Rowe et al. 2006, Koerner and Koerner 2006), the selected temperature range was considered to be as close as possible to service conditions in the LCS during the first two years of activity at the bottom of the landfill.

The test cell design was developed in order to observe the clogging potential of both the filter and core (perforated pipes) of the geocomposite. The test cells were installed in a building located near the perimeter of the landfill, close to a leachate sump, where fresh leachate could be easily pumped and injected into the test cells. The building was maintained at a temperature of $25\pm 5^\circ\text{C}$ year round in order to maintain a biological activity of a similar nature than what is likely to be experienced by the geosynthetic drainage products at the bottom of landfill during their first years of operation. Preservation of anaerobic conditions was ensured by the design of the test cell, which was achieved by positioning the outflow weir above the top of the cell to submerge the interior of the cell in leachate, and relatively small diameter pipes were used to inject the leachate into the cells. The leachate was circulated through a gravel layer first, then through the geocomposite, and collected through the exit of the pipe on one end of the cell, (Figure 3). Although the tested product is not sensitive to normal load, a normal load in the range of 100 kPa was used to represent conditions at the base of a landfill cell within 18 months of operation. The normal load was achieved by controlling the compression of calibrated springs (Figure 4).

3.3 Leachate Injection

The system used to control injection of a fixed quantity of leachate in the conditions of the test is described as follows:

1. A large volume of leachate was pumped into a 'buffer reservoir' located above the cells, then allowed time to equilibrate with room temperature.
2. The first series of electro-valves were opened simultaneously to allow flow of the leachate from the buffer reservoir into smaller calibrated reservoirs, each equipped with a valve to control the leachate to a fixed volume.
3. A second series of electro-valves were opened to permit flow of the leachate into the test cell a short time after stabilization of the second step.

One standard pump was needed to inject leachate into the 'buffer reservoir'. The pump and the electro-valves were controlled using timers. Overall, this system allowed injection of one liter of leachate into the test cells ten times per day, (at a frequency of 144 minutes), which was considered sufficient to maintain a constant supply of nutrients to the micro-organisms likely to develop into the system, while maintaining the test conditions.

Figure 3. Cross section of a test cell

Figure 4. Control of the 100 kPa normal stress

3.4 Monitoring Technique

As mentioned at the beginning of this paper, this project involved a collaborative effort from the landfill owner, a geosynthetics manufacturer and a laboratory. In addition to the supply of the test area, the personnel available on-site was used for periodic control of the experiment, as well as to perform simple measurements and to report their observations to the laboratory.

The monitoring technique was designed to ensure the performance of this approach. As the objective of the project was to observe a lack of clogging after 18 months, a simple measurement of the time needed for leachate to percolate through the system under fixed conditions was adopted. A container was thus installed in parallel to the pipe used to inject the leachate. A falling head infiltration test was then performed using the same path as the one used by the leachate itself. Although this technique cannot be used to quantify potentially minor adverse effect of the leachate on the system, the blocking of any component of the system can be easily detected.

Figure 5 presents the system used to monitor the infiltration rate. The time needed for the water to enter the system was measured by observation of the water level traveling between the lines marked 'H₀' and 'H₁'. An infiltration rate was calculated, expressed as the velocity of the water entering the cell, under an average head of 0.15 m (0.15 m being half of the allowable head according for many regulations). From these observations, a clogging index was defined as the ratio between the infiltration rate at a given time, and the initial infiltration rate.

3.5 Experimental Program

Three configurations were tested, and each was replicated three times for a total of nine test cells. Two out of the three configurations involved tubular drainage geocomposites with anti-bacterial filters (Table 1). The third configuration was involving only gravel (Figure 6). The gravel was selected according to the current regulatory requirements prevailing in France: crushed gravel, sieved between 20 and 40 mm. An overview of the complete test set-up is presented in Figure 7.

Table 1: Tested geocomposite properties

	Standard	type 'A'	type 'B'
Test cell number		1, 4, 7	3, 6, 9
Mass per unit area of the filter (g/m ²)	EN 9864	160	240
Mass per unit area of the cushion (g/m ²)	EN 9864	800	800
In-plane transmissivity ($\sigma = 400 \text{ kPa}$, $i=0.1$, m ² /s)	ISO 12958	$5,7 \times 10^{-4}$	$5,7 \times 10^{-4}$
Antibacterial treatment		Embedded, non-leachable silver ions	

Figure 5. Periodic monitoring system.

Figure 6. Gravel (dimensions of the cell: 250 mm x 250 mm)

4. OBSERVATIONS

No significant clogging could be detected using the technique described above. At the end of the test, the cells were dismantled to observe the quantity of biomass accumulated in the system and to proceed with observations, measurement of the pore volume, and weighing the quantity of biomass accumulated in the gravel.

4.1 Clogging

Figure 8 presents the change of the clogging index with time for each of the three configurations. After 18 months, it was observed that none of the systems had lost their efficiency, with a 'clogging index' in the range of 3 to 5.

Figure 7. View of the 9 cell test apparatus

4.2 Residual Volume of Voids in the Gravel

In order to determine the residual porosity at the end of the test, the quantity of water that freely flowed out of the saturated cells was collected and compared to the total volume of the inside of the cell. It was found that the measured void volume ranging from 27% to 34% for all three drainage types, demonstrating the presence of a significant amount of voids in the granular drainage layer (Table 2).

4.3 Weight of Biomass and Fine Particles Trapped into the Components

After measurement of the volume of voids, the accumulated biomass and minerals trapped into the system were collected at the end of the project using the following procedure:

- Gravel and test cell were washed in clear water;
- Biomass in the water was filtered from water on a geotextile;
- Wet biomass was weighed;
- Biomass was dried in the air, at room temperature;
- Dry residual material was weighed.

The corresponding measurements are presented on Table 2. It can be observed that a significant amount of biomass has developed into and immediately above the geotextiles (cushion component of the tubular drainage geocomposite), which is consistent with previous observations of clogging (Rowe 2005).

Table 2: Measurements conducted after testing

	Cell #	Void ratio %	Mineral particles		Biomass	
			In the gravel Kg/m ²	On the geocomposite Kg/m ²	In the gravel Kg/m ²	On the geocomposite Kg/m ²
Type A	1	34%	0.288	1.472	6.016	5.856
	4	33%	0.736	1.696	6.912	6.464
	7	27%	0.672	1.696	7.040	5.408
Gravel	2	30%	0.608	0.800	4.832	4.448
	5	32%	0.480	0.896	5.344	7.104
	8	30%	0.736	0.992	5.184	5.184
Type B	3	33%	0.256	1.456	5.696	6.448
	6	34%	0.640	1.808	6.464	6.352
	9	30%	0.928	2.064	6.656	6.160

Figure 8. Clogging index

4.4 Visual Observations

Although a shiny black film of biomass could be observed in the gravel and as well as on the geotextile of the tubular drainage geocomposite, connected void spaces were still existent, allowing water to flow through the gravel and the geocomposite. These observations were consistent within the entire set of experiments ran. No visual evidence of

buckling or damage of the pipes arising from the combination of leachate exposure and normal load could be observed. Examples of the dismantled drainage components are presented in Figures 9, 10, and 11.

5. DISCUSSION AND CONCLUSIONS

A thorough literature review was conducted regarding the regulatory required and actual drainage capacity of the LCS over the life of a “dry tomb” landfill. This literature review led to the conclusion that leachate flow potentially reaching the leachate collection layer of a “dry tomb” landfill is significantly less at the end of its lifespan, than what is required in the early stages of its lifespan. This particular observation allowed for some flexibility regarding the long term performance of geocomposite drainage layers with respect to chemical and biological clogging. Specifically, the highest anticipated leachate supply rates are anticipated during the early stages of the landfill; while once the final cover is installed the anticipated leachate supply rates have significantly dropped off.

This particular observation is basically in line with the second component of this research; which shows that although clogging increases over time; the drainage media may not completely clog, thus still allowing the reduced leachate supply to be removed from the bottom liner and meeting the set goals of maintaining the hydraulic head below the prescribed threshold (typically 0.3 m).

Figure 9. Gravel in cell 8.

Figure 10. Side view of the geocomposite in cell 4 (type A).

Figure 11. Side view of the geocomposite in cell 7 (type A).

On the other hand, experimental confirmation was presented herein that a tubular drainage geocomposite incorporating a geotextile treated with silver ions as a biocide agent can remain functional for up to 18 months, when exposed to leachate in representative conditions as what would be present at the bottom of a LCS in an active landfill classified as ‘class 2’ (municipal solid waste and non-hazardous industrial waste) under the French regulation. Both styles of tubular drainage geocomposites and the gravel used as the control did not experience complete clogging to the point they would be no longer functional after 18 months of testing. However, it was not possible to detect any statistical difference in clogging between the various configurations due to the preferred monitoring strategy.

Based on these considerations, it is possible to conclude that replacement of 0.50 m of gravel by a tubular drainage geocomposite and 0.30 m of gravel represents a solution which can meet the performance-based regulatory requirements related to LCSs in dry tomb landfills in many jurisdictions, with the following assumptions:

- The system composed of the drainage geocomposite + gravel layer is designed to fulfill the drainage requirements prevailing at the initial stage of the life of the landfill, when mainly rainfall water is to be drained, and
- The 0.30 m gravel layer is designed to fulfill the drainage requirements prevailing after 18 months, which is only a fraction of the initial requirements.

ACKNOWLEDGEMENTS

The authors wish to thank Dr. Melissa Chappel, Ph.D. (CTT Group), for fruitful discussions regarding regulatory requirements related to drainage layer performance requirements prevailing on the North American Market.

Bituminous Geomembranes Liner at Agnico-Eagle Mine in Kittilä, Finland

Bertrand Breul, Axter Coletanche Montréal Canada, BBreul@axtercoeltancehe.com
Bernard Breul, Axter Coletanche, Irvine USA, Breul@eirnet.com

ABSTRACT

This paper discusses the reason behind the choice of a bituminous geomembrane to line two process-water ponds at the Agnico-Eagle gold mine in Kittilä, Finland. The Kittilä Mine lies within the Arctic Climatic Region (150 km north) where daylight reaches a minimum of 1 hour per day in winter and a maximum of 24 hours in summer with an average annual temperature of zero degrees Celsius. The paper describes the mine in general, reviews the regulatory framework for the liner system, and provides details about design, construction and Construction Quality Assurance activities and the benefits associated with the bituminous geomembrane liner such as the use of large aggregate under and above with no cushion geotextile, flexibility of schedule, and the possibility to install in cold weather.

1. INTRODUCTION

1.1 Background

Kittilä Gold Mine is operated and owned by Agnico-Eagle Mines Ltd headquartered in Toronto (Ontario, Canada). This mine is the second mine located the northern region of Finland. Environmental permission for the mine operations was granted by Northern Finland Environmental Permit Authority in 2002. Mining started its operations with an open pit with an anticipated depth of 150 m. After 3 years of pit mining, underground mining via ramp access will begin with a target depth of 450 m. The Kittilä mine in northern Finland is approximately 900 kilometers north of Helsinki and 40 kilometers from Kittilä (Figure 1).

Figure 1: Location

Key numbers about the mine include

- Area 860 ha
- Annual ore mining (Suurikuusikko deposit) 1,000,000 tons
- Annual waste rock mining 4,000,000 tons
- Annual gold production 5 tons
- Roads 4 km
- Pipelines. 15 km

The mine opened in the summer of 2008 and has an estimated lifetime of 15 years.

1.2 Weather

The Kittilä Mine lies within the Arctic Climatic Region (150 km north) where daylight reaches a minimum of 1 hour per day in winter and a maximum of 24 hours in summer. Temperatures are cold (Figure 2), with an average mean monthly temperature in July of 15 °C and in January of -15 °C. The mean annual air temperature at the site is approximately 0 °C. Winds are moderate and generally from the west. Average wind speeds are about 25 km/hr.

Figure 2: Average Monthly Temperatures in Kittilä

As shown on Figure 3 precipitation averages over 50 mm per month with rain generally occurring between May and October. Figure 3 also shows that it rains or snows almost half of every month. As shown on Figure 2 and 3, the warmest period is between June and September, but it is the wettest too.

Weather conditions are therefore not conducive to the deployment of geosynthetics which typically requires dry weather and relatively warm temperatures for proper seaming.

Figure 3: Average Monthly Precipitation Totals in Kittilä

2. PROJECT

2.1 Purpose

The mine facility plan calls for a small and a large pond for a combined area of 54 hectares to receive the process water from the gold processing plant. Water from the ponds is then recirculating back to the process. So the water circulation is practically a closed system. As part of the environmental permit for the mine, a watertight liner was required by the Finnish Ministry of Environment.

2.2 Schedule

The two ponds (Figure 4) had to be lined by the fall of 2008. However the construction season for earthwork runs from June to November. Prior to June the ground is frozen and cannot be excavated and after November very low temperature, snowfall, and darkness limit work. It was decided to excavate and line the ponds in two phases:

- Phase 1 in 2007: excavate and line the smaller pond and excavate and begin lining the bottom of the larger pond.
- Phase 2 in 2008: finish lining bottom and slopes of the larger pond.

The work went in accordance with the schedule and the ponds were finished lining by the fall of 2008 and are currently being used by the mine.

Figure 4: Aerial view of the two ponds

2.3 Design

The design of the ponds called for an excavation surrounded by dikes to get the required volume. The cross section of the dam consists of a core built with blasted rock with particle size up to 600 mm in diameter. The water side of the dike was covered with a layer of blasted rock but with a maximum diameter of 300 mm itself and protected by a layer of gravel not exceeding 55 mm in diameter. This last layer was compacted using an excavator equipped with a compacting plate (Figure 5) to provide a smooth surface with no ruts. The dikes were designed to function like a zoned dam built with material recovered from the mining operation. A 1 meter thick sealing layer was then placed on the bottom of the pond. The sealing layer consist of the excavated moraine rolled and compacted exhibiting a saturated hydraulic conductivity less than 5×10^{-8} m/s. The ponds were then lined with a geomembrane as discussed in the next section.

The concept behind the zone cross section and varying grain size is for the dike to perform like a drain should leakage occur an reduce the risk for piping failure or catastrophic flow though the large pores of the 600 mm rock if the dikes were built only with this size rocks

Figure 5: Compaction of side slopes

2.4 Liner System

The project was initially designed with a polymeric geomembrane (HDPE or LLDPE) but the client expressed interest in switching to a bituminous geomembrane to line the ponds at Kittilä because:

- It can be installed at temperatures as low as -30 degrees Celsius which was a critical element with respect to schedule when considering the construction season in Lapland and the fact that it was anticipated that construction would extend until October to make the deadline imposed by the mine for use of the ponds.
- It can be installed in moist/humid connections
- It can be installed directly over the sealing layer and does not require a protective sand layer or cushion beneath. This provided a time and cost savings.
- It has a low thermal expansion coefficient so the geomembrane does not expand (i.e. wrinkles) or contract throughout the day when temperature varies. Therefore the geomembrane lays flat on the ground (Figure 6) and provides in combination with low permeability moraine a very efficient composite liner system meeting the requirements of the permit for water tightness.

Figure 6: Liner on bottom of pond – note absence of wrinkles

In order to optimize the cost for the design of the liner system a 3.5 mm-thick bituminous geomembrane was used on the bottom and a 4.0 mm-thick bituminous geomembrane thicknesses was used on the slopes

The design based on using a bituminous geomembrane was subject to regulatory review and a public survey to obtain approval from the local to the national agencies. The approval was granted in three months.

2.5 Bituminous Geomembrane

The structure of the bituminous geomembrane used, is shown on Figure 7 and consists of

- A non-woven polyester long fiber geotextile with a mass per unit area of 200 to 400 g/m²,
- A glass fleece reinforcement which provides stability during fabrication and contributes to the strength of the geomembrane,
- A bituminous mastic consisting of a blown 100/40 pen bitumen, and filler. This mastic impregnates the whole structure and give the waterproofness of the product and ensure the longevity in protecting the non-woven geotextile and the high resistance of the product,
- A Terphane film bonded to the underside when the membrane is hot, which prevents penetration of the membrane by plant roots, and
- A coating of fine sand on the upper surface to provide a greater traction on slopes, giving greater operator safety by any kind of weather even in case of snow and security, and increases protection from the degrading effects of UV radiation.

Figure 7: Schematic cross-section of bituminous geomembrane

This manufacturing system results in a geomembrane with a long life expectancy due to its resistance to high levels of mechanical stress and negligible ageing characteristics. Grades range in thicknesses from 3.5 mm up to 5.6 mm.

3. CONSTRUCTION

The installation was completed by a local company (Destia Oy) based in Helsinki (Finland) hired as the general contractor. Its business area is primarily the planning, construction, upkeep and maintenance of roads. Destia Oy, with no previous experience in laying bituminous geomembrane, installed the bituminous geomembrane in the ponds and provided the Quality Control testing and reporting after being trained by a supervisor of the manufacturer.

3.1 Installation

For the preparation of the support two workers removed sharp gravel and natural organic fill from the surface with rakes while another operated a compactor. Installation of bituminous geomembrane is similar to that of all other geomembranes using spreader bar hooked to excavator. The difference is that a hydraulically controlled spreader bar is used to control deployment of the bituminous geomembrane on the slopes. The hydraulically controlled spreader bar allows rewinding the geomembrane if too much is unrolled. Two workers unroll the geomembrane and one other operates the excavator. Two welders were needed to weld the joints and one assistant to roll and seal the joints after welding (Figure 8).

In essence a crew of 6 to 8 people is all that is needed to prepare the subgrade and deploy the bituminous geomembrane

On average, approximately 5 000 m²/day of bituminous geomembrane were installed with two welding teams,

Figure 8: Welding of adjacent panels of bituminous geomembrane

3.2 Quality Controls

One lab technician from the general contractor was trained by the supervisor of the distributor to follow the quality control plan all along the work. This technician was completely dedicated to this work. All seam testing and destructive samples were documented daily and recorded in a computer-generated report.

Ultrasound testing (Figure 9) was used to monitor quality of the total width of the seam on the project. The quality of the seam is essential for any geomembrane. The Ultrasound testing probe is used to check the entire 20 cm width of the seam. Ultrasound waves are able to detect imperfections in the seam and to measure the width of the defect.

Any defect was repaired by placing a patch over the defective area.

Figure 9: Ultrasound testing

4. CONCLUSION

The choice of bituminous geomembrane was validated by a successful construction of the two ponds. The use of bituminous geomembrane provided several benefits at the Kittilä mine. The most important were:

- Ability to work in cold wet weather which allowed the ponds to come on line on time and did not affect opening of the mining operations.
- Cost reduction since local materials were used for bottom and slopes. There was no need for a fine sand or cushion layer under the geomembrane
- Installation by the general contractor rather than a specialty subcontractor. This gave a better control of the schedule which was a critical element of the project.

Campbell Shipyard Receives a Massive Underwater Geosynthetic Sediment Cap Adjacent to San Diego Hilton Convention Center

Rich Sack, P.E., TenCate Geosynthetics, USA, r.sack@tencate.com

ABSTRACT

A site known as Campbell Shipyard adjacent to the Hilton San Diego Convention Center in Downtown San Diego, California has been used for over 100 years for industrial activities that included commercial fishing ships and naval ship repair early on and eventually moved to a petroleum tank farm, municipal refuse incinerator and gas manufacturing and waste facility. In the 1990s, the shipyard lease expired and a massive cleanup of the site soon began. After many years, the port completed cleanup of the above water portions of the site, but found it too expensive to test and safely remove all of the 37,000 SM (9.2 acres) of polluted sediments hidden below the water's surface on the bay floor. Engineers decided to create a massive underwater permanent cap over the contaminated soils. At the heart of this mammoth size underwater cap is a high strength woven geotextile panel that was created with a unique blend of both polypropylene and polyester fibers (to yield a specific gravity greater than water) that sinks. The geotextile rolls were sewn into massive panels and fitted with PVC encased rebar that were deployed directly from a moving sectional barge using GPS tracking to assure proper over-lap and location of adjacent panels.

1. INTRODUCTION

The Port of San Diego was required by the California Regional Water Quality Control Board (RWQCB) to clean up below water polluted sediments at the former Campbell Shipyard. Campbell Shipyard is an extremely highly visible sight located along the San Diego Convention Center in San Diego, California, as shown in Figure 1. Initially, it was proposed to simply dredge (remove) all of the contaminated material from the underlying surface of the 37,000 SM (9.2 acres) of the bay (a massive undertaking). Unfortunately, the removal of all the contaminated sediment would cause instability to many existing structures in and along the bay and be too costly to remove (due to the highly variable elevation changes of the polluted sediments). The demolition and removal of many of the old structures brought even more sediment up to the surface – (almost doubling the sediment quantities in some areas) adding to the quantity of the contaminated sediments. The Port found that capping the contaminated sediments using a composite layer of high strength woven geotextile, gravel, rock and sand was the best option to control the contaminated sediments.

Figure 1. Project Site

2. CAP DESIGN

2.1 Project Overview

The contaminated unconsolidated sediments were found to have an undrained strength of 48.8 to 488 kilograms per square meter (10 to 100 pounds per square-foot). Wang et al. (2006). The cap to be placed over the contaminated sediments consisted of several layers – each placed individually. The high strength woven geotextile panel was to be deployed directly from a floating sectional barge and laid out directly onto the bay surface. The high strength woven geotextile panel was placed at the bottom of the cap to maintain separation between the existing contaminated bay sediments and the layers of gravels and sand to be placed on top of the geotextile. The high strength woven geotextile panel also helped increase the bearing capacity of the underlying sediments – so thicker lifts could be placed while constructing the cap layer. The increase in bearing capacity helped reduce the risk of mud waves (sediments displacement in a wave shape adjacent to the fill loading area). With the decrease risk of mud waves occurring, the use of the high strength woven geotextiles allowed the maximum lift placement to increase from 15.3 cm to 30.6 cm (double the lift thickness) – speeding up the overall construction process. Wang et al. (2006).

2.2 Sediment Cap Cross-Section

The sediment cap was designed with a single high strength woven geotextile panel placed directly over the contaminated sediment. Some of the very soft areas had a composite layer of gravel and high strength woven geotextile over the existing sediment. A 61 cm thick layer of sand was then placed directly over the geotextile panel. The sand layer was designed to act as a fine filter that allows water pressure to be released, while sediment gets trapped deep within the layer. A 30.5 cm thick layer of gravel was then placed over the sand layer. The gravel layer acted as a transitional interface between the sand layer and the final layer. A final 61 cm thick layer of armor rock was placed over the gravel layer to resist erosion from underwater currents and boat prop thrust. Wang et al. (2006). A cross-section of the sediment cap is shown in Figure 2.

Figure 2. Sediment Cap Cross-Section

2.3 Habitat Restoration Cap

A 6,475 SM (1.6 acres) portion of the site was developed for habitat restoration. The habitat restoration zone consists of a 30.5 cm layer of well graded sand that is used to contain any contaminated sediments; the same high strength woven panel used in the other areas of the site to contain the underlying sand layer and block any contaminated sediments from escaping to the upper habitat layer; a 61 cm layer of non polluted ocean sediments mixed with sand sediments; and a final living layer of eelgrass to support ocean wildlife.

2.4 Geosynthetic Properties

Typical woven geotextiles used for subgrade stabilization are manufactured from polypropylene due to their stable weave, resistance to installation damage, high UV resistance and strength properties. The high strength woven cap geotextile had several physical requirements: high strength was required to help improve bearing capacity of the overall cap section; robust fibers that resist installation damage during deployment and during rock/sand placement; and a construction weave pattern that remains stable without tearing, unraveling, or sliding open holes when rebar is attached to it during deployment. Typical polypropylene geotextiles have a specific gravity less than ocean water, therefore it floats. A fabric that is too buoyant, such as polypropylene, would be too difficult to intimately lay over the changing contours of the bay floor without floating upward off the surface. A high strength geotextile that met the required physical requirements and uses a blend of polyester and polypropylene fibers was manufactured specifically for the project that

would have an overall specific gravity greater than 1.0 (sinks in water). The high strength woven geotextile chosen for use on this project was manufactured with a specific gravity of 1.075. This sinking geotextile will remain in place more easily than a polypropylene geotextile or geogrid and not float away from the bay floor once installed.

The final requirement of the high strength woven geotextile was high water flow rate (high permittivity). The high strength geotextile was required to pass large volumes of water through its surface, so that pore water pressure doesn't build under the sediment cap – reducing the risk of armor rock displacement.

The project engineer required that the high strength woven cap geotextile be sewn into very large panels that were approximately 13.7 M wide and 274 M long to reduce the number of overlaps. To meet the panel width requirements for the project, three rolls of fabric, that were approximately 4.7 M wide and 274 M long, were each sewn together by the fabrication department of the manufacturer prior to being shipped out onto site. The large panels were then re-rolled onto the sectional barge's roller for easy deployment. Figure 3 shows the high strength woven panel seam. Figure 4 shows the panel roller aboard the sectional barge.

Figure 3. High Strength Woven Panel Seam.

Figure 4. Roller on Barge with Panel.

Some key physical properties of the high strength woven geotextile used in the cap construction are shown in Table 1.

Table 1. PET/PP Woven Cap Geotextile Panel

Mechanical Properties	Machine Direction	Cross-Machine Direction
Ultimate Tensile Strength (kN/m)	105.1	113.8
Tensile Strength at 5% (kN/m)	52.5	57.8
Ultimate Factory Seam Strength (kN/m)	58.3	
Specific Gravity	1.1	1.1
Water flow rate (l/m ² /min)	2241	

3. CAP CONSTRUCTION

3.1 Project Overview

All of the protrusions such as large debris, large rocks and pier column remnants that may penetrate through the cap were removed to create a somewhat flat surface before placement of the high strength woven cap geotextile panel. The massive high strength woven panels were rolled up and brought out to a floating sectional barge. The 13.7 M wide panels were deployed directly from the moving sectional barge. To keep the panel from folding over on itself and being pushed aside by underwater currents, No. 4 rebar that was placed in sealed PVC pipe (to protect it from salt water corrosion) was zip tied onto the panel at approximately 9.1 M intervals. The zip ties had to be pushed through the fabric panels and around the rebar by hand. The rebar was attached across the width of the panels as it came off the roller, before deployment into the water, as shown in Figure 5. The fabric panels remained dimensionally stable and did not allow the zip ties with rebar to slide threads over and cause open holes in the panel.

Figure 5. Rebar Attached to Woven Panel Being Deployed.

An I-beam was attached to the leading edge of the high strength woven panels and carefully lowered onto the ocean floor by a large crane, as shown in Figure 6. The I-beam served as an anchor for the panel. Once the I-beam was in place on the ocean floor, the barge would move back slowly (by pulling off from a series of anchors located outside the panel area) unrolling the panel onto the sea floor.

Figure 6. I-beam Attached to Cap Panel.

The centerline of each panel placement was used to position adjacent panels and assure proper overlap of the panels. Figure 7 shows the barge's onboard GPS tracking and location plotting of the panels as they are deployed.

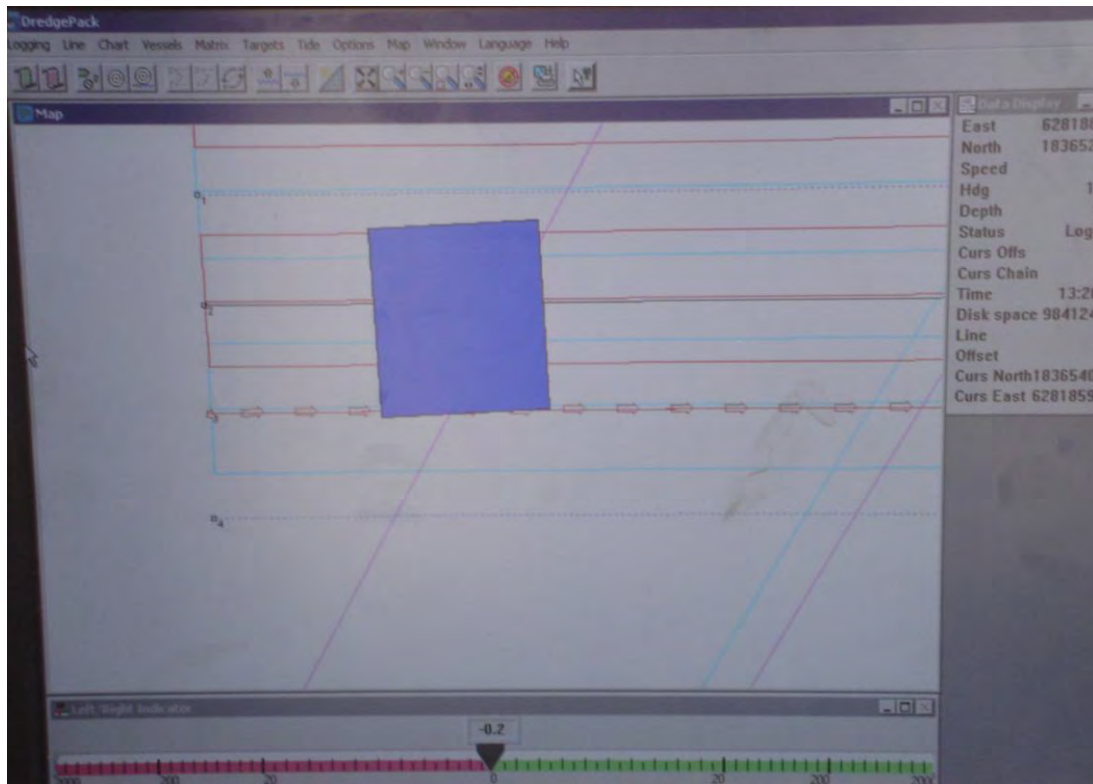

Figure 7. GPS Tracking of Panel Placement

4. CONCLUSIONS

Campbell Shipyard sediment capping project was a highly visible environmental cleanup project. The project was performed under high levels of scrutiny and regulation. The high strength woven geotextile panels increased the underlying sediment bearing capacity – allowing twice the thickness in lift thickness to be placed and cutting the fill placement time in half. The capping project was completed successfully in 2007 and the high strength woven geotextile panel was installed with great flexibility and has performed perfectly in both the sediment cap system and the eel grass habitat system area as well. A total cost of more than \$72 million has been spent on the entire Campbell Shipyard project area, including: demolition and dredging; all above and below water environmental cleanup; capping; site preparation, and construction of a large parking facility to accommodate further development. O'Connor et al. (2006). As of today, the system is still functioning perfectly.

Case History –Geomembrane & Floating Cover System, South Australia Water Corporation, Wattle Park Potable Water Reservoir

Brian W. Fraser, Layfield Group Limited, Vancouver, British Columbia, Canada
Paul Vince, South Australia Water Corporation, Adelaide, South Australia, Australia
Alex Gersch, Fabtech, Wingfield, South Australia, Australia

ABSTRACT

As part of a water security review to address severe drought conditions, South Australia Water Corporation (Owner) identified the need for several essential infrastructure projects which included an upgrade to the Wattle Park potable water reservoir. The Wattle Park reservoir, with an 84 million litre (22 million gallon) capacity, required a new geomembrane liner and floating cover system. At prior storage and treatment reservoirs using normal levels of chlorination for a disinfectant, the Owner had experienced premature failures with certain liner and cover materials. Based on the operational importance of the Wattle Park project, a new performance specification for the geomembrane and floating cover material was developed. Meeting this specification required a specially stabilized and formulated geomembrane. This paper addresses the technical review criteria for selecting a new geomembrane as well as a number of project challenges and techniques used by the contractor related to the installation of a new liner and floating cover.

1. INTRODUCTION

Around 2003, South Australia began experiencing severe drought situations which impacted water supplies, and resulted in strict water restrictions being enforced in many regions of the State. As part of a 2010 strategic review of its water security, the South Australia Water Corporation (Owner) identified the need to proceed with several essential water management infrastructure projects. Among these, included was an important upgrade to the Wattle Park potable water storage reservoir that provides drinking water to the City of Adelaide, the capital of South Australia. The Wattle Park water storage reservoir, with an 84 million litre (22 million gallon) capacity, required a new 14,500 m² (156,000 ft²) geomembrane liner and

Figure 1: Wattle Park Potable Water Reservoir Floating Cover nearing installation completion stage

14,500 m² (156,000 ft²) geomembrane floating cover system. The reservoir which was originally constructed in 1929, was concrete lined. After leaks in the concrete reservoir resulted in local flooding, a Chlorosulphonated Polyethylene (CSPE) liner and floating cover was installed in 1986. In 2010, independent material testing conducted on behalf of the Owner determined that the CSPE geomembrane had only 10% remaining of its original retained tear strength. This created a

number of safety and performance concerns, which resulted in the Owner prohibiting any walking on the cover system required for maintenance purposes until a new floating cover system could be commissioned. In 2010 the Owner and its consultant undertook a technical review process of geomembranes that would be suitable for the Wattle Park reservoir liner and floating cover.

2. MATERIAL SELECTION

The material selection for the geomembrane and floating cover was a critical component of the Wattle Park project. SA Water has vast experience with floating covers as a result of operating eighteen (18) cover systems from the period of 1986 to 2010. The two main materials previously used for these floating covers included Reinforced Polypropylene (RPP) and CSPE. At a number of sites using normal levels of chlorination, the Owner had experienced premature failure and lower than expected service life of the covers specific to the use of RPP. It was determined by the Owner that these failures were likely linked to chemical degradation of the material when exposed to chlorinated water. The Owner co-authored and published a 2011 technical paper on the deterioration of flexible polypropylene liners and covers (Moore et al. 2011). Based on these past material problems, SA Water performed a detailed technical review of available industry lining materials. Their intent was to source a more fortified geomembrane technology that could be used for both liners and floating covers. A fortified geomembrane is defined as a product heavily treated with stabilizers providing enhanced heat, UV stability and chemical resistance (Schiers, J 2009). The Owner specifically targeted material endurance properties including high pressure oxidative induction time (HP OIT) normally tested in accordance with ASTM 5885. The GRI GM 17 (Geosynthetic Research Industry) industry standard specifies 400 minutes of HP OIT. The Owner also required long term weathering capabilities and paid particular attention to the ultra violet (UV) protection and long term weathering capabilities of the material. The objective was to specify a geomembrane and floating cover material with a 25 year weathering warranty and proven resistance to chlorinated potable water. The Owner required proven testing and certification on the geomembranes chemical resistance for chlorine and UV resistance. The geomembrane and floating cover materials also needed to be fit for purpose in terms of suitable mechanical properties including sufficient tensile, elongation, puncture, and flexibility properties. Another important requirement was for the material to be potable water compliant and meet both the National Sanitation Foundation NSF/ANSI Standard 61 Drinking Water System Components (NSF/ANSI Standard 61) and the Australian and New Zealand standards for testing of products for use in contact with drinking water (AS/NZS 4020:2005).

Layfield (Manufacturer) submitted performance specifications on its Enviro Liner[®] 6040^{HD} (Polyolefin Alloy) geomembrane as well as material samples required for independent third party testing and verification. This specific geomembrane is a polyolefin alloy product and is categorized as a fortified material as a result of being produced from a highly stabilized formulation with an advanced UV antioxidant (AO) package. The materials endurance properties include a 2,000 minutes HP OIT and 90% tensile strength retention after 30,000 hours of accelerated UV testing in accordance to ASTM D4329. Table 1 below illustrates a number of the polyolefin alloy properties in comparison with GRI GM 17.

Table 1. Geomembrane Material Properties Comparison

HD Performance Properties	ASTM	Polyolefin Geomembrane	GRI GM 17
Thickness (min. ave)	D 5199	40 mils (1.00 mm)	40 mils (1.00 mm)
Tensile Strength at Break	D638 /D6693	191 ppi (33.5 N/mm)	152 ppi (27 (N/mm)
Elongation at Break	D638/ /D6693	1200%	800%
Puncture Resistance	D 4833	70 lbs (311 N)	56 lbs (250 N)
Critical Cone Height	D 5514	1.97 inches (50 mm)	N/A
Flexibility – Cycles without Cracking	D 6182	> 8000	N/A
Axi-Symmetric Break Resistance -% (min.)	D 5617	50%	30%
High Pressure OIT(min .ave)	D 5885	> 2000 mins	400
UV Resistance - Strength Retained	D 4329 30,000 hrs	90%	N/A
Certifications (Potable Water)			
NSF 61		Pass	N/A
AS/NZ 4020		Pass	N/A
Ozone Resistance 100 pphm @ 40°C	D 1149	No Cracks Observed	N/A

In addition to material specifications and samples, the Manufacturer submitted additional accelerated stress crack testing performed previously on its Polyolefin Alloy geomembrane with chlorine following ASTM D1693 for Environmental Stress Cracking of Ethylene Plastics. This testing protocol included immersing the geomembrane to a 1% (by volume) solution of sodium hypochlorite or the equivalent to 10,000 parts per million (ppm) at a constant fluid temperature of 50°C(122°F). The

conclusion of this testing indicated that the polyolefin alloy geomembrane retained over 800 minutes of HP OIT after 1,000 hours of immersion with no noticeable surface cracking. This helped provide the Owner with additional assurance of the geomembranes strong chemical resistance to chlorine as a disinfectant in a longer term geomembrane and floating cover application. The Manufacturer also submitted testing and a published technical paper (Mills, 2009) on its geomembrane which completed 30,000 hours of accelerated UV testing. This testing demonstrated the polyolefin alloy geomembrane retained over 90% of the materials tensile strength after 30,000 hours of accelerated UV weathering testing in accordance to ASTM D 4329.

Based on the Polyolefin Geomembranes performance specifications and the Owners testing verification, the Manufacturer's material was specified for the Wattle Park project.

3. RESERVOIR LINER & COVER

Fabtech (Contractor) an experienced liner contractor based out of Adelaide, South Australia was awarded the design, supply and installation contract for the Wattle Park containment project. The Contractor had previous fabrication and installation experience working with the manufacturer's polyolefin geomembrane including floating cover applications which proved to be a valuable asset on the project. The scope of work for the Contractor included removing the existing CSPE liner and cover, repairing the concrete reservoir surface, fabrication and the installation of a new 14,500 m²(156,000 ft²) polyolefin geomembrane liner and design, fabrication, and installation of a 14,500 m²(156,000 ft²)floating cover. A leak detection system was also designed and installed by the Contractor utilizing the existing concrete lined reservoir as the secondary liner. This required the concrete expansion joints to be sealed using a flexible epoxy to ensure any leakswere contained and did not seep into the subgrade. A penetration through the concrete floor was made to access the redundant sub grade drainage system below the concrete lined storage. A 316 stainless steel grate and collection sump was installed to transfer any leakage to a monitoring and inspection sump outside the main reservoir. Overtop of this stainless steel grate a 10mm HDPE (0.4") plate was installed to prevent the liner from penetrating into the grate and becoming damaged. The slopes of the concrete reservoir were lined with a 550 grams/ m² (16 oz/ yd²) non woven geotextile to act as both a protective cushion and as a leakage flow path on the slope walls. The floor of the reservoir was lined with a geocomposite drainage layer and an additional layer of 550 grams/m² (16 oz/ yd²) geotextiles cushion to provide sufficient flow rate and protection to the liner so it would handle the 9.5 meter (31.2 ft) of fluid head pressure. The Contractor also supplied and installed electric mixers and an upgraded electrical perimeter security fence.

Figure 2: 130 Ton crane used to remove old liner

The project faced a number of challenges including very tight site access impacting the removal of the old liner and cover system, as well as installation of the new containment system. To help address the tight space constraints, the Contractor incorporated in-depth project management controls ensuring the sequencing of all suppliers and subtrades were properly planned and stayed on schedule. The contractor also prefabricated as much of the system components as possible including the slope sections of the liner and floating cover. The reservoir was situated in a major urban neighborhood resulting in required noise control, enhanced safety systems and traffic management. The crest of the dam varied between 1.5m (4.9 ft) wide and 3.6m (11.8 ft) with an electrical security fence on a concrete parapet wall at the top of the reservoir, and a chainmesh security fence on the outside of the crest. To facilitate removal of the old CSPE liner and cover and to prepare for the installation of the new geomembrane the electrical security fence was removed. The condition of the concrete surface could not be properly assessed until sections of the liner and cover were cut out and moved manually to inspect the surface. At this point in the project it was determined that

mechanical equipment with a contact surface pressure of less than 100kPa (14.7 psi) could be safely used without damaging the concrete surface. Two Bobcats were winched down the 1:2 side slopes and used to bundle the old geomembrane into 500kg (1,102 lbs) bundles. To achieve the reach required to remove the old material a 130Ton (286,600 lbs) crane was employed positioned on the edge of the storage to lift 6Ton(13,440 lb) loads from the basin floor into waiting dump trucks which transported the used CSPE to an approved landfill site. In total 120 Tones (264,554 lbs) of material were removed.

The new floating cover system incorporated a central plate cover design which was required to address the size of cover, depth of the reservoir, batter gradient, and awkward configuration of the storage reservoir. The design required a primary and secondary ballast system. The primary ballast consisted of 200mm (7.9") diameter sand tubes around the 5 sides of the central plate system which provided the necessary tension in the cover system. The primary ballast line was designed to be 1.0m (3.28 ft) deep at top water level with 1.9m (6.2') between the paired floats. The secondary ballast made of 150mm (5.9") diameter sand tubes were installed in the corners and at the structures to take up excess material and enhance drainage. Another project challenge was the existing inlet configuration to the reservoir. There were 2 inlet points consisting of a single pipe at the northern end, and 3 pipes at the southern end of the reservoir. The pipes were surface mounted and encased in concrete. As a result, the cushion layer, liner, and cover all had to be installed up and over the structures. The cover design required a secondary ballast to help tension and control the excess material. To help reduce installation time and construction cost the Contractor prefabricated the slope panels for the geomembraneliner and floating cover. Site field welding was required for the floor section and the central plate cover system due to depth of the reservoir and access constraints. To ensure weld seam integrity, all factory and field seams were completed in accordance with the Manufacturer's recommended seem strength values of 12.2 N/mm (70 ppi) in accordance with ASTM D6392.

Figure 3: Geomembrane being installed over Geotextile

The storm water removal system was designed to handle record levels of daily rainfall as recorded by the Australian Bureau of Meteorology in a twenty four hour period with a redundancy factor of 33%. This was achieved by using three individual submersible stainless steel pumps that were fixed in pump wells located on floating platforms in different sections of the primary ballast lines which divided the cover roughly into thirds. The pumps have integral level switches for automatic operation and are permanently connected with isolators at the ring beam. The level switches are set to operate when the ballast lines have 300mm (11.8") of water, and are set to stop operation with 150mm (5.9') of water in the ballast line. The pumps are connected via flexible PVC hoses and non return valves, to HDPE pipes laid beside the walkways to additional connection points at the ring beam. The storm water is discharged to the natural local water course adjacent the main reservoir.

Figure 4: Plan view of Storm Water Pumps & Hatches

The design, manufacture and testing of the containment system was required to conform to (AS/NZS 1170) (AS NZS 1657). The central plate cover system incorporated a design closely following the AWWA California-Nevada Section Reservoir Floating Cover Guidelines.

During installation of the liner, the geomembrane was progressively electrically leak tested and was verified to be leak free by the contractor. The floating cover at completion was then hydrostatic tested and also confirmed to be leak free. The liner and cover system then went through a final disinfectant treatment which was a requirement for potable

4. CONCLUSION

The installation of the new geomembranes and floating cover system commenced on December 14, 2011, with the liner installation completed including electrical leak detection testing on January 2012. The new floating cover installation commenced on January 13, 2012 with completion of the cover system including all surface ancillaries on February 2, 2012.

The hydrostatic testing of the cover was concluded in late February 2012. The project was completed on time and on budget. This project highlights advancements being made with today's geomembrane technology through the use of improved film extrusion, high performance prime grade resins and advanced UV/AO additive packages. It also demonstrates the design, fabrication and installation capabilities available today in the Australia geomembrane market. In conclusion, the project's success can also be accredited to excellent communication, cooperation and experience from all parties involved to design, manufacture, and construct an important potable water storage containment project.

Case History on the Use of Geonet Composite in Red Willow Dam Modifications

ABSTRACT

The Bureau of Reclamation constructed Red Willow Dam in 1962. In 2009 sinkholes were found on the downstream face and upon further investigation cracks associated with the sinkholes were found. The solution was to use a geonet composite layer on the upstream side of a new chimney filter/drain. This geonet composite would provide three beneficial functions: secondary filter and drain to the primary chimney filter/drain; span any cracks to prevent filter from falling into cracks; and prevent propagation of new cracks across the new chimney filter system. In addition, the geonet composite will be used as the primary filter/drain above the 10,000-year flood level. Red Willow dam will be the first Reclamation dam to use such a large quantity of geonet composite drainage material (48,000 m²) in this manner. This case study covers the design of the geonet composite, positive and negative aspects of using the geonet composite, and construction techniques.

1. INTRODUCTION

Red Willow Dam and Hugh Butler Lake, completed in 1962, are features of the Frenchman-Cambridge Division of the Pick-Sloan Missouri Basin Program. The dam is located on Red Willow Creek, a tributary of the Republican River, approximately 10 miles north of McCook, Nebraska. The reservoir is primarily used for storing irrigation water, but also provides flood control benefits. Red Willow Dam is a modified homogeneous earthfill embankment constructed from silt of low plasticity. A 1.5 meters thick sand and gravel drainage blanket extends 34 meters downstream from the embankment centerline to the downstream toe where a gravel enveloped corrugated metal pipe toe drain exists. There is no cutoff trench beneath the dam and the embankment rests on windblown foundation soils, which were stripped of vegetation, pre-wetted, and compacted before constructing the embankment.

1.1 Flaws in the Embankment

During a site investigation in 2009, sinkholes were found on the downstream face near the outlet works. Upon further investigation several cracks were found on the downstream face of the dam. The outlet works and spillway conduits located at the right abutment of the dam were reportedly founded on competent Ogallala foundation. Immediately left of the outlet works the firm foundation dives steeply, so the majority of the dam is not founded on firm material. The valley fill to the left of the outlet works consists of both sands and silts, with the upper portion being mostly silt. It appears that the valley silts may be either loess or at least partially reworked loess, as they have low densities and settlement characteristics similar to that of the Peorian Loess. Severe differential settlement of the dam during and after original construction was thought to have caused the tension cracks in the embankment immediately adjacent to the outlet works and original diversion channel.

The compressible foundation silts comprising the valley fill showed settlements of up to 1 meter directly adjacent to the outlet works. The foundation above and adjacent to the outlet works conduit was shaped in a manner that would promote arching, with a 1:1 slope into the valley. This unfavorable geometry creates the potential for low stress conditions and tension cracks. These factors combined with the extremely brittle and erodible nature of the embankment and foundation soils (silts with an average plasticity index of 3) made the embankment susceptible to both cracking and erosion. On October 21, 2009, the first of several sinkholes were discovered on the downstream face of Red Willow Dam along and near the alignment of the outlet works. Further investigations revealed the presence of cracking in the embankment above the outlet works conduit and other areas along the downstream face of the dam.

Figure 1. General plan of dam.

The potential for cracks extending through the embankment are a major concern when the embankment is made of a highly erodible material and does not have an existing filter that intercepts these cracks downstream of the embankment. Case histories suggest that the most likely potential failure mode under normal operations is internal erosion through the embankment. Furthermore, case history data suggests that close to half of embankment internal erosion failures have been associated with penetrating conduits. This type of potential failure mode is the most significant concern at Red Willow Dam given the number of cracks in the embankment that were identified near the outlet works conduit and previous issues with particle transport through undertrains at the outlet works stilling basin. Therefore, modifications were determined to be necessary in order to reduce the risk of internal erosion through the embankment.

Modifying the existing foundation to limit further settlement and cracking of the dam and/or providing a cut-off wall through the embankment was not economical due to the significant depth of bedrock beneath the majority of the embankment and the high costs associated with cutoff wall construction. Therefore, an alternate solution to address cracking and the potential for internal erosion would be to install a two-stage filter downstream of the existing embankment. The filter would ensure that existing or new cracks could not erode the embankment leading to severe seepage and ultimately failure of the dam.

2. EMBANKMENT MODIFICATIONS

Twenty three alternatives to address dam cracking were highlighted by a Reclamation design team covering a wide spectrum of concepts that included downstream filters and drains, cutoff walls, filter trenches, geo-net composite filters, upstream geomembranes, and/or various combinations of these concepts (Corrective Active Study, 2010). Among these alternatives the most cost effective and technically acceptable modifications were the alternatives that had some type of two stage or single stage filter with a berm and buttress downstream of the existing dam. Using a geonet composite as a primary filter was initially suggested, but quickly determined to be inappropriate for a federal dam, per Federal Emergency Management Agency, FEMA. According to the FEMA filter manual (2011), geotextiles cannot be used: where inspection or repair of the material is not possible, in locations critical to the safety of the dam, and as a component that could potentially lead to failure of the dam. As the design process continued and cost estimates were calculated it was determined that the most economical and state-of-the-art design would be to install a two-stage chimney filter and drain system in the downstream portion of the dam to prevent migration of fines through existing cracks that could lead to an internal erosion failure. In addition, a geonet composite would be placed upstream of the chimney filter as discussed later. Downstream of the filter, a berm and buttress would be installed to equal the reservoir pressure to prevent a blowout on the downstream face assuming full reservoir head from an open crack that extends all the way to the chimney filter/drain. Final design modifications for Red Willow Dam are shown in Figure 2.

The modified embankment depicted in Figure 2 represents the final design modifications for Red Willow Dam where Zone 1 material is fine grained material with more than 15 percent passing the 200 μ m sieve, Zone 2 material is C33 fine aggregate filter sand with less than 2 percent passing the 200 μ m sieve, and Zone 3 material is C33 number 67 coarse aggregate (ASTM C33/C33M). A geonet composite layer is rarely, if ever, used in Federal dams; therefore the design and specification of this layer played a major role in the final design process.

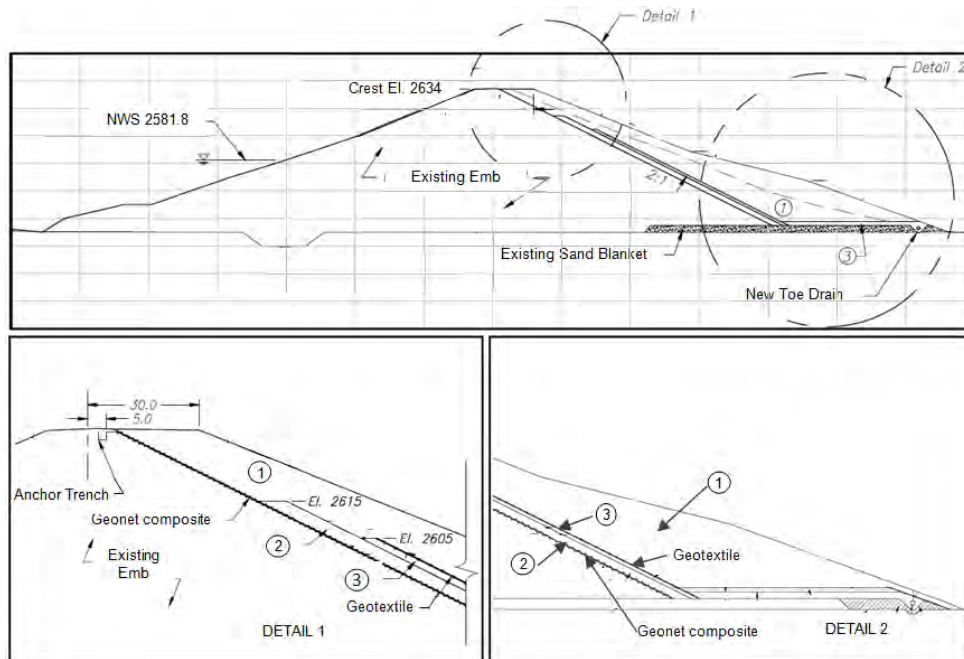

Figure 2. Modified embankment section and details.

2.1 Geo-net Composite Design

As mentioned previously, Reclamation rarely uses geosynthetic materials in embankment dam modifications. Typically only two types of geosynthetics have been used by Reclamation: geomembranes used on the upstream face or as a reservoir lining to reduce seepage and geotextiles to separate incompatible materials. Using a geomembrane upstream of the embankment was initially proposed for Red Willow Dam but was judged to be inadequate for reducing the risk for internal erosion through the embankment due to concerns with seepage flows entering the embankment below the bottom of the upstream geomembrane. Alternative configurations for the geomembrane were evaluated to intercept the seepage path but; they would have reduced storage below acceptable reservoir operations and/or required underwater placement of a geomembrane. Reclamation needed an economic solution that would help reduce the expense of importing filter materials for what likely would have to be a relatively wide chimney drain to provide both drainage and mitigate cracks in the embankment.

A double sided geonet composite was one of many solutions considered. The design team also considered using only a heavy weight geotextile, a single sided geonet composite, or only a geonet. All of these options were believed to provide significant risk reduction related to embankment cracking concerns. The decision to use a double-sided geonet composite for the modification was based on engineering judgment and lengthy discussions regarding positive and negative factors for using different geonet composite combinations. Listed below are some of the factors discussed when choosing the double sided geonet composite:

- The double sided geonet composite provides additional crack spanning ability across an open crack when compared to a single layer of geotextile or a single sided geonet composite.
- The geotextile protects the net from contamination during construction of the downstream filter and berm.
- The design only specifies a chimney sand filter being installed up to the 10,000 year flood reservoir water surface (RWS). Above this elevation a double-sided geonet composite would act as the primary filter and drain. Using a double sided geonet composite below the 10,000 year flood RWS eliminates transitioning to a different layer.
- There is a possibility that the void space in the annulus of the drain portion of the geo-net could be a repository for fines that migrated through the upstream geotextile fabric. This space was determined to be insignificant when using a biaxial geonet sandwiched between two geotextiles. The geotextiles are expected to fill the majority of the geonet void space once overlying fill is compacted over the geonet composite. Also, a thick,

heavy weight (540 g/m² with smaller AOS) upstream layer of geotextile reduces the potential for embankment fines migrating into the geonet.

- A negative factor for using double sided geonet composite is; if the excavated surface is not smooth the double sided geonet composite may not conform to the excavated slope, possibly creating a repository for fines.
- For all options, there is a potential for blinding or clogging of the geotextile; which could lead to excessive hydraulic pressures and high exit gradients behind the filter. Using a double sided geonet composite could allow for additional drainage capabilities providing better relief for potential excessive hydraulic pressures.

The double sided geonet composite was designed with a 200 mil (5mm) geonet inserted between a heavy weight 540 g/m² non-woven needle punched geotextile, and a light weight 200 g/m² non-woven needle punched geotextile. Since seepage through the embankment has never been measured or observed at Red Willow Dam, theoretical gradients were calculated above the 10,000 year flood RWS where the material will act as the primary filter. Below the 10,000 year flood RWS the geonet composite was placed upstream of a two stage filter to prevent filter sand from falling into cracks and to assist in collecting any seepage passing through the embankment. The two stage filter is expected to handle excessive seepage flows that surpass the drainage capacity of the geonet composite.

In addition, retention and permeability criteria for the two geotextiles were considered. The heavy weight geotextile was designed to be placed upstream of the geonet against fine grained embankment material and the light weight geotextile was designed to be placed downstream of the geonet against zone 2 filter sand. Design calculations used for retention assumed that the apparent opening size, AOS, of the geotextile would be less than two to three times the D₈₅ of the base materials. The term D₈₅ refers to particle size of the fine grained material, as determined by gradations, where 85 percent of the particles pass. The AOS of the upstream geotextile was specified to be less than or equal to 0.15 mm (#100 sieve) which is approximately 2.5 times the average D₈₅ of the embankment material at Red Willow Dam. The AOS of the downstream geotextile was specified to be less than or equal to 0.212 mm which will be adequate to retain the chimney filter sand.

Reclamation also verified the impact the geonet composite would have on the stability of the embankment and estimated the flow capacity for the geonet composite above the 10,000 year flood RWS. The geonet composite was modeled in the embankment stability analysis as a thin layer with a friction angle of 14 degrees. Laboratory tests were not conducted to verify the interface friction angle between the zone 1 soil and geonet composite. However, research conducted by the Geosynthetic Institute, GSI, (Koerner et al. 2005) showed significantly higher interface friction angles for geotextiles and geonet composites against cohesionless soils. Therefore, the designers felt confident that the strength was not being overestimated. Flow capacity of the geonet composite was also not verified with laboratory testing, but conservative values of transmissivity were used to calculate an equivalent gravel layer. Transmissivity was estimated from values provided by the manufacturer but reduced to account for the intrusion of geotextile into the flow path and reduction of flow from the possibility of lower gradients (Bamforth 2008). Even with these reductions the geonet composite was determined to provide the same amount of flow as a 60 centimeter wide gravel drain.

2.1.1 Installation Specifications

Physical properties for all components of the geonet composite material were specified to ensure the material performed adequately after installation. The geonet was to be comprised of 5 mm thick High Density Polyethylene (HDPE) with a tensile strength greater than 800 g/mm. Specifying a 5 mm thick geonet ensured that a reasonable flow could pass through if seepage occurred and that the material will not tear if the geonet composite has to span cracks up to 2.5 cm wide in the embankment. Similarly, physical properties were specified for both types of geotextile. The specification having the biggest impact was that the tensile strength should be greater than 70 percent after 14 days of continuous ultraviolet, UV, exposure. Specific procedures for installation and protection of the geonet composite were not detailed in the specification but were left for the contractor to decide. However, several manufacture guidelines were consulted to ensure that installation met the design intent.

Specifications were outlined describing preparation of the subgrade beneath the geonet composite. If the excavated surface beneath the geonet composite is not relatively smooth then air gaps could exist for fines to migrate into. Also, large displacements in the subgrade could place excessive tensile strength causing the material to tear. The surface was to undergo foundation inspection and approval by Reclamation before installation of the geonet composite. To achieve approval the contractor had to create a firm surface that was reasonably even and smooth, and free of offsets, abrupt indentations, and protruding materials greater than 3.8 cm. The surface was also to be void of any erosion damage and any cracks greater than 1.25 cm must be repaired before installation of geonet composite was to proceed.

To ensure surface erosion of the embankment from rainfall did not take place it was specified that the geonet composite be placed over the entire slope before installing the downstream chimney filter and berm. It was assumed the geonet

composite material would provide some level of protection to the excavated slope from erosion due to rainfall. Along with placing all of the geonet composite before constructing the filter and berm, the material had to be placed transverse to the crest, machine direction running down the embankment, with any horizontal joints located in the bottom third of the embankment. Installing the panels in this direction insured that all horizontal joints were closer to the toe of the filter where the highest overburden stresses are acting. Typically, the longest roll length a manufacture will produce is 60 meters but the downstream slope required several rolls greater than 60 meters. Specifications for seaming the geonet composite required the contractor to overlap the side by side joints of the geonet a minimum of 15 centimeters and the end to end joints were required to overlap a minimum of 30 centimeters. Along the joints the geotextile portion of the composite would be sewn or continuously welded. The geonet was overlapped to allow the panels to be tied together; the net was tied at 60 centimeter intervals for side to side joints and at 30 centimeter intervals for end to end joints. Only the most critical specifications to the design were included in this paper due to space limitations.

3. CONSTRUCTION

Construction for Red Willow Dam modifications began in the spring of 2012. The Contractor began by stripping the topsoil from the embankment and excavating 300,000 cubic meters from the downstream embankment slope. Next the existing toe drain was removed and replaced by a modern 30 centimeter diameter HDPE perforated toe drain. Once the toe drain was complete the Contractor began placing drain material over the existing sand blanket (see Figure 2) then geonet composite material was placed in panels on the downstream slope. The contractor acquired 58,500 square meters of geonet composite to place on the entire downstream face of the excavated surface. This required ordering 215 rolls of geonet composite; each roll was 3.7 meters wide and approximately 60 meters long. After a large portion of the geonet composite was installed, the chimney filter and berm were started.

3.1 Construction Issues

As discussed in the installation specifications section it was crucial for the Contractor to create a relatively smooth foundation to place the geonet composite material. The embankment surface had significant surface erosion and vegetation growth, because of the long duration between the original embankment excavation and the preparation for the geonet prior to its installation. Initially after excavating the downstream embankment the Contractor used a dozer to smooth the exposed embankment. Transverse passes were made going up and down the 2H:1V embankments slope. Crew members were then utilized to further smooth the surface using rakes. Small shrubs and other debris had to also be removed from the surface by the crew members, as shown in Figure 3.

Figure 3. Approved and unapproved subgrade below geonet. (Courtesy of Jack Gagliardi)

The contractor elected to install the geonet composite using their own crew. Using a relatively inexperienced crew meant that the geotextile could potentially be exposed to over 14-days of UV rays. A field test was conducted to see how many days the 200 g/m² geotextile could be subjected to UV rays before 30 percent of the tensile strength was lost. Three strips of geotextile were staked and sand bagged at the top of the excavated slope. Samples were taken every 7 days all the way up to 45 days and tested by Reclamation and the contractor's private quality control laboratory. Results from this trial revealed that the Contractor could leave the geotextile exposed to UV rays for a maximum of 30 days.

The contractor began placing the geonet composite on the left abutment moving across to the right abutment over the spillway and outlet works conduit. Geonet composite production rate averaged between 4 to 6 rolls per day initially but increased to 11 rolls a day after installation efficiencies were developed and an additional crew of four was added. Construction of the downstream filter and berm could not keep up with the placement of geonet composite. Therefore, a thin layer of sand was used to protect the top layer of geotextile from UV damage. The contractor originally tried dumping the sand from the crest with the intent for the sand to slide down the 2:1 slope. Complications occurred when the Contractor tried dumping the sand directly on top of the geonet composite from side dump trucks. The geonet composite was torn due to the excessive force exerted on the geonet composite by dumping the sand all at once. Also, the sand did not freely spread down the slope so crew members had to use rakes to spread the material down the 70 meter long slope. As a result of the unsuccessful efforts the contractor developed a system utilizing a telebelt (extending conveyor system) to spread sand over the entire slope as shown in figure 4. The telebelt was able to operate from the crest and toe of the embankment. This allowed almost the entire slope to be covered with sand and only a small portion, midway up the embankment, needed to be spread using hand labor.

Figure 4. Telebelt spreading sand over the geonet. (Courtesy of Jack Gagliardi)

After constructing a 60 cm wide and 90 cm deep anchor trench along the downstream edge of the crest; rolls of geonet composite were unrolled from the crest down to the toe of the excavated embankment. A long steel bar was attached to a skid-steer which secured the roll on top of the crest as two crew members pulled the geonet composite down the slope. A second roll was then unrolled down the slope parallel to the first. Each roll was manufactured with 30 centimeters of geotextile extending beyond the geonet on each edge. This posed minor difficulties when trying to fold and weld the excess geotextile underneath the geonet composite. So after rolling out the second geonet composite roll the bottom edge of the geotextile on the second panel was cut flush with the geonet. Next, two crew members worked their way down the slope making sure the panels lay relatively parallel and overlapped by 15 centimeters. After the geonet composite was deployed down the slope the bottom outside edge of the geotextile was staked to the embankment. Stakes (into the bottom geotextile) were used to anchor the material to the embankment so the wind did not lift the fabric, stakes were found to work better than sand bags on the steep slope. After the panels were secured the crew members began welding the bottom layer of geotextile. Another crew member followed tying the geonet together every 1.5 meters. Then another member was used to weld the top geotextile together. Welding of the geotextile was completed using electric heat guns powered by a gas generator located on the crest. Once this system was developed and perfected a crew of five members placed an average of 11 rolls per day. Due to relatively slow production rates the contractor was given approval from Reclamation to not seam the bottom geotextile and to only overlap the adjacent panels. Overlapping was only approved between stations 16+00 and 30+00 where no cracks had been identified in the embankment.

Figure 5. Shows sequencing of installation of geonet composite rolls.

As the contractor continued to work toward the center of the embankment where the slope length exceeded the roll length, a single roll of geonet composite could not extend to the toe of the excavated slope. At this point partial rolls of geonet composite had to be added at the bottom, which necessitated the need for horizontal (end-to-end) seams. Horizontal seams were constructed in a similar manner to vertical seams except the geonet had to be overlapped by 30 cm and tied together every 15 centimeters and the seams were staggered to eliminate any continuous horizontal seams. Constructing horizontal seams drastically decreased production rates. Therefore, the contractor added an additional crew to work entirely on horizontal seams. Typically, only 4 to 5 horizontal seams were completed in one day. Horizontal seams not only required additional overlap and closer ties but geotextile had to be manually peeled away from the geonet composite to accommodate the 30 cm of geonet overlap required.

The number of horizontal seams might have been reduced if a panel layout was prepared before ordering the geonet composite material. This would mean that each panel would be made to the correct length and less cutting and splicing would be needed. However, this would mean each roll would have to be labeled and shipped in a specific order. This would require organizing the rolls onsite so that they can be accessed when needed for installation. Also, some cost savings might have occurred if the contractor had ordered longer rolls of geonet composite for a majority of the dam. Then rolls would only have to be cut reducing the number of horizontal seams; however this would lead to more wasted material. Horizontal seams are both costly and undesirable from a design perspective since they introduce another potential weakness in the geonet composite. Note, rolls longer than 60 meters may have been limited due to the weight and size of the roll and shipping requirements but avoiding/limiting horizontal seams is recommended.

Figure 6. Installation of geonet composite panels and horizontal seams.

Inconsistencies and defects in the geonet composite caused additional production issues for the contractor. During the manufacturing process geonet roll widths can vary by ± 15 centimeters. According to the manufacturer this is unavoidable and caused as the material cools at different rates. The manufacturer also had issues bonding two different geotextile densities to the geonet. The $540\text{g}/\text{m}^2$ non-woven needle punched geotextile required additional heat to bond to the geonet. This additional heat caused melting of the geonet and holes in the lighter geotextile on some panels. Patching the lighter geotextile was easily completed by the manufacturer before shipping to the construction site. However, the geonet cannot be patched. The melted geonet caused some difficulty with tying adjacent panels together, as shown in figure 6. However, the combination of melted geonet along with varying roll widths was addressed by adding additional ties. These types of inconsistencies and defects caused additional installation time that the Contractor had not anticipated. If the same density of geotextile had been bonded to the geonet some of these defects might have been avoided. Also, specifying a larger geonet that could withstand the heat necessary to bond a $540\text{g}/\text{m}^2$ geotextile to both sides could have helped reduce some defects. However, the larger geonet would result in a larger void between the geotextile which the designers did not want.

Figure 6. Melted geonet at the edge of a geonet composite roll.

4. CONCLUSION

Reclamation does not typically use geosynthetics in embankment dams, especially for filtration, but the use of geonet composite material beneath the chimney filter at Red Willow Dam was specified as a result of the design intent discussed above. The geonet composite ensures that the chimney filter will not fall into any existing or new cracks, will serve as a layer to prevent mitigation of existing cracks into the chimney filter, acts as a primary filter and drain above the 10,000 year flood RWS, and reduces the cost of importing additional filter/drain material. Several design and construction factors were presented in this paper that will hopefully encourage the use of geonet composite. Key components presented in this case history were the discussion of the specifications and installation processes. Not including detailed installation procedures in the specifications allowed Reclamation and the contractor to work together and overcome any unforeseen issues. This saved time and allowed for a better installation. Additionally, protecting the large quantity of exposed geotextile from UV rays was crucial and the contractor's methods of using a thin sand layer was demonstrated to be very efficient. The issues encountered during construction of this modification can hopefully be avoided in the future. Geosynthetics will continue to be used for different applications and it is hoped that the results from this case history will allow embankment dam designers to consider these materials in their design and help increase construction efficiency.

ACKNOWLEDGEMENTS

The authors would like to acknowledge all of the individuals that helped ensure the construction and design of the geonet composite was possible. This includes: several designers and peer reviewers, the Reclamation construction crew that helped inspect the installation and ensure that the design requirements were achieved, and the contractor and manufacturer who made the installation possible.

Case History: HDPE Pipe Boot Failure Due to Thermal Contraction of HDPE Pipe

ABSTRACT

High-density polyethylene (HDPE) pipe boots are typical in landfill construction where leachate collection pipes need to be extended from within containment areas, towards storage ponds, tanks, or treatment facilities located outside of the containment system. The installation of a pipe boot creates a fixed point for the pipe at the location of the penetration. The remaining length of the attached pipes, which can be subject to thermal expansion and contraction cycles, can range from several hundred to thousands of meters. For typical pipe lengths, the potential deformation due to expansion and contraction can vary between several centimeters to several meters, depending on changes in temperature and length of exposed pipe. For this case history, a large temperature differential combined with over one hundred meters of unrestricted length of pipe led to an observed permanent pipe deformation of approximately 0.25 meters. The resulting tensile stress was responsible for the failure of the pipe boot at the end of the pipe alignment and subsequent release of fluid outside the containment area. To account for the potential for pipes to undergo expansion and contraction deformations during construction, several measures are recommended during the design process: 1) verification of expansion and contraction potential of exposed pipes based on expected temperatures during, and after, construction and length of pipes, 2) specifying pipe construction sequence in the construction documents to reduce pipe movements during construction, and 3) boot designs that include a flexible connection to allow pipe movements to be isolated from the boot itself.

1. INTRODUCTION

In landfills, geomembrane pipe boots are sealing elements whose purpose is to prevent leaks of leachate or gas at the penetration of a relatively rigid pipe through a relatively flexible geomembrane. Standard geomembrane pipe boots consist of several or all of the following elements, depending on the containment system configuration:

- 1) pipe to be booted,
- 2) primary geomembrane (from containment system),
- 3) boot (comprised of a geomembrane sleeve and apron),
- 4) silicon sealant,
- 5) stainless steel band clamps, and
- 6) extrusion welds.

There are two types of pipe boots prevalent in landfill construction projects: 1) field-fabricated or 2) pre-fabricated. Generally, small projects choose to install field-fabricated boots to ensure that they achieve a good fit based on conditions in the field that may be hard to determine in advance. Pre-fabricated boots are generally used in projects where the pipes to be booted have large diameters or where construction tolerances are tight enough that field variances are anticipated to be within the tolerance of the pre-fabricated boot.

Although pre-fabricated boots can be easier to install in the field if conditions are within design tolerance, they tend to be much more expensive than field-fabricated boots. In addition, field-fabricated boots can be made to accommodate as-built conditions, as the Contractor can cut each element of the boot to the dimensions needed in the field. For these reasons, field-fabricated boots are more commonly used.

2. TYPICAL DESIGN

A typical field-fabricated pipe boot consists of a geomembrane sleeve which is welded both to the pipe that will penetrate the containment system, as well as a geomembrane apron which is, in turn, welded to the containment system geomembrane, thus creating a flow barrier. In some cases the geomembrane sleeve is welded directly to the pipe. Alternatively, the sleeve can be sealed to the pipe using a flexible sealant and steel band clamps. Once the geomembrane sleeve is attached to the pipe, the sleeve is then welded to the geomembrane apron, which is then finally

welded to the geomembrane layer of the containment system, thus creating a completely contained system. A typical field-fabrication detail for geomembrane liner pipe penetration used in landfill construction is shown in Figure 1.

Figure 1. Typical pipe boot detail for single-containment landfill cell.

3. EXPANSION AND CONTRACTION POTENTIAL OF HDPE PIPES

HDPE is susceptible to expansion/contraction as a result of temperature variations. The coefficient of thermal expansion for unrestrained HDPE pipes is approximately 10 times that of metal or concrete. As a result large changes in HDPE pipe lengths may be observed due to temperature fluctuations.

Typical HDPE pipes used for landfill applications meet the properties of material designations PE3408 or PE3608. For such materials, the coefficient of thermal expansion typically ranges from 1.8 to 2.2×10^{-4} meters/meters-°Celsius (m/m-°C) [ISCO Industries and Performance Pipe, 2012]. Based on the equation for the theoretical change in pipe length for an unrestricted pipe,

$$\Delta L = L \cdot \alpha \cdot \Delta T, \quad [1]$$

where L corresponds to the pipe length, α to the coefficient of thermal expansion for the pipe material, and ΔT to the temperature differential. The range of α above implies that for a pipe length of 100 meters, we can expect a deformation (i.e., elongation or contraction) of approximately 0.18 to 0.22 meters, for every 10°C variation in temperature. In reality, some friction will exist between the pipe and adjacent materials, therefore deformation will be reduced, resulting in tensile or compressive stresses within the pipe. The estimated potential deformation therefore corresponds to a maximum deformation limit.

A closer look at the three variables contained in Equation 1 shows that for any project, the designer only has control over one of these three factors. The coefficient of thermal expansion is an intrinsic property of the material and varies little from one manufacturer to another. If temperature changes are solely due to climate, the designer has very little control over the maximum potential temperature differential. For unrestricted pipe length, the designer has control by using anchors along the way that can limit the stresses developed on the pipes, and hence the potential deformation, by reducing the length of pipe which can be affected by temperature variations.

4. CASE HISTORY: PIPE BOOT FAILURE OBSERVATIONS

4.1 Site Conditions

The site for this case history is an active landfill in the United States that has been in operation for many years. It is located in a region which experienced typical temperature differentials of 18 °C during the construction season (i.e., summer to early fall). During the day temperatures range between 26 to 35°C, but at night the temperatures can drop into the 10 to 16°C range.

4.2 Existing Cell and Pipe Boot Design

Due to field constraints, new waste containment cells at the site have been built upgradient from future cells. The result of this construction sequence is that leachate generated from new cells flows towards the low point in the cell, where a leachate conveyance pipe is booted through the containment system and then discharged beyond the cell into a tank or leachate pond (see Figure 2).

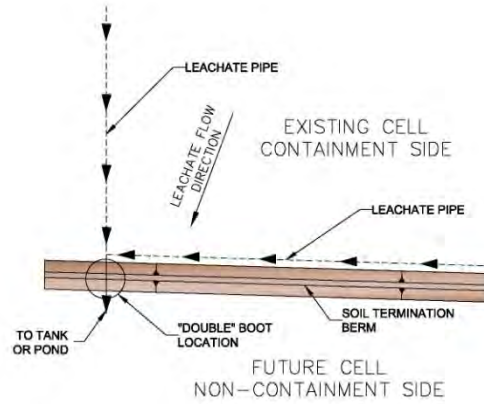

Figure 2. Leachate pipes configuration relative to pipe boot location.

With the future cell adjacent to the upgradient cell, the pipe boot is designed as a permanent feature for the cell, as it cannot readily be removed during construction of the future cell while maintaining leachate containment. As a result of this, the pipe penetration was designed as a “double” pipe boot, wherein both the upgradient containment side of the leachate pipe, as well as the downgradient non-containment side is booted through the containment system (see Figure 3). The “double” pipe boot provides a connection of the pipe to the geomembrane apron, which in turn is connected to the containment system geomembrane. Note however that the containment system geomembrane is located below the pipe penetrations to keep leachate from escaping the containment system in the event of a leak. The leachate pipe is converted to a double-containment pipe after it exits the geomembrane footprint on the downgradient non-containment side.

Figure 3. “Double” pipe boot schematic.

4.3 Failure Observations

During construction of a new landfill cell that would tie to the existing upgradient cell, a construction quality assurance (CQA) technician noted that there was ponded fluid on the downgradient non-containment side of the existing pipe boot. Additionally, the geomembrane apron around the pipe boot appeared to have been compressed (pulled) towards the upgradient containment side of the pipe boot (see Figure 4).

Figure 4. Containment system geomembrane and geomembrane apron around downgradient non-containment side of pipe boot upon discovery of ponded fluid.

A closer look at the pipe boot on the downgradient non-containment side revealed that the weld between the pipe sleeve and the surrounding geomembrane apron had been broken and the compacted soil within the “double” boot appeared to be saturated. Given the condition of the downgradient non-containment side of the pipe boot, it was decided that the in-place soil and waste would be excavated from the area above the pipe boot on the containment side in order to assess the condition of that boot. Figure 5 illustrates the condition of the pipe boot on the containment side, where the weld between the pipe sleeve and the geomembrane apron was broken and the booted pipe, along with its geomembrane sleeve, had moved approximately 0.25 meters away from its original location.

Figure 5. Observed displacement between original pipe boot weld location and final post-failure weld location (the knife and the finger are pointing to the two sides of the original weld).

4.4 Failure Causation Analysis

Once the condition of the pipe boot on the containment side was carefully documented, it became evident that the weld connecting the pipe sleeve to the geomembrane apron had been subjected to significant tensile stress. The failure causation analysis was therefore focused on potential sources for the tensile forces that ruptured the weld and pulled the pipe sleeve and geomembrane apron apart. As part of this evaluation, photos and daily records from the original construction of the existing cell were reviewed in order to establish the timeline of events for the installation of the existing pipe boots.

Several potential causes of the damage were considered including improper pipe welding procedures and damage by heavy equipment, but were dismissed due to the observed mode of failure. During initial cell construction, as verified by the construction photos, the entire length (approximately 180 meters) of leachate pipe was exposed and unrestrained after connection to the pipe boot. Estimates of potential thermal deformation for the pipe were then developed based on the method previously described. Using a typical site temperature differential of 18°C and the HDPE coefficient of thermal expansion of 2.2×10^{-4} m/m-°C, a maximum potential pipe deformation of approximately 0.7 meters was computed. Given the mode of failure, and the magnitude of the displacement observed in the field, we concluded that thermal deformation was the most likely cause of failure.

4.5 Modified Pipe Boot Design

The failure of the existing pipe boot was an obvious indicator that the design had to be modified prior to the construction of the new pipe boot for the new cell. Based on the results of the failure mode analyses, the first thing that was evaluated for the new design was the maximum potential thermal deformation that could be experienced by the proposed leachate pipe configuration within the new cell. With the large resulting value, similar to the 0.7 meters calculated for the existing cell, the design of the new pipe boot was focused primarily on how to isolate the movement of the leachate pipes from the pipe boot itself in order to keep the pipes from exerting tension or compression forces on the pipe boot.

Figure 6 shows the approach developed to isolate the two incoming leachate pipes from the segment of the pipe that would be booted. As shown, the new design incorporates a pipe sleeve to encase both segments of the main leachate pipe, as well as a distance between the two ends of the leachate pipes within the sleeve, to allow the pipes to freely move during the installation process. By removing a segment of the main leachate pipe, two main objectives are achieved: (1) the two segments are now given extra space, in the event that they experience thermal expansion/contraction, and (2) the length of unrestricted pipe attached directly to the pipe boot is reduced from over 100 meters, to less than two meters, thus reducing the maximum potential thermal deformation that could be experienced by that segment of booted pipe to approximately one centimeter.

Figure 6. Schematic view of new pipe sleeve for leachate pipes on the containment side.

The revised design in Figure 6 shows a distance of "X" to separate the two ends of the leachate pipes within the sleeve, and a total pipe sleeve length equivalent to three times the value of "X". The value of "X" should be based on the estimated maximum deformation potential due to thermal expansion/contraction on the longest section of potentially exposed pipe that would otherwise be in contact with the pipe boot. The authors recommend that the distance "X" be estimated conservatively.

4.6 New Pipe Boot Construction

In addition to the new pipe sleeve design, modified field installation procedures are recommended to ensure that the new system is constructed as designed and that all aspects of the design can be verified prior to covering the boot with drainage gravel and the operations layer soil for the new landfill cell. A step-by-step sequence of construction was developed for the pipe boot and adjacent features that was added as a note on the construction drawings for the new

cell, alongside the sketch of the new pipe sleeve design. The step-by-step description included actions to be taken not only by the contractor, but also by the construction quality assurance (CQA) manager in the field. The new sequence of events included the following steps:

- 1) mark the two segments of leachate pipe to be inserted inside the pipe sleeve with 0.3-m markings starting at the edges to be inserted inside the sleeve;
- 2) slide the edges of the leachate pipes inside the pipe sleeve;
- 3) verify the distance between the edges of the leachate pipes inside the sleeve, by using the markings on the leachate pipes;
- 4) install geotextile wrap around the pipe sleeve and a portion of the leachate pipe inserted into the sleeve, and secure in place with band clamps;
- 5) place drainage gravel and operations soil everywhere along the new cell, except at the location of the new pipe sleeve and geotextile; and
- 6) verify the location of the leachate pipe within the sleeve, based on the pipe markings, and backfill the area above the sleeve with the drainage gravel and the operations layer if the distance between the edges of the leachate pipes within the pipe sleeve are found to be satisfactory; otherwise, remove the geotextile wrap, and pipes within the sleeve, cut a portion of the pipes to be inserted in the sleeves and return to step 2, proceeding through the steps as before.

The established sequence allows the CQA manager the opportunity to verify that the leachate pipes within the sleeve have enough space between them prior to burial to accommodate significant subsequent displacement. At the same time, by verifying this space just prior to burial (i.e. constraining) of the pipe, the potential for movement from thermal expansion and contraction is greatly reduced.

Figure 7. Leachate pipes and pipe sleeves configuration prior to geotextile wrap, pipe boot welding and local trench backfilling.

Figure 7 illustrates the constructed pipe sleeves (with markings) for each of the two leachate pipes that connect in the vicinity of the pipe boot. In the picture, soil can be seen in the background, which illustrates that all areas of the cell, including the trenches, were backfilled with drainage gravel and operations layer soil, as required, except for those areas directly above the new pipe sleeves. Once the distance between the two edges of the leachate pipes within the pipe sleeve was verified by the CQA manager, the area above the sleeves was backfilled and the final pipe boot inspection and work was completed.

5. CONCLUSIONS

Field conditions, including temperature fluctuations, are different for every site and can vary significantly depending on the time of the year when projects are built. The potential for pipe deformations due to thermal expansion and contraction of pipes should become a routine consideration when designing with HDPE pipes, even when the pipes will be buried. In addition to evaluating the buckling, crushing, and ring-deformation strength for the planned pipes, designers should consider all potential scenarios where expansion and contraction for a length of pipe can have an impact on other elements of the design. In addition, given the importance and critical nature of features such as pipe boots, special attention should be given to both the design and the construction of such elements to protect them from damage and ensure their proper performance in the field. If potentially affected, the construction sequence of critical elements should be specified on the construction drawings to provide assurance that pipe movements will be accommodated by the structure.

ACKNOWLEDGEMENTS

The authors would like to acknowledge the help of the skilled field technicians for the referenced case history, who were instrumental in detecting the original failure, properly documenting the original cell construction, and ultimately monitoring the construction of the new cell to ensure that the modified construction sequence and design were properly implemented. We would also like to recognize the mentorship provided by Dr. Hari Sharma during the initial evaluation of the failure, and subsequent re-design effort.

Centrifuge Modelling of Geotextile Reinforced Slopes

AKLIK, P. Phd., Universität für Bodenkultur, Vienna, Austria, pelinaklik@gmail.com
WU, W., Universität für Bodenkultur, Vienna, Austria, wei.wu@boku.ac.at

ABSTRACT

Geotextile is being increasingly used for slope reinforcement. The failure mechanisms are important to make safe and economic design of geotextile reinforced slopes. Centrifuge modelling is a powerful tool for physical modelling of reinforced slopes and offers the advantage to observe the failure mechanisms. In this paper, we report a series of model tests on geotextile reinforced slope with three different slope inclinations of 65, 75, and 85 degrees in a geotechnical centrifuge. The aim is to identify the possible failure mechanisms. All reinforced slope models have the same height of 270mm. Dry sand was used in the experiments. The model box was subjected to increasing centrifugal acceleration until failure occurred. Photographs of the slope models were taken in flight with a digital camera and the deformations were evaluated with Particle Image Velocimetry (PIV).

1. INTRODUCTION

Geosynthetic-reinforced slopes and walls became very popular in recent years because of their financial, technical, ecological advantages. A wide range of geotechnical problems can be investigated using physical modeling techniques. Centrifuge modelling has become a successful technique in geotechnical engineering for studying the stability of prototype slopes. In order to replicate the gravity induced stresses of a prototype structure in a geometrically 1/N reduced model, it is necessary to test the model in a gravitational field N times larger than that of prototype structure (Viswanadham and König, 2009). Substantial research demonstrated the effectiveness of centrifuge modelling for studying the behaviours of geosynthetic reinforced walls and slopes, as reported by Porbaha & Goodings (1994, 1996), Zornberg et al. (1997; 1998a,b), Zornberg & Arriaga (2003), Viswanadham & Mahajan (2007), Chen et al. (2007) and Viswanadham & König (2004, 2009).

However, researches on slope with different slope angles are very rarely mentioned in the literature. In this paper, a series of reinforced slope models with a slope inclination of 65, 75, and 85 degrees were tested in a geotechnical centrifuge. The aim is to identify the possible failure mechanisms. Moreover, a technique called Particle Image Velocimetry (PIV) is used in this research to reveal the failure mechanisms of the geotextile reinforced slopes.

2. MODEL DESIGN

2.1 Centrifuge

The geotechnical centrifuge at Universität für Bodenkultur (BOKU) in Vienna was manufactured by Trio-Tech, USA and was put into operation in 1990 with partial financial support from the Austrian Science Foundation (Trio-Tech 1988). The centrifuge has the following components: a swinging basket, a balancing counterweight, a DC motor and aerodynamic enclosure. It is equipped with 56 electrical slip rings for process control and data acquisition. By using the dual platforms, two models can be tested at the same time. However, it is usual to have only one swinging basket carrying a model, while a balance weight is loaded on the other platform. The technical specifications of the centrifuge are listed in Table 1 and illustrated in Figure 1.

Table 1. Technical specifications of the centrifuge.

Diameter of the centrifuge [m]	3.0
Radius of the swinging basket [m]	1.3
Maximum angular velocity [1/min]	400
Maximum radial acceleration [g]	200
Maximum model weight [kg]	90
Maximum model height [cm]	56

Figure 1. Photo of the centrifuge and its swinging basket.

2.2 Model Box

The model box (Figure 2) has the dimensions of 440mm*400mm*155mm in depth. A transparent Plexiglas plate with a thickness of 30mm was used on one side of the box to enable digital images to be taken during the experiment. The other walls of the box were aluminum plates with a thickness of 15mm.

Figure 2. Geotextile reinforced slope model with a digital camera in the front and LED lights on the left and right sides.

2.3 Slope Model

Reinforced slope models have three different slope inclinations of about 65, 75, and 85 degrees. The geotextile reinforced slopes had the same height of 270mm and was built on a 40mm of soil layer of the same properties. Only half of the slope was modelled.

The model textile is an interlining. Six layers, seven layers and eight layers of model textile with a length of 200mm were placed in the geotextile reinforced slope models having 65, 75, and 85 degrees respectively.

2.4 Soil

The soil used in the experiments was uniform coarse sand (Table 2), Standard Sand II (DIN 1164/58). The tests were accomplished under dry conditions. The sand was inserted from a height of approximately 10 cm, not compacted and therefore in a loose condition.

Table 2. Properties of soil (Ferstl 1998).

Specific weight	ρ_s [g/cm ³]	2.644
Density range	ρ_{min}, ρ_{max} [g/cm ³]	1.44 – 1.65
Void ratio	e_{min}, e_{max}	0.607 – 0.844
Coefficient of uniformity		1.4
Friction angle	Φ [°]	34
Cohesion	c [kN/m ²]	0

2.5 Instrumentation

The displacement of the geotextile reinforced slope models was measured by PIV (White et al. 2001; 2003). For this purpose, a 14.7 MP Canon G10 digital camera was used to obtain high resolution digital images of the sand grains behind the Plexiglas wall. Black dots surrounded by white circles were applied to the Plexiglas, and were used as reference points for monitoring displacements within the soil. Two panels of 33 LED lights were used on both sides of the model box for lighting the centrifuge during the experiment. A laptop computer was mounted close the rotating axis of the centrifuge and connected to the main computer in the control room to save the photos during centrifuge test.

2.6 Method

The soil displacement analysis was carried out with GeoPIV8 software, developed by White & Take (2002). The first image was divided into a grid of test patches. Each test patch consists of a sample of the image matrix of size 20 * 20 pixels and the images were captured in 6 s intervals until the failure of the slope model. The recorded photographs were used to reveal the failure mechanisms of the slope after the experiment.

3. RESULTS

The results of PIV analysis of geotextile reinforced slopes are given in Figs. 3-5. In all the figures, X and Y coordinates are the lengths of the slopes in cm. Figure 3 is the geotextile reinforced slope with a slope inclination of 65 degrees. As seen from Fig. 3, the failure is occurred along the surface of the slope. Figure 4 is the slope having an inclination of 75 degrees. It can be easily seen from Fig. 4 that the shear band is occurred clearly starting in the middle of the slope and extending to the surface of slope. Figure 5 is the steepest slope with an inclination of about 85 degrees. Two shear bands were seen easily from Fig. 5 and the surface deformation of this slope has the highest values of all three models.

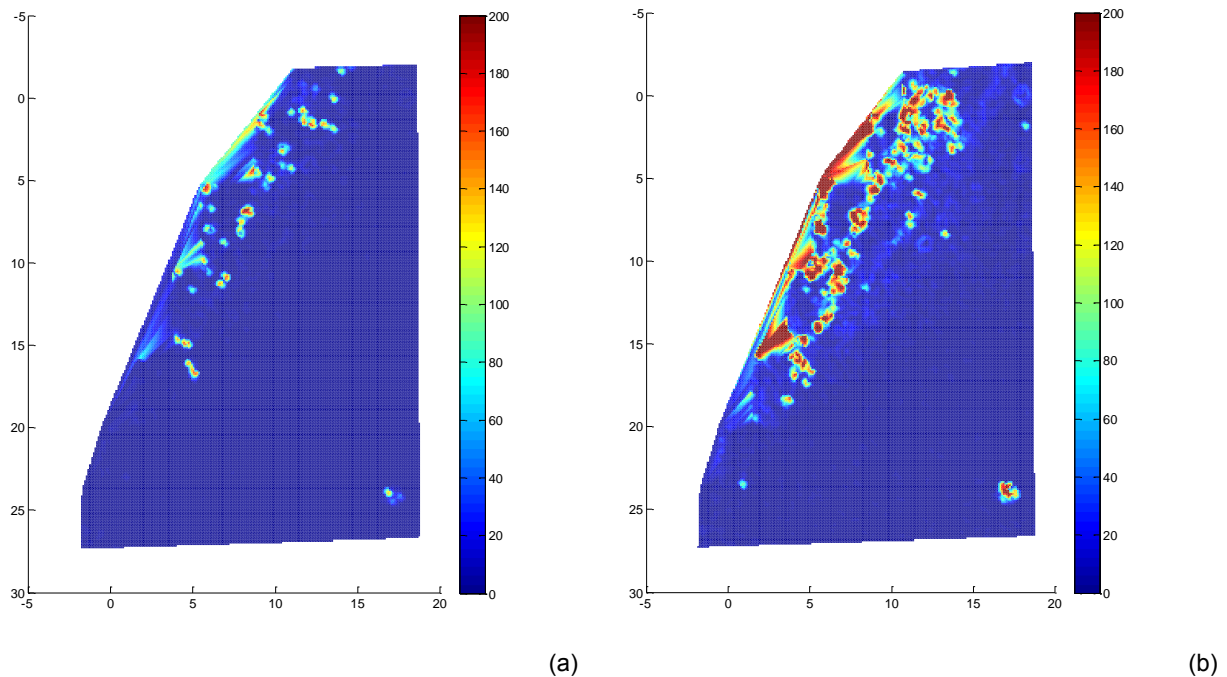

Figure 3. Pre (a) and post (b) failure mechanisms of geotextile reinforced slope with an inclination of 65 degrees.

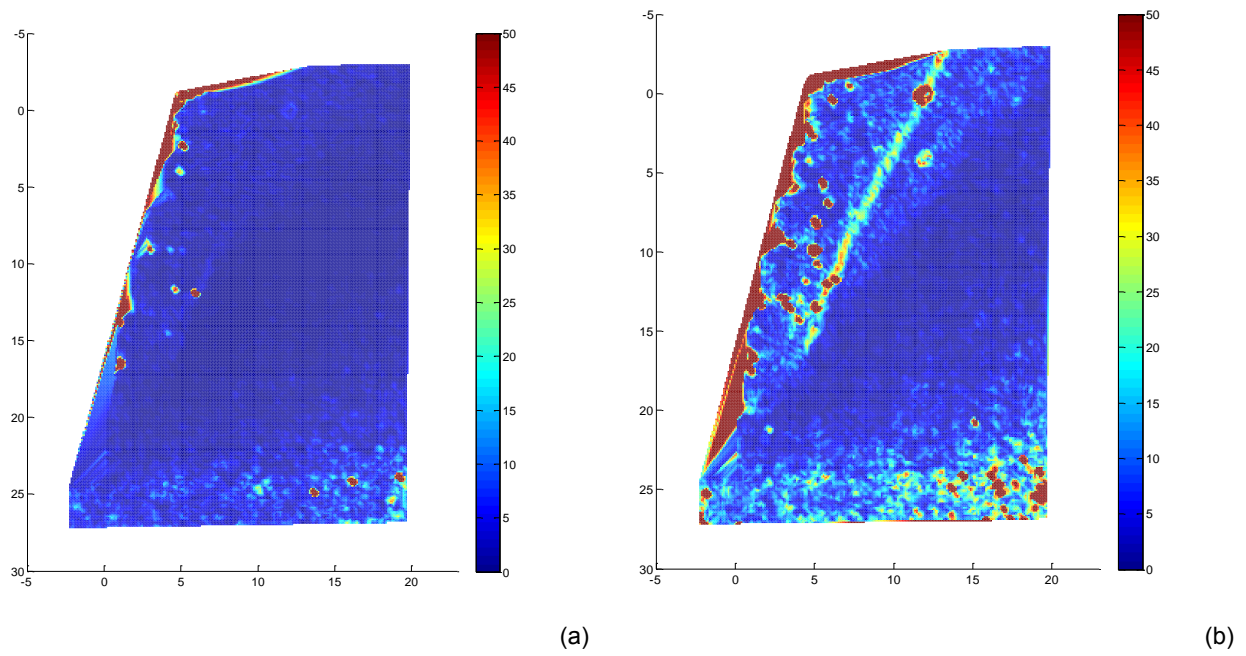

Figure 4. Pre (a) and post (b) failure mechanisms of geotextile reinforced slope with an inclination of 75 degrees.

Figure 5. Pre (a) and post (b) failure mechanisms of geotextile reinforced slope with an inclination of 85 degrees.

4. CONCLUSIONS

- ✓ The required acceleration at slope failure decreases with increasing slope inclination.

- ✓ Slope failure is dictated by the tensile strength of geotextile rather than by pullout when geotextile is intersected by the failure surface.
- ✓ Failure of the centrifuge models was characterized by shear surfaces and initiated at midheights of the slopes.
- ✓ PIV is an efficient tool to instrument the slope failures in a geotechnical centrifuge.

ABSTRACT

Geomembranes are one of the commonly used geosynthetic in landfill cover systems. Even though, geomembranes are widely used as a part of composite barriers in landfill cover systems, studies pertaining to its behavior at the onset of differential settlements are very limited. Considering the advantage of centrifuge modelling technique to achieve identical stress-strain behavior in model and prototype, centrifuge modelling technique was adopted in the present study to examine the deformation behavior of geomembrane at the onset of differential settlements. Two types of geomembranes with different thicknesses and tensile stiffness were modelled. The stiffness of geomembranes was found to have significant influence in the deformation behavior of composite barriers. The upward or downward thrust exerted by the geomembrane on the clay barrier was more for stiffer and thicker geomembrane. The mobilization of downward thrust exerted by the deformed geomembrane layer in a composite barriers acts like a fictitious overburden pressure and helps in maintaining sealing efficiency of clay-based composite covers. The downward thrust exerted by geomembrane on barriers suppresses the formation of cracks due to differential settlements.

1. INTRODUCTION

In modern landfills, geomembranes (GM) are considered to be one of the most commonly used geosynthetic in landfill construction and are laid above the clay barrier of cover systems. The geomembranes used in landfill covers must be able to withstand substantial strains due to settlement of the waste and must resist penetration by construction equipment, rocks, and roots. High-density polyethylene (HDPE), linear low-density polyethylene (LLDPE), polypropylene (PP) and polyvinyl chloride (PVC) are the most common materials for GM in final covers. LLDPE geomembranes have greater ability to maintain their integrity under localized differential settlements without puncturing, tearing, or cracking than HDPE geomembranes; because of their flexibility, higher tensile break elongation, higher puncture resistance and particularly suitable to landfill cover applications (Scheirs, 2009; Islam et al. 2011).

Geomembranes are generally available in 6 - 15 m roll widths, making field seaming a very large endeavour. The seams should obviously not leak, but in addition, they should also be physically strong and maintain their integrity over a long period of time. Quality-control testing is typically performed on geomembrane barriers after installation to verify the integrity of the installed GM overlying clay barriers (composite barriers). Regardless of all the precautions taken while manufacturing, transportation, handling, storage and installation; defects in geomembranes in the form of wrinkles, holes, installation defects particularly at seams are widely reported (Rowe, 2005; Bouazza and Vangpaisal, 2006; Take et al. 2007). The main property of a seam is that it must ensure a continuous seal between two geomembrane sheets to prevent liquid or gas to escape through the impervious layer installed in landfills. Consequently discontinuity, unbonded areas and lack of adhesion between the geomembrane sheets must not be found within a seam (Rollin and Fayoux, 2005).

Differential settlements of landfill covers are inevitable in municipal solid waste landfills due to the biodegradation and settlement of underlying waste (Reddy et al. 2009; Sivakumar Babu et al. 2010) and in low level radioactive landfills due to the toppling of cover due to the voids present between waste containers (Gourc et al. 2010). Differential settlement studies of clay barriers have been reported by several investigators by performing full-scale model tests and centrifuge model tests (Jessberger and Stone, 1991; Scherbeck and Jessberger, 1993; Viswanadham and Jessberger, 2005; Gourc et al. 2010; Rajesh and Viswanadham 2011). Zhu et al. (2009) reported the differential settlement and degree of wrinkling in a geomembrane around a circular structure. The studies pertaining to the deformation behavior of composite barriers subjected to differential settlements in a centrifuge are very limited. Very recently, Divya et al. (2012) reported the influence of intact geomembrane layer on the hydro-mechanical behavior of landfill covers by varying thickness of the clay barrier by performing centrifuge model tests.

Centrifuge model tests were used to study the deformation behavior of barriers in the present study due to the practical difficulties and time delay in performing full-scale model tests and also due to the limitations of reduced scale model tests for simulating stress dependant phenomena. Hence, the motivation behind this study is primarily to evaluate the deformation behavior and sealing efficiency of composite barriers subjected to differential settlements in a geotechnical centrifuge. In the present study, an attempt has been made to study the influence of geomembrane stiffness on the

performance of composite barriers at the onset of differential settlements. However, the influence of stiffness of geomembrane was studied only using seamed low stiffness geomembrane. Centrifuge model test with low stiffness and continuous geomembrane is beyond the scope of this paper.

2. CENTRIFUGE MODEL TESTS

2.1 Centrifuge Equipment

A 4.5 m radius large beam centrifuge available at IIT Bombay was used for conducting centrifuge model tests. The centrifuge capacity is 2500 kN with a maximum payload of 25 kN at 100 g and at higher acceleration of 200 g the allowable payload is 6.25 kN. Centrifuge modeling technique was essential in the present study to simulate identical stress conditions in the model barrier as that of in the prototype. This can be achieved by subjecting a model reduced by 1/N to N times acceleration due to gravity in a controlled environment (where N = scale factor or g-level). The centrifuge model tests reported in the present study were conducted at 40 gravities (N = 40).

2.2 Model Geomembranes

Model geomembranes were selected from a number of commercially available polyethylene sheets by measuring their thickness (ASTM D6988) and by conducting tensile tests following the sample dimensions and procedure outlined in ASTM D6693. Two model geomembranes were selected with different thickness and stiffness. The stiffer geomembrane is referred herein as GM1 and weaker geomembrane as GM2. The thickness (t_{mg}) of GM1 is 0.135 mm and of GM2 is 0.05 mm in model dimensions. The thickness of the selected geomembranes GM1 and GM2 correspond to 5.4 mm and 2 mm thickness in the prototype respectively, at 40 gravities. The scaling considerations for modelling geomembranes were explained in Divya et al. (2012). Based on the scaling considerations for geomembranes, linear dimensions of the geomembrane (length and thickness of the geomembrane) and the tension developed in the geomembrane per unit width are to be reduced by 1/N times that of corresponding prototype values. The value of initial stiffness for GM1 is 480 kN/m and for GM2 is 280 kN/m in prototype dimensions at 40g. The ultimate tensile stress (kN/m²) for GM1 was 28148 kN/m² and ultimate tensile strain (%) was 450%. The corresponding values for GM2 were 21569 kN/m² and 52%.

2.3 Barrier Soil

Model clay barrier material was selected in such a way that it represents the bandwidth of properties of clay used in landfill covers (Benson et al. 1999). Out of the various combinations tried, a blend of kaolin and sand in the ratio of 4:1 (i.e. 80:20) by dry weight was selected as a model clay barrier material. The liquid limit of the model soil was 38% and plasticity index was 16%. The maximum dry unit weight was 15.9 kN/m³ and the corresponding OMC was 22% (according to standard Proctor compaction). Average value of coefficient of permeability of the model soil barrier at maximum unit weight and optimum moisture content was found to be 4.39×10^{-9} m/s and at 5% wet of optimum, it was found to be 4.23×10^{-9} m/s. The value of coefficient of permeability of the model barrier material is well within the range usually adopted for constructing barriers.

2.4 Model Test Package and Test Procedure

A strong box with front side made with Perspex sheet and back and rear side made with well machined stainless steel plates with stiffeners was used to prepare the model composite barrier. The dimensions of the strong box were 720 mm in length, 450 mm in breadth and 440 mm in height. Motor based differential settlement simulator (MDSS) was used to induce the settlements at 1 mm/min to the model barrier. A settlement rate of 1 mm/min at 40 g is equivalent to 36 mm/day in the field. This settlement rate may not be realistic when projected to the prototype dimensions but to some extent these settlement rates represent localized depressions and or sudden collapse of waste container or ground subsidence in waste disposal sites (Qian et al. 2002; Keck and Seitz, 2002; Gourc et al. 2010). The details of the MDSS system were explained by Rajesh and Viswanadham (2009). It works on a simple mechanism in which the rotational movement of the motor shaft is converted to translational movement of the central platform through a screw jack and series of gears. The MDSS system consists of a central support system and two side support system on either sides of central support system with a hinged plate resting on central support system symmetrically. Figure 1 shows the model test package used in the present study for carrying-out centrifuge tests.

A thin layer of white petroleum grease was applied to reduce the friction and adhesion between the inner walls of the container and soil layers. Model clay barrier of 15 mm (0.6 m) was prepared on top of pre-drained 30mm coarse sand layer followed by 30mm fine sand layer and separated by thin filter papers. These layers are used to induce smooth continuous differential settlements to the overlying barrier and to avoid stress concentration at the onset of differential settlements. They are referred herein as sacrificing layers. After the clay barrier of required thickness was prepared, geomembrane was placed on the top without any wrinkles. Water tight seal made-up of a thick bentonite paste was

applied all along the sides of the clay barrier and thereafter bunds were constructed along the sides to retain water during centrifuge tests. It also helps to simulate the lateral extent of the geomembrane (i.e. geomembrane covering large areas) in the field. Discrete markers were embedded 5mm below the top surface of the model clay barrier at 20mm centre to centre and also on the geomembrane.

Figure 1. Model test package for centrifuge tests

The availability of an intact geomembrane layer covering large area of landfill is not practical. Geomembranes are available to a maximum roll width of 10 m. There are different techniques used for seaming of the joints like welding, use of adhesives, chemical fusion etc. The seamed joints can act as continuous geomembrane, if properly seamed. However, there can be a possibility of slippage or tearing at joints especially when the landfill cover is subjected to differential settlements. Subsequently, this leads to reduction in actual stiffness of the geomembrane.

In the present study, an attempt has been made herein to study the effect of seams (or stiffness) on the sealing efficiency of composite barriers. Also, the influence of stiffness of geomembranes on the deformation behaviour of composite barriers was also addressed. The model geomembrane sheet was cut in to 8 pieces and an overlap of 10 mm was provided such that the centre to centre distance of each GM piece is 90mm, as shown in Fig. 2. This was done to have one of the overlaps exactly along the hinge axis of the differential settlement simulator. The geomembrane sheets were overlapped in the laying direction and the joints were sealed with bentonite paste. The geomembrane type was varied, keeping the thickness of the clay barrier, overlapping of geomembrane sheets and overburden pressure as constant (Model: DCL9). The details of model preparation with intact or continuous geomembrane and its deformation behaviour are explained in Divya et al. (2012).

An overburden of 25kN/m^2 was induced with the help of fine sand layer of 27mm thickness at a dry unit weight of 15kN/m^3 and a calculated quantity of water was added so that it forms 10mm free standing water on the sand surface. Various sensors, like pore water pressure transducers (PPTs) to measure leakage through the model composite barrier and linear variable differential transformers (LVDTs) to obtain deformation profiles of the composite barriers at the onset of differential settlements were used in the present study. One digital photo camera was mounted along with the model

to view the front elevation which helps to monitor the crack development across the barrier. Also, a CCD video camera was placed on the top, to view the portion of top surface of the model and to register the depletion of water level retained on the top of the barrier during the centrifuge test. The centrifuge tests were conducted by maintaining a constant angular velocity of 93 revolutions per minute (rpm) so that 40 gravities were maintained within the clay barrier. A maximum central settlement a_{max} of 25 mm was induced which corresponds to 1 m in prototype dimensions. After attaining a maximum central settlement of 25mm, motor of MDSS was turned off and then centrifuge was initiated to stop. Differential settlement may be characterized by the distortion level a/l , which is defined as central settlement a , over a horizontal distance l where the settlement becomes negligible or by settlement ratio a/a_{max} . Limiting distortion level a_{lim}/l is defined herein as the ratio of central settlement at which a drastic change in water volume above barrier was observed to the influence length l . In the present study an influence length l of 200mm in model dimensions was used.

3. ANALYSIS OF TEST RESULTS AND DISCUSSION

The co-ordinates of the markers on the geomembranes were obtained after performing digital image analysis of the photographs of front elevation of model composite barriers captured by the front digital photo camera at different settlement stages. Coordinates of the pre-determined permanent markers were used to standardize the image to be digitized. The error involved in digitizing the permanent markers i.e., standardizing the image can be obtained from the GRAM++ software (GRAM++, 2004). Once the error is within the tolerable limit (kept as $\pm 0.055\text{mm}$, for all the images and for all centrifuge tests), digitization of the discrete markers i.e. markers embedded on soil and markers glued on

geomembrane was carried-out. A deformation profile was fitted for the marker positions at various central settlement values. Strain distributions along the geomembrane layer at the onset of differential settlement was computed using the combined bending and elongation method proposed by Tognon et al. 2000 for geomembranes. Strain in the geomembrane along its length was computed by using $\epsilon_g(x) = \epsilon_{lg}(x) \pm \epsilon_{\kappa g}(x)$. The elongation strain $\epsilon_{lg}(x)$ in the geomembrane was obtained from the deformation profile of geomembrane, $w_g(x)$ as $[(1 + [w_g'(x)]^2)^{1/2} - 1]$. The curvature strain in geomembrane $\epsilon_{\kappa g}(x)$, was obtained from the neutral layer coefficient $R_g = 1/2$, curvature of geomembrane $\kappa_g(x)$ and thickness of geomembrane t_g as $R_g \cdot \kappa_g(x) \cdot t_g$, where x is the horizontal distance from center of the composite barrier. The curvature strain in geomembrane was negligible due to small thickness of geomembrane.

Further by using: (i) computed strain distributions along the geomembrane layer and (ii) the curvature of the deformed geomembrane layer and (iii) stiffness of the GM, the vertical thrust exerted by the geomembrane layer in the cover system was calculated by using membrane theory (Espinoza, 1994). The thrust distribution is calculated as $q_g(x) = J_g \cdot \epsilon_g(x) \cdot \kappa_g(x)$. Where, J_g is the stiffness of geomembrane in kN/m and this was obtained from the tensile load-strain curve of geomembrane GM1 and GM2 used in the present study. Figure 3 shows the typical variation of $\epsilon_g(x)$ and $q_g(x)$ along the horizontal distance from the centre of the composite barrier.

a) Geomembrane strain $\epsilon_g(x)$

b) Thrust exerted by the geomembrane $q_g(x)$

Figure 3. Typical variation of $\epsilon_g(x)$ and $q_g(x)$ along the composite barrier for model DCL6.

The variation of maximum downward thrust with distortion level a/l and settlement ratio a/a_{max} is shown in Fig. 4. The downward thrust, q_g exerted by geomembrane layer on the clay barrier at the zone of maximum curvature was found to increase with an increase in distortion level and the increase was more beyond a distortion level of 0.075 and settlement ratio of 0.6 and found to depend upon the stiffness of the geomembrane layer. It is clear from the curve that, the stiffness of geomembrane is an important parameter which decides the performance of composite clay barrier.

The value q_{gmax} for GM1 without any overlaps for model DCL6 is 23 kN/m² at distortion level of 0.125. This implies that a total downward thrust is of the order of 48 kN/m² (this includes overburden pressure of 25 kN/m² in the form of cover) is acting at the zone of maximum curvature of the clay barriers. For model DCL7 provided with similar type of geomembrane, GM1; but with seams the total downward thrust is around 45 kN/m². However, the value of q_{gmax} for model DCL9 provided with a weaker geomembrane GM2, was found to be relatively lower than GM1. This indicates that the stiffer geomembrane can exert more downward thrust on to the clay barrier surface at the onset of differential settlements.

Figure 4. Variation of maximum downward thrust exerted by geomembranes

The hydraulic performance of the composite barrier can be obtained by measuring the change in height of water inundated on the top of barrier using PPTs. Volume per unit width of water is obtained by performing the numerical integration of the area under measured water profile. The height of the water along the width of the container is taken as identical to the measured value at the mid width of the container. The total volume of water above the clay barrier is twice the volume of water computed for one-half sections, which is the product of volume per unit width of water to the width of the container. Ratio of initial volume of water v_0 and volume of water at any instance v_a to the initial volume of water v_0 is defined as the infiltration ratio IFR.

Figure 5 shows the variation of infiltration ratio with distortion level and settlement ratio for composite barriers with continuous and overlapped geomembranes. Based on the variation of infiltration ratio with distortion level registered for models DCL7 and DCL9, a limiting distortion level of the order of 0.09 - 0.1 was observed, as shown in Fig. 5, irrespective of the type of geomembrane and the corresponding strain at breakthrough, ϵ_b was of the order 1.54-1.6%. The limiting distortion level was determined by back tangent method from the curve showing the variation of infiltration ratio with distortion level and settlement ratio. This indicates that the presence of seams along the length of the geomembrane (especially at the zone of the maximum curvature) can affect the sealing efficiency of a clay-based landfill composite covers.

Further, in order to understand the relative displacements of geomembrane seams provided at the zone of maximum curvature (i.e. at hinge axis) or in the tension zone, displacement vectors of markers on either side of hinge axis with and without geomembrane overlaps were compared for different settlement stages. Figure 6 presents variation of $(\Delta s/s)$ with a/l and a/a_{max} . As shown in the inset of Fig. 6, the distance between two markers is s mm initially at $a/l = 0.0$ at 40g. Subsequently, with an increase in distortion level, distance between the same markers change to $(s+\Delta s)$ mm; wherein $(s+\Delta s)$ mm includes both horizontal and vertical component of distances. A very limited increase in $(\Delta s/s)$ was registered

for model DCL6 with increasing distortion level and settlement ratio. In the case of a geomembrane with overlaps or improper joints, an adequate care was taken while selecting markers stuck to geomembrane sheets. The value of $(\Delta s/s)$ for distortion level 0.1 and settlement ratio 0.8 correspond to only 0.045-0.048. However, a steep increase in $(\Delta s/s)$ with an increase in distortion level was noted for model DCL7. The value of $(\Delta s/s)$ for model DCL7 at distortion level of 0.08 is 0.135.

Figure 5. Variation of infiltration ratio with a/l and a/a_{max} for composite barriers

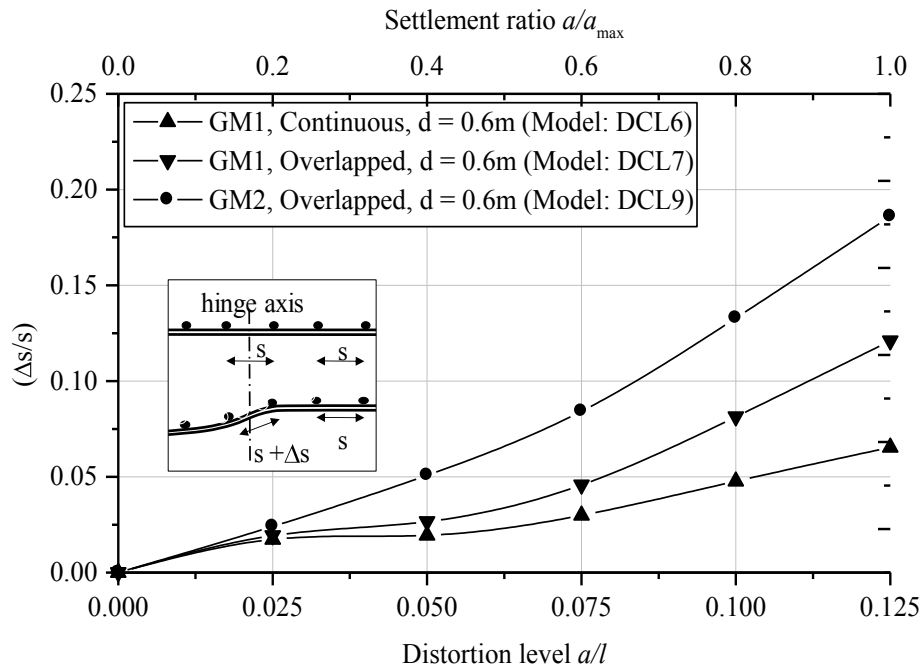

Figure 6. Variation of $(\Delta s/s)$ with a/l and a/a_{max} for barriers with continuous and seamed geomembrane

Even with a stiffer and thicker geomembrane, for a clay barrier provided with geomembrane overlaps the relative displacements in the tension zone are found to be clearly evident. This increase in $(\Delta s/s)$ for centrifuge models with

geomembrane resulted in an increase in infiltration ratio at the onset of a limiting distortion level $a_{lim}/l = 0.1$. However, till models are subjected to distortion level of 0.1, sealing provided by means of thick bentonite paste along geomembrane seams have restrained changes in infiltration ratio. Observations made during post-test investigation concur with the trend presented in Fig. 6 and can be clearly seen in Fig. 2b also. This explains the observed variation of IFR for model with weaker GM layer (GM2).

Figure 7 shows the cross-section of composite barriers at the end of centrifuge tests. The crack widths were increased in the case of composite barrier provided with overlapped geomembrane especially with weaker geomembrane compared to composite barrier provided with continuous geomembrane. The average crack width was 48 mm and 60 mm in prototype dimensions for barriers with overlapped GM1 and GM2 respectively. However with continuous geomembrane layer GM1, the crack widths were reduced to 36 mm. Though full-depth cracks were observed to occur in clay barriers, the presence of geomembrane helped in restraining catastrophic water breakthrough at the onset of differential settlements. Though catastrophic water breakthrough was not observed for composite barriers, full-depth cracks were observed to occur in clay barrier layer of composite barriers. Hence relying solely on the geomembrane presence to minimize crack formation in clay covers may be risky when defects in geomembranes occur. It will be interesting to explore the possibility of adoption of strengthening techniques to reduce the crack formation for clay barriers along with the provision of geomembranes which maintain the sealing efficiency of barrier at the onset of differential settlements.

4. CONCLUSIONS

Performance of composite barriers at the onset of differential settlements was studied by conducting a series of centrifuge model tests. Tests were also conducted using continuous geomembrane layer as well as seamed geomembranes. Two types of geomembranes with different stiffness were used. The analysis and interpretation of centrifuge test results indicate that observed response of a clay-based landfill cover with a geomembrane layer at the onset of differential settlement is attributed to the mobilization of downward thrust, q_g at the zone of maximum curvature. It was found to depend upon the stiffness of the geomembrane layer. It is very interesting to note that deformed geomembrane induces a downward thrust on the surface of the clay barrier. With an increase in distortion level the magnitude of downward thrust was observed to increase. This implies that the presence of geomembrane imposes a fictitious overburden on the surface of clay barrier of landfill composite cover subjected to differential settlements. This could be one of the reasons for not observing water breakthrough through the composite barrier at the onset of differential settlements and was found to sustain large distortion levels. The present study shows the significant influence of geomembrane in maintaining the hydraulic sealing efficiency of landfill cover system even after subjecting distortion level equal to 0.125. When seams are provided for the GM layer, the sealing efficiency of composite barriers was found to get affected after attaining a distortion level of 0.1.

Cleveland Harbor, Ohio Interim Dredge Disposal Plan: Geotextile Reinforcement of Placed Dredge Fill

Eugene N. Lenhardt, P.E., U.S. Army Corps of Engineers (Buffalo District),
Eugene.n.lenhardt@usace.army.mil

ABSTRACT

The available capacities of the Cleveland Harbor confined disposal facilities (CDFs) are reaching the point where hydraulic placement of dredged material is no longer feasible and will reach the minimum 2 foot containment free-board by the end of 2014. A new disposal facility will not be available until at least 2018. Therefore, in order to provide interim dredge material disposal capacity from 2015 - 2018 the existing CDFs will require dredged material to be stacked in the facilities above the original containment dike crest height. Imposed loading from the stacked dredged fill has raised some global stability concerns. A number of alternative stabilization schemes were investigated including the use of geotextile reinforcement in combination with wick drains. This presentation/paper discusses the results of the engineering analysis performed using geotextile reinforcement as part of a stabilization method.

1. INTRODUCTION

The U.S. Army Corps of Engineers (USACE), Buffalo District dredges the Cuyahoga River in Cleveland, Ohio on an annual basis to maintain adequate depth for commercial shipping. These dredged sediments are not suitable for disposal in Lake Erie and are required to be placed in a confined disposal facility (CDF). The sediments are mechanically dredged into scows, transported to the CDF, and ultimately placed by hydraulic method. At the present time there are three disposal facilities available for disposal of dredged sediments in Cleveland Harbor. These facilities are identified as CDF 9, CDF 10B and CDF12 with locations shown in Figure 1.

The available capacity of the CDFs are reaching the point where hydraulic placement of the dredged material is no longer feasible and will reach the minimum 2 foot free board by the end of the 2014 dredging season. A new disposal facility will not be available until at least 2018. In the interim period 2015-2018, it is proposed to stack dredged material by mechanical means in each CDF above the original crest height of +14 ft (4.3 m) above low water datum (LWD) for CDF 10B and CDF 12 and +12 ft (3.7 m)LWD for CDF 9.

The stability of the CDFs' perimeter rubble mound containment dikes is of critical importance to insure public safety and to insure that dredge sediments placed in the CDFs do not spill into Lake Erie. A geotechnical stability analysis was performed to determine the effects of stacking dredge material above the original CDF containment dike crest height with respect to over all global stability and local (internal) stability. Several alternative stabilization measures were investigated including the use of geotextile reinforcement in combination with foundation wick drains. The remainder of this presentation centers on the geotechnical analysis performed using geotextile reinforcement to obtain a stable stacked fill configuration for each CDF.

Figure 1 - Confined Disposal Facility (CDF) Locations

2. DREDGE MATERIAL STACKING OPTIONS

Approximately 1,000,000 (765,000 m³) cubic yards (CY) of dredged material will be placed in the CDFs for the years 2015-2018. CDF 9 is located on property owned by the City of Cleveland and CDF 12 is located on property owned by the Cleveland Port Authority. CDF 10B is currently owned by the U.S. Army Corps of Engineers. To cover any potential problems with respect to obtaining lease agreements with the city of Cleveland or the Cleveland Port Authority for CDFs 9 and 12 various stacking options were investigated based upon assumptions made with respect to the availability of the aforementioned CDF properties.

2.1 Option No.1 (CDFs 9, 10B, and 12 Are All Available)

The assumption made for this option is that all three (3) CDF properties will be available for placement of 250,000 CY (191,000 m³) of dredge material annually. Splitting the annual dredge quantity between each of the 3 CDFs and considering the aerial space available in each CDF results in a final dredge fill stack height of +20 ft (6.1 m) LWD at the

end of year 2018. These results include maximum dredge fill heights of 6 feet (1.8 meters) for CDF 10B and CDF 12 and 8 feet for CDF 9.

2.2 Option No.2 (CDF 12 No Longer Available, Placement in CDFs 9 and 10B)

The assumption made for this option is that a lease from the Cleveland Port Authority could not be obtained for CDF 12 therefore, the annual dredge quantity of 250,000 CY (191,000 m³) will be split between CDF 10B and CDF 9. This results in a stacked dredged fill height of +24 ft (7.3 m) LWD at the end of year 2018 or maximum fill heights above the original CDF crest elevations of 10 feet (CDF 10B) and 12 feet (CDF 9).

2.3 Option 3 (CDF 9 and CDF 12 No Longer Available, Place in CDF10B and Upland Landfill)

The assumption made for this option is that a lease from the City of Cleveland could not be obtained for CDF 9 nor a lease obtained from the Port Authority for CDF 12. The annual dredge quantity of 250,000 CY will be split for placement into CDF 10B and an unspecified upland landfill. At the end of year 2018 the dredged fill in CDF10B will be stacked to +28 feet LWD or 14 feet above the original CDF crest height.

2.4 Option 4 (CDF 9 and CDF 12 No Longer Available, Place All 1,000,000 CY into CDF 10B)

The assumption made for this option is to place all 1,000,000 CY (765,000 m³) for the years 2015-2018 into CDF10B. The maximum dredge fill height at the end of year 2018 is dependent upon the stacked fill height that is geotechnically stable which is estimated to be +44 feet (13.4 m) LWD.

3. FAA RESTRICTIONS (BURKE LAKEFRONT AIRPORT)

Burke Lakefront Airport is located immediately adjacent to CDFs 9, 10B, and 12 (Figure 1). The Federal Aviation Administration (FAA) mandates airspace restrictions around the runways for aircraft safety. These restrictions complicate the stacked dredge filling operations in that the dredge fill stack heights cannot exceed the FAA safety restrictions and must be placed within a vertical prism established by the FAA. Thus, as a result of these restrictions only part of the CDF foot print is available for the stacking of dredged fill.

4. SUBSURFACE CONDITIONS

The CDF rubble mound containment dikes are founded on the Lake Erie bottom sediments which have a top layer that consists of about 9 feet (2.7 m) of very soft organic silt (OL, Unified Soils Classification System) and Silty Clay (CL). Underneath the recent deposits are stiffer glacial lake deposits consisting of grey medium stiff to stiff Silty Clay (CL) with embedded pebbles. The stacked dredged fill will be placed on previously placed hydraulically dredged fill of variable composition consisting of very loose silty sand (SM), very soft organic clay (OH) and Silty Clay (CL,CH). The previously placed dredged fill material composition varies within each CDF depending upon where the hydraulic dredge discharge pipe was located. Coarser material (sand, gravel) is located near the outlet of the pipe while finer grained material settles out with distance from the end of the pipe.

4.1 Subsurface Conditions CDF 12 and Foundation Problems in "S Curve" Area

Of the 3 CDFs, the foundation conditions along the south side of CDF 12 are the most problematic. Figure 2 is the boring plan and location of geologic soil profile A-A which is presented in Figure 3. As shown in this profile the underlying previously dredged fill and recent lake deposits consists of fine grained sediments classified as organic clay (OH), silt (OL), and clay (CH) with standard split spoon penetration resistances of 0 blows/ft.

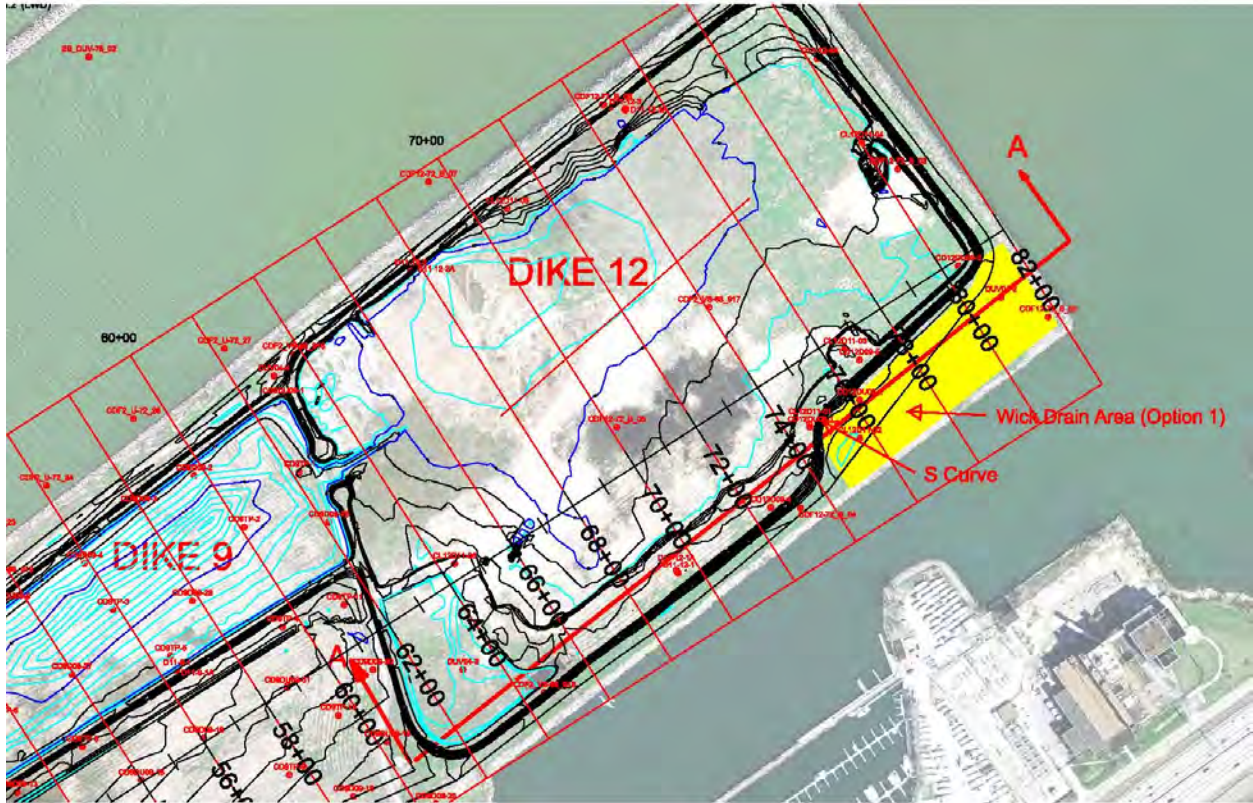

Figure 2 – Boring Plan CDF 12

To provide additional disposal capacity in CDF 12 a raised phase 1 dike was constructed in 2008. The phase 1 containment dike had a maximum crest elevation of +18 feet (5.5 m) LWD increasing the maximum potential capacity by 4 feet (1.2 m). Due to the poor foundation conditions along the south side of CDF 12 geotextile reinforcement was incorporated into the design of the containment dike. A typical section for this portion of the containment dike is presented in Figure 4 which shows that the geotextile reinforcement extended across the main portion of the containment dike and ended at the start of the flanking stability berms. During construction a portion of the south dike called the “S Curve” area experienced failure in which it appeared that the main dike and foundation had translated towards the center of the CDF and tension cracks formed at the toe of the main dike in the lake side stability berm. After the failure occurred test pits were dug into the phase 1 dike to determine the depth and location of the geotextile reinforcement. After the test pits were dug it was observed that the reinforcement had settled as much as 4 feet (1.2 m) from its initial placement location. The actual cause of the failure could not be determined but it is believed that if the reinforcement had been extended further out into the stability berm the failure may have been prevented.

Figure 3 – Geologic Profile A-A, CDF 12

Figure 4 – Phase 1 Dike Typical Section (S Curve Area)

Shown in Figure 5 are graphical plots of the laboratory undrained shear strengths and excess pore water pressures obtained from piezometers installed along the southern side of CDF 12 after the phase 1 dike construction was completed. The graphic plot reveals that the foundation undrained shear strengths decrease with depth varying from about 350 psf (16.8 kPa) near the water table (lake level +1.5 ft (0.5 m) LWD) down to 100 psf (4.8 kPa) at the original lake bottom (-18 ft LWD). Excess pore water pressures increased with depth from about 700 psf (4.8 kPa) near the lake

level to 1,450 psf (69.4 kPa) near the bottom of the recent lake deposits at about -25 ft (-7.6 m) LWD. The excess pore water pressures in the foundation are most likely due to the imposed loads from the phase 1 dike construction which reduces the effective stresses in the foundation and thus reduces the undrained shear strengths.

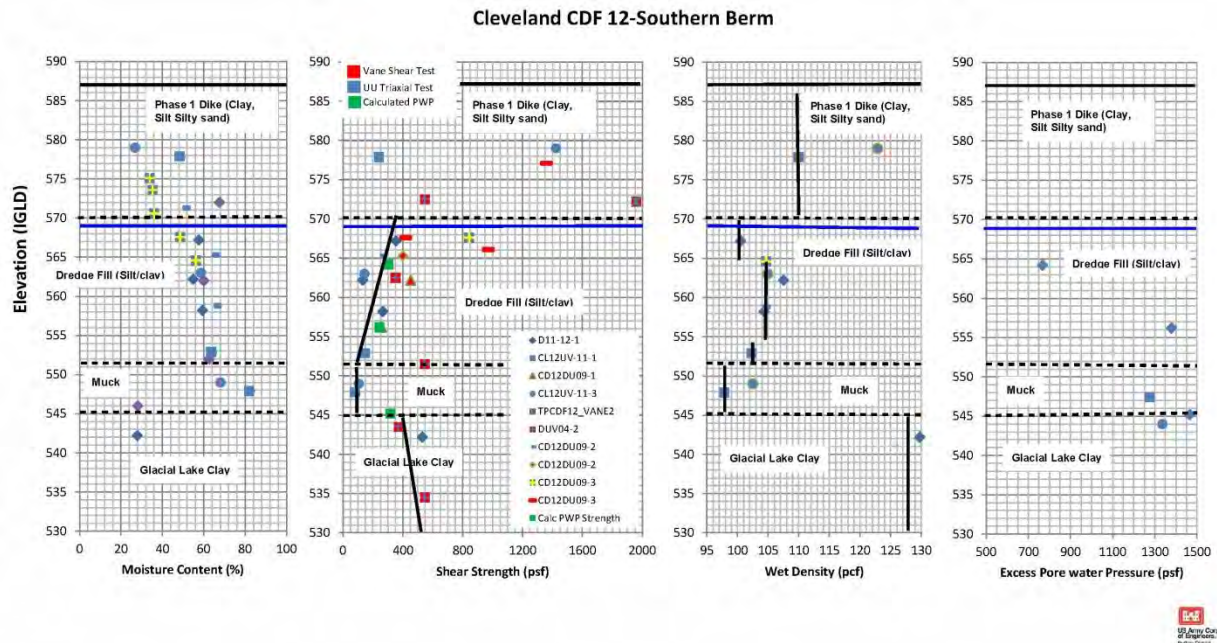

Figure 5 – Graphic Plot of Shear Strength, Moisture Content, Density and Excess Pore Pressures

5. CDF 9 PHASE 1 DIKE RAISING

In 2010 the CDF 9 was raised to +15 feet (4.6 m) LWD to provide additional dredge fill capacity. Prior to construction the ground surface was at +7feet to +9 feet (+2.1 m to +2.7 m) LWD. Thus the raised containment dikes varied from 6 to 8 feet (1.8 m to 2.4 m) in height depending upon the preconstruction ground surface elevation. Considering the lessons learned from the CDF 12 S Curve Dike failure the geotextile reinforcement was extended further out into the stability berms to force the failure to go around the fabric. The fabric was extended until the critical failure surface met an acceptable factor of safety of 1.4 (disposal side) and 1.5 (airport runway side). Presented in Figure 6 is the stability section for the south containment dike (airport runway side) which shows the critical failure surface, computed factor of safety of 1.508, and geotextile reinforcement. During construction and up until the present time there has been no evidence of any failure of these containment dikes despite similar foundation shear strengths as the CDF 12 S curve area. Thus, it appears that this design approach worked for CDF 9 Phase 1 dike raising.

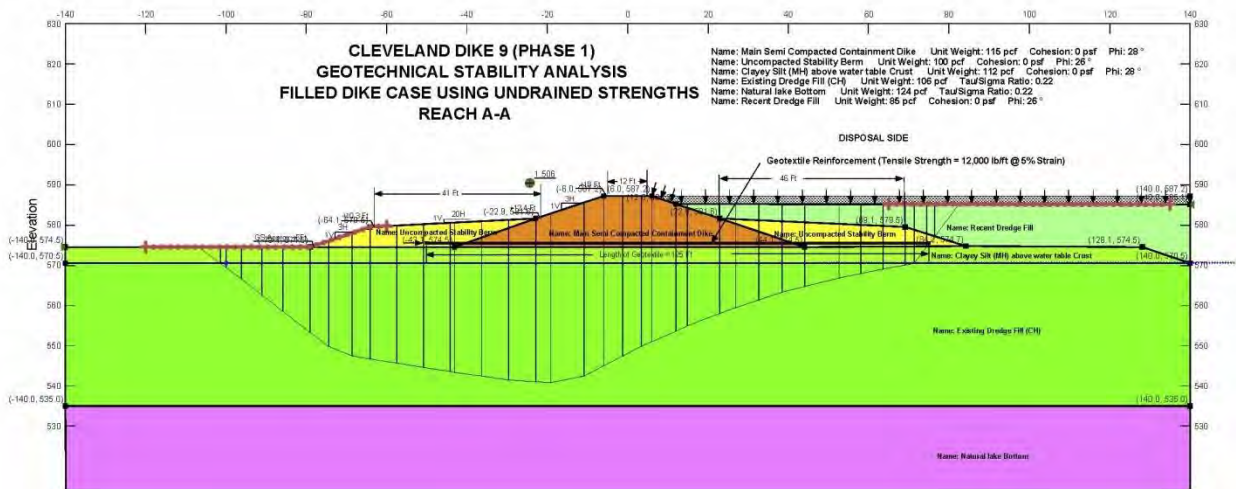

Figure 6 – CDF 9 Geotextile Reinforcement Stability Section

6. GEOTEXTILE REINFORCEMENT DESIGN APPROACH FOR 2015-2018 DREDGE STACKING

The 2015-2018 option No.4 alternative plan (all 1,000,000 CY (765,000 m³) of dredge fill placed in CDF 10B) results in the highest stacked fill height (to +44 ft (13.4 m) LWD) of all of the alternative options. Thus, this option requires the most extensive use of geotextile reinforcement and wick drains. The focus of the remainder of this presentation is the geotextile design approach used for this option. The other options also include geotechnical reinforcement at CDFs 9 and 12 but are not as extensive as the reinforcement used in CDF 10B.

6.1 Wick Drain Design CDF 10B

A cost effective method to improve the foundations undrained shear strength is to install vertical wick drains. Wick drains alleviate excess pore water pressures, increase the foundation effective stress and, therefore increase the undrained shear strength. A vertical wick drain system requires the installation of a drainage pad to transport water collected by the wick drain away. The amount of excess pore water pressure to be dissipated by the wick depends on the elevation of this drainage pad with respect to static water level (i.e. lake level). Since the ground surface in the in each of the CDF's will be above lake level after hydraulic dredging ends in 2014 (+12 ft to +16 ft or +3.7 m to +4.9 m LWD), the wick drains will have limited capability in reducing excess pore water pressures as the drainage pad would have to be placed above these elevations. Thus, full dissipation of excess pore water pressures is not possible using wick drains. However, by placing surcharge fill or by controlling the rate of dredge fill stacking the recovery of excess pore water pressures in the foundation induced by the fill will increase effective stress and thus increase shear strength.

To sufficiently increase the foundation undrained shear strengths as a result of implementing a wick drain system, specific drain pattern spacing is required in order to obtain the necessary consolidation.

The required drain spacing was determined using the computational procedure contained in Federal Highway Administration Report FHWA/RD-86, August 1986. The coefficient of consolidation and permeability of the dredge fill was obtained from laboratory consolidation tests performed as part of this study. Results of the wick drain analysis using the above referenced computational procedure requires a drain spacing of about 10 feet (3.1 m) to obtain the required strength gain and consolidation within a 1 year period. The estimated foundation strength gain was then input into the Slope/W computer model as a spatial strength function to determine the factor of safety against failure of the containment facility as a result of the imposed loads from the stacked dredged fill.

6.2 Geotextile Reinforcement Design CDF 10B

There are several references available for designing geotextile reinforcement for embankments built on soft foundations. The following two references were used for the design of geotextile reinforcement for the Cleveland CDFs: (a.)

“Geosynthetic Engineering”, Robert D. Holtz, Barry R. Christopher and, Ryan R. Berg, 1997 AND (b.) Army Technical Manual TM 5-818-8, “Engineering Use of Geotextiles”, July 1995. Both of these publications outline three possible modes of embankment failure and required stability analysis required for the design of geotextile reinforcement:

1. Bearing Failure
2. Rotational Failure
3. Lateral Spreading

The focus of this presentation is on the rotational aspect of potential foundation failure. The computer software model Slope/W (Geoslope International, Ltd) was used as the computational tool for designing the geotextile reinforcement for this mode of failure. This computer model uses limit equilibrium analysis to determine the factor of safety against failure and determines the required geotextile strength (tensile) and anchorage embedment requirements needed to obtain the minimum required factor of safety against failure. The computer model has two alternative methods on how the geotextile reinforcement is included in the stability calculations by flagging a check box option for the reinforcement as “factor of safety Dependent”, Yes or No. If the selection option is “No”, then the reinforcement forces used in the analysis are *allowable* forces and are not divided by the factor of safety calculated during stability analysis. If the selected option is “Yes” then the reinforcement forces used in the analysis are *ultimate* forces, and are divided by the factor of safety calculated in the slope stability analysis. The “No” option was used in this analysis which means that the specified tensile strength used in the computer model is the allowable strength. In addition to the allowable strength a limiting strain is specified for the geotextile that is compatible with the foundation strain developed under the mobilized shear forces. This strain was selected to be 5% as appropriate which is the limiting tensile force divided by the geotextile secant modulus (E_s).

When using the Slope/W computer model to design the geotextile reinforcement either of the two following components control the calculated resisting forces and thus computed factor of safety: (a.) Geotextile anchorage or bond resistance to prevent fabric pullout, (b.) Tensile strength of fabric to resist driving forces. In Slope/W the required bond length is indicated by a red box around the reinforcement. Graphically, if the red box occurs within the lateral extent of the fabric and behind the critical failure surface then the fabric tensile strength controls the computed factor of safety. If the factor of safety is less than the minimum required then the fabric tensile strength would have to be increased until an acceptable factor of safety is obtained. If the red box occurs at the end or beyond the lateral extent of the fabric then bond resistance controls the factor of safety. In this case the resisting fabric force is limited to the computed bond resistance in the stability calculations. If the factor of safety is less than the required minimum then the fabric bond length has insufficient anchorage and must be increased until an acceptable factor of safety is obtained. Another aspect to consider in designing the geotextile reinforcement is the potential for failure around the lateral extent of the fabric. This is what may have occurred at the CDF 12 S curve containment dike failure. The design only considered resistance offered by the fabric strength but did not consider the potential that failure could occur around the fabric. Evidence of this is the development of tension cracks just beyond the lateral extent of the fabric. The CDF 9 Phase 1 Dike raising and the current 2015-2018 stacking geotextile design considers this aspect of design and extended the fabric out until suitable factors of safety of the critical failure surface around the fabric was obtained.

Figure 7 shows the location of the CDF10B option No.4 dredge fill stack fill stacking to +44 ft (13.4 m) LWD using geotechnical reinforcement for stabilization. Note that wick drains are used in combination with the reinforcement to provide the necessary stabilization. The use of wick drains as opposed to geotextile reinforcement is more cost effective (\$7.50/SY or \$8.97/m²) installation as opposed to \$15.00/SY or \$17.95/m²) and thus would be the preferred alternative. However, wick drains have a time component associated with their application. Wick drains are used to consolidate the underlying soft fine grained foundation which increases the foundation effective stresses and thus undrained shear strength. However, the consolidation process is a time dependent process with the length of time dependent upon the wick drain spacing. Even with controlled rate of filling (staged construction) practical use wick drains would require a minimum of several months of consolidation to occur until the foundation has gained sufficient strength needed to support the imposed stacked loads. Therefore geotextile reinforcement is necessary in order to provide stability until the wick drains provide enough consolidation and thus foundation strength gain needed to support the imposed stacked fill loads. The CDF 10B Option 4 (Fill to +44 ft or +13.4 m LWD) design analysis indicated that 4 layers of high strength geotextile reinforcement (allowable tensile strength of 14,500 lbs/ft (210 KN/m) at 5% strain) was needed until the stack fill height reached a height of +24 ft (7.3 m) LWD after which enough foundation consolidation and strength gain was obtained by using wick drains to support the final stacked fill height of +44 ft (13.4 m) LWD. A final design cross showing the lateral extent of the wick drains and the geotextile reinforcement is shown in Figure 11.

7. CONCLUSIONS

The available capacity of the Cleveland CDFs are reaching the point where hydraulic placement of the dredged material is no longer feasible and will reach their original intended capacities by the end of 2014 . A new disposal facility will not

be available until at least 2018. In the interim period 2015-2018 it is proposed to stack dredge material by mechanical means in each CDF above their original design crest heights. Stacking this fill raises concerns with respect to both internal and global stability of the original rubble mound containment dikes. The application of geotextile reinforcement in combination with wick drains was investigated to obtain a stable configuration of the rubble mound containment dikes. A previous raising of CDF 12 in 2008 used geotextile reinforcement. However, failures occurred in the "S Curve" area where very weak fined grained dredge fill foundation and Lake Bottom occurs. It appeared that this failure may have occurred around the lateral extent of the geotextile reinforcement. The design analysis only considered the resistance offered by the fabric strength but did not consider the potential of failure around the fabric. Tension cracks that developed beyond the lateral extent of the fabric provide possible evidence of failure around the fabric. CDF 9 was raised in 2010 in similar fashion but as a lesson learned from the CDF 12 failure designed the fabric considering this aspect of design. To date results of this design approach have been positive with no noted failures occurring during construction up to present time.

When using computer models such as Slope/W or any other similar type limit equilibrium computer models to design geotextile reinforcement, 3 design aspects must be considered: (1.) Fabric must have enough tensile strength to prevent failure thru the fabric, (2.) The fabric must have enough anchorage or bond length to prevent pull out from driving loads and, (3.) the fabric must be extended enough to force the failure around the fabric until a sufficiently high factor of safety is obtained. This same design approach was used in the current dike stacking design analysis.

The use of wick drains to stabilize the stacked fill is the most cost effective and preferable method of stabilization. However, wick drains have a time component associated with their use. Wick drains are used to consolidate the soft fine grained foundation which increases the foundation effective stresses and thus shear strength. However, the wick drains need to be in place for at least several months before the foundation gains enough strength to be able to support the imposed stacked fill loads by themselves. In order to provide stability in the interim geotextile reinforcement is needed. Thus the combination of wick drains and geotextile reinforcement was used in the current analysis to stack dredge fill for the Cleveland 2015-2108 disposal period.

Comparative Evaluation of Different Aperture Geogrids for Ballast Reinforcement through Triaxial Testing and Discrete Element Modeling

ABSTRACT

Geogrids are commonly used in transportation applications for stabilization and reinforcement due to their higher tensile strengths compared to geotextiles as well as the stiffness improvement they provide through arresting and interlocking granular particles in the geogrid apertures. Influenced by many factors, such as the aperture shape and size of geogrid, the degree of interlocking contributes significantly to the reinforcement benefit of geogrid for improving the performance of any geogrid reinforced system. This paper describes recent research efforts at the University of Illinois focused on conducting permanent deformation testing of geogrid reinforced ballast specimens using a large-scale triaxial test device. As part of the very preliminary evaluations, two different geogrids with rectangular and triangular aperture shapes were studied for reinforcement benefits of cylindrical specimens compacted and prepared with uniformly graded ballast sized aggregate materials. To further investigate the geogrid reinforcement mechanisms, an aggregate image-aided numerical modeling approach based on Discrete Element Method (DEM) was also adopted with the capability to create actual ballast aggregate particles as three-dimensional polyhedron elements having the same particle size distributions and imaging quantified average aggregate shapes and angularities. Preliminary results from both laboratory experiments and DEM simulations indicated that geogrids with triangular apertures performed more effectively in arresting particle movements through improved interlock.

1. INTRODUCTION

Geogrids are geosynthetic polymeric materials having large openings, i.e. apertures. They have been successfully used for decades in highway pavement applications, e.g., subgrade stabilization and base reinforcement. Geogrids have also been used in railroad track structures for stabilization and reinforcement purposes, especially for ballast reinforcement. Ballast is an essential layer of the railroad track structure, primarily provides drainage and load distribution. The benefit of geogrids in railway applications mainly comes from the interlocking between ballast particles and the geogrids. The degree of interlocking between geogrids and aggregate particles depends upon many factors, such as: aggregate gradation and shape properties, geogrid types and properties, compaction effort during installation, and loading conditions. Large scale triaxial tests or cyclic plate loading tests have been traditionally performed in the laboratory to evaluate the individual effects on the ballast behavior (Suiker et al. 2005, Brown et al. 2007, Anderson and Fair 2008, Aursudkij et al. 2009, Indraratna et al. 2010). Rectangular aperture geogrids with tensile strength properties in both machine and cross-machine directions have been commonly studied and recognized as useful materials that can effectively reduce the permanent deformation accumulation in the ballast under repeated loading (Bathurst and Raymond 1987, Shin et al. 2002, Raymond and Ismail 2003, Indraratna et al. 2006, Brown et al. 2007, Qian et al. 2011a). Recently, geogrids with triangular aperture shapes have also been introduced and studied for performance improvements of geogrid reinforced transportation systems (Qian et al. 2011b, Qian et al. 2012).

This paper describes preliminary findings from a research study recently initiated at the University of Illinois with the objective to conduct permanent deformation testing of geogrid reinforced ballast specimens using a large scale triaxial test device and model the micromechanical interlock behavior of geogrid-aggregate systems. Both rectangular and triangular aperture shaped geogrids were initially tested for permanent deformation behavior using a large scale triaxial testing device. To further investigate the geogrid reinforcement mechanisms, a numerical modeling approach based on Discrete Element Method (DEM) was also adopted with the capability to create actual ballast aggregate particles as three-dimensional polyhedron elements having the same particle size distributions and imaging quantified average shapes and angularities. This paper will present the laboratory test and the DEM simulation results for ballast specimens reinforced with the rectangular and triangular aperture geogrids under repeated loading.

2. REPEATED LOAD TRIAXIAL TEST OF BALLAST SPECIMENS

2.1 The University of Illinois Triaxial Ballast Tester (TX-24)

A large scale triaxial test device (The University of Illinois Triaxial Ballast Tester or TX-24) has recently been developed at the University of Illinois for testing specifically ballast size aggregate materials. The test specimen dimensions are 30.5 cm (12 in.) in diameter and 61.0 cm (24 in.) in height. The acrylic test chamber has dimensions of 61.0 cm (24 in.) in diameter and 122.0 cm (48 in.) in height. An internal load cell (Honeywell Model 3174) with a capacity of 89 kN (20 kips) is placed on top of the specimen top platen. Three vertical LVDTs are placed around the cylindrical test specimen at 120-degree angles between each other to measure the vertical deformations of the specimen from three different side locations. Another LVDT is mounted on a circumferential chain wrapped around the specimen at the mid-height to measure the radial deformation of the test specimen. Figure 1 shows the picture of a compacted and instrumented ballast specimen assembled inside the acrylic chamber ready to be transported to the loading frame.

The permanent deformation tests reported in this paper were conducted at a constant confining pressure of 34.5 kPa (5 psi) and the deviator stress applied was 172.3 kPa (25 psi). The repeated loading pattern was realistic field haversine load pulse with loading time of 0.4 seconds and 0.6-seconds of rest period between two loadings as shown in Figure 2.

Figure 1. Compacted ballast specimen with instrumentation assembled inside the acrylic chamber ready to be tested using the University of Illinois Triaxial Ballast Tester (TX-24)

Figure 2. Repeated loading pattern used in permanent deformation tests to closely resemble field train loading

2.2 Ballast Specimen Preparation

The ballast material used in the permanent deformation tests was a clean limestone having 100% crushed aggregates. Figure 3 shows the gradation properties of the ballast material which adequately met the AREMA No.24 gradation requirements. Besides the grain size distribution, aggregate shape properties, especially the flat and elongated (F&E) ratio, the angularity index (AI), and the surface texture (ST) index, are key indices quantified by the recently enhanced University of Illinois Aggregate Image Analyzer (UIAIA) (Rao et al. 2002). One full bucket of the ballast material was scanned and analyzed using the UIAIA to determine the values of the F&E ratio, AI, and the ST index. These shape indices were then used as the essential morphological data to generate ballast aggregate particle shapes as 3D polyhedrons, i.e., individual discrete elements utilized in the ballast DEM model (see Figure 4). Table 1 lists the gradation properties and the average values of the limestone ballast shape UIAIA indices used in the DEM simulations.

An aluminum split mold was used to prepare the ballast test specimens. Three layers of a latex membrane, with a total thickness of 2.3 mm, were fixed inside the split mold and held in place by applying vacuum to prepare each specimen in layers. A thin layer of geotextile was placed on top of the base plate to prevent clogging of the vacuum port in the base plate. Approximately 68 to 73 kg (150 to 160 lbs) of ballast material was poured into the mold evenly in four lifts, with each lift compacted approximately 15-cm (6-in.) high. Each layer was compacted using a 27.2-kg (60-lb.) electric jack hammer for about 4 seconds. After compaction of the first two lifts, one layer of geogrid was placed carefully in the middle of the test specimen. At the end of placing all four lifts, each test specimen was checked for the total height and leveling of the top plate. The void ratios computed were consistently around 0.68. Figure 5 shows the photos of the geogrids tested. The detailed properties of the geogrids are given in Table 2. Figure 6 shows the aluminum split mold (on left) and the compacted ballast specimen (on right) ready for instrumentation assembly and subsequent testing.

Figure 7. (a) Permanent axial deformations of ballast specimens; (b) Circumferential deformations of ballast specimens

2.3 Experimental Results

Figure 7 presents the preliminary results of the ballast permanent deformation tests performed in the laboratory for up to 10,000 cycles. For the first several hundreds of loading cycles, the permanent deformation and circumferential deformations increased rapidly, which was primarily due to the initial rapid “shakedown” of the ballast material. After around 1,000 loading cycles, the permanent deformation accumulated much slower and became relatively stable and so did the circumferential or radial/horizontal deformations. All the unreinforced and geogrid reinforced test specimens accumulated similar magnitudes of permanent deformation during the first one hundred load cycles and this was primarily due to the fact that geogrids were not yet fully mobilized at that time. With a single layer of geogrid placed in the middle of the test specimen, the geogrid reinforced test specimens accumulated less permanent deformation compared to the unreinforced case as the load cycles increased. When the reinforced test specimens accumulated certain amount of deformation, the geogrid’s reinforcement effect was fully mobilized and the interlock between geogrid and aggregate particles prevented further specimen bulging. This caused the specimen to stiffen and made it more resistant to deformation accumulation upon further loading. Triangular aperture geogrid reinforced test specimen accumulated the smallest permanent deformation compared with the unreinforced as well as the specimen with rectangular aperture geogrid. This indicates the triangular aperture geogrid better arrested aggregate movement with improved interlocking in all horizontal directions which can be confirmed from circumferential or radial/horizontal deformations, which happen to be of similar magnitude. Note that the triangular aperture geogrid also has thicker ribs and much higher radial stiffness when compared to the rectangular one (see Table 2). After 10,000 loading cycles, the permanent deformation for the unreinforced test specimen was 5.98 mm, the permanent deformation for the test specimen with rectangular aperture geogrid was 5.72 mm, and the permanent deformation for the test specimen with triangular aperture geogrid was 5.17 mm, respectively.

3. SIMULATION OF REPEATED LOAD TRIAXIAL TEST USING THE DISCRETE ELEMENT METHOD (DEM)

3.1 DEM Model Preparation

To investigate the mechanism of interlock and how this minimizes particle movement and causes local stiffness increase through friction and interaction of ballast particles with geogrid, a numerical modeling approach was adopted based on the Discrete Element Method (DEM) combined with image analyses of tested aggregate particles for size and shape properties. Compared to other research studies focusing on simulating triaxial tests by DEM, which often use spherical elements or element clusters (Indraratna et al. 2010, Lu and McDowell. 2010), the image-aided DEM simulation approach developed at the University of Illinois has the capability to create actual ballast aggregate particles as three-dimensional polyhedron elements having the same particle size distributions and imaging quantified average shapes and angularities. Ghaboussi and Barbosa (1990) developed the first polyhedral 3D DEM code BLOKS3D for particle flow; and Nezami et al. (2006) enhanced the program with new, fast contact detection algorithms. Tutumluer et al. (2006) combined the DEM program and the aggregate image analysis together to simulate the ballast behavior more accurately and realistically by using polyhedral elements regenerated from the image analysis results of ballast materials. This DEM approach was first calibrated by laboratory large scale direct shear test results for ballast size aggregate application (Huang and Tutumluer 2011). The calibrated DEM model was then utilized to model strength and settlement behavior of railroad ballast for the effects of multi-scale aggregate morphological properties (Tutumluer et al. 2006, 2007). More recent applications of the calibrated DEM model investigated ballast gradation (Tutumluer et al. 2009) and fouling issues (Tutumluer et al. 2008, Huang and Tutumluer 2011) that are known to influence track performance. A successful field validation study was also conducted with the ballast DEM simulation approach through constructing and monitoring field settlement records of four different ballast test sections and then comparing the measured ballast settlements under monitored train loadings to DEM model predictions (Tutumluer et al. 2011). The effect of geogrid aperture shape was recently studied by this DEM approach (Qian et al. 2011a).

Similar to the laboratory repeated load triaxial tests conducted for studying permanent deformation trends, comparative performance evaluations were also targeted for unreinforced and geogrid reinforced ballast specimens through DEM model simulations. The goal was to investigate the effects of different aperture shaped geogrids on the effectiveness of interlocking and the overall performance of the geogrid reinforced ballast. Considering the rather long DEM simulation run times that would be required for modeling the complete permanent deformation tests, the DEM simulations in this study were intended for only a small number of 100 load cycles deemed to be sufficient to enable practical comparisons of the ballast triaxial tests with or without geogrid for effectiveness within reasonable computation time. At the same time, the DEM simulation results would still help to qualitatively evaluate the influence of different aperture shapes of geogrids.

To simulate large scale repeated load triaxial compression tests using the DEM approach, the first challenge is to model the membrane which holds the specimen upright and applies the chamber confining pressure on it during testing. Previous modeling studies used rigid boundaries and chains of circular or spherical particles to simulate the membrane (Bardet 1994, Iwashita and Oda 2000, Markauskas and Kacianauskas 2006, Wang and Tonon, 2009). Lee et al. (2012)

recently used rigid rectangular cuboid discrete elements positioned in a cylindrical arrangement to simulate a flexible membrane with BLOKS3D. A similar approach was used in this study. A total of 96 rectangular cuboid discrete elements (in eight-layers) were used to form a cylindrical chamber to confine the ballast specimen as shown in Figure 7. Each layer had 12 equal size elements and the dimension of each single element was 20.32 cm (8 in.) long, 10.16 cm (4 in.) wide, and 7.62 cm (3 in.) high. These membrane elements were only allowed translational movement in radial direction. Rotation and translation movement in other directions were restricted to replicate the deformation of membrane. Note that these elements were required to have certain thickness to avoid any gap between adjacent layers when differential radial displacements between them were relatively large. Similarly, the elements were also allowed to have sufficient lengths to overlap adjacent elements to keep the circular chamber closed during simulation of triaxial tests. No contact detection was performed between these elements to allow for each element to move freely, independent of neighboring elements. The friction between the membrane elements and the ballast particles in contact with them was ignored during the DEM simulations. For the unreinforced ballast specimen, after the membrane was formed, around 500 particles were poured into the cylinder and the top platen was placed on top of the specimen to compact the ballast specimen to the same initial density under 34.5 kPa (5 psi) confining pressure as achieved in the laboratory experiment. For the geogrid reinforced ballast specimens, after the membrane was formed, about 500 particles were also poured into the cylinder in two different sets following the same gradation and shape properties of the actual ballast particles. In between, a sheet of geogrid element was generated in the middle of the ballast specimen as shown in Figure 8. The geogrid element has the same dimensions as the geogrid used in experimental study but is rigid and cannot deform. When the ballast specimen in the DEM simulation was prepared as in the similar condition as the laboratory test specimen, the repeated loading was applied to the top platen.

3.2 DEM Simulation Results

Figure 9 presents the accumulated permanent deformations as predicted by the DEM simulations for up to 100 load cycles. The deformation values at the 100th load cycle were 10.32 mm for the unreinforced case, 9.42 mm for the rectangular aperture geogrid reinforced case, and 7.97 mm for the triangular aperture geogrid reinforced case, respectively. As the purpose of the DEM simulations was to qualitatively investigate the relative performance of geogrids with different aperture shapes, due to the long DEM run times associated with each loading case, the DEM simulations for the permanent deformation predictions here considered only up to 100 cycles of the load application. Although the permanent deformations for the first hundred load cycles were somewhat similar for the unreinforced and different geogrid reinforced specimens during the laboratory testing (see Figure 7), with better control in compaction during specimen preparation in DEM simulations and the significantly high number of aggregate particle contact forces computed and checked for global granular assembly equilibrium at each iterative time step, a relatively low number of initial load cycles, such as 100 achieved here for three different simulation cases studied, was deemed to be sufficient for identifying the main reinforcement mechanisms and interlocking trends also identified in the experiments. Clearly, with DEM simulations of only up to 100 load cycles, the differences among the different ballast triaxial tests were apparent.

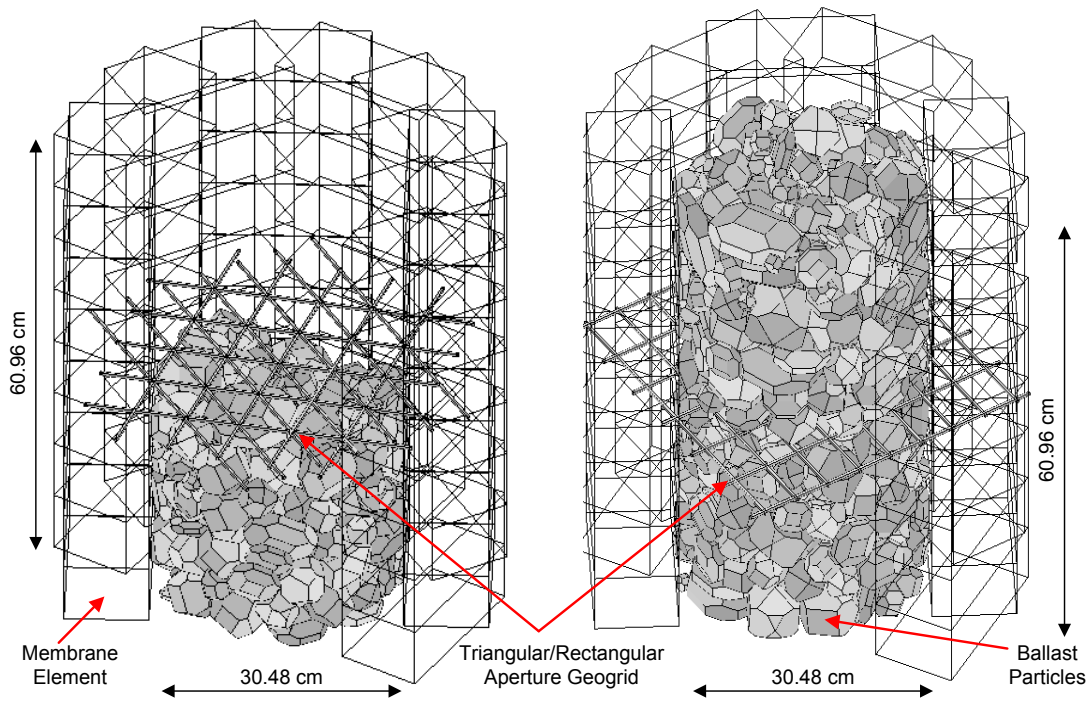

Figure8. Flexible membrane, geogrids with different apertures and ballast specimenformed in DEM simulations

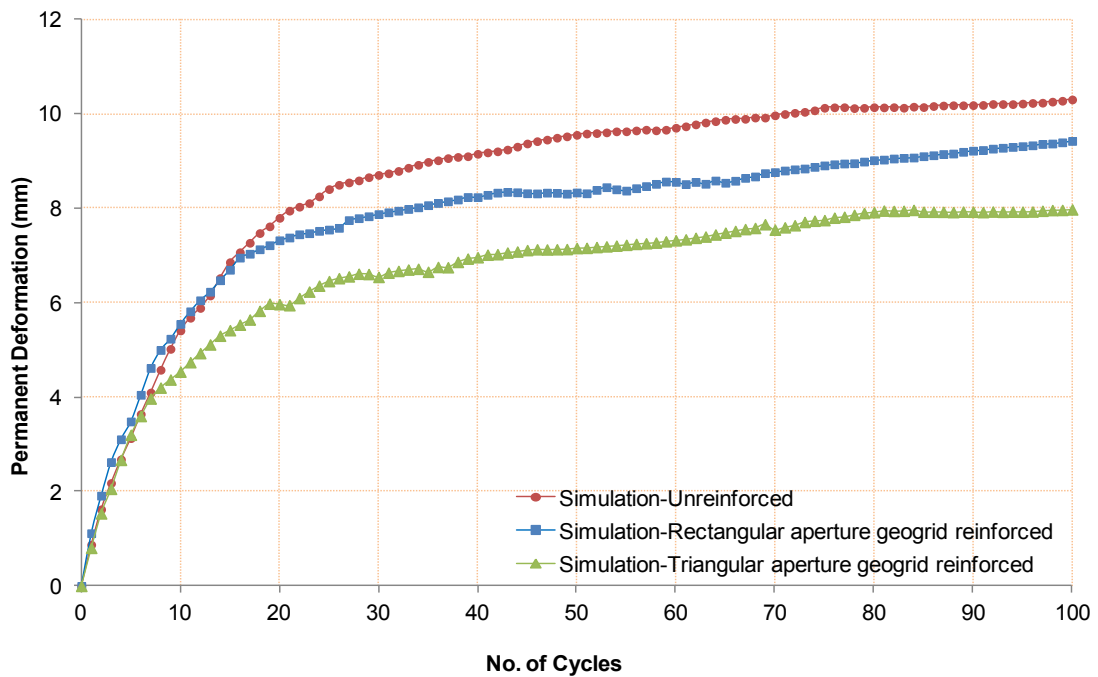

Figure9. Predicted ballast permanent deformation trends from DEM simulations with and without geogrid cases

The geogrid reinforced ballast specimens similarly yielded less permanent deformations compared to the unreinforced ballast specimen. The rectangular aperture geogrid did provide considerable reinforcement, but the triangular aperture geogrid with more uniform reinforcement in all horizontal directions provided the most significant improvement as indicated in Figure 9. These results from DEM simulations agree well with the trends observed in the

laboratory experiments. It is interesting to note that the first five DEM simulation load cycles also yielded similar magnitude deformations (approximately 4 mm) for all the unreinforced and geogrid reinforced test specimens, which means the geogrids were not fully mobilized yet. However, as the load cycles increased, the triangular aperture geogrid started to show improvement at around the 8th loading cycle during the simulation, while, the rectangular geogrid started to take effect at around the 16th loading cycle (see Figure 9). Again, the DEM simulations were intended to qualitatively compare the relative performances of geogrids with different aperture shapes using the minimum computational time. The intention has never been to match the predicted permanent deformation rates or the magnitudes at the different load cycles with the experimental results directly.

4. CONCLUSIONS

This paper focused on the permanent deformation behavior of geogrid reinforced ballast specimens as obtained from a large scale repeated load triaxial test device in the laboratory with both rectangular and triangular aperture geogrids. Further, the goal has also been to demonstrate the applicability of a repeated load triaxial testing and aggregate particle imaging based three-dimensional (3-D) numerical modeling approach, based on the Discrete Element Method (DEM), for studying geogrid-aggregate interlock reinforcement mechanism. Based on the very preliminary testing with limited data for two geogrids, the following conclusions can be drawn from this study:

1. The large scale triaxial device dedicated for testing ballast size aggregate materials developed at the University of Illinois was used successfully to investigate the permanent deformation behavior of ballast specimens under repeated loading with and without geogrid reinforcement. Both rectangular and triangular aperture geogrids were found to effectively reduce the permanent deformation accumulations of ballast materials. Triangular aperture geogrid with uniform resistance in all horizontal directions yielded the lowest permanent deformation.
2. The aggregate imaging based DEM simulation platform developed at the University of Illinois could model the repeated load triaxial tests for permanent deformation behavior of ballast specimens. Both confinement and applied deviator stress conditions on the cylindrical ballast specimens with and without geogrid reinforcement could be properly applied to investigate the interlock mechanism and micromechanical interactions between geogrids and aggregates.
3. Both the laboratory experiments and the DEM model simulations of the repeated load triaxial tests, for significantly lower number of load repetitions applied compared to the 10,000 load cycles applied in the laboratory experiments, gave similar benefits of using geogrids. The triangular aperture geogrid had better performance than rectangular aperture one in arresting particle movement in the lateral direction to yield the lowest vertical permanent deformation. More studies are needed to fully investigate aperture shape effects on the overall geogrid reinforcement mechanism.
4. The DEM simulation platform, currently being further developed, has the potential to be a quantitative tool to predict the ballast-geogrid interactions. This methodology has the potential for quantifying individual effects of various geogrid products.

ACKNOWLEDGEMENTS

The authors would like to acknowledge Tensar International, Inc. for providing the geogrids studied. The help and support of James Pforr, Research Engineer at the Illinois Center for Transportation (ICT) and Mr. Hasan Kazmee, PhD student at the Department of Civil and Environmental Engineering (CEE) at UIUC with the laboratory triaxial tests are greatly appreciated.

Comparison of the Effect of Multifilament and Fibrile Types of Polypropylene Fibers on the Unconfined Compressive Strength of High Plasticity Clay

Yuksel Yilmaz, Ph.D., Gazi University, Turkey, yyuksel@gazi.edu.tr
Kemal Karatas, B.Sc., Gazi University, Turkey, kemal221287@hotmail.com

ABSTRACT

An experimental program was undertaken to investigate the effects of discrete multifilament and fibrile types polypropylene fibers on the unconfined compressive strength behavior of clayey soil. Both type of fibers used in three different lengths (6.0mm, 12.0mm, and 19.0mm) and three fiber dosages (i.e. 0%, 0.5%, 1.0% and 2.0% by dry weight of soil). At first, compaction characteristics of the untreated soil were evaluated at standard compaction energy. Using compaction characteristics of untreated soil various fiber-soil mixtures were composed, and their unconfined compression test were carried out after 1-, 7-, and 28-days curing periods. The obtained test results indicated that the effect of fiber dosage on the unconfined compressive strength behavior is superior to the effect of fiber length and fiber type.

1. INTRODUCTION

Fine grained soils with high plasticity are not desirable for use as a structural support unless their engineering properties are improved. For many years, extensive research has been carried out on the usability of some additives (e.g. lime, cement, fly ash, cement kiln dust, chemicals, enzymes, fibers, etc.) to improve the quality and/or stability of fine grained soils.

The effect of randomly oriented discrete fibres on the engineering behavior of coarse grained soils mainly by means of strength increase is well studied. On the other hand there are a few studies on the effect of randomly oriented discrete fibres alone (not in combination with other additives such as cement, fly ash, etc.) on the geotechnical behavior of fine grained soils (Maher and Ho, 1994; Nataraj and McManis, 1997; Miller and Rifai, 2004; Mollamahmutoglu and Yilmaz, 2009; Viswanadham et al. 2009a; Viswanadham et al., 2009b; Jiang et al. 2010; Senol, 2011; Plé and Lê, 2012). In these attempts the performance of fibres on the strength characteristics of fine grained soil is incomplete and needs to be researched further.

In the present investigation, the effect of multifilament and fibrile types polypropylene fibers, fiber dosages and fiber lengths on time-dependent unconfined compressive strength behavior has been investigated.

2. PROPERTIES OF MATARIALS

2.1 Clay

The physical properties of the clay including particle size distribution, consistency limits and specific gravity were determined in accordance with (ASTM D 422-63), (ASTM D 4318) and (ASTM D 854), respectively. Based on Casagrande plasticity chart (ASTM D 2487), the soil was classified as high plasticity (CH) clay. Some of the basic characteristics of the clay are summarized in Table 1.

Table 1. Some of the physical characteristics of Ankara clay

Basic characteristics and descriptions	Value
Passing No. 200 (75 μ m) U.S. standard sieve (%)	80.2
Liquid Limit, LL (%)	97
Plastic Limit, PL (%)	28
Plasticity Index, PI (%)	69
Specific gravity, G _s	2.72
USCS Soil Class	CH

2.2 Fiber

Multifilament and fibrille polypropylene fibers with three different lengths were used in the study. 6.0mm, 12.0mm, and 19.0mm long fibrillated Multifilament polypropylene fibers are denoted as M06, M12 , M19, and fibrille polypropylene fibers are denoted as F06, F12 , F19 respectively.

Table 3. The physical characteristics of the fibres (Ployfibres, 2009)

Properties	Fibrillated polypropylene fibre	Multifilament polypropylene fibre
Appearance	Fully oriented collated fibrillated (network) form	Fully oriented multifilament fibrous form
Content	100% virgin homopolymer Polypropylene(C ₃ H ₆)N	100% virgin homopolymer Polypropylene(C ₃ H ₆)N
Compliance	ASTM C 1116-1997 Type III	ASTM C 1116 1997 Type III
Color	Transparent	Transparent
Density (g/cm ³)	0.91	0.91
Tensile strength (MPa)	400	700
Young Modulus (MPa)	2,600	3,500
Elongation at yield, %	15 %	20 %
Softening point (°C)	150	150
Melting point (°C)	160	160
Solubility in water	Insoluble	Insoluble
Hazardous ingredients, %	Nil	Nil
Acid/Alkali resistance	Stable	Stable
Abrasion resistance	Stable	Stable
Biologic durability	Stable	Stable

3. COMPOSING FIBER-CLAY MIXTURES

The mixture design of fiber amended clay samples were based on dry weight percentages of fiber in the clay matrix. The proportions of dry mass of fiber to dry mass of clay were chosen as 0% (fiberless), 0.5%, 1.0% and 2.0% based on the literature (Jadhao and Nagarnaik, 2008; Kumar et al., 2007).

4. DETERMINATION OF LABORATORY COMPACTION CHARACTERISTICS

Maximum dry unit weight of clay was achieved by applying an energy level of 600 kN-m/m³, which is equivalent to the (ASTM D 698-00a, 2006), the recommended standard compactive effort. The compaction curve of the clay is shown in Fig. 1. The maximum dry unit weight and optimum water content of the clay are 13.4 kN/m³ and 29.8%, respectively. The optimum moisture content and maximum dry unit weight of pure clay were also used to prepare samples for strength tests of fiber-clay mixtures for all fiber inclusions.

Figure 1. Standart Proctor compaction curve of the pure clay

5. PREPARATION OF FIBER-CLAY SAMPLES FOR STRENGTH TESTS

The fiber was mechanically mixed with the dry clay prior to the compaction until homogenous mixtures were obtained. A compaction mold was used to prepare cylindrical compacted samples of various fiber-clay mixtures at optimum water content and maximum dry unit weight during sample preparation. The compaction mold was designed for unconfined compression and triaxial testing specimens with a height-to-diameter ratio of 2.01. The compaction mold apparatus was made of stainless steel, and split into two parts longitudinally.

Before compaction, the inner surface of the split mold was lightly lubricated to prevent the sample from being damaged while removing it from the compaction mold. Next, the mold was assembled and a soil sample was poured into the mold in three equal layers. Each layer was compacted to a height of 33.5 mm using a stainless steel tamp with a base diameter of 49.50 mm to achieve the desired maximum dry unit weight before placing the next layer. After placing the last layer, the top and bottom end-rings of the compaction mold were unfastened. Finally, the two longitudinal split parts were removed from one another, and the cylindrical sample was gently released. All specimens measured as 50.0 mm in diameter and 100.50 mm in height.

Following compaction at optimum moisture content using standard compactive effort, the fiber stabilized soil samples were stored in sealable plastic containers to prevent moisture loss in a moist room (relative humidity above 70%) at room temperature until the day of testing. As discussed previously, the optimum moisture content and maximum dry unit weight of clay were also used to prepare samples for strength tests of fiber-clay mixtures.

6. UNCONFINED COMPRESSIN TESTS

Unconfined compression tests were performed on the specimens using strain controlled application of the axial load in accordance with ASTM D 2166 standard (ASTM D 2166-00, 2006). The strain rate was kept constant at 0.5 mm/min throughout the testing program.

Unconfined compressive strength (UCS) of the compacted untreated clay samples and fiber-clay samples, for various fiber contents, fiber types and fiber lengths, were plotted with reference to curing periods in Figures 2, 3 and 4. Figures 2, 3 and 4 reveal that UCS of the compacted untreated clay samples decreases slightly with curing period. From Fig.2 it is seen addition of fiber decreases the UCS. Comparing the effect of fiber type and length on the UCS of the fiber-clay mixtures, Fig. 2 shows that for Fiber/Clay = 0.5% mixture and Fiber/Clay = 2.0% mixture, F06 (fiber with 6 mm length) and F19 (fiber with 19 mm length) exhibit the highest UCS, respectively. Fig. 2 also shows the effect of fiber type on the UCS in such a way that for M type fibers as the length of fiber increases the UCS of the fiber-clay samples slightly increases. On the other hand, for F type fibers there is no such a certain relationship between the length of fiber and the UCS. From Figs. 2, 3 and 4 it is seen that as the curing time increases some of the fiber-clay mixtures exhibit higher UCS than those of the untreated clay samples. From Figs. 2, 3 and 4 it is also clear that as the fiber percent in the mixture increases, for example Fiber/Clay = 2.0% mixtures, the longer the fiber the higher the UCS.

Figure 2. Variation of USC of the Fiber-Clay mixtures with type and length of fibers for 1 day curing period

Figure 3. Variation of USC of the Fiber-Clay mixtures with type and length of fibers for 7 days curing period

Figure 4. Variation of USC of the Fiber-Clay mixtures with type and length of fibers for 28 days curing period

7. CONCLUSIONS

Fiber-clay mixtures were composed by using high plasticity clay, multifilament (M type) and fibrile (F type) types polypropylene fibers at various proportions. The effect of fiber content and length on the strength characteristics was evaluated at the end of various curing periods. The following conclusions were drawn from this experimental study.

- 1) Addition of any type of fiber (M type and F type) with different dosages and various lengths (except 2.0% F19 and 0.5%M06) decreases the USC for 1 day curing period. As a general tendency it may be stated that for 1 day curing period addition of fiber reversely affected the UCS performance of the clay.
- 2) F19 sample (fibrile polypropylene fiber, length 19 mm with Fiber/Clay= %2.0) gives the highest increase USC at all curing periods. As a general conclusion it may be stated that primarily the percentage of fiber in the mixtures controls the UCS not the length of the fiber.
- 3) For small dosage of fibers, although the effect of length on the UCS is not clear for F type fibers, for M type fibers it is seen that as the length of the fiber increases the UCS also tend to slightly increase. For long periods of curing time the effect of type of fibers on the UCS is similar for 19 mm long fibers and Fiber/Clay= %2.0 mixtures.

ABSTRACT

Large-scale static tension pullout tests were performed on two different metallic reinforcement connection systems embedded in gravel to compare the performance of the connections and to determine the effect of confinement pressure on the system load capacity. The metallic reinforcement elements were connected to full-scale reinforced concrete wall panels. One system consisted of a loop anchor and crimp connector with wide bar mat soil reinforcing and the other system consisted of a dual plate shaft (DPS) anchor and TAB connector with a discrete-strip bar mat soil reinforcing. The stabilized earth wall elements were confined in aggregate base material placed at a compactive effort of 95% modified Proctor (ASTM D1557). Three different overburden pressures ranging from 6.7 kN/m² to 73 kN/m² (140 psf to 1525 psf) were applied to the confined elements corresponding to wall heights of 0.3 m to 3.4 m (1 ft to 11 ft). Beyond the embedded connection, the section of reinforcement with transverse bars was isolated from the aggregate base material to prevent interaction with the soil and corresponding reduction in load at the connector. A controlled and increasing axial tensile force was applied to the free end of the reinforcing element. Instrumentation measured continuous displacement at the connector and the end of the reinforcing element until failure. This paper reviews test procedures and the instrumentation used to monitor the load and deformation response of different system components during full-scale laboratory testing. Test results are presented in terms of load and serviceability failure states as compared to AASHTO design requirements.

1. INTRODUCTION

Mechanically stabilized earth wall (MSEW) systems comprised of precast segmental concrete facing panels and inextensible metallic grid-type soil reinforcements (as shown in Figure 1 and Figure 2, respectively) are governed by applicable design and construction criteria in AASHTO LRFD Bridge Design Specifications (AASHTO 2010a), AASHTO LRFD Bridge Construction Specifications (AASHTO 2010b), and the FHWA guidelines for the Design and Construction of Mechanically Stabilized Earth Walls and Reinforced Soil Slopes (FHWA 2009).

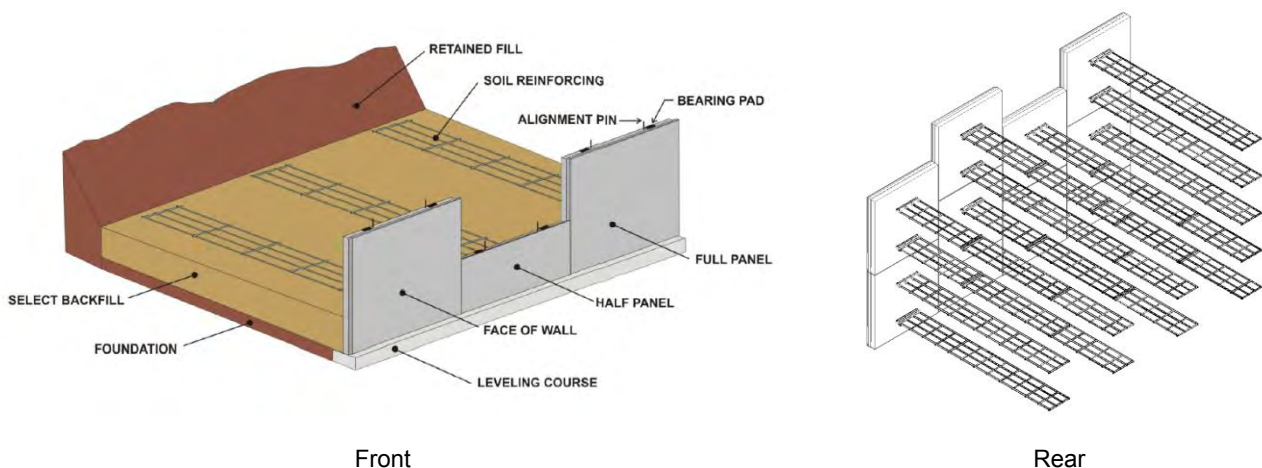

Figure 1. Isometric view of MSEW System-1 showing front and rear faces.

Figure 2. Isometric view of MSEW System-2 showing front and rear faces.

The basic difference in various MSEW systems is the type of reinforcements and their connections to the facing elements. Currently, evaluation of the facing connection component for design purposes involves performing unconfined tensile testing on single anchor elements embedded in concrete face panel segments. In accordance with AASHTO (2010a) requirements, evaluation of the deformation response at the connector is not required. However, the deformation of the connector required to lock up and continue to support the load is of interest as it can be used to evaluate anticipated lateral movement. In addition, a test on a single connector does not evaluate the distribution of stress over multiple connectors typically required to engage and fully mobilize the strength across welded wire reinforcements. Finally, unconfined tests do not provide an evaluation of confinement induced by overburden stress on connection systems in MSEW, which may influence both the deformation response and ultimate strength of the connection system.

The study presented herein involves full-scale laboratory testing of the complete connection system with confinement in suitable backfill material at three different overburden pressures to determine the effect of confining pressure on the connection response of the MSEW system. The complete setup for each connection type is shown schematically in Figure 3. The metallic reinforcement was isolated from the backfill with a sleeve placed beyond the embedded connection to prevent interaction with the backfill and corresponding reduction in load at the connector. Instrumentation was attached to the connection elements, as well as at the rear of the reinforcement, to monitor deformation with increasing tensile load. The soil reinforcing was extended beyond the rear of the confining box to create a free end where the force system could be attached. The tests were performed by applying an axial tensile force to the free end of the reinforcing element.

2. LABORATORY TESTING PROGRAM

2.1 Materials

The primary components of the mechanically stabilized earth walls (MSEWs) evaluated for this study include galvanized welded-wire grid-type reinforcing elements, rectangular precast reinforced concrete facing panels, galvanized steel connectors cast into the facing panel, steel connector elements, and select granular backfill. Standard precast panels having a face area of 2.3 m^2 (25 ft^2) and a thickness of 150 mm (6 in.) were used in the laboratory testing study. Metallic connection components are cast into the panel and used to secure the end of the soil reinforcement to the panel. In typical MSEW construction, standard panels and half-size panels are placed in the first course and special size panels are placed in the top course to match the required design and grade variations.

Two different types of MSEW systems were evaluated in this study. The first system consisted of a loop anchor and crimp connector (Loop-Crimp). This Loop-Crimpsystem consisted of 457 mm (18 in.) wide soil reinforcing (SR) elements of welded metallic grids that contained four 150 mm (6 in.) spaced longitudinal wires and 305 mm (12 in.) spaced transverse wires. The SR welded wire grids consisted of longitudinal and transverse wires of equal diameter with designations of W11 x W11, W15 x W15, and W20 x W20 corresponding to wire diameters 9.5 mm (0.374 in.), 11.1 mm (0.437 in.), and 12.8 mm (0.504 in.), respectively. The second system consisted of a dual plate shaft anchor (DPS) and TAB connector. The TAB connector is welded to narrow two-wire discrete-strip reinforcement. The yield strength of the steel wire in both systems is 450 mPa (65 ksi). The nominal tensile strength for the loop connector was equal to 290 MPa (42.3 ksi) which represents 65 percent of yield. The nominal tensile strength of the TAB connector was equal to 336 MPa (48.8 ksi) which represents 75 percent of yield. The difference in percent yield conforms to AASHTO requirements for systems with multiple point connections and single point connections, respectively.

2.1.1 Loop-Crimp Connector System

The Loop-Crimp system evaluated in this series of tests consisted of a four-wire grid-type SR element with 150 mm (6 in.) longitudinal wire spacing and 305 mm (12 in.) transverse wire spacing. The SR element is fabricated with a "V" shaped crimp placed in the longitudinal bars of the welded wire grid reinforcement directly behind the lead transverse wire for connection to the facing panel.

The reinforced concrete facing panels for the Loop-Crimp connection system are cast with a minimum of four loop anchors symmetrically placed and extending from the back face. The loop anchors are fabricated from a single 9.5 mm (0.375 in.) diameter (W11) wire into a series of four parallel loops. The end of the loop is deflected downward at a 45° angle over a length of 51 mm (2 in.). The soil reinforcement is connected to the panel by engaging the longitudinal V-crimped end of the SR element into the parallel looped panel anchor. The SR element is joined to the panel anchor by passing a 610 mm (24 in.) steel connection pin made of 9.5 mm (0.375 in.) diameter (W11) wire through the passages created at the interface of each of the crimped ends and downwardly deflecting panel anchor ends. A photo of the connection system setup for laboratory testing is shown in Figure 4(a). After the connection is made, the soil reinforcement is tensioned in order to remove any slack at the connection and seat the crimp into the loop. Failure to remove the slack will cause the connection to deform more under load.

2.1.2 Dual Plate Shaft Anchor and TAB Connector System

The dual plate shaft (DPS) anchor and TAB connector system consists of a narrow two-wire discrete-strip soil reinforcing (SR) element sometimes referred to as a grid-strip. The discrete-strip consists of two 9.5 mm (0.375 in.) diameter (W11) longitudinal bars that are spaced at 51 mm (2 in.) and with 76 to 100 mm (3 to 4 in.) wide 9.5 mm (0.375 in.) diameter (W11) transverse bars that are resistance welded to the longitudinal bars at their intersection and at a 150 mm (6 in.) interval spacing. A special forged metal TAB is resistance welded to the lead end of each of the longitudinal bars for connection to the concrete facing panel. The lead end of the TAB consists of a flat 38 mm (1.5 in.) wide by 9.5 mm (0.375 in.) thick steel plate that contains a 14 mm (0.562 in.) diameter central bolt hole. The terminal end of the TAB consists of a 16 mm (0.625 in) shaft that contains special longitudinal grooves and serrations.

The reinforced concrete wall facing panel for the DPS–TAB connection system is cast with at least one DPS anchor extending from the back face. The DPS anchor consists of two forged steel parallel 9.8 mm (0.375 in) thick flat plates extending 50 mm (2 in.) at its exposed end, and converges into a 16 mm (0.625 in.) diameter and 130 mm (5 in.) long shaft that terminates into a perpendicular 44 mm (1.75 in.) disk that is embedded into the face panel. The dual plates of the DPS anchor each have a centrally located 14 mm (0.562 in.) diameter aligned bolt hole. The discrete-strip is attached to the DPS anchor by passing the TAB end between the parallel plates so the bolt holes align and is secured from removal using a 12.7 mm (0.5 in.) diameter A325 bolt and nut. The DPS-TAB system is designed to rotate in the horizontal plane and deflect in the vertical plane without adding additional stress to the connection. Shown in Figure 4(b) is the DPS-TAB connection setup in the laboratory.

(b) DPS–TAB connection

Figure 4. Photos of full-scale connection systems in laboratory.

2.1.3 Aggregate Base Material

The aggregate used as backfill material was poorly graded gravel with sand (GP). It was classified as A-1-a based on gradation analysis and according to the AASHTO system. Modified Proctor compaction tests (ASTM D1557) performed on the gravel determined a maximum density of 21.3 kN/m³ (135 pcf) at an optimal moisture content of 6%. Applying an oversize correction factor the maximum dry density was determined to be 23.2 kN/m³ (148 pcf) at 3.9% optimal moisture. For the connection tests, the gravel was compacted to approximately 95% of the oversize corrected maximum dry density value with moisture at optimum to slightly higher than optimum.

3. FULL SCALE TESTING

3.1 Test Section Construction and Procedures

Confined (i.e., soil) static tensile connection tests were conducted in the GTX Stabilization Box as was previously shown schematically in Figure 3 for the Loop-Crimp connection and the DPS-TAB connection system. Each connection test involved applying an axial tension force to the free end of the metallic grid or discrete-strip SR element that extended from the back end of the box. Wire extensometers were used to monitor movements of the connection and the embedded portion of the metallic SR element. The extensometer wires were encased in small metal tubes to prevent friction on the wire. Each extensometer wire was connected to a low voltage linear displacement transducer (LVDT) on one end and to the connection or the SR element on the other end. The length of the SR that contained transverse wires was isolated from the backfill using a sleeve to prevent interaction and corresponding reduction in load at the connector. The isolation sleeves were designed to allow the reinforcement to move freely. Shown in Figure 5 are photos of the sleeve assembly. Displacement was monitored using LVDTs connected to the wire extensometers. The LVDTs provide continuous readings of displacement in the direction of the applied load during testing.

Figure 5. Photos of DPS-TAB connections and discrete-strip with sleeve enclosure.

Three overburden pressures were applied to the confined connection. For the purpose of discussion, they will be referred to as low, mid and high. Low overburden pressure corresponds to an average of 6.7 kN/m^2 (140 psf) and was attained by placement of a 300 mm (1 ft) thick layer of compacted gravel onto the connection and the SR element. Mid overburden pressure of 37 kN/m^2 (775 psf) was attained by placement of a 300 mm (1 ft) thick layer of compacted gravel onto the connection followed by stacking dead weight on top of the gravel layer. High overburden pressure corresponding to 73 kN/m^2 (1525 psf) was attained using the same method as the mid overburden pressure and the stacking of additional dead weight on top of the gravel layer as shown in Figure 6.

Two 180 kN (20 ton) pneumatic/air-over-soil jacks with a steel reaction beam were used to apply the pullout force. The jacks were interconnected to provide simultaneous loading. The SR element specimens were gripped in a steel clamp that was attached to the pullout piston using swivel connections. The swivel connections allow for adjustment in the case where SR elements do not exit the box exactly straight. The axial tensile force was measured by a calibrated load cell attached to the pullout piston. The horizontal displacement at the rear of the SR element was monitored outside the box by two LVDTs (one on each side) mounted to the longitudinal bars. In addition, LVDTs were positioned on the outside of the front face of the segmental concrete panel to monitor possible movement of the panel in the direction of the applied tensile load.

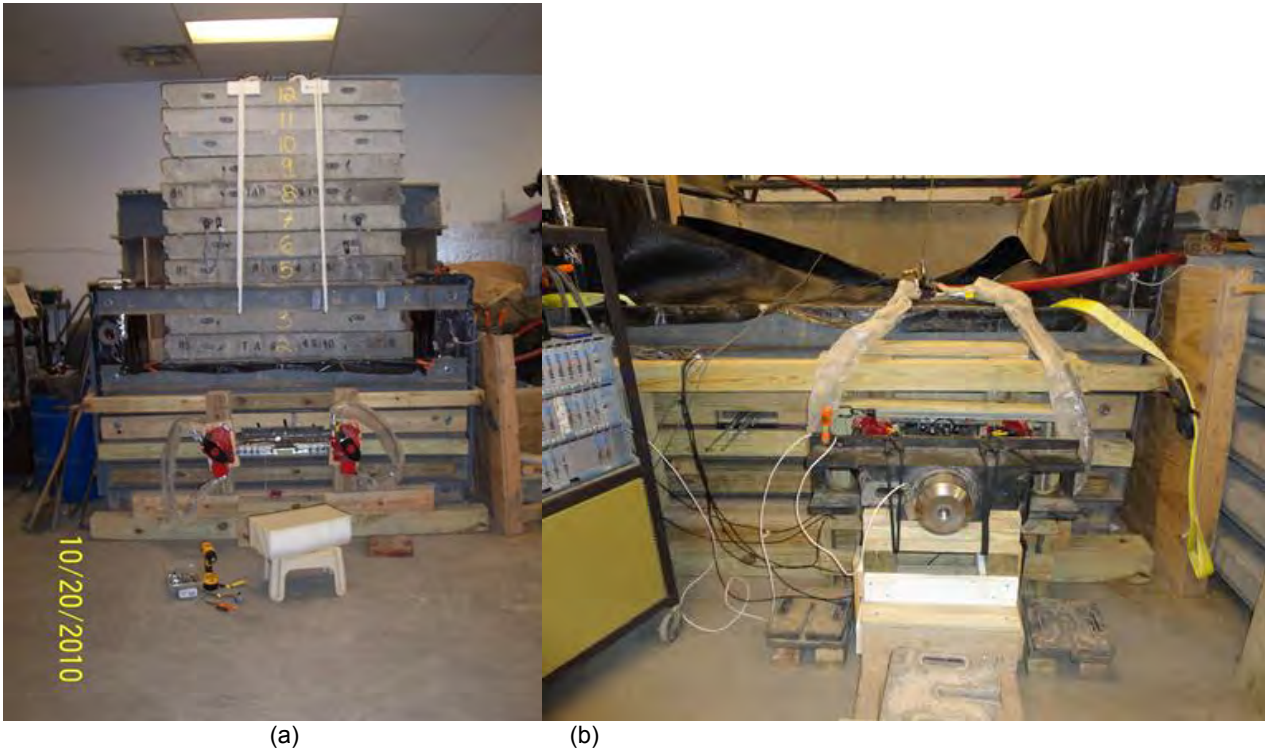

Figure 6. Full-scale confined connection laboratory test setup for (a) Loop-Crimp connection test with high overburden pressure of 73 kN/m^2 (1525 psf) and (b) DPS-TAB connection test with low overburden pressure of 6.7 kN/m^2 (140 psf).

3.2 Test Section Results

The laboratory confined connection test results for the Loop-Crimp connection and the DPS-TAB connection system are shown in Table 1. The peak load is the maximum axial tension load applied to the connection system at failure or termination of the test. The applied vertical load is the overburden pressure. Movement corresponds to displacement measured at the rear of the metallic grid using wire extensometers connected to LVDTs on the longitudinal bars. Additional measurements on where movement occurred in each element of the connection was collected and provided to the supplier for optimizing the design of the connection system.

For the Loop-Crimp connection the peak tensile load values measured during testing ranged from 103.6 to 109.5 kN (23.3 to 24.6 kips) for W11 x W11 grid, 133.0 to 159.1 kN (29.9 to 35.8 kips) for W15 x W15 grid, and 142.2 to 203.6 kN (32.0 to 45.8 kips) for W20 x W20 grid. Failure of the connection tests for the W11 x W11 and W15 x W15 metallic grids were due to longitudinal bar tension failure as exhibited in the post-test exhumed connection shown in Figure 7. Tests that terminated before failure showed no observable damage to the concrete panel. The connection tests on the W20 x W20 metallic grid failed by pullout of the loop connectors from the concrete prior to reaching 19 mm (0.75 in.) of deformation.

The peak tensile load values measured during testing of the DPS-TAB connection ranged from 82.2 to 94.3 kN (18.5 to 21.2 kips) and tend to increase slightly with confining stress as shown in Table 1. With the exception of one test, the DPS-TAB connection system exhibited structural failure of the concrete panel or the test was terminated before 19 mm (0.75 in.) of deformation was reached. For all DPS-TAB connection scenarios, no shear failure of the bars or bolts was evidenced, however the connection bolts deformed.

Figure 7. Photos of excavated Loop-Crimp connection after full-scale laboratory testing with confinement.

4. DISCUSSION OF RESULTS

The test results found that the nominal tensile strength of the Loop-Crimp connection system exceeded the nominal strength at the connection. In the W20 x W20 metallic grid test, notwithstanding the connection was unable to be observed at the design strength level, the tensile loads at failure were well above the design strength requirements such that the concrete still had significant reserve resistance compared to the nominal strength of the connection.

Calculations in accordance with LRFD design for the allowable tension (T_{al}) load for 75-year design life are determined by the following relationship:

$$T_{al} = n \cdot A_c \cdot \phi_y \cdot F_y \quad [1]$$

Where, n is the number of longitudinal bars, A_c is the area of longitudinal bar after degradation, ϕ_y is the resistance factor, and F_y is the yield strength of the steel bars.

For purposes of comparison, the maximum design tension load for a 75-year design life for the Loop-Crimp connector using LRFD and a resistance factor of 0.65 is equal to 60.0 kN (13.5 kips) for W11 x W11 grid, 85.8 kN (19.3 kips) for W15 x W15 grid and 119.1 kN (26.8 kips) for W20 x W20 grid. As shown in Table 1, the ultimate tensile strength of the Loop-Crimp connection system tested exceeds the LRFD values for each corresponding metallic grid.

The maximum design tension load for a 75-year design life for the DPS-TAB connector system using LRFD and a resistance factor of 0.75 is equal to 34.7 kN (7.8 kips). As shown in Table 1, the ultimate tensile strength of the DPS-TAB connection system tested exceeds the LRFD value.

The reported test results also provided a measurement of the load at 19 mm (0.75 in.) deformation, which is the limiting deformation for pullout tests (FHWA 2009). This deformation represents a serviceability limit state rather than a strength limit state. The laboratory test results can be used to conservatively estimate the connection capacity for the Service I limit based on a reduction in the load factor from $\gamma = 1.35$ for the Strength I limit state to $\gamma = 1.0$ for the Service I limit state (AASHTO 2010a). Therefore, the factored load is equal to a 26 percent reduction (equivalent to a reduction in the load factor from 1.35 to 1.00) in the nominal load at the loop connector. The laboratory test results indicate that all final test results exceeded this requirement at 19 mm (0.75 in.) of measured deformation.

Consideration of the DPS-TAB connection design using LRFD and a reduced load factor for the Strength I limit state to the Service I limit state, the factored load is equal to a 35 percent reduction in the allowable load at the connector. Laboratory test results for the DPS-TAB connections show that the reduced loads range from about 53.3 to 61.3 kN (12.0 to 13.8 kips) for the confining stresses used with the system and exceed the calculated maximum design tension load of 34.7 kN (7.8 kips) by a factor of 2.3 to 2.8.

Presented in Figure 8 is the measured deformation at peak tensile load for each of the connection systems tested in relationship to the applied normal load (overburden pressure). The peak tensile load for each test is shown at the top of each bar in the graph and connection scenarios are grouped by normal load. The graph demonstrates that increasing

confinement pressure increases the peak tensile load. By comparison of the two different types of connections, consideration of the number of connection points in each test influences to some degree the measured peak load and is dependent on the extent of non-linear loading at each connection element (i.e., loop or dual plate shaft). Further, the data reflects that ridged single point connectors do not deform under load as compared to multiple single point connectors. This demonstrates even distribution of stress at the connection for a single point connector and possible uneven stress distribution at a multiple point connector.

Figure 8. Deformation at Peak Tensile Load vs Normal Load.

The peak tensile loads measured during confined connection system testing and the corresponding trend lines for each test series of reinforcement type and normal load are presented in Figure 9(a). Data points enclosed in circles represent tests that did not experience bar shear failure or panel failure and were terminated. Shown in Figure 9(b) are the serviceability tensile loads measured for each Loop-Crimp connection test at 19 mm (0.75 in.) of movement and corresponding trend lines compared to the peak tensile loads.

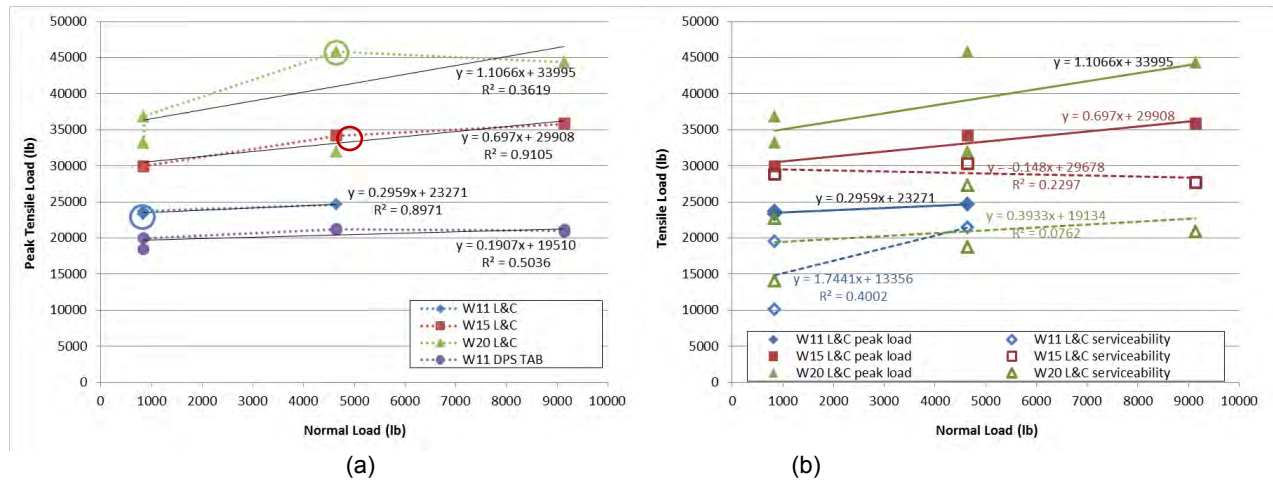

Figure 9. Measured Tensile Load vs Normal Load in terms of (a) peak tensile load and (b) serviceability tensile load.

5. CONCLUSIONS

Based on the limited confined connection tensile testing defined and discussed herein, the following conclusions can be advanced.

1. Full scale connection tests can be performed on MSEW connection systems and provide an evaluation of the influence of confinement as well as the influence in ultimate strength resulting from load distribution across multiple connectors in welded wire reinforcing systems.
2. By measuring the deformation response of the connector under confined conditions, a good assessment can be made on the various components of the connector that contribute to panel deformation and an assessment of stress in the reinforcement at serviceability limits can be made.
3. Rigid single point connectors deform less under load than systems that contain multiple connection points.
4. According to AASHTO, the limiting deformation target value is 19 mm (0.75 in.) for pullout tests. This is a serviceability limit state and not a strength limit state that is required for evaluating connection capacity.

ABSTRACT

The creep behavior of geosynthetics usually characterized by standard tests which present two main concerns: they are time-consuming and may not consider the possibly significant effect of soil confinement. Several approaches have been presented in the technical literature in order to address each of these aspects, but only independently. Recently, a new apparatus was developed in order to conduct confined-accelerated creep tests using geosynthetics and both concerns were addressed simultaneously. This paper presents a new set of creep tests conducted under different conditions with the new equipment. A biaxial geogrid and a nonwoven geotextile were used in these tests, which comprised creep rupture and creep deformation ones, both in in-isolation and in-soil conditions. The results highlight the importance of both using elevated temperatures to expedite the determination of geosynthetics creep behavior and studying the effect of soil confinement in both creep test types (creep rupture and creep deformations tests).

1. INTRODUCTION

The creep behavior of geosynthetics commonly plays an important role in the computation of the design tensile strength of these materials when used in reinforced soil structures. Among the reduction factors used to define this parameter, the one related to creep of geosynthetics usually presents the highest values (Koerner, 2005). The reduction factor due to creep behavior is quantified by conducting standard tests (ASTM D 5262), in which in-isolation specimens are subjected to a continuing and constant force while their elongation is measured. These tests are performed under controlled temperature and relative humidity conditions. In addition to the determination of the design tensile strength, creep strains obtained from such tests may be used to evaluate the reinforced soil structure behavior prior to its construction. Therefore, it can be noticed that the geosynthetics standard creep tests are used to define both the design strength and the behavior in such type of geotechnical structure.

Geosynthetics standard creep tests have been widely used to quantify the creep behavior of geosynthetics materials, mainly due to its simplicity. However, this type test presents two main concerns. Firstly, it is time-consuming, with test duration reaching 10,000 hours. Secondly, the configuration used in standard tests does not consider the possibly significant effect of soil-geosynthetic interaction (soil confinement). Together, these aspects may lead to expensive test sets and conservative results.

Geosynthetics creep response may be accelerated by conducting standard creep test at elevated temperatures (Bueno et al. 2005). These tests are commonly referred as accelerated creep tests. The creep strains at the reference temperature (e.g. room temperature) are inferred by calculations based on time temperature superposition techniques and their results. Therefore, several in-isolation accelerated creep tests with different specimens must be performed at the same load, yet at different temperatures. This set of test results is used to compose a creep master curve, which represents the creep response of the geosynthetic at the reference temperature and reaches greater times than those used in each accelerated test. This method is very well established in the technical literature. Several studies have been reported using accelerated creep tests to define geosynthetics creep response (Jeon et al., 2002; Zornberg et al., 2004; Bueno et al., 2005; Jones and Clark, 2007; Tong et al., 2009; Yeo et al., 2009). In addition, Thornton et al. (1998) proposes a new approach for evaluating tensile creep behavior of geosynthetics by means of accelerated tests, which is described by ASTM D 6992. This new method is based on increasing the test temperature in stages, which reduces the implications of material variability in the test results.

Soil confinement may have a great influence on the stress-strain behavior of geosynthetics. This aspect is usually referred to different mechanisms that restrict fibers and yarns relative movements (Elias et al., 1998). Thus, it is expected that the soil confinement effect on stress-strain behavior of geosynthetics is more substantial in geosynthetic materials manufactured with elements (fibers and yarns) which are free to move or adjust their position within the geosynthetic matrix (e.g. nonwoven geotextiles). Accordingly, geogrids are commonly considered as an example of the geosynthetic materials which stress-strain behavior is not affected by soil confinement. The geogrid ribs are not allowed to change position while loaded due to the strength of their connections. In addition, woven geotextile are generally considered as intermediary materials in this regard. Despite these stress-strain behavior pattern is frequently reported in the technical

literature, Elias et al. (1998) emphasize the importance of defining the influence of soil confinement concerning this aspect in every geosynthetic prior to real structure construction. This suggestion was based on test results in which the stress-strain behavior of a woven geotextile was dependent on soil confinement. Conversely, Boyle et al. (1996) reported a set of tests in which samples of woven geotextiles stress-strain behavior was not affected by soil confinement.

The soil-geosynthetic interaction may restrain creep strains while a continuing and constant load is applied to a geosynthetic specimen. In fact, the creep behavior of geosynthetics is commonly reported to be similar to that mentioned for their stress-strain behavior. This aspect is related to the second concern of standard creep tests (lack of soil confinement). Creep tests conducted in special chambers with in-soil specimens are more likely to address this concern. This approach was pioneered by McGown et al. (1982) and several recent studies in which other types of equipment were used are reported in the technical literature (Costa, 2004; Mendes et al., 2007; Ding, et al., 2009; Kamiji et al., 2009). Although there are a vast number of available publications, a standard approach to perform in-soil creep tests was not established so far.

Confined creep tests using geosynthetics are commonly reported using three different loading systems. Firstly, as presented by McGown et al. (1982), the specimen is loaded by means of clamps attached to a portion of the specimen located outside the testing chamber, while normal stresses are applied. The second type of loading system applies a vertical stress over the confining soil and, at the same time, the testing chamber side walls are allowed to move laterally. This produces a soil horizontal strain due to the vertical stress application. This type of equipment was used by Costa (2004) and Kamiji et al. (2009). A third type of confined creep test on geosynthetics has also been reported. This includes tests conducted with pullout testing equipment in which the load is maintained constant during the pullout test, while normal stresses are applied (Elias et al., 1998).

Each type of creep tests loading systems represents a different location of the geosynthetic material inside the reinforced soil mass. The first one, in which the specimen is loaded by means of clamps (external loading), may be used to characterize the creep behavior of the portion located in the passive zone, where insignificant soil mass movement is noticed. The portion in the active zone of the reinforced soil mass is more likely to be represented by means of creep tests in which the soil is allowed to deform laterally during the test and the load is transmitted by soil-geosynthetic interaction. Finally, creep tests using pullout testing equipment may represent the region at the end of the geosynthetic reinforcement inside the passive zone. A similar description was reported by Palmeira and Milligan (1989) regarding the mechanisms of interaction in reinforced soil structures.

Both elevated test temperature and in-soil specimen approaches have been successfully reported in the technical literature, but only independently. Regarding this, França (2012) fully presents a new device capable of conducting simultaneously confined and accelerated creep tests. This equipment was developed in the Laboratory of Geosynthetics of the School of Engineering of the University of São Paulo at São Carlos and was firstly presented in França and Bueno (2010). Further descriptions are presented in França et al. (2011) and França and Bueno (2011). Improvements have been added to this new equipment concerning the loading system. In addition, further tests were performed with both a biaxial polyester geogrid and a polyester nonwoven geotextile. This paper presents a brief description of the new device and the improvement provided to its loading system. Moreover, the results of additional tests are presented and discussed.

2. NEW CREEP TESTING EQUIPMENT

The main objective of the new creep testing equipment development was to simultaneously address both main concerns of conventional creep tests. Therefore, it comprises several systems which are responsible for confining the specimen in soil, elevate the temperature, apply the continuing and constant load, measure specimen elongation and acquire data from the tests. Figure 1 presents a general view of the new equipment with the main components.

The testing procedure consists of positioning a 200 mm wide geosynthetic specimen (1100 mm long) into the upper portion of the testing chamber (400 mm wide, 400 mm long and 200 mm high). This part of the chamber is filled with soil in order to reproduce soil-geosynthetic interaction. A thermocouple is installed in this procedure to measure the temperature nearby the specimen, which is considered as the test temperature. The lower portion houses three electrical resistances and a second thermocouple and is also filled with soil to improve heat transfer to the upper portion. The thermocouple in the lower portion controls the temperature of the electrical resistances. A pressurized air bag is placed over the top of the soil fill and is used to apply normal stresses up to 150 kPa. The chamber lid is attached to its walls and provides the reaction necessary to reach such values. Finally, a polystyrene cover surrounds the testing chamber to prevent heat loss during elevation of test temperature.

Both side walls of the upper portion of the testing chamber are provided with apertures wide enough (5 mm) to allow the specimens to reach the outer roller grips. The grips are connected to dead weights by steel cables. Thus, dead weights

are used to apply the continuing and constant load to specimens during creep tests. Besides, a set of pulleys is used to multiply to load that reaches the specimen by a factor approximately equal to 5.7. The loading system also comprises two load cells to register the load in each side of the specimens.

Figure 1. Main elements of the new creep testing equipment (França et al., 2012).

Two hydraulic jacks were used in the first version of the new equipment to apply creep load in a constant, smooth, proper way. Hence, the loading process should be performed by two operators at the same time. As a result, some tests presented different load rates in each side of the specimen. Concerning this, a new loading system was implemented to the equipment developed by França (2012). It consists of a steel beam that simultaneously supports the dead weight from both sides of the equipment. Then, an electrical rotor controls the downward movement of the beam, providing a smooth and homogenous loading rate in both sides of the specimen. Loading rate can be programmed by means of an automated controller. Figure 2a illustrates the new apparatus implemented to the loading system of the new creep testing equipment, while Figure 2b presents the load level during the first five minutes of a confined-accelerated creep test performed with a nonwoven geotextile loaded to 70% of its ultimate tensile strength (UTS). This test was conducted at 36.2°C and with normal stress equal to 50 kPa.

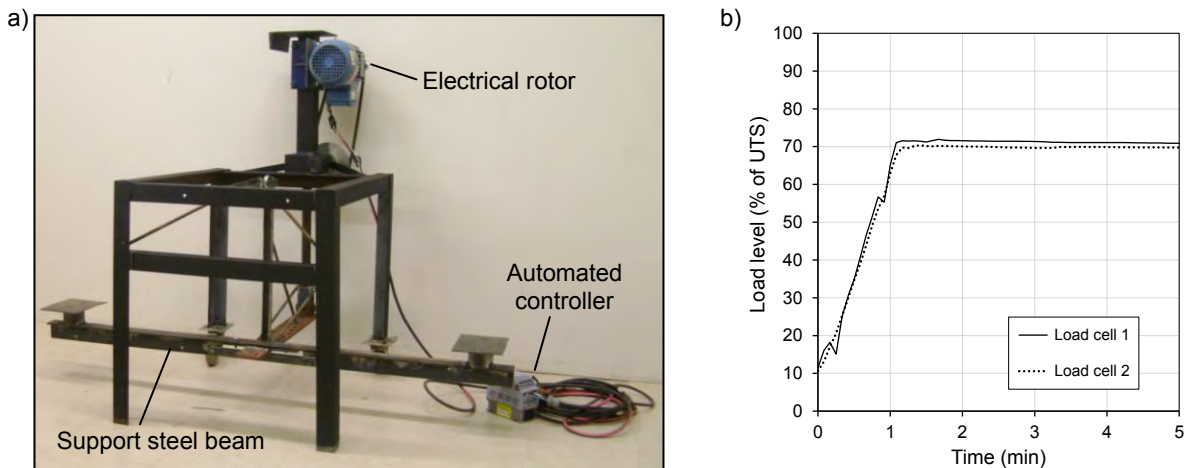

Figure 2 – New apparatus implemented to the loading system of the new creep testing equipment: a) General view; b) Load level during the first five minutes of a confined-accelerated creep test performed with a nonwoven geotextile.

The new equipment requires 1,100 mm long geosynthetic specimens. However, the specimen preparation procedure consists of reinforcing the outermost portions with a two-component adhesive in order to result in two rigid, smooth surface regions. Consequently, only the central segment (100 mm long and 200 mm wide) is subjected to creep deformations during the tests. This segment is reported as “length of interest” in this paper. At the end of the specimen preparation procedure, two pieces of stainless steel wires are attached and glued in the length of interest of the specimens. They are connected to displacement transducers in order to measure the displacement of each of these two points. Then, specimen elongation is computed by the sum of both values divided by the initial distance between them.

The new creep testing equipment is also provided with an automated data acquisition system. It is responsible for registering reading from thermocouples, load cell and displacement transducers.

3. CREEP TESTS

The new creep testing equipment was used in three different types of tests: confined, accelerated and confined-accelerated. Tests with in-soil specimens conducted at room temperature are referred as confined creep tests. On the contrary, tests conducted with in-isolation specimens and under elevated temperature are named accelerated creep tests. Finally, tests in which both measures were used simultaneously are entitled confined-accelerated creep tests in this paper. Besides, creep tests conducted under the regulations presented by ASTM D 5262 are referred as conventional creep tests and were performed in order to characterize geosynthetics creep behavior regarding the current practice. The following sections describe the materials used and the tests performed during this study. Moreover, the results from such tests are presented and discussed.

3.1 Geosynthetic Materials and Chamber Fill

Two different geosynthetic materials were used in the creep tests presented in this paper: a nonwoven geotextile and a biaxial geogrid. Both geosynthetic materials were manufactured with polyester fiber. Table 1 summarizes the main characteristics of each geosynthetic material.

Table 1. Characteristics of tested geosynthetic materials.

Characteristics	Nonwoven geotextile	Biaxial woven geogrid
Manufacturing process	Needle punched	Woven
Predominant polymer	Polyester	Polypropylene
Mass per unit area (g/m ²)	263 (6.1%) ¹	N/A ²
Aperture size (mm)	N/A ²	35.0
Nominal thickness (mm)	2.8 (5.6%) ¹	N/A ²
Tested direction	Cross-machine direction	Machine direction
Short-term tensile strength (kN/m)	14.11 (12.4%) ¹	19.72 (1.9%) ¹
Elongation at rupture (%)	68.12 (9.34%) ¹	9.6 (4.4%) ¹

¹the numbers in parentheses correspond to the coefficient of variation computed in each parameter.

²non-applicable.

Confined and confined-accelerated creep tests were performed with testing chamber filled with a dry poorly graded sand sample, classified as SP according to USCS system. Its coefficient of uniformity and coefficient of curvature were equal to 1.01 and 0.72, respectively. Maximum dry density of 16.7 kN/m³ and minimum dry density of 15.0 kN/m³ were found for the sand sample used as confining medium. The sand was used with density equal to 45% of its maximum dry density. Direct shear tests at this condition resulted in peak friction angle equal to 34.4° and residual friction angle equal to 27.5°.

3.2 Tests Performed

Firstly, the creep behavior of both geosynthetic materials were determined by means of conventional creep tests (ASTM D 5262). In fact, the geogrid was not subjected to other types of creep tests so far in this research. The nonwoven geotextile was also used in accelerated, confined and confined-accelerated creep tests. Tests with in-soil specimens were performed under normal stress of 50 kPa. Accelerated and confined-accelerated creep tests were conducted under different test temperatures. Note that some tests were performed until specimens rupture (creep rupture tests). Table 2 summarizes the characteristics of the creep tests presented in this paper.

Table 2. Characteristics of creep tests.

Type of creep test	Nonwoven geotextile			Biaxial woven geogrid	
Conventional	20 to 60% of UTS ¹ 1000 h; Room temperature			20 to 50% of UTS ¹ 80 to 95% of UTS ¹ 100 h; Room temperature	
Accelerated	50% of UTS ¹ 112 h; 35.1°C	---	---	---	---
Confined (50 kPa) ²	50% of UTS ¹ 160 h; 26.0°C	70% of UTS ¹ 131 h; 24.1°C	80% of UTS ¹ 160 h; 24.4°C	90% of UTS ^{1,3} 0.78 h; 24.5°C	---
Confined-accelerated (50 kPa) ²	50% of UTS ¹ 131 h; 36.9°C	70% of UTS ¹ 191 h; 36.9°C 265 h; 47.7°C 464 h; 59.1°C ³	80% of UTS ^{1,3} 17.5 h; 36.5°C	---	---

3.3 Creep test results and analysis

Nineteen creep tests are presented in this paper. Among them, ten tests were conducted with the new creep testing machine developed by França (2012). Despite geosynthetics creep curves are commonly plotted as specimen elongation versus time in logarithmic scale, the effects of temperature and soil-geosynthetic interaction in creep strains are not clearly identified since this representation reflects both initial and creep strains. On the contrary, Zornberg et al. (2004) proposed a creep curves representation in which only the creep strain of the specimens are used. In this plot, the creep strains are plotted versus the logarithm of the ratio between the current time and the time at the end of load application. Moreover, the slope of the resulting line indicates the rate of creep strain occurrence during the tests, which is designated as creep index (T_α). Hence, creep index values can be used to indicate the effect of any parameter in creep strains of any geosynthetic material. Due to this aspect, the representation suggested by Zornberg et al. (2004) was used in the analysis of the creep tests presented in this paper.

3.3.1 Nonwoven Geotextile

Different creep test types were performed with the nonwoven geotextile. Initially, tests conducted at conventional conditions and at 50% of the ultimate tensile strength (UTS) in non-conventional conditions were used to quantify the geotextile creep behavior regarding creep deformations. Figures 3a and 3b present the results obtained in conventional creep tests with specimens subjected to 20 to 60% of UTS and in creep tests under both conventional and non-conventional conditions with specimens loaded to 50% of UTS, respectively. Note that a few points are represented in this plot in order to make it clearly. However, data acquisition was performed with one minute intervals. This measure was used in every plot presented in this paper.

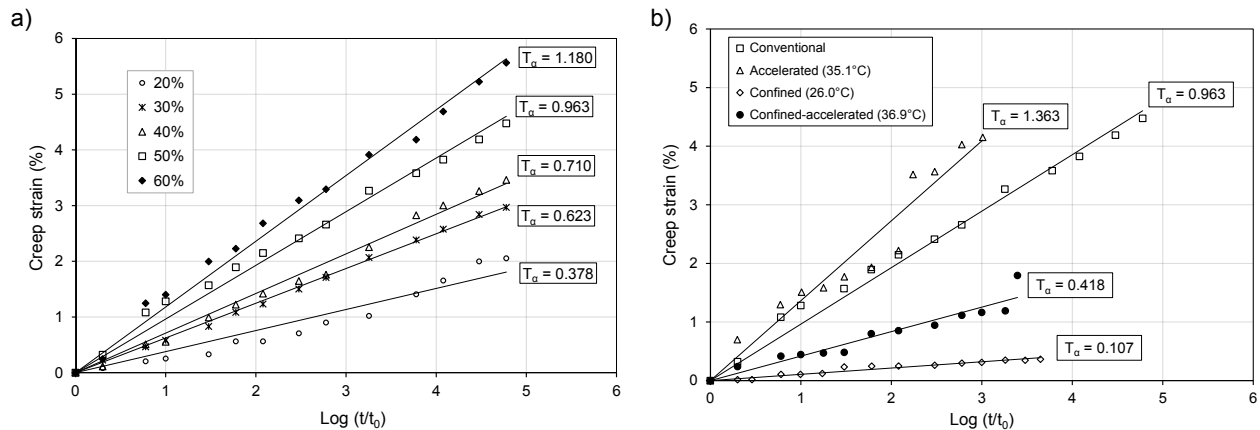

Figure 3 – Results from creep tests conducted with the nonwoven geotextile: a) Conventional creep tests with specimens subjected to load levels from 20 to 60% of UTS; b) Creep tests under both conventional and non-conventional conditions with specimens subjected to 50% of UTS.

Unsurprisingly, nonwoven geotextile creep index values are proportional to the load applied to the specimen during the test. The relationship between load levels and creep index values is approximately linear, with slope equal to 0.019 (coefficient of determination of 0.98). Regarding the specimens subjected to 50% of UTS, the nonwoven geotextile creep behavior was found to be highly affected by soil confinement in the tested conditions. A normal stress of 50 kPa was able to reduce the creep index to approximately 11% of the value obtained in the conventional condition. Note that both tests were performed at room temperature. A similar trend was found at elevated temperatures; however, the creep index change was slightly less significant. Creep index value in confined-accelerated creep test (36.9°C) was approximately equal to 30% of the one obtained in accelerated creep test (35.1°C).

Creep strain reduction due to creep reached significant levels at room temperature. Note that the creep index obtained in the confined test with the specimen loaded to 50% of UTS is smaller than the one found at conventional conditions with the specimen subjected to 20% of UTS. It indicates the high influence of soil confinement in this geotextile creep behavior. However, it is important to mention that this condition cannot be extrapolated for every nonwoven geotextile in every condition. At elevated temperature, creep index reduction was not as substantial as found at room temperature. Besides, different loading systems may induce unlike behavior, as reported by Elias, et al. (1998) and Costa (2004).

In addition to the tests described so far in this paper, a new set of tests was performed at 70, 80 and 90% of UTS with geotextile in-soil specimens. It was used to characterize the geosynthetic creep rupture behavior in confined condition. Firstly, a creep rupture confined test at 90% of UTS was performed, which caused specimen rupture approximately after 47 minutes (0.78 h). It was followed by two confined creep tests with specimens loaded to 80% of UTS, at room temperature and with temperature equal to 36.5°C. The specimens rupture did not occur in the test conducted at room temperature (until 160 h) and took place after 17.5 h at elevated temperature. Finally, four creep tests were performed with in-soil specimens loaded to 70% of UTS (at room temperature and at temperature values equals to 36.9, 47.7 and 59.1°C). The rupture only occurred at the highest temperature after 464 h.

The set of creep tests conducted with in-soil specimens loaded to 70 and 80% of UTS at elevated temperature (confined-accelerated creep tests) was interpreted in order to establish the creep master curves for each load level. Additionally, the confined creep test at 90% of UTS was used to determine the time to rupture at this load level. Figure 4a presents the creep master curves for specimens loaded to 70 and 80% of UTS. Moreover, Figure 4b presents the creep rupture curve found with this set of tests.

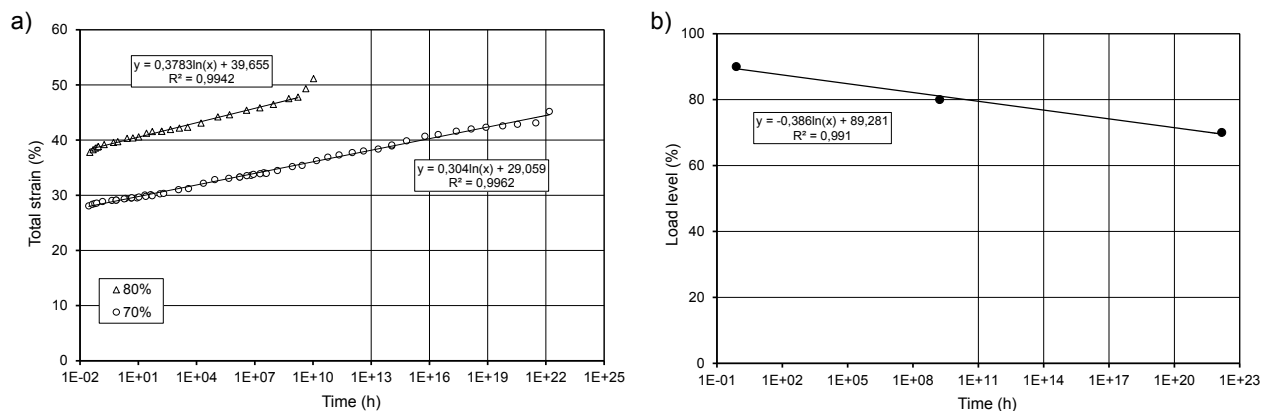

Figure 4 – Results from confined creep tests conducted with the nonwoven geotextile: a) Creep master curves for specimens loaded to 70 and 80% of UTS; b) Creep rupture curve obtained with in-soil specimens.

Creep rupture curves are used to determine the reduction factor due to creep behavior. This parameter is considered in the computation of the geosynthetics tensile design strength. Note that the reduction factor due to creep obtained with the tests performed so far would reach lower values than those suggested in the technical literature (1.5 to 3.0). For instance, the reduction factor obtained from the data presented in Figure 4b is equal to 1.20 for a service life of 50 years. However, it is important to mention that this computation is based on one single set of tests and comprises preliminary results with this geosynthetic material. Further tests are predicted to be conducted with the nonwoven geotextile using in-isolation specimen. As a result, the creep behavior at higher load levels (70 to 90% of UTS) with in-isolation specimens will be compared with that found with in-soil ones.

3.3.2 Biaxial Woven Geogrid

The biaxial woven geogrid was subjected to fewer creep tests in this research. In fact, only conventional creep tests have been performed so far. These tests were used to evaluate both creep deformations, with specimens loaded from 20 to

50% of UTS, and to determine the creep rupture curve, with specimens subjected to loads from 80 to 95% of UTS. Figures 5a and 5b presents the plots from each set of tests

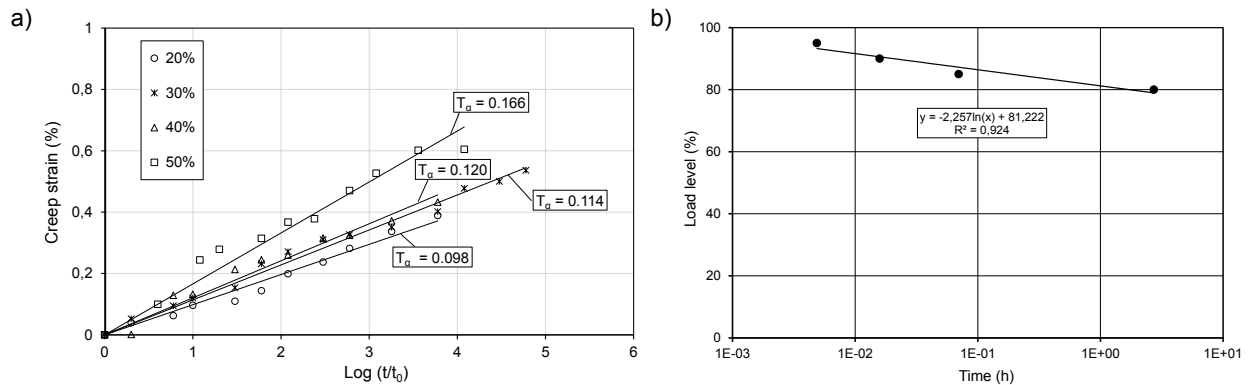

Figure 5 – Results from creep tests conducted with the biaxial woven geogrid: a) Conventional creep tests with specimens subjected to load levels from 20 to 50% of UTS; b) Conventional creep rupture curve obtained with specimens subjected to loads from 80 to 95% of UTS.

The creep index was found to be proportional to the load level, as expected for any geosynthetic material. According to the creep rupture curve, the reduction factor due to creep would be approximately 1.9 for a service life of 50 years. However, it is important to notice that this value refers to an approximate prediction since it is based on very few tests and the extrapolation process exceeded the recommended standard of one order of magnitude (ASTM D 5262).

Further tests are predicted to be conducted with the geogrid. Firstly, these tests will comprise complimentary creep rupture tests with in-isolation specimens and confined creep rupture tests using in-soil specimens. Tests with specimens loaded to lower load levels will be accelerated by elevating the test temperature. Thus, creep master curves will be established and time to rupture will be determined at these load levels. Creep rupture tests will be followed by confined creep tests at lower load levels in order to determine the effect of soil-geogrid interaction on the geosynthetic creep behavior.

4. CONCLUSIONS

This paper presented a brief description of the creep testing equipment developed by França (2012) to conduct simultaneously confined and accelerated creep tests on geosynthetics. It was also presented an additional improvement, which was implemented to its loading system. A nonwoven polyester geotextile and a biaxial woven geogrid were subjected to different creep test series. The following conclusions are drawn from the present study:

- The influence of soil-geosynthetic interaction in creep strains of the nonwoven geotextile was found to be very significant at both room and elevated temperature. Creep index values were reduced to 11 and 30% of those found with in-isolation specimens at room temperature and at 35.1°C, respectively.
- Creep rupture tests conducted using nonwoven geotextile specimens under confined condition led to reduction factors due to creep considerably lower than those usually applied in geotechnical structures design. However, this aspects still requires further investigation.
- Preliminary creep tests using biaxial woven geogrid indicated an expected creep behavior for this geosynthetic material (creep index was proportional to load level).
- A conventional creep rupture curve was suggested for the biaxial woven geogrid. Despite it was based only on four load levels, extrapolation of this curve led to recommended values.
- The new creep testing equipment performance was improved by adding the new loading system. It was able to apply the creep load at a constant rate on both sides of the specimen simultaneously;
- Further tests are predicted with both the nonwoven geotextile and the biaxial woven geogrid. Additional creep tests with other geosynthetic materials are also predicted in order to develop a larger data base regarding in-soil creep behavior of different types of geosynthetics.

ABSTRACT

In the course of site development a 12 m high and 350 m long noise barrier wall is constructed at an existing hill slope. A construction method with the use of onsite available cohesive soils, which is improved by using mixed binders and Polyester-geogrids in connection with a steel mesh facing element was chosen. The steel mesh facing elements are connected to the geogrid via frictional interaction. During the design process the lateral pressure on the facing has been calculated according to the German design guideline for geosynthetic reinforcements, EBGEO 2010, by using a reduced active earth pressure. The construction is accompanied by an extensive monitoring program. The available test results achieved for the facing area of the construction show very low deformations of the facing, low earth pressures and a very low rate of stress of the geogrids as well as of the steel mesh facing elements.

1. INTRODUCTION

These days geosynthetic reinforced soil structures belong economically to the most attractive construction methods due to their flexibility and versatility. Also under the ecological point of view, as e. g. CO₂ reduction, further positive impulses for this type of application can be expected in future. DIN 1054:2005 as national document, DIN EN 14475 as document for execution as well as the revision of EBGEO 2010 as design standard for geosynthetic reinforcements are corresponding state-of-the-art standards in Europe and even used in Asia due to the link to Eurocode 7 (EC7) in order to safeguard the constructions.

In the case of this presented construction (Figure 1), design and verification elements of the revised EBGEO have been implemented. The type of construction and design, first measurement results and numerical analysis on the wall have already been documented by Ilchmann et al. (2009), Pries & Meshkinghalam (2010) and Vollmert et al. (2010). Actual measurements show a slight increase of strain and stress values based on up to now three circles of years.

2. PROJECT

2.1 Survey

In the course of development measures for a residential area the installation of a noise protection wall is planned. This construction consists of a reinforced earth wall and a piled noise barrier on top of the construction. As a result of its hillside situation (compare Figure 3) the total height of the construction is partly more than 18 m with an inclination of the facing of 70°.

Figure 1. View in construction phase (without piled noise protection wall).

2.2 Construction Material

During the profiling of the construction site of the residential area soil has been excavated in a significant amount. This should be used as building material for the reinforced earth wall. This building material mainly consists of loess, loess clay, residual clay and cohesive fluvial soils, i.e. cohesive soils with differentially high sand contents. The in-situ soil on the construction area was mixed with binders (lime-cement-stabilization) on site, transported to the installation location and installed by compacting layers (Figure 2).

Figure 2. Construction site.

The required shear parameters ($\varphi \geq 27.5^\circ$ and $c \geq 10 \text{ kN/m}^2$) have been achieved and verified by shear box tests. Also the required compaction, especially in the facing area of the system, has been observed carefully.

The facing of the geosynthetic reinforced soil structure consists of welded, specially aluminium galvanized steel wire mesh (square, 100mm x 100mm). A corresponding erosion control mat made of a synthetic monofilament is used in front of the elements.

Geogrids with a high extensional stiffness are used as reinforcing elements. For economic reasons and to improve the reliability of the construction (danger of mixing up different grid types in the case of a similar visual appearance of the product) only two geogrid types, in this case Secugrid[®] 200/40 R6 and Secugrid[®] 40/40 Q6, are installed. The design strength according to EBGEO, taking creep, installation damage, $\text{pH} = 12.5$ and a partial factor of safety for material of 1.4 into consideration, is given to 87.3 kN/m (Secugrid[®] 200/40 R6) resp. 17.5 kN/m (Secugrid[®] 40/40 Q6). For the chosen reinforcing type of Polyester, long-term tests have been performed at high pH-values of up to $\text{pH} = 12.5$ as a high sensitivity against hydrolysis is known for products made by multifilament yarns. It has been found in these tests that using monolithic bars in combination with certain Polyester raw materials is much less sensitive, so that just a reduction by approx. 15% had to be taken into account for a life time of 120 years.

The connection between the front element and the geogrid is realised by friction without additional measures and verified by static design.

3. GEOTECHNICAL VERIFICATION

3.1 Structure

The proofs are performed in analogy to Eurocode 7 according to DIN 1054:2005-01 and EBGEO using the partial safety factor concept. Simplified, the verification of the stability of the geosynthetic reinforced soil structure is carried out in three steps:

- proof of reinforced soil structure
 - internal stability (two-part wedge failure mechanism, circular slip circles)

- external stability (sliding, bearing failure, eccentricity)
- proof of ground failures of the complete system (wall and fill)
 - slice method according to Bishop, where the circular slip circles can intersect with parts of the geosynthetic reinforced soil structure
- proof of earth pressure on facing

3.2 Steel Mesh Facing

The earth pressure affecting the facing has been reduced according to Pachomow et al. (2007). Therefore the dimensions of the steel mesh facing elements could have been reduced and the connection geogrid/front element has been carried out as to friction. The comparative earth pressure measurements (as documented as follows) show that the calculation approaches for the earth pressure have been on the safe side. In the meantime this process has been included into the design recommendations of EB GEO.

3.3 Serviceability

In the run-up the ground expert has forecasted settlements in a range of up to 30 cm. In the soil body of the geosynthetic reinforced soil structure itself the settlements might be up to approximately 1 cm for each layer. Thus, during the construction it was planned to carry out settlement and deformation measurements in order to confirm the forecasts and to be able to adjust them, if necessary.

4. CONSTRUCTION WORK

Before installation of the geogrids an accurate formation level had to be prepared for the front elements in the front area. Afterwards the geogrids were installed up to the leading edge of the front elements, whereupon the layers were cut by using an angle grinder.

During an effective construction time of approximately 2 months the company Nacken Landschaftsbau with their average staff of 7 workers installed or moved, respectively, approximately 25,000 m³ of prepared soils resulting from the construction site, 25,000 m² geogrid, 4,000 m² steel grid front elements as well as 300 m³ of half-gabions with a long arm excavator and a wheel-type loader. The compaction was carried out in three steps with a tamper in the front area between the bars of the steel grid elements, vibrating plate up to approximately 1 m distance to the front and a single drum vibrating roller.

5. MONITORING

5.1 Purpose

For the design of reinforced soil bodies, which can be regarded as compound system due to their small layer distances, the question must be raised how to determine the earth pressure on the facing. Evaluations of literature and comparative calculations of Pachomow et al. (2007) clearly show - depending on the flexibility of the facing elements - a reduced horizontal stress - compared to the active earth pressure - at the facing of a reinforced soil construction. Due to this fact the active earth pressure can - resulting from the compound effect of the reinforced soil structure - be reduced by 30% in the case of facing systems which are restrictedly deformable according to DIN EN 14475:2006.

For cohesive soils with continuously increasing shear strengths only few experiences are available. As for the use of inferior construction materials which require the use of binders another increase can be expected as to the economic point of view, and additional validation of the above mentioned design approaches is required. Moreover a structurally engineered and complex constructive connection of the facing elements with the geogrids can be omitted under consideration of the reduced horizontal strengths.

Thus, the instrumentation focuses upon the facing area of the construction. It is the aim to determine the dynamics at a facing element and the subsequent reinforcement layer depending on the construction progress and the time-dependent development of the shear behaviour of the soils.

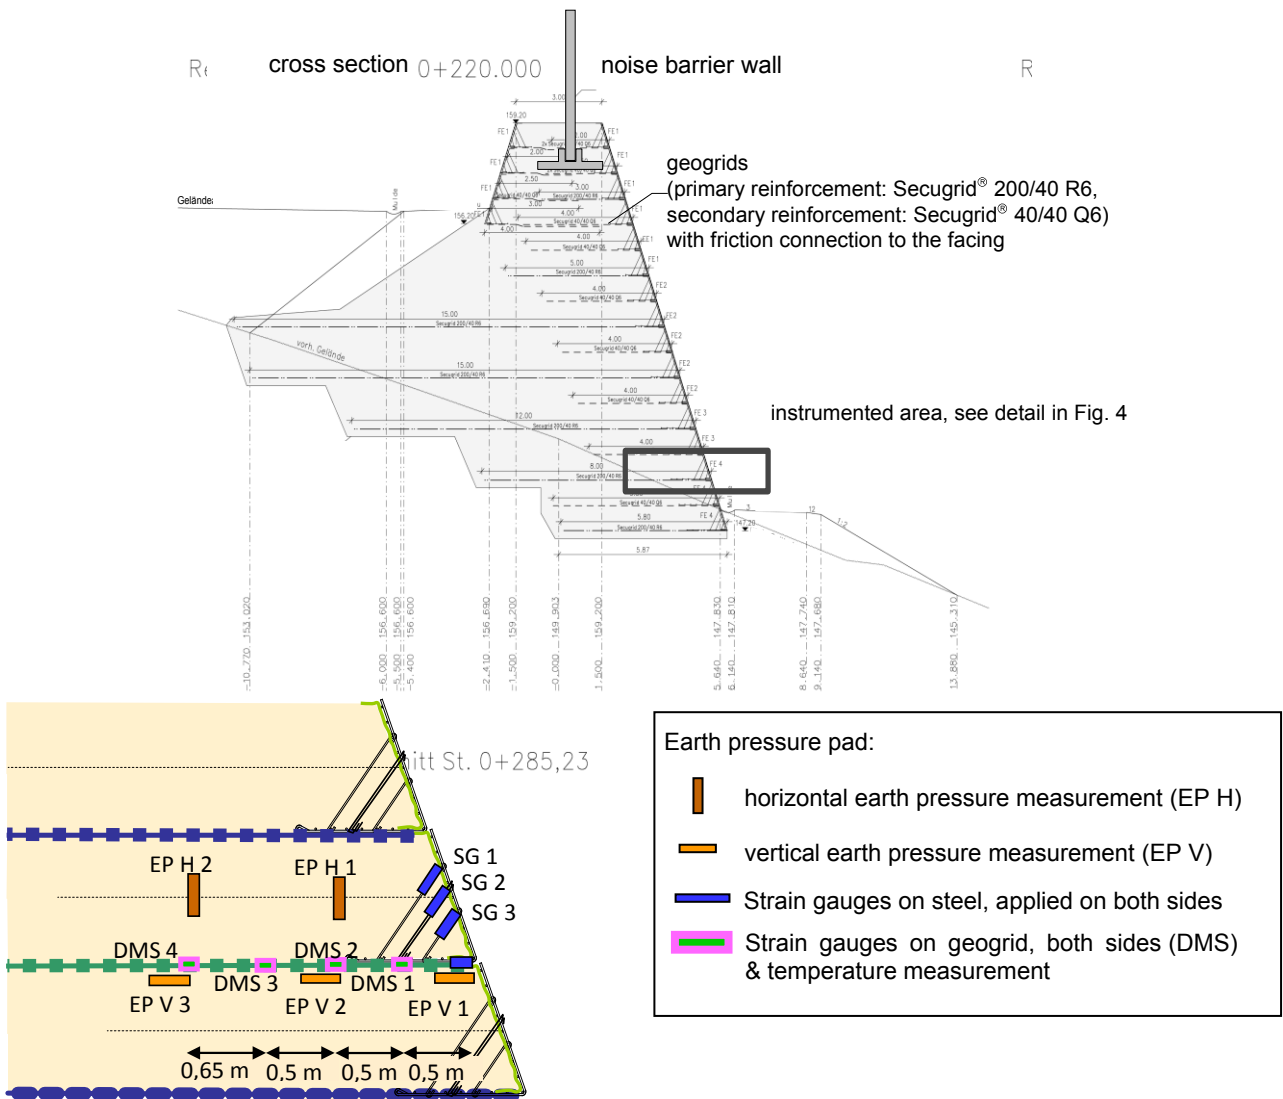

Figure 4. Instrumentation of the measuring cross-section.

5.2 Measurement Concept

The measurement concept which has been established (Figure 4) allows a determination of the horizontal stress affecting the facing by means of an instrumentation of the steel mesh facing element. For the strains measured at the geogrid the influence of the thermoplastic properties (curing process with corresponding heat development, creeping, relaxation) remains partly undetermined and must be completed in the following by means of corresponding laboratory test results.

Moreover it is necessary to carry out earth pressure measurements in order to be able to register the influence and the effect of the formation of restraints and arches (see Pachomow et al., 2007) between two reinforcement layers as well as the vertical strains and thus the load distribution in the facing area. This measurement concept has been realized by the tBU - Institut für textile Bau- und Umwelttechnik GmbH & Co. KG, Greven, Germany.

For the realization of this measurement concept the following detectors are used:

- earth pressure cell (Glötzi)

- strain gauge (HBM)
- temperature sensor

In order to guarantee the long-term monitoring of the construction complex preliminary tests had been carried out in the laboratory before the detectors were installed. The preliminary tests were carried out under hindered simulated environmental conditions as e.g. an increased water pressure of up to 3 m water column on the applied strain gauges. For the strain measurements on the steel wire and the geogrid, different strain gauges - suitable for each subsoil / strains - were used. Both strain gauge types were carried out as temperature and deformation compensated full bridges. The measured value acquisition was carried out by means of a carrier wave amplifier. Also undisturbed samples were obtained from the soil during installation to measure the shear strength at predefined time steps.

6. RESULTS STATUS 2011

6.1 Deformation Measurements

The settlement and deformation measurements which have been carried out up to now show:

- Settlements in the soil body already occurred during the construction phase with values of predominantly < 1 cm per layer. The settlements could be balanced already during the construction process by means of corresponding corrections.
- In analogy to the vertical deformations only very low horizontal deformations could be detected at certain levels (W01 up to W15 in Figure 5), which were within the measuring tolerance and which did not increase with the rising installation height.
- The settlements in the subsoil were clearly below 30 cm. Already at the end of December 2008 only just minor settlements in the range of millimeters were detected. It can be assumed that the decisive settlements have been subsided.

Figure 5. Horizontal Deformations (Layer 1 to 15).

6.2 Earth Pressure (Figure 6)

For the earth pressure cell (EP V1, EP V2 and EP V3) corresponding absolute values were measured immediately after installation of the respective covering. The proceeding covering did not lead to another increase for the cell which was placed near the facing area. The obtained values for all three cells were within a range which was expected. However, a reduction towards the facing area could be determined.

The horizontal strain gauges show at first - together with the increase of the coverage during the construction phase - a continuous increase up to 20 kPa in both gauges before a continuous decrease occurred in the front gauge down to approx. 10 kPa after finalization of all earth works.

6.3 Temperature

Figure 7 shows the measured temperature, located at the strain gauges of the geogrids. It can be seen quite clearly that the temperature gradient changes during the cycle of a year. The changes of the gradients are less significant with increasing coverage with soil.

Figure 6. Earth pressure measurements.

Figure 7. Temperature.

Figure 8. Strain measurements on geogrid and steel mesh facing element.

6.4 Strains of the Geogrids

Figure 8 shows the measured strains in the geogrid. All strain gauges are temperature-normalised, so these values are real strain. For the instrumented product Secugrid 200/40 R6 an absolute tensile strength value of 3.5 kN/m was achieved - assuming a linear-elastic behavior without consideration of the thermoplastic material influences. With time, a slight increase can be found.

6.5 Steel Strains

In analogy to the elongation of the geogrid also the steel tensile strengths for elongations < 0.01 % remain low.

7. EVALUATION OF TEST RESULTS

Within the framework of the preliminary evaluation of the results the measured earth pressure strains were checked as to their plausibility. The values which were obtained directly after installation were verified with the values after the first fill and construction levels. Compared to the expected values the test values show qualitatively as well as quantitatively a good correlation - without any further corrections. Especially noticeable are:

- the very low horizontal strains of less than 5 kPa in the front earth pressure cell and the
- tendency to unitize the vertical stresses (relocation of the vertical stresses to the front area).

Besides the very low total level of the operational demands of the geosynthetics also the good correlation of the above mentioned tensile strength of average 3.5 kN/m together with the horizontal stress of less than 10 kN/m measured in the first strain gauge is noticeable.

Involving the horizontal stress derived from the steel mesh facing element and the very low horizontal deformation which was determined by means of the geodetic measurement it can be noted that the horizontal stresses in the facing area apparently remain very low despite increased vertical stress rates. Compared to the ratio of the active earth pressure approach, horizontal stresses are strongly reduced also under consideration of the specific soil properties with a high cohesive percentage of the shear strength.

8. CONCLUSIONS AND FUTURE PROSPECTS

For the noise protection barrier located on a slope very low horizontal deformations could be detected. These deformations correlate qualitatively very well with the small strains in the reinforcement and the very small tensile strength which affects the steel mesh facing element. The approach of the reduced earth pressure by 30% which has been used - according to EBGeo 2010 - could thus be verified also for fill material with strong cohesive properties. For this construction the approach is still clearly on the safe side for the currently measured strains and stresses.

Besides the calculative verification of the earth pressure distribution especially the long-term monitoring of the tensile forces affecting the steel mesh facing element remain interesting, because the influences resulting from weather and thermal fluctuations could - near to surface - possibly result in a loosening and stress relocation. The instrumentation is dimensioned for a long-term monitoring of the construction.

Deep Soil Mixed Foundation Using Geosynthetics for Levee Support

B. C. Baillie, P.E., M. ASCE, Huesker Inc., USA, brian@hueskerinc.com

ABSTRACT

The construction and design of flood protection levee embankments within coastal areas has become a focal point for infrastructure management. The levee systems are usually constructed over soils with very poor bearing capacity due to their proximity to flood plains. These foundation soils create issues with long-term settlement, changing the protection height and creating the need to periodically build the levee back to the design height. In order to reduce settlements and the maintenance required to preserve design height protection, a deep foundation is required for load transfer. Deep soil mixing (DSM) has become a popular deep foundation solution for just this type of geotechnical issue. Deep soil mixing is a technique used to create cement/soil bonded columns that are utilized as end load bearing elements. The columns are used to bridge the soft foundation soils and create a semi rigid foundation for support of the levee embankment. This solution was recently used by the Corp of Engineers in New Orleans for a protection levee. For this project, a high strength geosynthetic was incorporated into the design and installed over the columns. This paper will outline the considerations necessary for geosynthetic inclusion within deep soil mixed foundations. With the proper use of reinforcement, these applications can become even more efficient in time and cost vs. unreinforced.

1.0 INTRODUCTION

Deep soil mixing has grown very popular as a soft soil foundation support solution. This construction method is used to increase bearing capacity, stabilize global failure planes and mitigate liquefaction. The key advantages of DSM installations over other solutions are cost, time, over excavation disposal and construction vibration during installation. The columns created for levee embankments are designed to reduce settlements, removing the need for staged construction and providing immediate protection at required design height. The levee can be constructed to design heights immediately providing protection much faster than other ground improvement techniques.

The installation method employs rotor tilling a cementitious material into the existing soil down to a designed bearing depth. The cement is carried to the auger shaft or shafts and into the surrounding soil by either hydraulic or pneumatic methods. The moisture content of the soil will dictate which carrier method is appropriate. Both methods however do create an excess mix of soil / cement or soil / water / cement depending on the carrier method. The volume of this excess slurry is dependent on mix design, column area and carrier method.

The constructed columns can be installed in either individual or interconnected forms. Interconnected or overlapping columns are used to form a wall or panel. The increased density of column area can provide greater bearing capacity or reinforce failure planes occurring along the outer edge of the levee.

The use of geosynthetic reinforcement for a piled or column foundations is not uncommon and the available design models have been studied, Stewart & Filz, 2005. This paper will not discuss the different design models but will instead focus on geosynthetic reinforcement selection variables specific to DSM projects. Geosynthetic reinforcement provides a high tenacity mechanism for efficient load transfer to the columns. This load transfer platform allows for reductions in the required area replacement ratio or required column density (Lawson 1992, Russell and Pierpoint 1997, Kempton et al. 1998, Han and Wayne 2000, Han and Gabr 2002) (cited in Stewart & Filz, 2005). The use of reinforcement can also reduce the required column density on the outer portion of the levee embankment used to intersect failure plains for what is called edge stability. The common design and construction approach used on DSM projects for edge stability is incorporating overlapping rows of columns or panels. The additional shear area and strength provided by the panels helps intersect these failure planes providing the necessary design stability. With the use of reinforcement, its tensile strength can be used to offset this failure mode. Another benefit is the minimization of bending forces acting on the columns.

There are many benefits in using geosynthetic reinforcement for levee's supported by DSM columns. In order to use synthetic material in this application however, certain application specific details must first be understood. This paper will discuss reinforcement variables that need to be considered before use within DSM embankment or levee structures.

2.0 SLURRY ENVIRONMENT AND HYDROLYSIS

In order to understand the variables that control reinforcement selection, the environment in which it is placed must first be discussed. The construction process for DSM columns produces an excess volume of treated soil or slurry which collects at the surface during installation. The volume of the slurry is controlled by the mix design, column diameter and depth. This excess slurry is collected and spread across the column / embankment interface within direct contact of the geosynthetic reinforcement. The slurry environment, due to the cement constituent, has a negative effect certain types of reinforcements. The cement added during the mixing process increases the pH of the slurry. This increase is dependent on soil properties and the amount of cement added, which does vary based on project specific needs. Although the extent of pH increase will vary, its effect on the reinforcement and how it governs the design process is always present.

The nominal pH range for geosynthetics commonly used in geotechnical applications is between 4 and 9. Any environment outside this range subjects certain reinforcements to hydrolysis and permanent loss of strength. The amount of hydrolysis and strength loss increases greatly as the pH increases, especially above a pH of 10. Above this level, hydrolysis inflicts exponential damage to the reinforcement and greatly affects the intended design performance and possibly the project itself. The consequence of pH variations outside nominal application ranges has been studied, Testing Protocols for Oxidation and Hydrolysis of Geosynthetics FHWA-RD-97-144 July 1999. The effect of hydrolysis on geosynthetics is measured as a percentile of ultimate strength loss per time. Per the results of this test, the unit for time is one year. Depending on the pH range within the reinforced zone, the rate of reinforcement deterioration can be very dramatic and detrimental to design for long term projects.

In order to verify the pH within the reinforced zone on a DSM project recently, three random tests were done. The data for these tests are in Figure 1. These tests were conducted on the reclaimed slurry at various areas along the foundation axis and within the area of reinforcement installation. All three tests indicated an average pH of 11.2. This pH level is well outside the nominal range for standard reinforcement applications and needs to be observed within the design procedure.

Figure 1. pH testing of DSM slurry

In order to choose the appropriate reinforcement type, the effect of the high pH environment on the base polymer needs to be understood. Both polypropylene (PP) and High Density Polyethylene (HDPE) have a pH range between 2 and 13 without loss of strength. Another reinforcement polymer type within the tested range is Polyvinyl Alcohol (PVA). PVA has a pH range between 2 and 12.5 without loss of strength and minor reductions beyond this boundary. The final and most popular reinforcement, due to availability and high strength, is Polyester (PET). PET has a normal design range between a pH of 4 and 9. Within this range on either side of pH = 7, there are small reductions in strength and they are usually taken into account during design procedures with a factor of safety for chemical and biological degradation. The reduction of strength usually utilized is between 1.05 and 1.1 and is taken directly off of the ultimate tensile strength available. But, with a tested pH environment of 11.2, this reduction is much higher. The referenced FHWA paper has tested reduction factors for coated PET reinforcements within environments outside the typical 4 to 9 range. Based on this data for a pH of 11.2, the calculated strength loss is expected to be around 0.8% per year. So, with this reduction in place, a 75 year design life can expect a 60% reduction in ultimate strength while a 100 year design has its strength reduced by 80%. These reductions should also be used before the long term performance analysis is done to properly

predict material performance. The use of PET reinforcements on DSM projects can be done, but without proper design procedures the actual strength available can be drastically underestimated.

3.0 REINFORCEMENT SELECTION AND STRAIN COMPATIBILITY

Another important variable for the proper selection of reinforcement on DSM levee projects is strain compatibility. The analysis of strain compatibility between the soils being reinforced and the material acting as the tensile reinforcement has been studied, Jewell, R.A. (1996), Zornberg, J.G. (2002) et al. As stated earlier, this paper will not discuss reinforced column design methodology. But the input for the soils contribution to arching between installed columns is universal and this is where the analysis for strain compatibility needs to be evaluated.

During the design procedure, the input for embankment or levee fill materials has a great effect on the overall efficiency and cost for the project. The designer has a choice to either use peak or residual shear strengths for the levee clay fill. The most common approach is to use peak values due to the efficiency in design it produces. A problem exists when the available long term strength in the reinforcement is not also properly analyzed for its compatibility to retain design strength at the utilized deformation limit for the intended design life.

On the same DSM project where pH was evaluated, a study of the clay embankment fill was also done. This data can be seen in Figure 2. The available peak shear strength of the clay was found to be 455 psf with 33° of internal friction. The residual strength results of the same clay were 90 psf with 16° of internal friction. The testing also yielded the amount of displacement at peak which was at around 2%. The clay tested was Corp of Engineers approved levee material and could be viewed as indicative results for most approved levee clays. These results easily show why using the peak values create a much more efficient design. But, if peak shear properties are used, there are certain performance related properties for the reinforcement that must be reviewed to ensure proper compatibility performance.

Figure 2. Direct shear test of approved levee clay

All of the previously reviewed polymers used for geosynthetic reinforcement behave much differently under load. This is especially true for long term strain analysis. All these materials will strain under load. How much so depends on certain factors like polymer type, manufacturing and magnitude of load per maximum allowable tensile capacity. The latter is expressed as a percentile of ultimate tensile strength, UTS, based on the allowable strain per time. As the design life of the structure increases, the amount of allowable UTS available decreases in relation to strain limitations. When a designer calculates the required tensile strength for reinforcement, they must then assign an expected time frame for the structure. This timeframe along with peak or residual shear displacement data will guide the designer into selecting the correctly compatible reinforcement.

The load handling ability of a selected reinforcement must be studied to ensure proper compatibility with the design variables used for time and soil shear displacement. In order to calculate the available strength within the reinforcement at strain limits per time, testing is required and can be accomplished using ASTM D-6992. This test procedure, known as the Stepped Isothermal Method or SIM, creates strain data as a function of expected design time and can be used to predict long-term strain behaviors. The data gathered, Figure 3, can then be used to calculate the UTS required for a specific manufacturers reinforcement based on project specifics.

Figure 3. SIM results for one type of reinforcement

The data in Figure 3 is a sample of a SIM test for one manufacturer's polymer product type. With this data, the designer can match the displacement range of the clay with the appropriate reinforcement strain. The expected time frame for structural performance is also used to finalize the UTS reduction calculation. If a peak shear of 3% is used based on site specific data and the structure is expected to perform no less than 100 years, then the test data indicates a maximum allowable UTS of 20% for this specific material. A common misconception is the use of fast, wide width tensile tests to achieve the same selection process. If a designer was to use a short-term, wide width constant rate test, based on 3% strain, the results are much different. With the same design information, using a short-term testing analysis, the allowable UTS is now 30%. This difference becomes larger with other polymer types. The function of time is very important and needs to be review for each manufacturer's reinforcement. Short-term strain data will not properly align soil deformation with the required tensile strength at compatible strain rates with typical DSM foundation design lives.

4.0 CONCLUSION

The improvement and upgrading of floodplain protection levees and embankments has become a focal point for costal management agencies. The use of Deep Soil Mixed, DSM, columns has proven to be a cost effective solution for embankment support. The semi rigid columns provide foundation stability creating a flood protection system capable of staying at design protection heights with reduced maintenance requirements.

The use of geosynthetic reinforcement on DSM projects has the ability to create a more efficient and cost effective design. Reinforcement can decrease the area replacement ratio required by design and provide embankment edge stability. The use of reinforcement for edge stability can reduce or eliminate the need to increase column density along the outer edge. Localized column separation may also be minimized with the reinforcement acting as a binding tensile platform.

In order to utilize the benefits derived by geosynthetic reinforcement, special attention must be given to the selection process. The DSM construction process creates a high pH environment within the reinforced zone and over the installed columns. The high pH does degrade certain polymeric reinforcements reducing available design strength over time. The longer the design life, the more strength loss accumulates possibly affecting the stability of the entire system. Steps can be taken to evaluate the reinforced environment and account for proper strength reduction.

In order for the reinforcement and embankment soils to act as a cohesive unit, there must be compatible strains between the two materials. During the design process, the use of peak or residual shear strengths for the embankment clays will dictate what the allowable strain in the reinforcement will be. The maximum allowable strain within the reinforcement must also be examined with reference to time. The design life of the structure places great importance on understanding how the reinforcement reacts to designed tensile loads over time, especially long periods of time. Reviewing available test data will help correctly estimate the required reinforcement tensile strength to account for polymer and

manufacturing variability's. If all these factors are reviewed and employed in design, the use of DSM columns for the foundational support of levee systems over poor soils can provide a cost effective solution for long-term protection.

ABSTRACT

Since the early 1970s, Geosynthetic materials have been developed and used as reinforcement in earth-retaining structures. Since then, the use of Geosynthetic's as reinforcing material for reinforced soil structures has proven to be economically attractive based on the many thousands of mechanically stabilized earth (MSE) retaining walls and reinforced soil slopes (RSS) successfully completed.

Mines, unlike other facilities usually require tall earth retaining structures. In recent years, these solutions are frequently used within the mining sector, with excellent results because of their technical and economic characteristics proven in many structures such as retaining walls along primary crushers, dams and tailing deposit containment areas.

The performance of reinforced soil retaining structures have demonstrated that they are often an optimum solution for mining structures compared to traditional retention solutions, combining structural strength, flexibility, versatility and cost effectiveness.

1. INTRODUCTION

Soil reinforcement has been used since prehistoric times for improving soils. The use of straw to improve the quality of mud or clay bricks dates back to early human history. Tree trunks and branches have been used to strengthen buildings with mud walls. Examples include bamboo and tree branches which have been used as soil reinforcement in China for over 1,000 years and along the Mississippi River in the 1880s. Other examples include wooden pegs used in England for the control of erosion and landslides. Natural soil reinforcement can also be achieved by the growth of plant roots. Reliable long term performance using natural materials however is questionable.

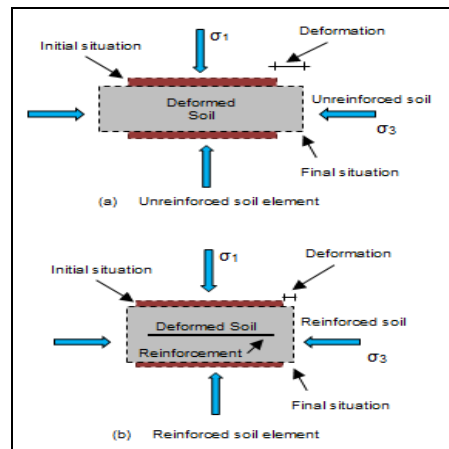

Figure 1. Deformation of a soil with and without reinforcement.

Modern methods of soil reinforcement for the construction of containment barriers were pioneered by the French architect and engineer, Henri Vidal in the early 1960s. His research led to the invention and development of the "Reinforced Earth System", in which steel straps are used as soil reinforcement. The first wall using this technology in the United States was built in 1971 in California.

Figure 2. Reinforced Soil in Malaysia (1979).

The first documented structure featuring a combination of gabions and reinforced soil was built in Sabah, Malaysia in 1979. A near vertical gabion fascia was anchored back into the ground with steel straps. This 14m high structure supports a stretch of highway between Kota Kinabalu and Sinsuran (Figure 2). Due to this success, the same solution was adopted in other sections of the highway over the subsequent years.

Seeking to ensure continuous reinforcement in the horizontal plane, a system was developed and the individual steel straps were replaced with continuous panels of hexagonal double twisted steel wire (DTSW) mesh. A panel of mesh ensures continuous longitudinal reinforcement is developed, not only by friction against the wire section, but interlock between the mesh and the soil and mechanical interlock between the particles of soil material. This is due to the large size of the mesh apertures in relation to the diameter of the wire, resulting in an overall increase in the efficiency of the reinforcement compared to reinforcement materials that provide frictional resistance alone. Corrosion resistance and structural durability is provided by heavy galvalume galvanization (Zinc/ Aluminum alloy) with an additional polymer coating. This experience enabled the optimization of a hybrid product using hexagonal double twist steel wire mesh along with extensible geosynthetic reinforcements offered the technical performance required, yet which was as simple as possible to install. The combination is well suited for use in heavily loaded/tall structures where elongation of the reinforcement is possible and requires flexibility to tolerate lateral deformations and is aptly suited in mining applications.

2. DESIGN OF DTSW MESH/GEOSYNTHETIC REINFORCEMENT SYSTEM REINFORCED WALLS

Gabion fascia DTSW mesh/Geosynthetic reinforcement system reinforced soil walls are designed and sized considering limit equilibrium analysis using a coherent gravity structure approach to check the overall stability of the structure. The types of checks considered are external stability, internal stability and combined stability. Stability checks for reinforced soil walls with vertical face is made by assuming the reinforced soil mass acts as rigid body with earth pressures (Figure 3) developed on vertical pressure plane arising from the back end of the reinforcements.

Figure 3. Earth Pressures for External Stability checks: Horizontal Back slope with Traffic Loads.

External stability checks (Figure 4) involves the checks for overall stability of reinforced mass against four potential external failure mechanisms:

- a) Sliding
- b) Overturning
- c) Bearing capacity
- d) Global Stability

Figure 4. External Stability Checks.

Internal Stability checks involves evaluating potential (Figure 5) slip surfaces within the reinforced soil mass for 'rupture'(Figure 5a) of the reinforcement and 'pull out'(Figure 5b) of the reinforcement from the reinforced backfill material.

Figure 5. Internal Stability Checks.

Geogrid rupture failures can be typically overcome by selecting a stronger geogrid or adjusting the grid configurations within the structural backfill. A pull-out failure indicates that there is insufficient transfer of load from the available geogrid length into the compacted backfill. To overcome this, either the geogrid bond length is increased, or the backfill is changed to one with improved characteristics, thereby increasing geogrid-soil interaction to generate the required pull-out resistance.

The design safety factors for external stability and internal stability must meet the minimum required for the specific project considerations.

The critical failure surface is considered for reinforced soil walls with extensible reinforcement type. Despite being made from steel, hexagonal double twist steel wire mesh is considered to be “Extensible” reinforcement (Chapter 2.4.2 Manual Design Reinforced Soil Walls of the U.S. FHWA FHWA-NHI-10-024). Using this design methodology, the minimum geogrid length required to avoid pull-out of the reinforcement is calculated using the following formula:

$$L_e \geq \frac{T_{\max}}{\phi F^* \alpha \sigma_v C R_C} \quad [1]$$

Where:

- L_e : Embedded length of the reinforcement beyond the rupture surface
- T_{\max} : Maximum factored tensile load in the reinforcement
- Φ : Pullout resistance factor for reinforcement
- F^* : Pullout friction factor
- α : Scale effect correction factor (=0.8)
- σ_v : Unfactored vertical stress at the reinforcement level within the resistant zone
- C : Reinforcement surface area geometry factor
- RC : Reinforcement coverage ratio factor (=1 for continuous reinforcement)

The calculations for external and internal stability of the hybrid system can be performed within any readily available software packages, including the MacSTARS software which was exclusively developed to analyze the stability analysis of DTSW reinforcement and Geosynthetic reinforced soil structures and slopes which include tensile strength reinforcement elements. It also enables users to conduct stability analyses using the limit equilibrium method and can also consider situations without reinforcement within the backfill/slope.

3. DTSW MESH/GEOSYNTHETIC REINFORCEMENT SYSTEMS IN MINING PROJECTS

Growth in the mining sector in recent years has led to increase in demand for different types of construction methods for the various types of works within a mine; roads, containment walls, primary crushers, dams and dewatering areas and hoppers.

The use of DTSW Mesh/Geosynthetic reinforcement system reinforced structures within mines has had great success not only because of its technical and economic characteristics but because of its ease of construction, utilizing unskilled labor. This important feature can generate jobs for people living in communities near the mine, thereby generating a positive social impact and enhanced mine-community relationships

3.1 Retaining Walls Within Mining Facilities

Within mines there is often the need to create large level platforms to accommodate camps, offices, industrial facilities and so on. DTSW mesh/ Geosynthetic reinforcement system reinforced soil walls and slopes have been used extensively to make these areas stand steeper, withstand greater loads and optimize space. Often the availability of on-site structural backfill can make these solutions very cost effective.

a) Retaining wall in “Poderosa” mine ($h_{\max} = 10.0\text{m}$ - Peru). b) Floating Area in Cerro Verde mine ($h_{\max} = 12.0\text{m}$ - Peru).

c) Floating Area in Cerro Verde mine ($h_{\max} = 12.0\text{m}$ - Peru).

Figure 6. DTSW mesh/ Geosynthetic reinforcement System for Retaining Walls in Mines.

3.2 Hoppers and Crusher Installations

DTSW mesh/ Geosynthetic reinforcement system structures are used to create a level difference between two areas. These can have vertical or near vertical faces to minimize the land-take / footprint of the facility. Hoppers or crushers can be installed within the DTSW mesh/ Geosynthetic reinforcement system structure. Mined material is taken to the upper terrace and unloaded into the hopper/crusher. DTSW mesh/ Geosynthetic reinforcement systems (often complimented with high strength geogrids such as Paralink, with strengths up to 1350kN/m) can accommodate the high loads from mine dump trucks and other vehicles.

a) "Orcopampa" mine ($h_{\max} = 9.0\text{m}$ - Peru).

b) "Orcopampa" mine ($h_{\max} = 9.0\text{m}$ - Peru).

Figure 8 DTSW mesh/ Geosynthetic reinforcement System and hopper installation.

3.3 Retaining walls on Access Roads

Most mines are in remote locations and often access roads have to be constructed. Many of these require retaining walls to stabilize slopes, as well as bridges or river defenses.

Figure 9. DTSW mesh/ Geosynthetic reinforcement System for access road to the "Antamina" mine (Peru)

Figure 10. DTSW mesh/ Geosynthetic reinforcement System platform bridge abutment Doe Run mine (Peru)

3.4 Tailings Deposits

Tailings materials left over after the separation of the valuable portion from the uneconomic portion of an ore, generally contain a mixture of soil, minerals, water and rock.

These tailings are often stored in areas known as a tailings or sedimentation ponds. Due to space constraints, the pond walls can become tall and need to be designed appropriately. DTSW mesh/ Geosynthetic reinforcement System has been frequently used to construct these retaining structures, due its speed of construction and reduced structural footprint requirement. A further cost benefit can be realized if structural backfill to the DTSW mesh/ Geosynthetic reinforcement System can be sourced from waste materials from the mine site; crushed waste material, or overburden has been used in the past.

a) "Sinaycocha" mine ($h_{\max} = 8.0\text{m}$ - Peru).

b) "Poderosa" mine (Peru).

c) "Yauricocha" mine ($h_{\max} = 21.0\text{m}$ - Peru).

d) "Ares" mine ($h_{\max}=8.0\text{m}$ - Peru).

Figure 11. DTSW mesh/ Geosynthetic reinforcement System Tailings Deposit in mines.

3.5 Primary Crushers

These large structures are part of the concentration facilities within the mine and crush the mined material to predetermined dimensions for further processing. The large mine dump trucks deposit the mined ores into the top of the crusher. Access to the top of the crusher and the maneuvering yard is provided by ramps and tall retaining walls. Reinforced soil is ideally suited to accommodating the high loads applied by these vehicles.

Figure 12. DTSW mesh/ Geosynthetic reinforcement System for walls for access to the primary crusher Alto Chicama ($h_{\max} = 23.50\text{m}$ - Peru).

Figure 13. DTSW mesh/ Geosynthetic reinforcement System walls providing access to the primary crusher. Gold Fields ($h_{\max} = 16.50\text{m}$ - Peru).

Figure 14. DTSW mesh/ Geosynthetic reinforcement System rockfall embankment for protecting the primary crusher and conveyor belts ($h_{\max} = 20.00\text{m}$ - Peru).

4. SUMMARY AND CONCLUSIONS

Soil reinforcement uses proven technology and is ideally suited to the demands of the modern mine. With the latest generation of geogrids and soil reinforcement systems, these structures are suitable for numerous mine applications including retaining walls, rockfall protection embankments and within mine infrastructure. DTSW mesh/ Geosynthetic reinforcement System provides a cost effective and rapid to install alternative to traditional solutions. These benefits can be further enhanced when the design process determines that site-won materials are suitable for use as structural backfill.

Due to the significance of these structures, the reliability and pedigree of the selected soil reinforcement system should be a pre-requisite for mine owners and operators.

ABSTRACT

Overtopping of earthen levees produces fast-flowing, turbulent water velocities on the landside slope that can damage the protective grass covering and expose the underlying soil to erosion. In this study, the design of an innovative levee strengthening technique – High Performance Turf Reinforcement Mat (HPTRM) is developed based on true full-scale flume tests conducted during overtopping conditions simulating waves or combined wave and storm surge. As the grass roots grow through the open space of HPTRM, roots become entwined within the turf reinforced mat. The interlocking between roots and HPTRM can enhance the resistance against hydraulic and shear forces created by high water flow hydraulic condition. Flow velocity, shear stress and average overtopping velocity on landward-side slope and levee crest are measured and calculated. This paper presents new equations for hydraulic overtopping parameters, and design guidelines for combined wave and surge overtopping conditions.

1. INTRODUCTION

Overtopping of the earthen levees may occur during the periods of flood due to insufficient freeboard. The most problematic case involves the levee being overtopped by both surge and waves when the surge level exceeds the levee crest elevation with accompanying wave overtopping (Akkerman et al. 2007, Hughes and Nadal 2009). Overtopping of earthen levees produces fast-flowing, turbulent water velocities on the landside slope that can damage the protective grass covering and expose the underlying soil to erosion (Sills et al. 2008). Hurricane Katrina caused catastrophic overtopping and extensive damage to the levee system that surrounds the New Orleans (Briaud et al. 2008, Ubilla et al. 2008). Post-Katrina investigations revealed that most earthen levee damage occurred on the levee crest and landward-side slope as a result of either wave overtopping, storm surge overflow, or a combination of both (ASCE 2007). Hence, the crest and landside slopes of those levees that are at risk of overtopping must be protected with some type of strengthening method such as turf reinforcement, soil strengthening, or hard armoring. The levee strengthening systems should resist the forces of fast-flowing, turbulent water that has overtopped the levee crest. High performance turf reinforcement mat is one of the strengthening systems that can be used on the crest and landward-side of earthen levee.

HPTRM is one of the most advanced flexible armoring technologies available today for severe erosion challenges. The HPTRMs are three-dimensional TRMs joined at the intersections of randomly oriented nylon filaments with high tenacity polyester geogrid reinforcement at low strains. As shown in Fig. 1a, nearly 95% of space is open in this material. As the grass roots grow through the open space of HPTRM, roots become entwined within the turf reinforced mat (Fig. 1b). The interlocking between roots and HPTRM can enhance the roots resistance against hydraulic life and shear forces created by high water flow hydraulic erosion. A specific gravity of nylon in the HPTRM more than 1.0 ensures that the HPTRM will not float under any hydraulic condition. The geogrid reinforcement in the HPTRM can help soil stabilization mechanically by taking over when extreme conditions exist (Goodrum 2011). This paper addresses the hydraulic design of HPTRM-strengthened earthen levees on the crest and land-side slope during the combined wave and surge overtopping. The performance of HPTRM is investigated by true full-scale overtopping hydraulic model in Large Wave Flume (LWF) at the O.H. Hinsdale Wave Research Laboratory (HWRL) of Oregon State University.

2. FULL-SCALE TESTS OF COMBINED WAVE AND SURGE OVERTOPPING

A vegetated HPTRM system was developed over a six-month period in the southern climate. With a uniform distribution of seeding spread over the mat, daily watering and weekly mow of the grass were conducted in Mississippi. The height of grass was over 0.15 m before the full-scale overtopping tests. The full-scale tests were conducted in the LWF of the HWRL. The dimensions of the LWF and the levee model are shown in Fig. 2. The HPTRM system was built into a steel tray, which was put into the test section before the tests. The gap between the tray and the side wall of test section was sealed with lumber.

(a) Detailed structure

(b) Vegetated HPTRM system

Figure 1. Illustrations of HPTRM system: (a) Details of the three-dimensional structure of HPTRM mat. Polyamide filaments thermally fused at the intersections and polyester fibers interwoven as geogrid interlock. U-Shaped pin is used to fix the HPTRM mat on clay, and (b) vegetated HPTRM system. The open space of HPTRM allows roots grow through and entwined with the HPTRM to reinforce the plant roots.

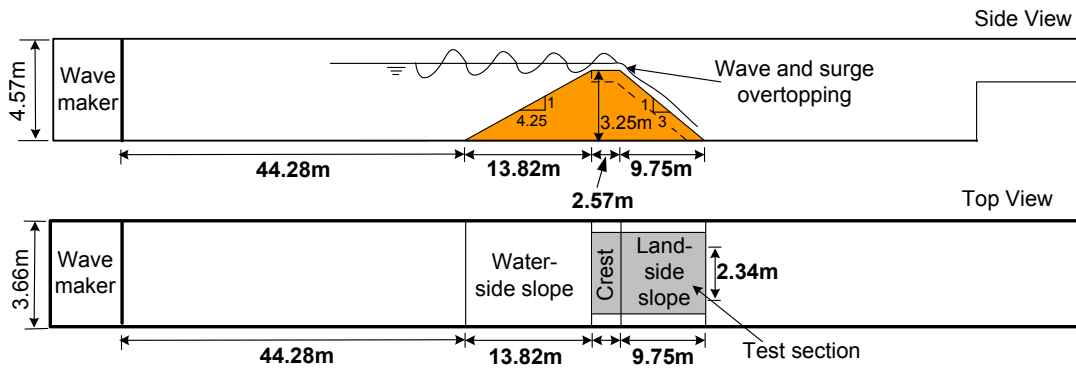

Figure 2. Profile view of the large wave flume and location of levee embankment.

Eight Acoustic Doppler Velocimeters (ADVs) were installed above the levee crest and the land-side slope to measure the x-component (parallel to the levee crest or slope) of flow velocity. Six acoustic range finders were employed to measure the flow thickness at the levee crest and the land-side slope. Based on the capability of the piston wave maker, nine combined wave and surge cases with different conditions were designed. The surge heights were in the range of 0.096 m to 0.317 m, and the significant wave heights ranged from 0.527 m to 0.908 m. The durations of each trial ranged from 10 min. to 90 min. In all the tests, irregular wave time series realization was generated conforming to the idealized TMA spectrum. Data collection started at the same instant the wave board was activated, and collection continued until the wave board stopped. Time series of water surface elevation data at five wave gauges and six acoustic range finders, and eight ADVs at were collected at a 50-Hz rate. All data were recorded for post-experiment processing. Details of hydraulic experiments can be found in Pan et al. (2012a, 2012b).

3. RESULTS

3.1 Steady Overflow Discharge

The time series of flow thickness and time series of flow velocity at the middle of the levee crest were used to estimate the time series of steady overflow discharge, q_s . Based on the formula of Henderson (1966), the steady overflow discharge can be calculated using the following equation:

$$q_s = 0.415(g)^{1/2}(-R_c)^{3/2} \quad [1]$$

where q_s is steady overflow discharge ($m^3/s-m$), g is gravity acceleration constant, R_c is freeboard (m), defined as vertical distance between the still water elevation and crest elevation. During the overflow or overtopping condition, R_c is

negative. In Eq. 1, the constant of 0.415 is smaller than Henderson's value of 0.5443 (Henderson 1966). This may be explained by the fact that the value given by Henderson (1966) is based on the assumption that minimal frictional energy losses exist along the crest and land-side slope. On HPTRM-strengthened levee crest and land-side slope, the frictional energy losses are not negligible due to the grass. Thus the frictional energy losses are the reason why the steady overflow discharge is smaller than Henderson's estimation.

3.2 Average Overtopping Discharge

The time series of flow thickness and time series of flow velocity at the middle of the levee crest were used to estimate the time series of overtopping "apparent" discharge, q_{ws} , for each test. Averages were calculated for data points 2000 to 260,000 (5160 s at 50-Hz rate). Fig. 3 shows the dimensionless combined wave and surge average overtopping discharge versus the relative freeboard for 9 tests. The measurements show a nice trend with increasing relative freeboard except for the two points with relative freeboard $-R_c/H_{m0} < 0.3$. The solid line is the best-fit empirical equation for the data points $-R_c/H_{m0} < 0.3$ given by the following equation:

$$q_{ws}/g^{1/2}/H_{m0}^{3/2} = 0.0053 + 0.378(-R_c/H_{m0})^{1.58}, \quad -R_c/H_{m0} < 0.3 \quad [2]$$

where q_{ws} is average overtopping discharge ($m^3/s\cdot m$), H_{m0} is energy-based significant wave height (m), dimensionless R_c/H_{m0} is the ratio of freeboard (R_c) and the significant wave height based on energy spectrum (H_{m0}). It reflects the proportional relationship between surge overflow and wave overtopping in the combination of surge and wave. Relative freeboard is an important parameter in the study of wave overtopping.

Figure 3. Dimensionless combined wave/surge average discharge versus relative freeboard

The best-fit equation had a correlation coefficient of 0.9868 and an RMS percent error of 0.0049. Hughes and Nadal (2009) concluded that peak spectral wave period (T_p) had negligible influence in the determination of q_{ws} . Based on their recommendation, the peak wave periods of the tests trials were set around 7 s to obtain a larger wave force and more severe erosion on the levee. Similarly, the peak wave period was not considered in the estimation of q_{ws} . Similar to other empirical equations, application of Eq. 2 is limited to the range of tested parameters. In particular, seaside levee slopes different from 1V:4.25H could influence the wave overtopping, but seaside slope effects should decrease as surge level increases.

Based on the value of the ratio q_{ws}/q_s , combined wave and surge overtopping cases with $-R_c/H_{m0} > 0.3$ can be summarized as surge-dominated cases. In surge-dominated combined wave and surge overtopping cases, the ratio q_{ws}/q_s is approaching unity. The combined wave and surge overtopping cases in which $-R_c/H_{m0} < 0.3$ can be summarized as wave-dominated cases. In wave-dominated combined wave and surge overtopping cases, the ratio q_{ws}/q_s increases sharply when R_c/H_{m0} approaches zero.

3.3 Flow Parameters on the Land-Side Slope of the HPTRM Strengthened Levee

Steady overflow on the steep land-side slope is supercritical with slope-parallel velocities increasing down the slope until a balance is reached between the momentum of the flow and the frictional resistance force of the slope surface. Flow down the land-side slope caused by combined waves and surge overtopping is unsteady and more complicated and thus needs more parameters to analyze.

The average flow thickness perpendicular to the slope, d_m , was calculated at the land-side slope starting with data point 2000 and continued to the end of the time series. The average flow thickness d_m on land-side slope can be described as:

$$d_m = 0.384(g\sin\theta)^{-1/3} q_{ws}^{2/3} \quad [3]$$

where d_m is average flow thickness (m), θ is angle of levee land-side slope to horizontal.

The mean flow velocity equation becomes the following:

$$v_{ws} = 2.6(g\sin\theta q_{ws})^{1/3} \quad [4]$$

where v_{ws} is mean flow velocity along the land-side slope (m/s).

The constants in Eq. 3 and Eq. 4 are related to the slope roughness, and the equations are strictly only applicable for landward side slopes of 1V:3H having armoring layer of HPTRM. The constants in Eq. 3 and Eq. 4 are close to the constants in Hughes and Nadal equations (2009) based on 25-to-1 scale laboratory tests on earthen levee, which is consistent with the description of Hughes and Nadal (2009) that the friction factors for grass levee slopes should not be much different from those of their experiments. Schüttrumpf and Oumeraci (2005) noted that friction factor is an influential parameter for wave-only flows over levees and dikes. More work is needed to determine appropriate representative friction factors for a range of slope roughness.

After several attempts using dimensionless combinations of the wave height, wave period, and steady surge discharge, the best empirical result for the wave front velocity was the relationship:

$$v_w = 4.33(gq_{ws})^{1/3} \quad [5]$$

where v_w is wave front velocity along the land-side slope (m/s). With the estimated q_{ws} given by Eq. 2, Eq. 5 can be used to obtain reasonable estimates for wave front velocity v_w . But application of Eq.5 is limited to the range of tested parameters.

4. CONCLUSIONS

A full-scale experiment of combined wave and surge overtopping of a trapezoidal levee cross section strengthened with HPTRM system was conducted to study the hydraulic overtopping parameters and design guidelines. Time series of various flow parameters associated with overtopping discharge and flow field on the land-side slope were estimated. The surge overflow discharge and average overtopping discharge in surge-dominated cases and wave-dominated case are presented. The mean flow thickness, mean flow velocity and wave front velocity associated with the unsteady flow field on the land-side levee slope were examined, and equations were developed based on the time series of flow thickness at measuring points on the land-side slope. Empirical equations for the mean flow thickness and mean flow velocity were expressed in terms of the slope angle and average overtopping discharge. The empirical equations are based on full-scale laboratory tests, which is the only way to test HPTRM on a levee embankment section with a seaside slope of 1V:4.25H and a land-side slope of 1V:3H. The equations associated with unsteady flow on the land-side slope may not be applicable for levees having different slopes.

ABSTRACT

The aim of this study is to develop a new type soil structure, Piled Geo-wall, which can be applied to diverse structures as substitute for concrete ones and contribute to reasonable and sustainable development of infrastructures. This study consists of several experiment studies, full scale static and impact loading tests and a dynamic centrifuge model test, and proposal of a simple design method that can reproduce the experiments' results. The experimental studies and the performance of the proposed structure have already published, hence, proposal of a simple design model and the reproducibility of the experiments' results with using the proposed design model are presented in this paper.

1. INTRODUCTION

The high ductility of soil structure reinforced by geogrid is well known, as is the possibility of building independent soil wall. The independent reinforced soil wall has been applied to such diverse structures as rock-fall protection walls, mud and snow avalanche protection walls and the suchlike. Since it can be built using existing soil at the construction site if it is compactable one, they are being used ever more frequently as one of economic and CO2 reducible structures. At present, however, the adoption of the spread foundation for the independent reinforced soil wall makes the design too wide for application to narrow construction sites, such as beside mountainous road. If a narrow independent reinforced soil wall as like as RC wall with using pile foundation is achieved, it could be widely applied. And it can also be substitute for concrete ones and contribute sustainable development.

Therefore, a new type of independent reinforced soil wall with inserting piles into the Geo-wall body, as shown in Figure 1, which is referred to "Piled Geo-wall or PGW" in this paper, has been developed. The practicability of Piled Geo-wall to diverse structures has been already confirmed from three experimental studies with full-scale static and impact loading tests and a dynamic centrifuge model test (25G) were carried out in the past years (Hara et al. 2010 and 2012).

Figure 1. Image of Piled Geo-wall (PGW).

Recognizing the practicability, a study on simple design model that can reproduce the experiments' results has been conducted. In this paper, because of paper limitation, the proposed simple external stability model in the study and the reproducibility of the proposed model with respect to the experiments' results are presented.

2. PROPOSAL OF SIMPLE EXTERNAL STABILITY MODEL

Piled Geo-wall was devised from an assumption regarding the interaction between pile and Geo-wall body, which the Geo-wall body with high ductility is possible to transmit lateral forces to the piles despite occurrence of large relative displacement between the pile and the Geo-wall body as shown in Figure 2. Hence, in the design, the responses of the pile and the Geo-wall body have to be estimated respectively. Figure 3 shows the proposed simple estimation model of the responses of the pile and the Geo-wall body of Piled Geo-wall

Figure 2. Interaction image between pile and Geo-wall.

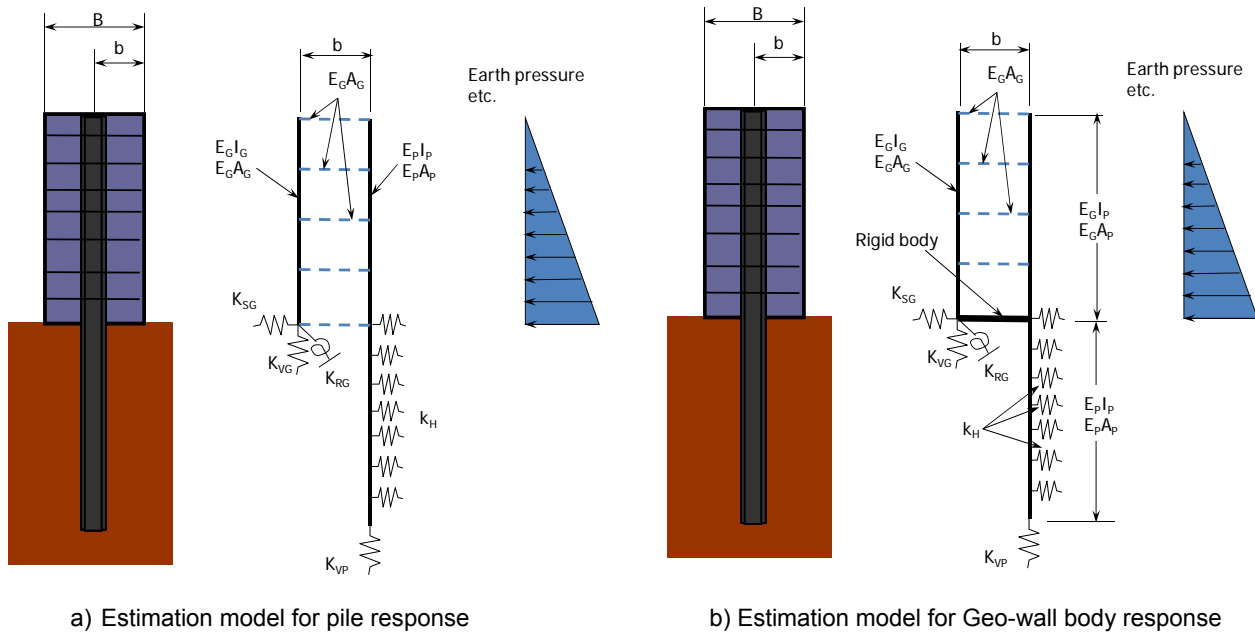

Figure 3. Fundamental external stability model.

Where, $E_P I_P$, $E_G I_G$: flexural stiffness of pile and Geo-wall (kNm^2/m), $E_P A_P$, $E_G A_G$: compressional stiffness of pile and Geo-wall (kNm^2/m), $E_G I_P$: extent without considering flexural stiffness of pile, k_H : elasto-perfectly plastic spring constant of horizontal subgrade reaction (kN/m) set from Eq. 1, the limited value of k_H is passive earth pressure, K_{VG} : elasto-perfectly plastic spring constant of vertical subgrade reaction beneath the Geo-wall body (kN/m) set from Eq. 2, the limited value of K_{VG} is ultimate bearing capacity, K_{SG} : elasto-perfectly plastic spring constant of horizontal shear reaction beneath the Geo-wall body (kN/m) set from Eq. 3, the limited value of K_{SG} , S_{\max} , is set from Eq. 4, K_{RG} : elasto-plastic rotation spring constant beneath the Geo-wall body (kN/rad) set from Eq. 5, the limited value of K_{RG} is determined by the ultimate bearing capacity, K_{VP} : elasto-perfectly plastic vertical spring constant beneath the pile (kN/m) set from Eq. 6, the limited value of K_{VP} is the ultimate bearing capacity of pile, k_h and k_v : coefficients of horizontal and vertical subgrade reaction (kN/m^3) in normal time or seismic situation, which are estimated from Specifications for Highway Bridges Part IV (JRA, 2012), D : pile diameter (m), d_u : unit depth, namely 1.0m, A_G and A_P : cross section areas of the Geo-wall body and the pile (m^2), c and ϕ : cohesion and shear resistance angle of foundation ground (kPa and rad)

$$K_H = k_h \cdot D \cdot d_u \quad [1]$$

$$K_{VG} = k_v \cdot A_G \quad [2]$$

$$K_{SG} = 1/3 \cdot k_v \cdot A_G \quad [3]$$

$$S_{max} = c \cdot A_G + \sigma \tan \phi \quad [4]$$

$$K_{RG} = k_v \cdot b \quad [5]$$

$$K_{VP} = k_v \cdot A_P \quad [6]$$

3. REPRODUCIBILITY OF PROPOSED DESIGN MODEL WITH RESPECT TO EXPERIMENTAL STUDIES

3.1 Full Scale Static Loading Test

The summary of the static loading test of Piled Geo-wall is shown in Figure 4, and the test Piled Geo-wall was built as follows; (1) Pile installing: H steel piles (H-300x300x10x15) of 6.0m in length are installed in 4.0m into the ground. (2) Setting of steel face member and installing of geogrid at each layer: steel face members were set on the both side of Geo-wall and a geogrid was installed at one layer. In the construction of Piled Geo-wall, a geogrid with holes located in the piles was installed through the piles, as shown in Figure 5-a). (3) Installing of longitudinal additional geogrid at each layer: the additional geogrid was installed on the loading side of piles, as shown in Figure 5-b), in order to transmit the load to the piles from the Geo-wall body smoothly. (4) The executions of each layer, 0.5m in thickness, were repeated until that the Geo-walls, 2.0m in height, were completed.

In this test, two jacks set at 1.0m in height to give static horizontal load. And the horizontal load is transmitted to the Piled Geo-wall as a distributed pressure through a H steel (H200 x 200 x 8 x 12), a steel plate of 0.12m and an EPS of 0.5m thickness. Therefore, triangle distribution pressure was loaded to the design model in the response analysis.

The test was performed to both Piled Geo-wall and normal Geo-wall without pile though; the test carried out to Piled Geo-wall is described in this paper.

Figure 4. Summary of full scale static loading test.

a) Installing of steel face member and geogrid b) Installing of longitudinal additional geogrid

Figure 5. Building of Piled Geo-wall.

Figure 5 shows the results of dynamic penetration tests converted to N value of standard penetration test (SPT) as the ground condition of the test. In the response analysis, the result of PD-2 obtained at the vicinity point of the target Piled Geo-wall was referred.

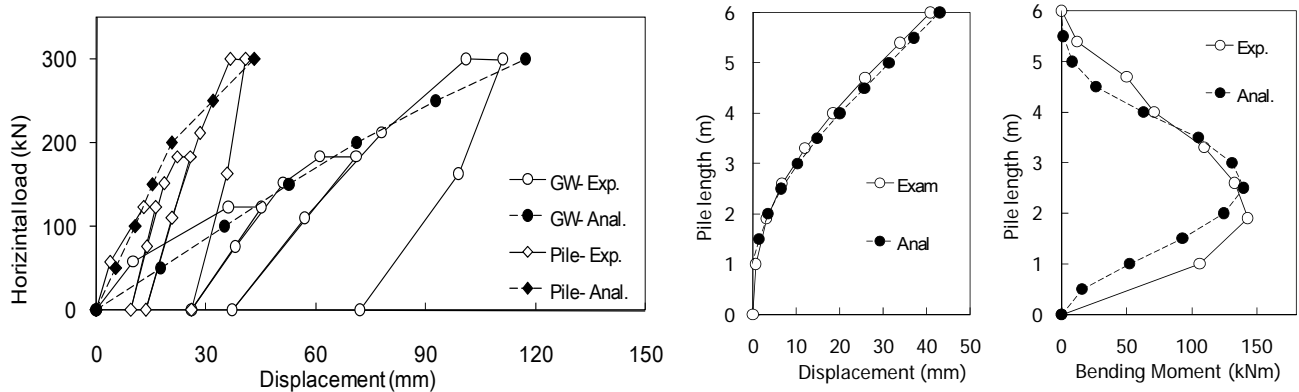

Figure 5. Ground condition.

Figure 7-a) shows the analysis results of the relationship between static load and displacement of Piled Geo-wall, top of the pile and Geo-wall body, which are compared with measured value from the test. And Figure 7-b) shows comparisons with the analysis results of maximum response of pile and measured ones from the test.

According to the results, it is confirmed that the proposed model can reproduce the response of the Piled Geo-wall and the interaction between pile and Geo-wall body as previous assumption as shown in Figure 2.

a) Relative displacement between pile and Geo-wall

b) Maximum response of pile

Figure 7. Comparison with experiment's results and analyzed ones.

3.2 Dynamic Centrifuge Model Test

Figure 8 shows the summary of the dynamic centrifuge test (25G) of Piled Geo-wall. The test was performed to both Piled Geo-wall and normal Geo-wall without pile, as shown in Figure 8-a), though, the test carried out to Piled Geo-wall is described in this paper. Figure 8-b) shows the transverse section of the Piled Geo-wall test model. In the building of Piled Geo-wall test model, installing of normal geogrid and longitudinal additional geogrid were executed as the same as real building as shown in Figure 8-c). Fig. 8-d) shows the input earthquake wave converted to actual scale.

Slope ground was made up of cement-stabilized soil and, the soil of the embankment and the Geo-wall body was compacted with density control. Geotechnical and structural parameters converted to actual scale are presented on Table.1 and 2, respectively.

Table 1. Geotechnical parameter.

	E_0 (kPa)	c (kPa)	ϕ (deg)
Slope	3.26×10^5	55	0
Embankment	3.0×10^4	0	40
Geo-wall	3.0×10^4	0	40

Table 2. Structural parameter.

	E (kPa)	A (m ² /m)	I (m ⁴)
Pile	2.0×10^8	4.79×10^{-3}	2.04×10^{-4}
Geogrid	8.0×10^5	1.0×10^{-3}	-

a) Centrifuge model

b) Transverse section

c) Geogrid installing

d) Input earthquake

Figure 8. Summary of dynamic centrifuge test (25G).

Because recognizing of dynamic interaction between structure and surrounding ground is necessary in order to design the structure by static analysis, dynamic interaction between the Piled Geo-wall and the embankment, transition of pile response and earth pressure at the embankment side of the Piled Geo-wall at the time that the maximum pile response was obtained are shown in Figure 9-a) to c).

According to the results, the antiphase between the response of Geo-wall body at 5th layer (the part with inserting pile) and ones of embankment and Geo-wall body at 10th layer (the part without inserting pile) is confirmed, as shown in Figure 9-d). And the states of inertia forces and earth pressure acting on the embankment side of Piled Geo-wall body at the time that the maximum pile response was obtained were confirmed, as shown in Figure 9-e).

Figure 10-a) shows the comparisons of analyzed maximum pile responses from the confirmed load states and obtained ones from the experiment. And the comparison of analyzed maximum Geo-wall body response and obtained one from the experiment is shown in Figure 10-b).

From these results, it could be confirmed that the proposed estimation model can reproduce well the actual maximum response of the pile and Geo-wall body.

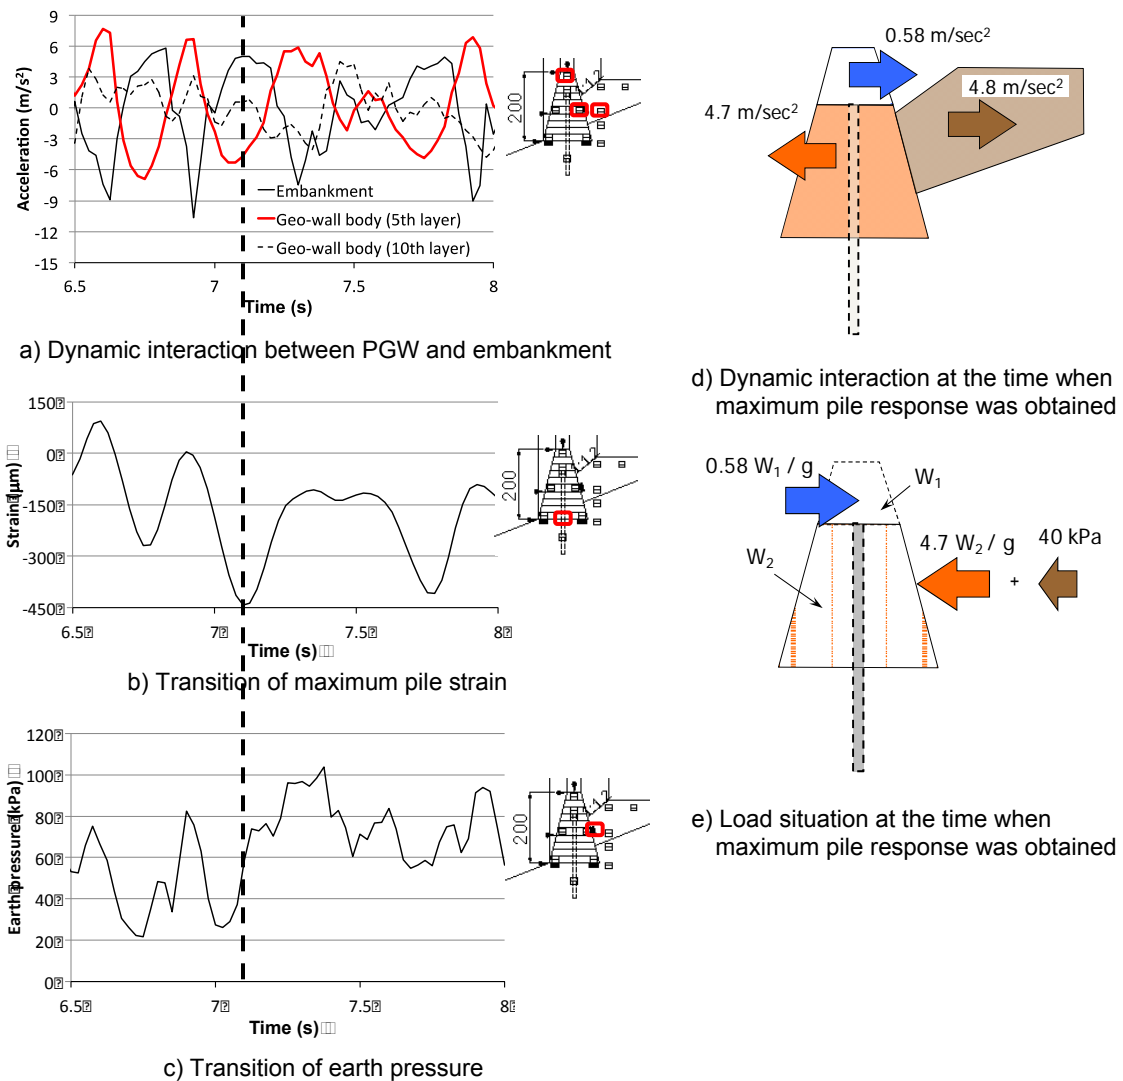

Figure 9. Dynamic responses of PGW and embankment.

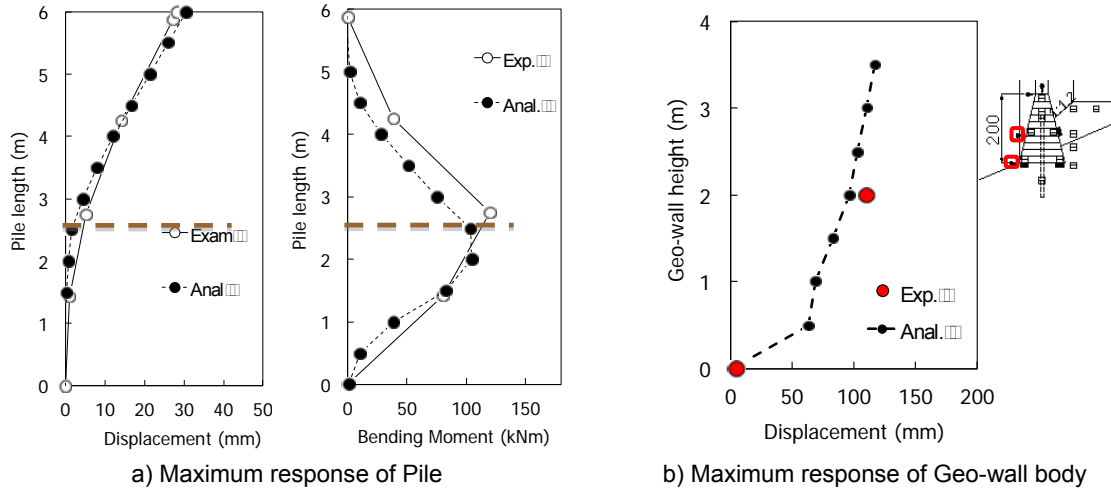

Figure 10. Comparisons of analyzed results and obtained ones from the experiment.

3.3 Full Scale Impact Loading Test

3.3.1 Static load Evaluation of Impact Load

Static load evaluation of impact load is important in case of estimation of the response of Piled Geo-wall receiving the impact load by the static analysis. Therefore the evaluation method was assumed in this study. Figure 11 shows the assumed evaluation procedure of design static load from impact-load.

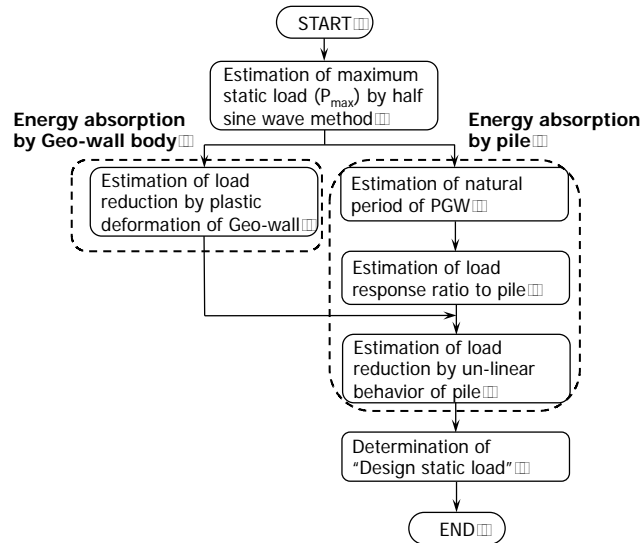

Figure 11. Evaluation procedure of design static load from impact load.

Where, the maximum static load (P_{max}) based on half sine wave method is estimated by Eq. 7. In this equation, m is mass, V_0 is initial velocity (m/sec) at the time of the rock-fall impact to the Geo-wall body, which is predicted by Eq. 8, T is sustaining period (sec) of the impact by PGW, which is assumed as 0.07sec from the experiments, g is G-force, h is falling height of the rock fall

$$P_{max} = \frac{\pi \cdot m \cdot V_0}{T} \quad [7]$$

$$V_0 = \sqrt{2 \cdot g \cdot h} \quad [8]$$

Energy absorption by Geo-wall body was assumed that the difference between entire energy and absorption energy by pile estimated from inverse analysis with using proposed model.

Load response ratio to pile expresses reduction (or amplification) effect of transmitting load to pile. It is well known that the response reduces if the structure with long natural period receives the impact load with short impact period; in contrast, the response amplifies if the structure with short natural period receives the impact load with comparative long impact period. Therefore, the coefficient considered the characteristics in case of using load estimated from half sine curve method was proposed from the past study (Clough et al. 1975). According to the study, the border of reduction and amplification of the response is said to be the case that the ratio of impact period of road and natural period of structure is about 0.26.

And finally, the design static load (P_D) is determined from the load reduction, which is estimated by equivalent energy method (Newmark et al. 1960) of both elastic and elasto-plastic analyses with using the proposed external stability model.

3.3.2 Test Results and Reproducibility of the Proposed Design Model

The impact-loading test of Piled Geo-walls is shown in Figure 12-a). In this paper, the results of two impact-loading tests to actual scale models, one is adopted in the static loading test (PGW-1) shown in Figure 4 and another is a new one (PGW-2), which the piles are installed at outside of Geo-wall as shown in Figure 12-b), are targeted.

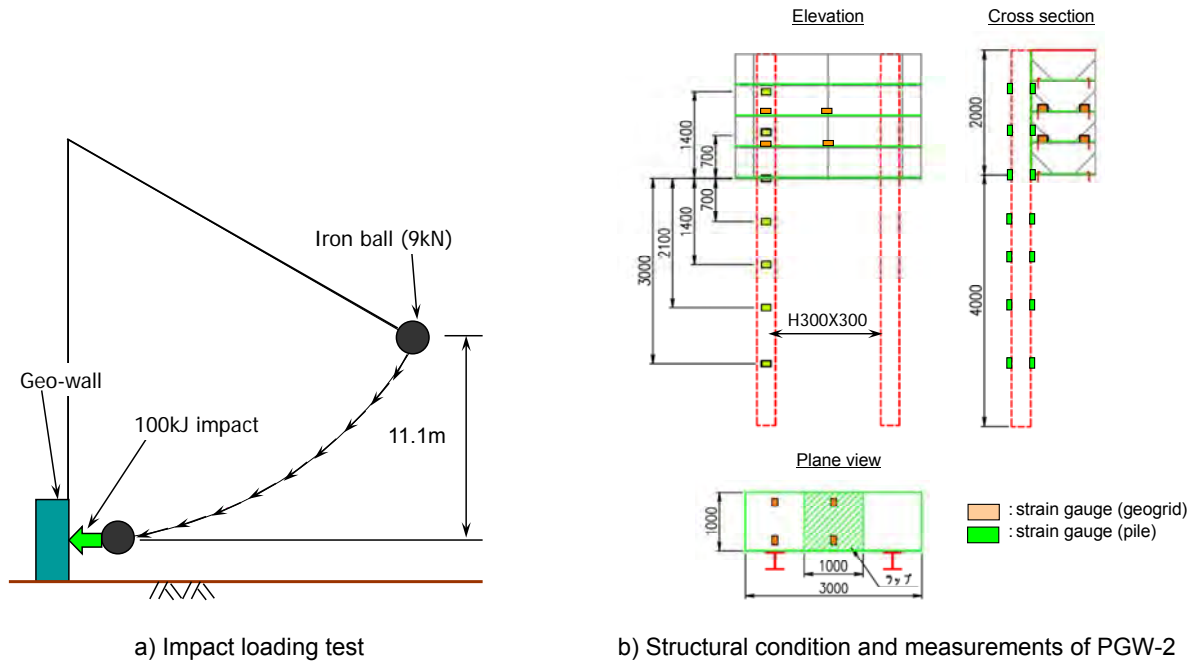

Figure 12. Summary of impact loading test.

Figure 13 show the maximum pile responses of PGW-1 and 2, respectively. According to the results, it can be confirmed that the proposed external stability model reproduces well ones obtained from the experiments. Where, it is no wonder that analyzed pile top displacements match up to obtained ones because the energy absorption of Geo-wall body was determined from inverse analysis of pile, however, the high reproducibility of the proposed model can be confirmed from the distribution in depth of the displacement and the bending moment of piles

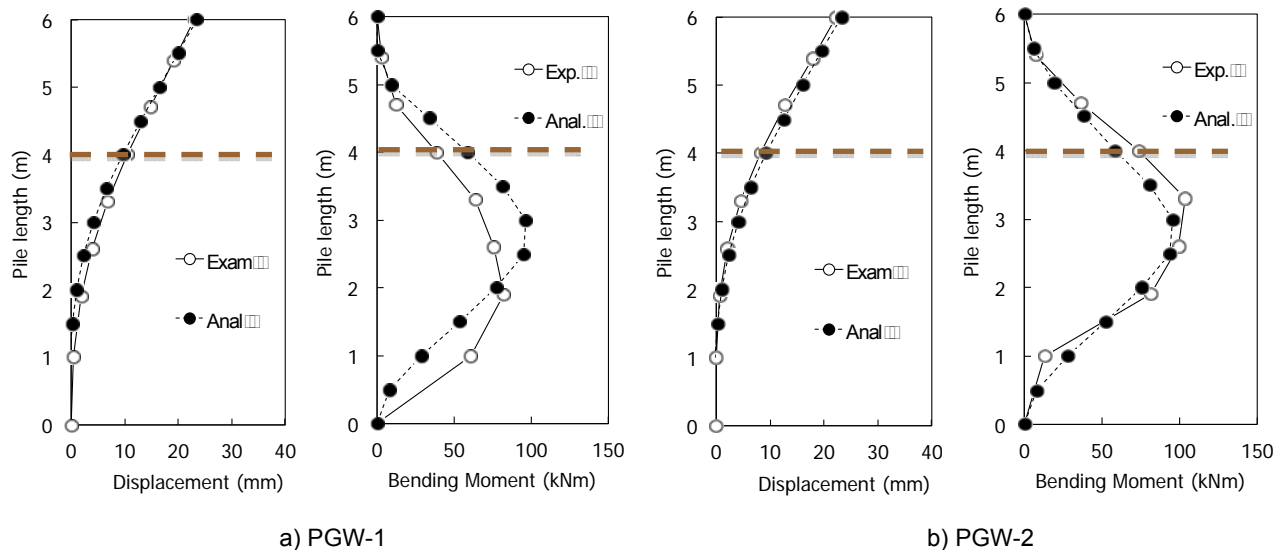

Figure 13. Maximum pile responses.

4. CONCLUSIONS

The contents of this paper are concluded as follows;

- Simple external stability model of Piled Geo-wall for practical design was proposed
- The practicability of the proposed design model was confirmed from good reproducibility of real responses obtained from full-scale static and impact loading tests, and a dynamic centrifuge model test
- In the response analysis on Piled Geo-wall in static load situation (a full scale static loading test), high reproducibility of interaction between pile and Geo-wall body by using the proposed design model was confirmed
- In the response analysis on Piled Geo-wall in seismic situation (a dynamic centrifuge model test), high reproducibility of the maximum response of pile and Geo-wall body deformation by using the proposed design model were confirmed
- In the response analysis on Piled Geo-wall in impact load situation (a full scale impact loading test) for design on rock-fall protection structure, an evaluation procedure on assumption of design static load from impact one was also proposed and its practicability was confirmed from good reproducibility of the maximum pile response by using the proposed procedure and design model

The following issues, however, have to be studied to apply the proposed model to more wide condition of Piled Geo-wall.

- Validity of the proposed model to design on larger scale (width, height) Piled Geo-wall than the test ones
- Practicability of the proposed model to the design on Piled Geo-wall with using steel-pipe pile or multiple rows' piles
- Improvement of static load conversion procedure from impact one as being able to apply to diverse conditions of Piled Geo-wall

Meanwhile, simple internal stability model has been also studied; it will be presented after more verification of validity.

ABSTRACT

The successful performance of geoelectric geomembrane liner integrity and leak location surveys requires a knowledge of the boundary conditions and limitations of the related technologies. If not properly performed optimistic results – no leaks – will be obtained. As the requirements for the implementation of this technology became required by liner design/ CQA engineers and regulators there was a recognized need for appropriate education and certification of the engineering community to help ensure that effective surveys are performed. In this paper we describe the development of such an educational and certification program.

1. INTRODUCTION

The geoelectric method of locating leaks in geomembrane liners was essentially developed simultaneously by three separate groups in the early/mid-1980s: 1) Daren Laine and Glen Darilek at Southwest Research Institute, San Antonio, Texas, USA; 2) Vladimir Nosko of Sensor spol. s.r.o., Bratislava, Slovakia, and 3) Dan Boryta at Foote Mineral Co, Santiago, Chile. The technology started to be adopted by engineers and regulators in the late 1980s and early 1990s for both construction quality assurance (CQA) of newly installed liners and problem leak location in functioning systems. In this paper the former will be referred to as liner integrity surveys (LIS) and the latter as leak location surveys (LLS). Each group developed its own proprietary package of equipment until Leak Sensors Inc. acquired a patent and equipment from Foote Mineral Co and started to lease equipment to somewhat trained operators. This equipment was for surveying liners covered by liquids and for exposed liners. Shortly thereafter Allied Associates in the UK started to sell equipment for surveying soil-covered liners. Subsequently, the Foote patent ran out, Leak Sensors was shut down, and Allied Associates concentrated more on their base geophysical testing equipment. Thus, there came the opportunity in the early 2000s for others to manufacture packages of equipment made available to CQA engineers, facility owners, and liner installers. However, along with that opportunity, came the responsibility for those using the equipment to perform quality surveys, the main concern being that if done improperly an optimistic result would be obtained – no leaks. Therefore, it was felt necessary for there to be a training course and certification program for those wanting to apply the technology which was, by this time, clearly capable of improving the performance of geomembrane lining systems as the final stage of a CQA program. This is evidenced by the fact that several states now require LIS as the final stage of CQA for a primary liner, and New York State will soon require it for secondary liners as well. Therefore, the authors decided to put a training course and certification program together.

2. PROGRAM PHILOSOPHY

The philosophy behind the program was simply that it was better for there to be some kind of training program than no program at all and that surveyors, facility owners, and regulators would recognize such a program. There was no attempt to present this as a formal national program. It was, in fact, based on similar programs introduced by manufacturers of welding machines for welding HDPE pipe a few years earlier.

3. COURSE CONTENT

3.1 General Education

It was first decided that there should be two components to the course, general education and practical certification, but that the latter would include the former. Nominally one day was allocated for classroom instruction. The topics covered include:

- Electricity 101
- Geomembrane liner leak statistics
- Theory and boundary conditions
- Liner design considerations to facilitate effective surveys
- GCLs and conductive geomembranes and geotextiles – advantages and disadvantages
- Case histories
- Standards and specifications
- Equipment
- Field procedures
- Business development

A second day is devoted to small scale survey work in test cells (Figures 1 to 3) using the variations on the basic technique; exposed liner surveys, soil-covered liner surveys, and water-covered surveys

3.2 Water Test Cell (Figure 1)

The water cell, approximately 2 m wide by 23 m long, with water about 200 mm deep, contained a single white surface HDPE geomembrane placed on a GCL (geosynthetic clay liner). The intent of the GCL was to prevent flow of water through the necessary holes in the liner so the students would not see the general locations of the holes from water seeping out from underneath the cell. While the GCL would effectively prevent the holes from actively leaking it would not prevent the flow of current through the holes. An artificial calibration/sensitivity test hole 1.5 mm in diameter could be placed in the water and connected directly to the power supply or connected to an electrode in the soil at the side of the cell to include soil subgrade in the circuit as would occur with a real hole.

There are two holes in the liner for the students to locate.

Figure 1. Water-covered liner test cell.

3.3 Soil Test Cell (Figure 2)

The soil test cell is one roll width wide (~6.5 m) and 23 m long. It has a single liner and is covered with about 200 m of stony soil. It contains about 5 holes of different sizes and types.

In one case a confident group requested that over lunch a new hole be placed in the liner for them to find. A 3 mm diameter hole was made. They could not find it. The instructor could not find it. The soil was removed and there was the open hole. On closer examination it was noted that the puncturing tool had made a cavity in the subgrade soil such that there was no conductive pathway from soil over the liner to soil under the liner through the hole. The electrical circuit was incomplete. When the cavity was filled with soil and soil replaced on top of the liner the hole was easily detected. A very good lesson learned!

Figure 2. Soil-covered liner test cell with calibration/sensitivity test flags.

3.4 Exposed test cell (Figure 3)

This cell is the same size as the soil cell, but is built on a slope so a reservoir of water can be maintained at one end. It is double lined to exclude the subgrade from the electrical circuit under holes in the primary. The cell is divided into thirds along its length. Along one third the primary liner is conductive geomembrane with transverse fusion and extrusion welds. The remaining two thirds have a non-conductive primary geomembrane. Underneath one half of the nonconductive sheet (one third of the total width) is a GCL. Under the final third is a conductive geotextile. Therefore, the impacts of different substrates can be assessed.

Figure 3. Exposed liner test cell.

The students are divided into three groups so that all three cells can be used at the same time with each group performing calibration/sensitivity test procedures, finding real holes, and generally experimenting with “what if” practices. Thus each group spends about 2.5 hr on each technique. In the soil cell students flag the location(s) of the hole(s) which are then excavated to see who is closest.

Since the first course in 2004 approximately 275 people have attended the education component held twice per year in the spring and fall. Attendees have come from Canada, Chile, Peru, Mexico, UK, Finland, Israel, Australia, Ghana and South Africa. The course has been taken on the road to New York, Canada (2), Houston, the Philippines, and the UK.

3.5 Certification

Those candidates seeking full certification undergo a one-day field audit on one of their production surveys, usually, but not always, their first. This requires a full calibration/sensitivity test procedure, and a continuing production survey. At the end of the day a closed book written test is undergone. There are 40 multiple choice and essay-type questions in the written test and 90 minutes are allowed to answer them. The multiple choice questions may have more than one correct answer. A point is given for each correct answer, but one point is deducted for each wrong answer. Maximum points are 151 and passing mark is 50. The highest score to date is 83. Twenty six surveyors have been certified, approximately half of those that have applied.

4.0 FIELD EXPERIENCES

As in most production surveys almost all field audits have included problems that have provided a challenge to the surveyor. Probably the most complex was a double lined pond on a mine site that had metal catwalks from shore to floats in the water with underwater pipes and pumps hanging from the floats. Leaked water was removed from the leak detection system (LDS) between the liners via a pipe penetrating the secondary liner leading to a monitoring manhole. The surveyor carefully considered the isolation of water in the pond and surrounding earth from water in the LDS, the material of the leaked water removal pipe, and the material of the manhole (HDPE or concrete). And if the manhole was concrete was the inside coated, and was the standing water entering the manhole from above or under the water in the manhole, and if above, was it a constant stream or was it dripping. There can be many points to consider before determining that an effective survey can be performed on any lining system. This facility features in a series of questions in the written test. Surveyors have found it necessary to wet gravel and to bury the injector electrode in a lens of sand in gravel. In a number of cases calibration/sensitivity testing has worked well when the artificial hole has been connected directly to the power supply, indicating that the equipment is functioning correctly. However, when soil is included in the circuit a leak signal is not generated. This is usually an indication of a lack of isolation between the water/ soil above the liner and the conductive subgrade and requires the surveyor to seek such features and to remedy them. It is often a haul road that requires cutting to solve the problem.

In one case in which the surveyors found it necessary to wet the cover soil a haul road was not a major problem to sensitivity testing but did generate increasing background signals close to the road. A persistent blip in the signal near the road caused the surveyors to thoroughly examine that location and they eventually agreed that there was a hole in the liner. The general contractor said that simply was not possible at that location. The soil cover was removed and there was a significant tear in the liner.

The ability to perform geoelectric liner surveys requires a basic knowledge of electricity but more importantly requires the ability to think logically about all the components in the lining system and their impacts on the location of the current return (ground) electrode and on the completion of an electrical circuit. Clearly some people can do this while others cannot and this is usually quite apparent during the day in the test cells. Some people, when they are audited performing a survey have difficulty in putting all the layers together to determine if there is a complete circuit and, if there is no current flow, which layer could be causing the problem. Others have great difficulty in coping with the exam-type environment of the written test.

In one case, audits were performed during a water survey but the candidates had difficulty in transferring the survey principles to the soil-covered liner questions in the written test. Since all lining systems have their own unique features it is important to ensure that the surveyor has this analytical capability.

What has been noted is that those people who do not take the course have more difficulty in performing surveys than those who do attend. This gives credibility to the need and value of both the education and certification components of the program.

To ensure the program maintains its relevance it is guided by an advisory board of respected industry experts in related fields.

5. SUMMARY

The education and certification components of the course appear to be achieving their objectives of promoting liner integrity and leak location technologies, identifying their requirements and limitations, and of developing a cadre of capable and competent liner integrity and leak location survey practitioners.

Dewatered and Decontaminated Disposal of Dredged Sediments Using Geotextile Bags, Containers and Tubes

G. R. Koerner, Ph.D., P.E., CQA, Geosynthetic Institute, USA, gkoerner@dca.net
R. M. Koerner, Ph.D., P.E., NAE., Geosynthetic Institute, USA, robert.koerner@coe.drexel.edu
W. Huang, Ph.D., Rutgers University, USA, whuang@envsci.rutgers.edu

ABSTRACT

The use of geotextile bags, containers and tubes has progressed over the past 30-years from sand filling to the dewatering of river and harbor sediments and, as described in this paper, to the decontamination of those sediments when they are polluted. Unfortunately, such pollution is the case for approximately 5% of sediments dredged annually in the United States.

After reviewing the enormity of the situation, various classifications of geotextile flexible forming systems are presented. A performance test, called the pillow test, is described and used in the evaluation of flocculants which are included to efficiently dewater fine grained silt and clay sediments. Such flocculants are critical so as to minimize the negative effects of filter cake buildup on the inside of the geotextile forming systems. The paper then addresses several decontamination possibilities aimed at encapsulating the contaminants within the dewatered sediments allowing for nonpolluted effluent removal. In this regard, examples of the efficiency of charcoal are presented along with estimated costs.

1. OVERVIEW AND BACKGROUND

The amount of sediment carried by rivers and streams into downgradient harbors, estuaries and deltas is enormous by any standard. The U. S. Army Corps of Engineers (NDC, 2012) in maintaining navigable depths has dredged about 115 M m³ of sediments in the first half of 2012 and this does not include private dredging. Of the total amount of dredged sediments, it is estimated by the Corps of Engineers that approximately 5% are polluted by various contaminating species. For example, there were eleven Superfund sites where the cost of removal and remediation exceeded \$50M (U.S. EPA, 2008) with one (the Fox River site) estimated to cost \$490 M (U.S. EPA and WDNR, 2007). The estimate for remediating 58 M m³ of contaminated sediment in the Great Lakes region ranges from \$1.5 B to \$4.5 B depending on the type of remediation selected (Great Lakes Regional Collaboration, 2005 and Nadeau, et al., 2009).

Coupling the nation's watershed pollution status and the continued necessity of dredging, a safe and efficient disposal strategy is necessary and this is the topic of this research program and paper. Of the various available strategies, the use of flexible geotextile bags, containers and tubes to not only dewater the dredged sediments but also to decontaminate them as well is the ultimate goal. By dewatering we mean to decrease the water content of the dredged material to a point where handling by standard earth-moving equipment is possible. By decontamination we mean the chemical bonding of the pollutants to the dewatered sediments (which are mainly fine grained silt and clay soils) within the geotextile flexible form thereby leaving the expelled effluent in a pollution-free and acceptable status. This combined dewatering and decontamination can be performed at the dredging site, adjacent to it, or contained within a nearby landfill.

After describing the various geotextile containment strategies, the paper describes the pillow test which will be used for experimentation, various flocculants (also called coagulants) for dewatering and reducing filter cake buildup, and lastly decontamination additives vis-à-vis specific types of sediment pollutants.

2. GEOTEXTILES AS FLEXIBLE FORMS

Textile fabrics in the form of bags, filled with soil of various types, and then tied off at the top, aka *sand bags*, have been used for centuries. While natural fibers degraded rapidly, the advent of polymer fibers increased the bag's lifetime substantially. Such bags were extended into *containers* at the Mission Dam in Canada (Terzaghi and Lacroix, 1964). Their task was to seal the end of a sheet pile cutoff wall to the sloping and irregular surface of the adjacent rock abutment. A fabric container, wide at the top and narrow at the bottom, filled with cement grout was proposed but first a 5 m high prototype was built. This was considered successful and the concept was used accordingly for the actual 45 m high structure.

Rather than using discrete bags or containers of finite length, tubes of unlimited length can also be used. Flexible sand-filled tubes were made as early as 1957, but initially they were not very successful. Eventually in 1967, a patent was granted to a Danish firm, Aldek A. S., in conjunction with the Danish Institute of Applied Hydraulics. Alidek's system was developed further in 1970 (Zirbel, 1975).

Since that time the area of geotextile tubes has developed considerably to the point where extremely long and large diameter prefabricated geotextile tubes are currently being used. The use of sand filled geotextile tubes for coastal erosion control systems is an ongoing and accepted practice. Furthermore, the infill material for all categories of geotextile flexible forms now varies from hard cementitious materials to contaminated fine grained soils and industrial waste sediments. A suggested categorization is given in Table 1 and examples of the three geotextile flexible form categories are given in Figures 1(a,b,c).

Table 1. Approximate dimensions of geotextile flexible fabric form applications.

Category	Length	Length/Circumference Ratio
Geotextile Bags	0.3-7 m (1-20 ft.)	0.2-2
Geotextile Containers	5-30 m (15-100 ft.)	0.5-10
Geotextile Tubes	15-100 m (50-300 ft.)	5-30

a) Large geotextile bags for coastal erosion control (compl. NAUE).

b) Geotextile containers for removal of harbor sediment (compl. TenCate)

c) Geotextile tubes for harbor sediment dewatering (authors)

Figure 1. Examples of geotextile flexible forming systems.

3. GEOTEXTILE TYPES AND PERFORMANCE TESTING

The geotextile type used in the fabrication of bags, containers and tubes varies considerably. While the decision is usually initiated by the designer, installer, and/or contractor it must eventually be agreed upon by the owner or agent doing the purchasing. The first, and obvious, criterion is to select a geotextile which provides for a successful project. This involves one which can be successfully installed and seamed, does not burst during filling, and meets the owners expectation for adequate serviceability and appropriate long-term durability. The second, and also obvious, criterion is that the cost of materials and the installation must be minimized. Hence, the all important ratio of “benefit/cost” must be maximized.

Regarding the geotextile type and as a broad generality, small geotextile bags are often woven slit-film fabrics while larger bags are often made from needle-punched nonwoven fabrics. On the other hand, geotextile containers and tubes are usually high-strength woven (or occasionally knit) fabrics. In this latter regard, the Geosynthetic Institute has a specification listing various physical, mechanical, hydraulic and endurance properties for both geotextile tubes and their associated scour aprons under both aggressive and typical conditions (GRI-10, 2001).

The performance of the selected fabric with respect to its infill and site-specific conditions can be assessed over time or can be predicted on the basis of laboratory testing. Insofar as large scale laboratory testing is concerned there are many options, but two seem to be most common. They are the *hanging bag test* and the *pillow test*. Both are the subject of a recent paper; see Koerner and Koerner (2009) from which the following is taken.

The hanging bag test was originated by Jack Fowler of the U. S. Army Corps of Engineers in the mid-1990’s (Fowler, 1995). It was eventually formalized as a standard in 2004 (GRI-GT14). There have been several papers written about the test which are generally favorable insofar as fabric selection is concerned, e.g., Zofchak (2001), Bezuijen, et al. (2007), Koerner and Koerner (2006) and Liao and Bhatia (2006).

The test uses a candidate fabric sewn into a cylindrical form and further sewn at the bottom. The top of the bag is left open. Several aspects of the test are shown in Figure 2 including a sand slurry being poured into the top of such a bag, water flowing out of the fabric at the bottom, some passing fine sand in the pan, and the residual soil in the bag after it was cut open.

The alternative pillow test was originated by Tom Stephens of Ten Cate about 2005 (Ten Cate Geosynthetics, Inc., 2007) and formalized as a standard in 2009 (GRI-GT15). The only somewhat related references in the open literature

are the work of Bhatia and her students at Syracuse University who developed and conducted research on a similar test which they called the pressure filtration test (Bhatia and Liao 2004; Satyamurthy et al. 2008; and Satyamurthy, et al. 2009). Hydraulic pressures were measured and quantitative data produced but the laboratory configuration was different than the field simulated pillow test to be described in this paper.

The pillow test per GRI-GT15 uses the candidate fabric prefabricated into the shape of a pillow from which a flanged connector and a calibrated vertical standpipe is attached. The fabric enclosure is quite small and the amount of slurry needed per test is much less than with the hanging bag test. More importantly, hydraulic head (easily converted to inlet pressure) can be monitored over time resulting in a quantitative assessment of the system including the specific effects of the fabric, slurry, and its additives. A pillow test in progress is shown in Figure 3.

Figure 3. Pillow test in-progress using a fine grained silty clay slurry.

Upon performing many comparison tests between the two methods, Koerner and Koerner (2009) arrive at the following conclusions:

“The hanging bag test is relatively large, cumbersome, and difficult to perform. It is also very qualitative in its performance. Conversely, the pillow test is quite the opposite in every respect. Importantly, the pillow test allows for flow rate measurements under varying hydraulic head, i.e., inlet pressures, which is quite valuable in quantitatively assessing fabric types, their filter cake behavior, flocculent effects, and the potential for using decontamination additives when handling polluted sediments. In this regard, the authors favor the pillow test over the hanging bag test.”

4. CHEMICAL FLOCCULANTS (OR COAGULANTS) FOR DEWATERING DREDGED SLURRIES

Most river and harbor sediments are fine grained silts and clays which are readily adaptable to aqueous suspension in the form of a dredged slurry. Dredging is a well advanced technology whereby large quantities can be pumped and transported from the removal site to its disposal destination, which in our case is within a geotextile bag, container or tube. The fundamental issue that arises, however, is that the pressure of the slurry must be contained by the fabric and of course its seams as well. Seams are typically the weak points in these fabric enclosures. Furthermore, the higher the pressure the quicker is the expulsion of water and the more efficient the entire process. With sand or gravel as the infill this is straightforward, but with silts and clays it is problematic insofar as the formation of a *filter cake* progressively built up on the inside of the fabric. This filter cake becomes thicker and more dense with continued pumping time and pressure and in so doing decreases its permeability, greatly limiting the entire infilling process; see Figure 4.

a) Filter cake buildup of sediment fines inside fabric bag enclosure

b) Close-up of the filter cake

Figure 4. Example of filter cake buildup inside a fabric during dewatering.

In order to minimize the adverse effects of this filter cake, chemicals are added to the dredged slurry during pumping. One group consists of standard chemicals (e.g., lime, alum and ferric chloride) and a second group consists of synthetic polyelectrolytes (e.g., polyacrylamide, acrylamide copolymers and others). The goal of these additives is visually illustrated in Figure 5.

a) Before using flocculants (compl. TenCate)

b) After using flocculants (compl. TenCate)

c) Flocculated vs. non flocculated sediments

Figure 5. Examples of the effect of adding flocculation chemicals.

In order to quantify the effect of adding a flocculant to a slurry of inorganic silty clay soil (which was a CL-designation), the previously described pillow test method was used. ZegaLyte 55®, a cationic flocculant, was used for this series of tests in 0.10, 0.20 and 0.40% volume additions. The flow rate response curves of three coagulant additions compared to the inorganic clay (CL) soil with no flocculant added are shown in Figure 6. The increased flow rate is pronounced with 0.10% flocculant added, and even moreso with 0.20% flocculant. The 0.40% flocculant data showed no additional improvement (the two curves identically overlap one another) indicating that the optimal amount of this particular flocculant for this particular soil is approximately 0.20% by volume. Further refinement between the different flocculant additions requires additional testing as does different flocculants and different soil types. In this regard, it appears to the authors that the pillow test is well suited for this type of evaluation.

Figure 6. Effect of flocculant additives on a silty clay (CL) soil slurry (top of pillow was at 30 cm).

5. DEWATERING PLUS DECONTAMINATION

When the river and harbor sediments under consideration are contaminated, recall that the Corps of Engineers estimates that 5% of all sediments are in this condition, the situation of disposal is of major (perhaps even of controlling) importance. In this regard, the pollutants of highest frequency are as follows:

Table 2. Pollutants of highest frequency (U.S. EPA)

• Acetone	• Lead
• Aldrin/Dieldrin	• Mercury
• Arsenic	• Methylene Chloride
• Barium	• Naphthalene (Pending)
• Benzene	• Nickel
• 2-Butanone	• Pentachlorophenol
• Cadmium	• Polychlorinated Biphenyls (PCBs)
• Carbon Tetrachloride	• Polycyclic Aromatic Hydrocarbons (PAHs) (Pending)
• Chlordane	• Tetrachloroethylene
• Chloroform	• Toluene
• Chromium	• Trichloroethylene
• Cyanide	• Vinyl Chloride
• DDT, DDE, DDD	• Xylene (Pending)
• 1,1-Dichloroethene	• Zinc
• 1,2-Dichloroethane	

Using the geotextile flexible forming method in the form of bags, containers or tubes, the addition of not only a dewatering flocculant but also a decontaminant is recommended. In selecting the specific decontaminant for the precise pollutant(s) the dual concepts of solubility and adsorption are necessary to consider. The flow chart of Figure 7 illustrates the situation. In order that attachment of the pollutant to the encapsulated soil occurs, i.e., the desirable result, low solubility and high adsorption are necessary. Conversely, the pollutants will become fugitive in the escaping effluent, i.e., the undesirable result, with high solubility and low adsorption. The two intermediate strategies also illustrated but neither is optimal in this regard.

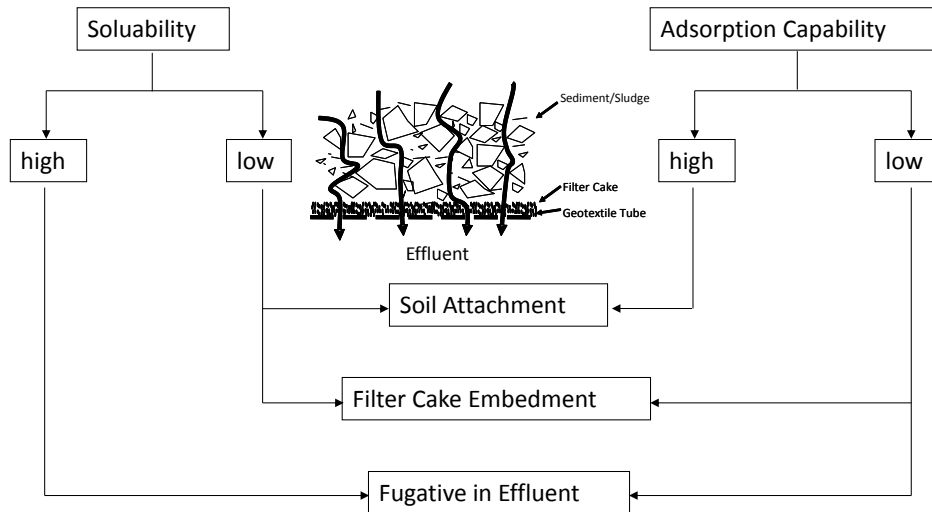

Figure 7. Alternative pathways for decontamination additives to address polluted river and harbor sediments.

The authors have considered the following decontamination additives which can be readily introduced to dredged slurries as they are filling geotextile bags, containers or tubes;

- activated carbon for removal of organic pollutants (a drinking water method),
- charcoal which is a strong sorbent for organic pollutants, or
- phosphoric rock which reacts with heavy metals to form insoluble phosphate salts.

An illustration in the form of a hypothetical example follows and uses charcoal at the rate of 5 gm/L of dredged slurry. The original contaminated slurry was 15% solids and 85% water, with a density of 1.2 kg/L, and had 100 ppm (100 mg/kg) of the following ten pollutants. The before and after dosage values are given along with the percent reductions of the individual pollutants which are all seen to be greater than 90%.

Table 3. Hypothetic example of decontamination reduction of various pollutants.

Type of Pollutant	Before (mg/L)	After (mg/L)	Reduction (%)
Polynuclear Aromatic Hydrocarbons			
Naphthalene	4.53	0.43	90.6
Fluorene	0.69	0.053	92.3
Phenanthrene	0.28	0.021	92.5
Anthracene	0.030	0.0022	92.6
Pyrene	0.077	0.0057	92.6
Benzo(a)pyrene	0.0033	0.00024	92.6
Chlorinated Chemicals			
1,2-dichlorobenzene	4.32	0.40	90.7
2-chlorobiphenyl	0.31	0.023	92.5
2,5-dichlorobiphenyl	0.063	0.0047	92.6
2,2',5,5'-chlorobiphenyl	0.0069	0.00051	92.6

Important in this regard is the cost of the added contaminant which in this case was charcoal. For the reductions illustrated in the above example, the cost at 5 gm/L is about \$1.31/m³. To achieve removal concentrations reductions of 98% or greater of the listed pollutants, the added charcoal required would be 20 gm/L thus \$5.23/m³. While such costs are far from trivial, the entire process of decontamination is critically important and can be the controlling issue insofar as the success of a project is concerned.

6. SUMMARY AND CONCLUSIONS

The flexible forming capability of fabrics lends itself to many unique situations. Nowhere is this more evident than with geotextile bags, containers and tubes used to dewater river and harbor sediments. These sediments are usually fine grained silts and clays which are dredged on an ongoing basis but unfortunately form relatively impermeable filter cake layers on the inside of the fabric enclosures. This greatly limits using high pressures and lengthens the dewatering time accordingly. As described herein, the addition of flocculants (also called coagulants), which are either standard chemicals or synthetic polyelectrolytes, serve to create flocs which increase the permeability of the filter cake thereby enhancing the process. This was shown in the paper using the pillow test method and a specific flocculent in different percentage additions.

Beyond dewatering, however, is the possibility of decontamination of polluted sediments of which there is an abundance of sites and situations. U. S. Army Corps of Engineers estimates that 5% of its dredged sediments are contaminated to varying degrees. For decontamination the additions of activated carbon, charcoal, or phosphoric rock are possible whereby the pollutants are adsorbed onto the soil particles and remain in the fabric enclosure while the effluent is decontaminated to the necessary degree. Examples of a number of polynuclear aromatic hydrocarbons and chlorinated chemicals were presented in this regard.

The geotextile bag, container and tube technology is being actively pursued by industry and the unanswered questions (primarily what type of additives and to what quantities) are presently being answered by simulated performance tests of which the authors favor the pillow test. This test was described in the paper as well as its utilization in evaluating one type of flocculating additive. The exact same test method can be used to evaluate various decontamination additives to polluted sediments and this research is presently ongoing.

Double Lining Systems: One and One Can Make Three!

Ian D. Peggs, I-CORP INTERNATIONAL, Inc., USA, icorp@geosynthetic.com

ABSTRACT

Double geomembrane lining systems have been used since 1974. That first geomembrane was made with two different materials, but since that time the same materials for each liner has become the norm. Thus the synergism of combining the best of different materials and of cancelling the disadvantages of each are not taken advantage of, thereby not achieving the maximum available performance of the superior double lining system. In this paper it is proposed we re-introduce the beneficial philosophy of using two different materials for the primary and secondary geomembranes of double lining systems, much like geomembranes and GCLs are combined to generate a better performing composite liner.

1. INTRODUCTION

As a general rule we now assume that all individual liners leak to some degree (Giroud and Goldstein, 1982) and design leakage collection and gas venting systems to deal with such leakage such that no further damage to the liner and/or subgrade occurs. However, a simple and easy solution to the negative perception of liner leakage - double lining systems - has been used for many years, but rarely is such a lining system optimized. The two geomembranes in a double lining system will, of course, likely have the same small number of flaws. However, provided the primary leakage is removed from between the two liners the secondary liner will only leak if the dribble of primary leakage passes directly over the equivalent leak in the secondary. The chances of this happening are remote (Shivashankar, et al., 1997). Thus, even though each liner may have a few flaws, the complete lining system does not leak.

However if we take this principle one step further we can perhaps optimize the performance and durability of some double lining system by using two different geomembrane materials whose performance characteristics interact synergistically to provide a combined lining system that performs better than each individually and better than double liners of the same material. In principle, this is not unlike combining a geomembrane and a geosynthetic clay liner (GCL), to generate a composite liner.

2. DOUBLE LINERS

The concept of a double liner was first presented by Giroud in 1973. The first double geomembrane liner was designed by J.P. Giroud in 1974 for a reservoir (Figure 1) in Pont-de-Claix, France (Cazzuffi et al., 2010). It consisted of a 1.5 mm butyl rubber primary liner on a bitumen-sprayed needlepunched nonwoven geotextile secondary liner with a leakage detection system (LDS) of rounded aggregate stabilized with concrete between them. It was a good example of two different lining materials complementing one another – a durable seamless uniform secondary liner on a firm compacted subgrade and a very flexible, essentially impermeable primary liner. For even more customized detail the butyl rubber was reinforced from 1 m under the water into the anchor trench so the induced stresses would be assumed by the reinforcement thereby reducing the degradation rate of the rubber. This lining system is still functioning very well. The secondary liner also prevented ground water entering the LDS and being interpreted as primary leakage.

Figure 1. Butyl rubber geomembrane bituminous geomembrane double liner constructed in 1974.
(Photo courtesy J.P. Giroud)

Many years later in 1991 the United States Environmental Protection Agency wrote “Geomembranes are not intended to be stress-bearing members, and the design should avoid stressing the material as much as possible” (United States Environmental Protection Agency, 1991, page 49). This is most important for HDPE for its susceptibility to stress cracking. Thus, that first double liner matched that requirement – the reinforced bitumen provided the flat secondary liner on a firm subgrade and the unwrinkled rubber provided the primary barrier function.

Strangely, these days we seem to have deviated from that different materials concept for double lining systems, which seems to be a missed opportunity for optimum liner performance. Most of our double lining systems in solid and liquid waste facilities are constructed with the same material, predominantly HDPE. Often the only difference between the two liners is that the secondary is thinner than the primary, it being considered as a back-up liner rather than an essential member of a sophisticated integrated high performance lining system.

Whatever the material, if both geomembranes are the same they have the same advantages and disadvantages in terms of their installation characteristics and in terms of their performance in service. This is somewhat surprising in an industry that recognizes the clear synergistic benefits of putting a geomembrane and a GCL together to make a composite liner that performs maybe three orders of magnitude better than each liner alone. It is also strange when we have available three-layer coextruded HDPE geomembranes with HDPE cores and LLDPE surface layers, or vice versa, in order to gain surface chemical resistance with increased flexibility and to blunt surface initiated stress cracks, or to minimize the potential for surface stress cracking while having a strong material. And now we have seven layer coextruded geomembranes containing a central ethylene vinyl alcohol (EVOH) layer for optimum retention of VOCs (Armstrong and Chow, 2012). Clearly, we are not optimizing our double lining systems to combine the advantages and to overcome the disadvantages of different materials, particularly in these days when many different geomembrane materials are available to us. However, a start has been made. For instance, it is generally recognized that HDPE is more suited as a basal liner where the subgrade can be well-compacted, but that LLDPE may be more suited as a landfill cap where differential settlement is more likely. That principle can be applied to double lining systems.

The intent of a landfill double lining system is for the sloping primary liner to collect, drain, and remove primary leachate. This requires a smooth flat geomembrane without wrinkles that might dam or hinder the flow of leachate. Between the

two geomembranes is a leakage detection system (LDS), often an HDPE geonet/geotextile composite that collects, drains, and removes leakage through the primary liner. The success of the double lining system is dependent upon the prevention of a hydraulic head on the secondary geomembrane. Therefore, the secondary geomembrane should also be laid flat for easy and rapid leakage removal and to prevent wrinkles from damming this flow and causing local pools that may just be in the same location as a hole in the secondary. That first double liner developed a small leak in the primary liner in 2004 which was rapidly located and repaired.

The secondary geomembrane is often placed on a low hydraulic conductivity compacted clay subgrade thereby generating a composite liner, but to achieve that synergistic composite function the geomembrane and the clay must be in intimate contact. If there are wrinkles in the geomembrane there is increased possibility of leakage occurring at the peak of the stressed wrinkles (wrinkles are not flattened by overlying soil or water) and the wrinkles allow more widespread distribution of leaked liquids. This is vastly different to the objective of the composite liner that if there is a hole in the geomembrane the local clay/GCL will be hydrated, will swell, and plug the leak. Leakage will preferentially occur along the geomembrane/clay interface until it finds a penetrable crack in the clay. A similar philosophy of parallelism applies to a double geomembrane system.

In many cases there will be a GCL under the primary geomembrane making that a composite liner which naturally requires the primary geomembrane and GCL to be in full intimate contact if maximum barrier performance is to be obtained.

Because of its broad chemical resistance HDPE is often used as a primary liner and inevitably, often by default, as a secondary liner in a double lining system. However, HDPE does have a high coefficient of linear thermal expansion that makes it difficult to install without wrinkles in locations where ambient and geomembrane temperatures are increasing during and after installation. The wrinkles preclude intimate contact with the primary clay liner, prevent rapid and effective removal of secondary leachate, and subject the HDPE geomembrane to undesirable stress when vertically compressed.

If wrinkles are not avoided when the secondary liner is installed it is difficult to place a geonet or geonet/geotextile composite LDS layer in good contact with the secondary liner. And of course it is then impossible to place a flat primary HDPE geomembrane, which itself will wrinkle, on top of two layers that are already wrinkled. All of the performance benefits we are seeking by using a double lining system are compromised. However, if good installers are cognizant of the weather conditions and can use them to advantage it is quite possible to install a good double HDPE lining system. If we install at a higher geomembrane temperature than that at which covering will occur we can theoretically build in some excess material such that at the lower temperature the liner will be flat and the covering medium will hold the liner in intimate contact with the subgrade. Of course there is the concomitant possibility that all wrinkles will not be removed or that the temperature will fall too far and bridging/trampolining will occur in corners and at the toes of slopes. No liner, particularly HDPE, should be forced into contact with the subgrade.

However, building in excess material (compensation) is much easier to talk about than to do. Ultimately it is the designer's responsibility to say how much compensation is needed because he/she knows most about the operating conditions of the liner, but mostly it is left to the installer to do the right thing.

Clearly, installing at low temperatures and allowing for covering or service at higher temperatures is another matter since wrinkles at the higher temperature cannot be avoided. Note again that wrinkles are not flattened when covered with soil or liquid.

To resolve the wrinkling concerns but to keep HDPE as the primary liner for its chemical resistance we could use a different geomembrane for the secondary liner. Clearly this should be a material with a lower coefficient of linear thermal expansion such as unreinforced PP (half the CTE of HDPE), or a reinforced geomembrane with essentially zero CTE, or even a prefabricated bituminous geomembrane. The choices are many. However, not only is CTE important so is the nature of the subgrade which may be another reason for seeking an alternative to HDPE. An unreinforced PP, PVC, or LLDPE will accommodate a rougher surface than HDPE and will be much more tolerant in the long term of the stresses associated with any differential settlement that might occur. However, if differential settlement is likely to occur one should carefully consider the break elongation of a proposed reinforced geomembrane in relation to the strain expected at any differential settlement. While traditional reinforcing scrims have break elongations of ~15%, newer scrims have break elongations close to ~40%.

The secondary liner of a double lining system probably does not need the chemical resistance of the primary. It certainly will not need the same UV resistance as the primary, unless it is to be exposed for some time before the primary is placed. And this highlights a stage in a liner's lifetime that is often ignored – the time between installation and being placed in service. It is not unknown for liners that are to be covered in service to be left exposed for 8 or 9 years before covering. A large pond HDPE liner in a windy environment was installed at low temperatures with compensation built in,

even though the liner would be covered several months later at a higher temperature. The increasing temperature generated more and larger wrinkles which were uplifted by the winds (no ballast) and blown to the downwind shore where a very large wrinkle formed and cracked after only 2 years (Peggs, 2012).

Why lay a wrinkled primary liner on top of a wrinkled secondary liner when the secondary could be laid flat? Why not use a strain resistant secondary liner that is tolerant of differential settlement, deformation, and rough subgrades and a more thermal oxidation resistant primary liner? Consider a primary liner that will better contain VOCs and a lay-flat, less costly, not-so-UV-resistant secondary liner. The combinations are virtually unlimited and can be made project specific to optimize lining system performance and durability.

Consider a MSW landfill being built in a very cold environment on a coarse gravel subgrade. It makes sense from the leachate chemistry aspect and for ease of permitting to use an HDPE primary geomembrane. This is placed on top of a primary GCL. Not only does the GCL provide a composite primary liner, it also acts as a cushion for the primary geomembrane, and with adequate moisture content allows a geoelectric integrity survey to be performed on the primary geomembrane when there is only a nonconductive geotextile/geonet/geotextile composite, often called "geocomposite", in the LDS. If the subgrade is too coarse for a secondary HDPE just meeting Geosynthetic Research Institute (GRI) standard GM13 specifications, then an HDPE with improved stress cracking resistance could be used to tolerate the surface roughness. On the other hand, if HDPE is required because of leaking leachate chemistry one could use a three layer co-extruded geomembrane with HDPE on the outside and LLDPE in the core. The HDPE would provide chemical resistance while the LLDPE would provide the flexibility to tolerate the surface roughness. And if the HDPE did start to stress crack, the cracks would be blunted and stop growing at the HDPE/LLDPE interface. While a short crack might give access of leachate to the LLDPE it would be in a very small area and not do too much damage.

One particularly interesting material combination is an HDPE primary liner with a prefabricated bituminous secondary liner. A bituminous geomembrane is relatively heavy and thick and will lay flat. It can be deployed and welded in very cold weather (-35°C). Its weight makes it more resistant than polymeric geomembranes to wind uplift. It will conform to rough subgrades, and it has a very low coefficient of linear thermal expansion. When soil is spread on top of it it does not wrinkle (Figure 2.) and it can be folded and unfolded on the ground without creasing. In a cold windy environment, such as the Arctic, it can be laid to remain flat. Welds are easily made and can be 100% nondestructively tested ultrasonically. It can make a good secondary liner.

For the primary liner engineers like to use HDPE geomembranes because many precedents have been set for its use, it has a very broad chemical resistance, and it is easier to get permitted by regulators. Regulators like HDPE, again because many precedents have been set, it requires no new thinking, and they do not have to go out on a limb to make decisions on novel materials.

Another possible option, while retaining an HDPE primary liner, is to use a more flexible (fPP, RPP, PVC, EIA, etc.) secondary liner that can be prefabricated into large panels to minimize the number of field seams for rapid installation. At the large ~350 ha (875 acre) Columbus Upground Reservoir project prefabricated panels of 1.00 mm fPP are being installed at the rate of almost 3.6 ha per day. A prefabricated secondary liner may or may not be reinforced to suit the nature of the subgrade, the potential for differential settlement, and the weather. But the ability to install a flat secondary liner exists.

Figure 2. Bituminous geomembrane. No wrinkles (top arrow). No creasing at fold (bottom arrow).

Many other examples could be provided, but it is really the principle of considering the installation, post-installation/pre-service, and in-service, requirements of the lining system that is emphasized and the realization that optimum performance may be achieved by using different materials for the primary and secondary geomembranes of a double lining system.

3. CONCLUSION

Where a double lining system is required optimum performance and maximum durability may be achieved by using different materials for the primary and secondary geomembranes. The specific materials used will be a function of subgrade quality, potential for differential settlement, installation temperature, time available for installation, temperature when line is covered, time between completion and placing in service, service temperatures, chemistry of liner content, etc.

Durability Studies on Coir Geotextiles

S Chandrakara, Professor, Department of Civil Engineering, N.I.T Calicut, India
Sreela.P.K, Assistant Professor, Department of Civil Engineering, Government Engineering College, Trichur, India

ABSTRACT

Coir geotextiles has prominent role in improving the properties of soils to utilize in pavements. Low shear strength and high compressibility, can be improved by the use of coir geo textiles. By the inclusion of coir geo textiles C.B.R value of the soil is found to be increases. One of the major deficiencies reported in using coir geotextiles is its decay. Attempts were made to improve the durability of coir geotextiles by various treatments. In this paper the results of an experimental study carried out on treated coir geotextiles with various chemicals and latex is presented. It is found that by treatment with latex durability of coir geotextiles is found to increase without causing much reduction in strength.

1. INTRODUCTION

Geo-synthetics are being increasingly used in various civil engineering applications to tackle a variety of problems. Geosynthetics may be made up of natural or synthetic materials. For the short term improvements geosynthetics with natural fibers are sometimes used. One of the popular natural geotextiles is made up of coir. Coir is 100% organic fiber which is obtained from the husk of the fruit of the coconut palm tree. It possesses the advantages of a ligno cellulose fiber .The material is not brittle, non-toxic and poses no waste disposal problems. Coir fiber has a lignin content of about 46 per cent .This strong natural fiber is also biodegradable, but at a slower rate than other natural fibers.

2. LITERATURE REVIEW

Varma et al (1986)“thermal behaviour of coir fibers” In this study the thermal characterization of naturally occurring coir fibers and modified bristle coir fibers was carried out . Balan (1995), conducted studies on “durability of coir yarn for use in geo meshes by the use of two types of coir yarns subjected to different environmental conditions. From the above study it was seen that the life of coir yarn was controlled by the type of embedment soil, climatic condition, water content, organic content and the type of coir used. The rate of degradation of coir yarn was studied in different soil environments. Sobha (1996) conducted studies on the suitability of coir felt, coir felt reinforced with nylon mesh, and combinations of coir mesh and nylon mesh. In this test the materials used to study the influence were plain coir felt, coir felt reinforced with nylon mesh and a combination of coir felt and coir mesh. Ajitha Bhasker and Mary John (1996), conducted studies using coir fabrics on improvement of subgrade for roads”. Penetration tests were carried on coir fabrics subjected to repetitive and impact loads.

Geethamma et al. (1997), conducted chemical treatments on coir fiber, to find out the effect of chemical modification, loading and orientation of fibre. Goulart et al (1999). Conducted studies on coir fibre from Brazilian north east coast on their mechanical and thermal characterization. Khalil et al. (2000) conducted studies on the effect of acetylation on interfacial shear strength between plant fibers and various matrices. Rout et al. (2001) conducted studies on “The influence of fiber treatment on the performance of coir polyester composites. Sreekala et al. (2001) conducted studies on “water- sorption kinetics in oil palm fibers” Alexander et al (2001) conducted experiments on surface characterization of natural fibers. In this study surface properties and the water up-take behaviour of modified sisal and coir fibers were examined. Not much attempts were made to enhance durability of coir geotextiles . In this paper results of an experimental study carried out on the durability of coir geotextiles on various treatments is presented. Attempts were made to treat coir yarn with different chemicals and also with latex. Durability studies conducted were restricted to certain aspects like effect of soil medium, presence of water, temperature etc.

3. MATERIALS USED FOR THE STUDY

Materials used for the study are clay, sand, coir geotextiles, natural rubber latex, and various chemicals that are required for the treatment.

3.1 Chemicals Used for Treatment

The various chemicals required for the treatment on coir are Sodium Hydroxide, Ethanol, Benzoyl Chloride, Acetic Acid, Acetic Anhydride, Sulphuric Acid, Potassium Permanganate Solution, Acetone and Dicumyl Peroxide.

Tests for identification and classification of soils and for the determination of engineering properties are done as relevant ASTM standards.

3.2 Properties of Materials

The various properties of clay determined are liquid limit 43%, plastic limit 19%, shrinkage limit 16%, Optimum moisture content (OMC) 19.5%, maximum dry density 16 k N/m³ and CBR soaked soil sample was 2%. Maximum density of sand used was 18 k N/m³ and specific gravity 2.6. The diameter of coir fibre is 16 microns and the length is 150-200mm. Density of coir fibre is 14 kN/m³ and moisture regaining capacity at 65% RH is 10-50%. The chemical compositions of coir are lignin content 45.84%, cellulose 43.44%, ash 2.22%, hemi-cellulose 0.25% and pectin and related compounds 3.3%. Properties of latex shown in the table.1

Table.1 Constituents of Natural Rubber Latex

Constituent	% Composition
Rubber particles	30-40
Protein	2-3
Water	55-65
Sterol glycosides	0.1-0.5
Resins	1.5-3.5
Ash	0.5-1.0
Sugars	1.0-2.0

3.3 Index Properties of Coir Geotextile

The index properties of the coir geo-textiles used in the experimental study is 2.5mm thickness, 9 k N/m² mass per unit area and mechanical properties such as percentage of elongation for warp is 31 and for weft is 28 also breaking strength for warp is 29 kN/mm² and for weft is 11.3 kN/mm².

4. RESULTS AND DISCUSSIONS

4.1 Chemical Treatments

Attempts were made to improve study the variation in strength of coir geotextiles by treating with various chemicals Coir geotextile yarns were dipped in chemicals for 24 hours and tested for their strength. The improvement in strength due to the chemical modifications is in the range 25-35 %. The strength is greatly affected by the concentration and the duration of treatment selected. Some of the chemicals used for treatment on Coir is harmful to the human body are dicumyl peroxide, acetic anhydride and benzoyl chloride and also these chemicals are costly and highly dangerous when handling. The sodium hydroxide treatment is less costly and harmful; but the improvement in strength is only marginal. Tensile strength behaviour of 2% Na OH treated coir yarn is presented in figure 1. It can be seen that not much improvement is achieved even after treating with 8% Na OH

Figure.1 Tensile Strength Vs Alkali Concentration

4.2 Effect of Natural Rubber Latex Treatment

The tensile tests were carried out with untreated coir yarn and after treating with different chemicals .Results obtained are presented in Table 2 . It can be seen that the latex coating carried out on Coir yarns has improved the tensile strength about 82 % of the untreated Coir yarn. This improvement is attributed to the binding action of latex on coir.

Table.2 Improvement in Tensile Strength

TYPE OF TREATMENT	TENSILE STRENGTH (NF/ Sqm)	PERCENTAGE INCREASE IN TENSILE STRENGTH
Untreated	23	---
Alkali	28	22
Benzylation	26	15
Peroxide	31	34
Permanganate	28	21
Acetylation	27	15
Latex	42	82

4.3 Durability Studies

Coir yarn is studied by immersing the Coir yarns in different solutions and in different soil media and tensile strength was measured at regular intervals. Results obtained are presented below.

4.3.1 Influence of Submergence in Clay and Sand

It is observed that by keeping in sand, Coir was able to retain its original strength up to one month where as in clay the Coir retained its strength up to 3 months before a reduction in strength was obtained. At the end of 6 months the percentage reduction in strength of Coir in clay was 16% and in sand was 32 %. The variation of reduction in strength in sand and clay is shown in Figure 2.

Figure.2 Reduction in Strength of Coir immersed in Sand and Clay

4.3.2 Influence of Submergence in Acidic Neutral and Alkaline Solution

Experiments were carried out to examine the strength of coir yarn in different pH medium. It is observed that at the end of 6 months the reduction in strength of Coir in acidic medium is 38 % and in alkaline medium is 45 %.The reason for the faster degradation in alkaline medium is may be the OH ions .The OH ions in the lignin content is made active by the OH negative ions in the sodium hydroxide solution which neutralize some of the lignin content in the coir, and accelerates the degradation. The degradation was found to take place in distilled water environment also. The results are presented in Figure 3.Similar tests were carried out in salt water and tap water environment. Not much change was observed.

Figure.3 Reduction in Strength of Coir in Water with Different pH

4.3.3 Influence of Alternate Wetting and Drying and soaking

Tests were conducted on coir yarns subjected to alternate wetting and drying and soaking in different environment. Reduction in the strength resulting from various treatments is presented in table 3. Alternate wetting and drying was done for 10 cycles in 6 month time

Table.3 Percentage Reduction in Strength in Different Soaked Media

SOAKED MEDIA	PERCENTAGE REDUCTION IN STRENGTH AFTER 6 MONTHS
Clay	16.08
Sand	32
Salt Water	20
Tape Water	23
Distilled Water	50
Acidic Solution (pH 3)	38
Alkaline Solution(pH 8)	45
Alternate Wetting	33

4.4 Influence of Water Absorption

Untreated Coir fibers absorb much more water compared to treated fibers leading to poor mechanical properties. The alkali treatment have resulted in the removal of waxy coating on the fiber surface, as a result the cellulose components of Coir are exposed making the surface more hygroscopic. In the case of latex treated Coir a protective coating on the surface makes it water repellent, thus absorption is less. The moisture content is measured by finding the weight gain of the material. The result was shown in the Table 4.

Table.4 Water Absorption Studies

TYPE OF TREATMENT	CONDITION	MOISTURE CONTENT
Untreated	Room temperature	12%
	Fully soaked in distilled water	31%
Alkali treated	Room temperature	18%
	Fully soaked in distilled water	39%
Latex treated	Room temperature	4%
	Fully soaked in distilled water	11%

4.5 Influence of Accelerated Thermal Ageing

Accelerated tests were conducted on Coir samples for understanding its behavior.. Table 5 represents the thermal ageing results on Coir. It is observed that on increasing the temperature a reduction in strength was observed in untreated and treated coir yarns.

Table.5 Results of Accelerated Thermal Ageing

TEST TEMPERATURE	UNTREATED COIR	ALKALI TREATED COIR	LATEX TREATED COIR
	PERCENTAGE REDUCTION IN TENSILE STRENGTH		
100+1	-	-	-
125+2	60	58	30
150+2	88	83	47
175+2	100	-	64
200+2	-	100	88
250+3	-	-	100

4.6 Determination of Strength Aspects of Subgrade Using Different Treatments on Coir Geotextiles

4.6.1 CBR Test Results

CBR test is carried out on clay sample with and without treatment Coir geotextiles. Result was shown in the figure 4.

Figure.4 Load-Penetration Curve

Table.6 CBR values of soil with the use of various treated coir geotextiles

MATERIAL USED	CBR VALUE (%)
Untreated clay	2
Untreated coir	4.5
Alkali treated coir	4
Latex treated coir	7.5
Thermal-latex treated coir	7.8

The CBR value for the untreated clay is 2 % which was improved to 4.5 % by utilization of coir geotextiles. Further studies were carried out by treating coir geotextiles with various treatments for improving CBR. Alkali treated coir and the untreated coir obtains approximately the same value of CBR. The use of the latex treated coir and the thermal latex treated coir shows a significant improvement in strength that 7.5% and 7.8% respectively.

5. CONCLUSIONS

Results of the limited experimental study carried out with coir geotextiles with various treatments shows that latex treated coir geotextile shows an improvement in CBR. Results of the study indicates that coir geotextiles degrade faster in water media than in salt water media. Also in sandy soil degradation was found to be faster than in clays. In the alkaline medium the degradation was higher compared to the acidic medium. The degradation was lesser for latex treated samples compared to untreated and other chemical treated samples. From the above study it can be inferred that the latex Coir geotextile can be effectively used to improve the strength of soft clayey soils and can be effectively used as subgrade.

Reduction in strength in alkali media is attributed to change in the pH. In the alkaline media with pH 8 showed a decrease in pH and the acidic solution showed a reduction in acidity after treatment. This is due to the replacement of OH ions, contributed by the reaction between the lignin content and the solution in which the coir is immersed. The degradation of coir in sand compared to clay is due to the mechanical breakdown of the coir, when placed in contact with sand.

Effective Strategies for Residual Polymer and Aquatic Toxicity Testing for Dredge Slurry Dewatering

Randy Wilcox, P.E., WaterSolve, LLC, USA, randyw@gowatersolve.com

Gregg E. Lebster, WaterSolve, LLC, USA

Bruce Rabe, Environmental Resources Management (ERM), USA, bruce.rabe@erm.com

ABSTRACT

Chemical conditioning is typically required to facilitate the solids and water separation in the vast majority of dredging and dewatering operations. Even with the best efforts in optimizing the chemical dose, a small fraction of the polymer may be released in the filtrate water after the dewatering operations. Site conditions and regulatory requirements specific to a particular location may dictate that aquatic toxicity testing of the discharge water be completed on individual projects.

After several products and/or combinations of products are tested in bench scale jar tests to determine the most effective products and the associated dose(s), a larger scale dewatering test is completed to determine or verify the suitability of the dewatering technology selected. The example projects discussed for this presentation utilized geotextile containers and the tests were completed accordingly. The geotextile container filtrate collected from the laboratory scale tests was subjected to a series of aquatic toxicity tests based on regulatory agency requirements.

Protocols for aquatic toxicity tests typically require acute and/or chronic toxicity test assessments on a representative sample of filtrate water after conditioned with a specified chemical. In some cases, a specific dilution with site water will be included with the procedure to simulate a mixing zone. The species selected for testing will be based on location, salinity, and other factors. It may be necessary to perform the aquatic toxicity testing using more than one chemical conditioning program.

The regulatory agency will typically approve the chemicals at the dose used in the testing. Additional toxicity testing may be required during operations. Some projects have residual polymer testing requirements. Qualitative testing is typically done in the field as a gross determination of polymer present in the water. The quantitative test is a more precise test meant to be conducted in a laboratory setting under controlled conditions.

Keywords- chemical, conditioning, regulatory, acute toxicity, chronic toxicity, whole effluent toxicity

1. INTRODUCTION

In order to effectively dewater dredged material, chemical conditioning is required. The most effective chemical conditioning program is determined by extensive bench testing. The selection of products is based on the project requirements and objectives. In many cases, two or more products are required to optimize the conditioning program.

During the dewatering operations, efforts are made to minimize the polymer use for several reasons. Even with the best efforts to optimize the use of chemical products, a small fraction of the polymer may not be captured with the solids and is released with the water. It has been demonstrated that the product will attach to any available solids in the receiving water. However, the products have toxic effects of aquatic life and any portion that is not rendered inactive by attachment to available solids has been shown to be harmful.

The material safety data sheets for the products typically contain basic ecological and toxicological information. Additional aquatic toxicity testing may be required using the water released from a simulated dewatering operation. The procedures for sample collection and testing are determined prior to testing. The products, application rates and doses are determined by testing. Samples for initial testing are collected by simulating the dewatering technique to be utilized for the specific dredging application. The aquatic toxicity tests are conducted according to the protocols prescribed by the regulatory agencies.

In certain cases, the residual polymer is measured in the filtrate water released. This measurement can be based on samples collected directly from the dewatering operation or in some cases is based on samples collected at

prescribed locations in the water body after the filtrate is released to the water body. The procedures for qualitative and quantitative testing are available to determine the presence of residual polymer and the amount of residual polymer in a specific sample.

2. CHEMICAL CONDITIONING

Based on the primary project objectives, such as dewatering efficiency, filtrate water clarity, contaminant removal or other objectives, the most effective chemical conditioning program is determined by bench testing. The sample solids concentration and other parameters are determined and required dilution is made to simulate dredge slurry with site water. The dry weight solids concentration of the dilution is also determined according to U.S. EPA Method 160.2.

Several products are evaluated in bench scale tests to determine the most effective product or combination of products to meet the project objectives. These evaluations are based on several factors including water release rate, water clarity, and flocculent appearance. These factors are used to compare the various products to isolate the most effective products and doses.

Chemicals most commonly used to enhance dewatering in dredging applications are:

1. Organic Flocculents
2. Organic Coagulants
3. Inorganic Coagulants
4. Hybrid Chemistries

The application of the chemicals is typically done by injection into the dredge line. Based on the mixing energy requirements or restrictions determined during the bench testing, the injection location relative to the dewatering mechanism can be placed. The effectiveness of the conditioning is frequently checked using a sample port placed downstream of the chemical injection. To optimize the application of chemical, the feed rate can be automatically adjusted based on variances in slurry flow rate and solids concentration.

3. AQUATIC TOXICITY TESTING

The National Pollutant Discharge Elimination System (NPDES) permitting authorities use Whole Effluent Toxicity (WET) testing program as one of the tools for achieving the Clean Water Act's prohibition of the discharge of toxic pollutants in toxic amounts. WET is defined as the aggregate toxic effect to aquatic organisms from all pollutants contained in a facility's wastewater (effluent) (54 Federal Register (FR) 23868 at 23895, June 2, 1989). WET testing methods have been developed to measure wastewater's effects on specific test organisms' ability to survive, grow and reproduce. These test methods were promulgated in 1995 and added to the list of U.S. EPA methods approved under Section 304(h) of the CWA (40 CFR 136) for use in the NPDES program.

Federal regulations establish different approaches for implementing a water quality criterion for toxicity in NPDES permits, depending on whether the criterion is expressed in a numeric or narrative form. States that have not adopted a numeric criterion for WET are expected to interpret the State narrative criterion so that the appropriate effluent limits, including any necessary toxicity numeric limits, can be established. States typically identify the method they intend to use in regulating toxics based on narrative criteria and describe how their toxics control program will protect aquatic life and attain the narrative criterion. Examples of some of the WET specific issues addressed in State toxic control programs include the following:

- how critical low flow and effluent dilution series are determined;
- receiving stream aquatic life use designations;
- frequency of monitoring;
- use of marine species or freshwater species for testing;
- sample type, test type, and biological and statistical endpoints; and
- conditions under which acute or chronic testing is required.

For the Southern Shores dredging project, treated water was discharged to a tidally influenced portion of the Dick White Bridge Channel. The State of North Carolina bases WET limitations upon the instream waste concentration (IWC) during conditions of maximum permitted effluent flow and 7Q10 receiving stream flow. The IWC for the Southern Shores project was determined to be 100 percent. In keeping with the State standard for facilities with IWC values greater than or equal to 0.25 percent, the facility was required to demonstrate that treated effluent was not chronically toxic at 100 percent.

For this application, the State required the City of Southern Shores to conduct a five concentration, pass/fail chronic toxicity test using the marine invertebrate, mysid shrimp (*Americamysis bahia*). Each of the five test concentrations consisted of 100 percent receiving water treated with a combination of water additives, bracketing the target application rate. An additional receiving water concentration without the water additives served as a negative control. A concurrent positive control consisted of aged synthetic seawater.

Per U.S. EPA Method 2002, the chronic test was conducted using 250 milliliter (mL) polypropylene containers containing 150 mL of control water or appropriate test solution. Five, seven day old test organisms were randomly introduced into each test chamber with eight replicate chambers per treatment. Organisms were fed 0.2 mL of a concentrated suspension of less than 24-hour old live brine shrimp nauplii (*Artemia* sp.) daily during the test. Organism survival was determined daily by enumerating of live mysids. Survival was defined as any body or appendage movement. At the termination of the test, mysids in each test chamber were counted, dried, and weighed to the nearest 0.01 milligram (mg).

The test was conducted at a temperature of 25 ± 1 degrees Celsius ($^{\circ}\text{C}$) under fluorescent lighting with a photoperiod of 16 hours light and 8 hours dark. Water quality measurements consisting of dissolved oxygen, pH, salinity, and temperature were performed daily on selected treatments.

Following termination of the test, statistically significant differences ($P=0.05$ or 0.01 depending on test endpoint) in mysid survival and growth were determined between the receiving water control and the various treatments. All statistical analyses were performed using the ToxCalc Version 5.0.23 software program.

To demonstrate compliance with the imposed discharge limitations, two sets of chronic toxicity tests were conducted during September 2010, on varying concentrations of Solve 3 and Solve 9330. The initial test incorporated a five concentration matrix of Solve 3 and Solve 9330 with concentrations ranging from 2.8 pounds of Solve 3 and 0.8 pounds of Solve 9330 per dry ton of product to 7.8 pounds of Solve 3 and 1.7 pounds of Solve 9330 per dry ton of product. The results from the initial exposure revealed no adverse survival effect to the five product combinations. Survival ranged from 79 to 100 percent, compared to 92.5 percent in the receiving water control (Table 1). Growth was adversely effected ($P=0.05$) in all five treatments and ranged from 0.140 to 0.247 mg per organism, compared to a control of 0.298 mg per organism (Table 1). Based on the adverse growth effects, a second set of samples were prepared and tested.

In the second set of samples, the concentration of Solve 3 was held consist at 4.5 pounds per dry product and concentration of Solve 9330 was varied from 0.16 pound to 0.8 pounds per dry product. Following the second exposure, mysid survival was again unaffected and ranged from 92.5 to 97.5 percent, compared to a receiving water control response of 95 percent (Table 2). Mysid growth ranged from 0.281 to 0.324 mg per organism; compared to a receiving water control performance of 0.336 mg per organism (Table 2). Unlike the initial test, adverse mysid growth effects ($P=0.01$) were limited to the maximum concentration of Solve 9330 of 0.8 pounds per dry ton of product. Mysid growth in the four lower concentrations of Solve 9330 was unaffected and resulted in a non-toxic response.

Table 1 - Data Summary of September 3 – 10, 2010 *A. bahia* Chronic Toxicity Test

Concentrations (lb/dry ton product)	Survival (%)	Growth Average Wt./ Organism (mg)
Laboratory Control	95	0.301
4.5 lb Solve 3 w/ 1.7 lb Solve 9330	80	0.140*
6.1 lb Solve 3 w/ 1.7 lb Solve 9330	79	0.140*
7.8 lb Solve 3 w/ 1.7 lb Solve 9330	87.5	0.188*
4.5 lb Solve 3 w/ 0.8 lb Solve 9330	95	0.247*
2.8 lb Solve 3 w/ 0.8 lb Solve 9330	100	0.240*
Receiving Water Control	92.5	0.298

* Statistically lower when compared to the control or the dilution control (P=0.05)

4. RESIDUAL POLYMER TESTING

When requested or required, the residual polymer can be determined according to “*Determination of the Presence of Polymer Using the Flocculation Method*”. This procedure includes qualitative and quantitative methods. The qualitative test is normally completed in the field as a gross determination of the polymer present in the sample of water. This can also be used as a comparative test for estimating the approximate quantity of residual polymer within a certain range. The quantitative test is more precise and is meant to be conducted in a laboratory setting under controlled conditions.

Initial data points are determined by using known concentrations of the flocculent and performing the test according to the method described above. The data points are then graphed and a best fit curve is added as shown in Figure 1. Samples collected are tested in the same manner and the settling times are plotted on the curve to determine the

residual polymer present. Table 2 shows the initial testing to create the data points on the left and the testing of the samples collected in the field on the right. Figure 2 illustrates the testing in a photograph showing how the settling times vary with the amount of residual polymer present.

5. CONCLUSION

Current regulatory trends in the dredging and dewatering industry dictate that approval of dewatering chemical products is required. The regulatory agencies for individual states have variable requirements for these approvals. In order to provide the most effective products that will meet the environmental suitability standards, the type of testing presented will continue to be required. We anticipate that this specific testing will be used to satisfy the growing desire to regulate these products. With the proper testing prior to and during the project implementation, along with the use of the most effective chemical feed systems, the chemical conditioning can be optimized for dewatering dredge slurry residuals.

Effects of Discrete Fibers on the Stress-dilatancy and Micromechanics of Fiber-reinforced Sand

ABSTRACT

The stress-dilatancy relationship plays a very important role in understanding of the mechanical behavior of granular soils. Numerous experiments on fiber-reinforced uncemented and cemented granular materials have been carried out over the last two decades. However, the effects of fiber, cement, and confining pressures on the stress-dilatancy behavior have seldom been investigated, especially at high confining pressures and at micro level. In this paper, the stress-dilatancy relations and micromechanics of fiber-reinforced uncemented and cemented sand at a wide range of confining pressures are investigated. Results obtained from drained triaxial compression tests carried out on sand with various fiber and cement contents are compared and analyzed. The effects of high confining pressure and fiber content on the stress-dilatancy behavior of cemented sand reinforced with polypropylene fibers are discussed. Scanning Electron Microscopy analysis of the effects of particle, bond and fiber damage on the stress-dilatancy behavior of the sand is presented.

1. INTRODUCTION

Numerous experiments on fiber-reinforced granular materials have been carried out by several researchers over the last two decades (e.g. Maher and Gray 1990; Michalowski and Zhao 1996; Consoli et al. 2004; Tang et al. 2007; Diambra et al. 2010; Ibraim et al. 2010; Silva dos Santos et al. 2010; Ud-din et al. 2011). However, the effects of varying fiber/cement contents and confining pressures on stress-dilatancy behavior have not been investigated very thoroughly. Furthermore, most experimental data on fiber-reinforced cemented materials have been obtained at relatively low confining pressures and at macro level. A detailed review of the literature regarding the dilation of fiber-reinforced granular materials reveals that the previous studies somehow lack detailed information on the stress-dilatancy behavior and the dilation angle of fiber-reinforced cemented soils.

The observed tendency of dense granular materials to expand in volume during drained shearing is termed as dilatancy. The physical manifestation of dilatancy was first identified by Reynolds (1885), and long afterward, Rowe (1962) introduced a stress-dilatancy theory. There are several factors that influence the dilatancy in cemented granular materials including relative density, cement content, and confining pressure (Coop and Atkinson 1993; Consoli et al. 2000, 2004, 2009, 2012; Yan and Li 2011). The volume change plays an important role in the stability of frictional materials (Bolton 1986, Lade 1988, Yu 2006). For instance, the increase in volume provides higher shear strength to geomaterials during shearing. The variation of dilatancy rate depends on the initial packing, with denser materials showing a more rapid decrease in dilatancy rate compared to loose materials. In addition, according to Yu (2006), bonding delays or prevents the tendency of soils to dilate at small strains. The effect of cement content on dilatancy has been further analyzed by Wang and Leung (2008). They found that at small strains, dilatancy is hindered by the intact bonding network that produces a web-patterned force chain. However, after yielding, the increase in the dilatancy accelerates. Moreover, they observed that the dilatancy at the peak state increases with increasing cement content. Marri (2010) and Marri et al (2010, 2012) reported a progressive suppression in the dilation of cemented sand by the gradual increase in confining pressure. According to Marri (2010) and Veiskaramia et al. (2011) a dense cemented soil exhibiting a dilative behavior at low stress levels may show a contractive behavior at higher levels of confining stress.

Since at high stresses, the suppression of dilatancy rate plays an important role in controlling the shear behavior of cemented sand, the influence of the confining pressure on the plastic properties of sand, mainly the friction and dilatancy angles are of significant importance. Moreover, the progressive suppression of dilation in cemented materials by the gradual increase in confining pressures needs to be incorporated into the design considerations and therefore, it needs further elaboration. This is because the mechanical response of cemented materials at high pressures can be significant for analysis of offshore piling, deep galleries and mine shafts, high earth dams and mechanics of oil-bearing strata. Recent developments of massive offshore constructions particularly for oil exploration have highlighted the importance of

high confining pressure, which affects design of foundations for these structures. For instance, many oil reservoirs reach depths over 1000 m subjecting naturally cemented soils to very high overburden pressures (Dalla Rosa et al. 2008). This leads to the question whether the stress-dilatancy behavior of a cemented soil at high confining pressures is similar or different from that at low confining pressures.

2. METHODOLOGY

2.1 Materials

Well-graded, medium quartz concrete sand from Sheffield in the United Kingdom, so-called Portaway sand was used as the base material for the cemented specimens. Portaway sand has the specific gravity (G_s) of 2.65, the mean grain size (D_{50}) of 0.35 mm, the coefficient of uniformity (C_u) of 2.2, and the coefficient of curvature (C_c) of 0.9. The minimum and maximum void ratios are 0.46 and 0.79, respectively, as shown in Table 1. A discrete polypropylene fiber was used as reinforcement (Figure 1). The properties of the fiber are given in Table 1.

Table 1 Index properties of sand and discrete fiber.

Properties of fiber	Values
Length, mm	22
Diameter, mm	0.023

2.2 High Pressure Triaxial Apparatus

A high pressure triaxial testing system, developed at the University of Nottingham (United Kingdom) in conjunction with GDS Instruments Ltd. was used for all the experiments presented in the paper. The high pressure triaxial system is

capable of testing various geomaterials including uncemented or cemented granular soils and soft rocks. The main components of the system are described by Marri (2010), Ud-din et al. (2011), Marri et al. (2012) and Ud-din (2012).

2.3 Testing Procedures

The fiber reinforced cemented and uncemented specimens (50 mm diameter and 100 mm height), were prepared by mixing sand, polypropylene fibers and/or cement. Fibers were mixed with sand prior to adding the water to achieve uniform distribution of fibers. Thorough mixing of dry materials was continued until a uniform appearance of the sand-cement mixture was obtained. For the preparation of the cemented specimens, a predetermined amount of Portland cement by weight of dry sand (5%, 10% or 15%) was added and mixed thoroughly with the sand-fiber composite. After that water was added to the mixture in accordance with the optimum moisture content of Portaway sand and further mixing was performed until a homogeneous appearance of the sand-cement-fiber mixture was achieved. The specimens were compacted in layers into a split mould to a target dry unit weight of 17.4 kN/m^3 . A thin plastic transparency sheet, cut according to the size of the mould, was used inside the mould before pouring the mix to prevent sticking the material to the walls and base of the mould. After compaction, the uncemented fiber reinforced specimens were ready for testing. However, the cemented specimens were cured for 14 days before shearing. All the specimens were saturated and isotropically consolidated to the mean effective stresses up to 20 MPa. After that the drained (CID) tests were carried out under a deformation-controlled loading mode at a constant deformation rate of 0.1 mm/min.

3. RESULTS

3.1 Homogeneity of the Mix

To investigate the mixing, distribution and homogeneity of fibers microscopically in cemented and uncemented samples, Scanning Electron Microscopy (SEM) analysis was carried out on samples before and after isotropic compression. Figure 2 shows SEM micrograph of fiber-reinforced cemented and uncemented soil samples before testing showing distribution of fibers in sand and cemented sand. It is important to note that SEM micrographs represent the qualitative information regarding the distribution as investigation is always limited to very small area and to a specific horizontal plane or to a plane of failure. The distribution of fibers which looks reasonably uniform and consistent at macro scale may not have the same level of uniformity and consistency at micro level as shown in Figure 2. It is also worth mentioning that SEM micrograph shown in Figure 2 is of about 2 mm to 5 mm wide area of the whole sample surface. In the fiber-reinforced cemented sample taken at the magnification of 50x shown in Figure 2(a), the sample was analyzed before isotropic compression and shows only the top surface of the specimen. There can be seen consistent bonding of the grains in their natural bedding plane. However, some poor bonding and cement deposition on the surface of the sand grains and fibers can also be seen. Figure 2(b) shows the SEM micrograph of fiber-reinforced uncemented sample taken at the magnification of 100x. It can be seen that fibers are distributed quite uniformly and produce a good network of fiber with sand grains. A similar distribution has also been shown by Tang et al. (2007).

Figure 2. Fiber-reinforced samples before testing: (a) 0.5% fiber and 5% cement reinforced sample, (b) 0.5% fiber-reinforced uncemented sample.

3.2 Compaction Characteristics

The concrete sand was tested for optimum moisture and fiber contents to achieve the maximum dry unit weight. The Proctor compaction test results plotted versus both moisture content and fiber content are presented in Figures 3(a) and 3(b), respectively.

Figure 3. Results of Proctor tests on fiber-reinforced specimens.

It can be seen from Figure 3 that the clean sand exhibits two peaks in the compaction curve; one at very dry conditions, where there are no capillary tension to resist the compaction effort, and the other at the optimum moisture content, where optimum lubrication between particles occurs. Similar two peaks in the compaction curves of clean sand have been reported in the literature (e.g. Rollings and Rollings, 1996). The maximum dry density for the concrete sand is achieved at zero moisture content. Moreover, similar trends can be seen for the fiber content of 0.25% and 0.5% (see Figure 3a). It is interesting to see that the effect of fiber content is not proportional to the dry density; therefore, compaction tests were carried out for optimum fiber content as well. The optimum fiber content at zero water content was determined to be approximately 0.25% as shown in Figure 3(b).

3.3 Dilatancy Angle

The effect of addition of cement in sand can be observed in Figure 4 in which the peak dilatancy angles are plotted versus the cement content. The peak dilatancy angle is defined as the dilatancy angle when granular soil reaches its peak strength, that is $\tan \psi = -(\delta \varepsilon_v / \delta \varepsilon_q)$, where ψ = dilatancy angle, ε_v = volumetric strain, and ε_q = deviatoric strain. The increase of cement content from 0% to 2% and 5% has increased the peak dilatancy angle of sand from 14.3° to 22.61° and 32.1°, respectively. The effect of addition of fiber in sand and cemented sand can be observed in Figure 5 in which dilatancy angles are plotted for all the composites. The fibers have increased the peak dilatancy angle of uncemented sand from 1.5° to 10.17° and from 15.95° to 18.9° for cemented sand. It can be seen the effect of fiber is more significant in uncemented sand than in cemented sand.

Figure 5. Effect of cement content on dilatancy angle of sand.

Figure 5. Effect of addition of fiber and cement on the dilatancy angle of Portaway sand.

It can be noticed from Figures 4 and 5 that peak dilatancy angles for cemented and fiber-reinforced cemented sand are relatively high. However, it should be pointed out that all the specimens were compacted to a dense state. The dilatancy in dense granular materials during shear is due to the tumbling and overriding of particles over each other. In the cemented sand there is bonding between the particles and during shear not all the bonds are being broken as was observed during SEM analysis (Ud-din et al. 2011, Marri et al. 2012). Therefore it may be presumed that for cemented sand there could be the overriding and rolling of bonded particles with significantly larger size compared to uncemented sand, which ultimately leads to higher dilatancy angles.

3.4 Effect of Cement Content and Confining Pressure on Fiber-Reinforced Cemented Sand

Some important macro scale observations of the effect of confining pressure, and cement content on the dilatancy characteristics of sand are summarized in this section. The volumetric strain curves for dense fiber-reinforced sand specimens with constant unit weight of 17.4 kN/m^3 are shown in Figure 6(a). A comparison of the effect of confining pressure reveals that the increase in confining pressure from 50 kPa to 20 MPa, results in a progressive suppression of dilation in the volumetric strain curves. This suggests that at relatively high confining pressures the significance of dilation decreases. For example, in some situations shown in Figure 6(a) the dilation may be entirely suppressed by the high confining pressure. It should be pointed out that the maximum dilation occurs at $(q/p')_{\text{peak}}$ for both fiber-reinforced cemented and uncemented sand (Marri 2010, Ud-din 2012). The points of maximum rate of dilation are identified on the effective stress ratio (q/p') versus dilatancy (D) relationships by solid circles, as shown in Figures 6(b) and 7(b).

The effect of confining pressure on the dilatational behavior of fiber-reinforced cemented sand is shown in Figure 7, which shows similar trend as that observed for fiber-reinforced sand (Figure 6). The dilatancy decreases with increasing confining pressure and axial strain to the point of maximum dilatancy increases with increasing confining pressures. The $\varepsilon_v - \varepsilon_a$ curve shows that dilation is gradually suppressed by increasing confining pressure up to 1 MPa where confining pressure overcomes the dilative behavior and totally compressive behavior can be seen at $\sigma'_3 = 4 \text{ MPa}$ and above. After comparing the responses of sand and fiber reinforced sand, as well as cemented sand and fiber-reinforced cemented sand, it can be concluded that they follow the same trend but there is more dilation and compression in fiber-reinforced materials. This additional dilation and compression observed in fiber-reinforced materials suggests that this might be entirely due to the effect of the addition of fiber.

3.5 Particle Crushing and Fiber Damage

Figure 8 shows two examples of SEM micrographs of the fiber-reinforced uncemented (Figure 8a) and cemented (Figure 8b) specimens, taken after drained shearing at the effective confining pressure of 1 MPa. A clear particle crushing in the uncemented specimen can be observed from Figure 8(a). A cement bond breakage accompanied by the particle crushing in the cemented specimen is also shown in Figure 8(b). However, only limited fiber damage in both uncemented and cemented specimens could be identified by the SEM analysis. This observation suggests that after the occurrence of particle and bond breakage, the fibers themselves could have resisted the shearing until their tensile strength was reached. In a brittle matrix composite such as the sand-cement with addition of fiber, the matrix will crack followed by gradual pull out of the ductile fiber.

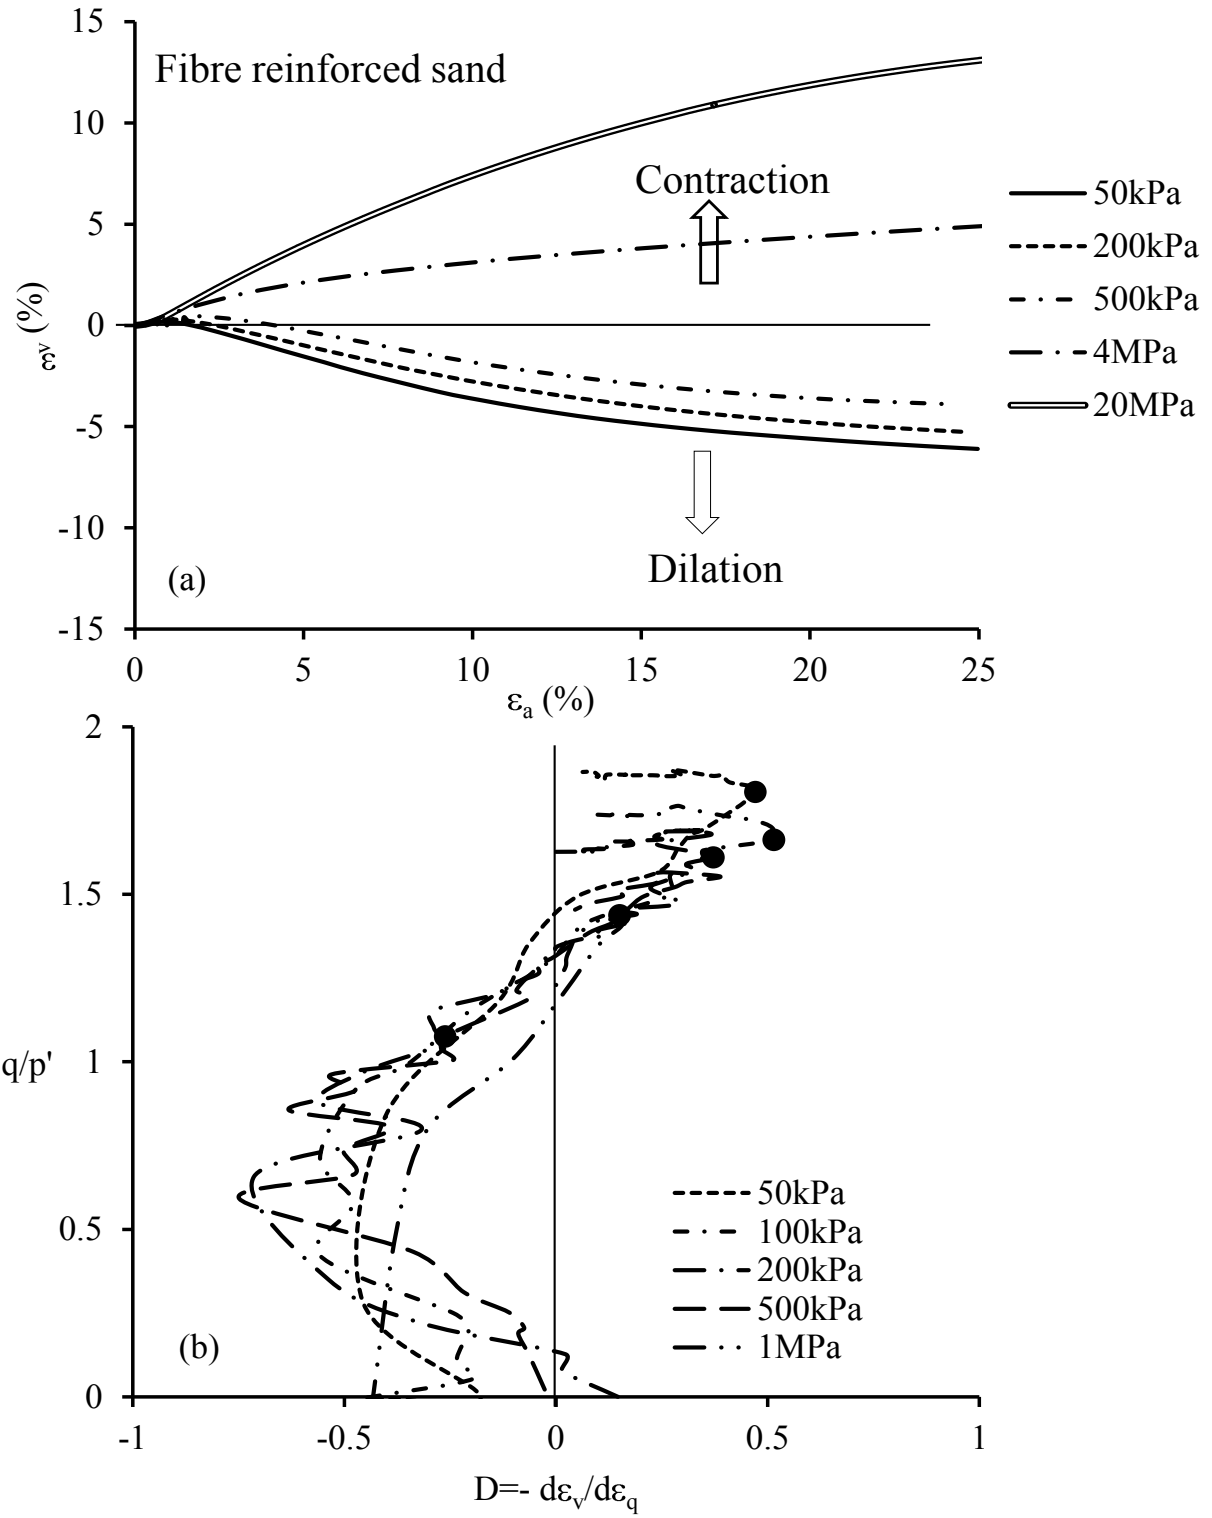

Figure 6. Dilatancy behavior of fiber-reinforced sand under varying confining pressures: (a) ϵ_v - ϵ_a , and (b) q/p' - D .

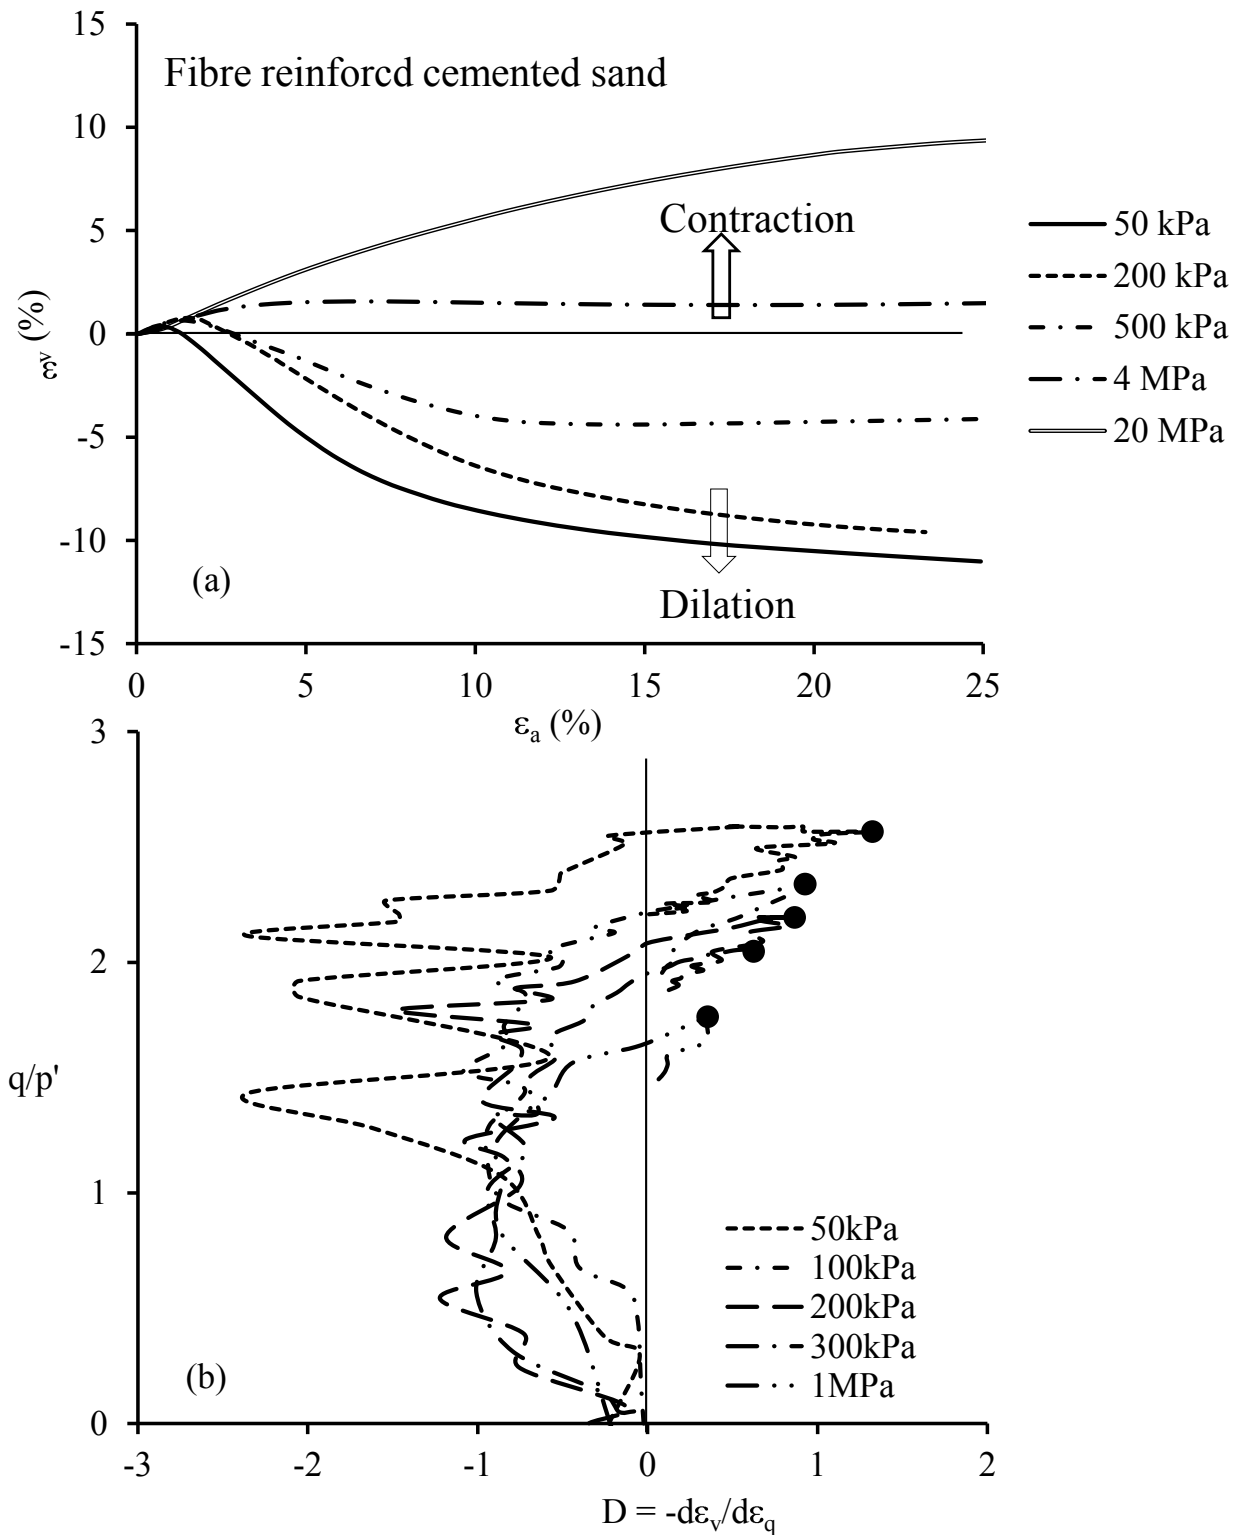

Figure 7. Dilatancy behavior of fiber-reinforced cemented sand under varying confining pressures: (a) ε_v - ε_a , and (b) q/p' - D .

It should also be pointed out that the tensile strength of the polypropylene fibres used in this study was quite high (see Table 1), so the fibres could provide a strong platform to the sand particle for rolling over when sheared to large strains. As a result, the dilation of fibre-reinforced specimens has increased significantly compared to that of unreinforced specimens. Finally, Ud-din (2012) also observed the lack of interfacial debonding at the fibre/matrix interface of the fibre-reinforced cemented specimens. Since fibres and the matrix have different Young's moduli, the interface regions have experienced minimal strains, which reduced compressibility of the specimens.

Figure 8. Examples of SEM micrographs of the fibre-reinforced specimens sheared at $\sigma_3' = 1$ MPa:
 (a) fibre-reinforced uncemented sand (0.5% fibre and 0% cement);
 (b) fibre-reinforced cemented sand (0.5% fibre and 5% cement).

4. SUMMARY AND CONCLUSIONS

In this study, drained triaxial compression tests were carried out on uncemented and cemented fiber-reinforced specimens of concrete sand with different fiber and cement contents at a wide range of confining pressures. The mechanism of dilatancy, its significance and dependence on fiber content, cement content and confining pressures was discussed. SEM analysis of selected specimens was also carried out. The results can be summarized in the following points:

1. It is challenging to achieve uniform distribution of fiber in sand specimens at microscale.
2. For uniform clean sand, it was noticed that the materials exhibit two peaks in the compaction curve; one at very dry conditions, where there are no capillary tension to resist the compaction effort, and the other at the optimum moisture content, where optimum lubrication between particles occurs. The addition of fiber has not changed the compaction characteristic of the sand. The maximum dry density was achieved at zero moisture content. The optimum fiber content for dry mix was determined to be around 0.25%.
3. The commencement of dilative behavior and the point of maximum dilatancy are fiber content, cement content, and confining pressure dependent. There is a significant effect of the addition of fiber on the response of both cemented and uncemented sand. The addition of fibers increases the dilative behavior of the composite.
4. The addition of fiber increases the dilatancy while increasing confining pressures reduces dilatancy of sand.
5. Due to addition of fiber the peak dilatancy angle increases from 1.5° to 10.17° in uncemented sand and from 15.95° to 18.9° in cemented sand. Thus, the effect of addition of fiber is more pronounced in uncemented sand compared to that in cemented sand.
6. Confining pressure affects dilative behavior of the sand. At higher pressures the effect of confinement was dominant. As a result, at the effective confining pressures higher than 1 MPa the behavior of fiber-reinforced uncemented and cemented Portaway sand was purely compressive (i.e. no dilation occurred).
7. SEM analysis revealed a significant particle crushing and bond breakage in the uncemented and cemented specimens sheared at high confining pressures. However, only limited fiber damage was identified. This suggests that the fibers provide a strong rolling platform to the sand particle during shearing to large strains,

which explains why the dilation of fiber-reinforced sand increased significantly compared to that of unreinforced specimens.

Electrical Leak Detection Surveys for Brine Ponds in SQM, Chile

Miguel Garcia, SQM, Chile, miguel.garcia@sqm.com
Alejandro Lara, SQM, Chile, alejandro.lara@sqm.com

ABSTRACT

SQM -- producer of lithium, iodine, nitrate and potassium salts -- operates brine evaporation ponds in various locations of the Atacama Desert, covering a total area of 42,000,000 m². High salinity of both contained liquids and subgrade, among other conditions, have posed difficulties for the performance of leak detection surveys. Solutions contained in these HDPE-lined ponds are saturated in sodium chloride and/or sodium sulfate and/or potassium chloride, and have presence of a wide gamut of other ions. Concentrations range from ~480 gpl of total salts to upwards of 720 gpl. Precipitated salts produce a layer of solution-impregnated layer as thick as 0.50 m on the floor of the ponds. Constructed on arid terrain, itself composed of up to 60% water-soluble salts, and interconnected by pumping lines, surveying of these ponds has required adaptations of equipment and technique, with satisfactory results. Difficulties faced to date are described here, as well as still-standing challenges.

1. INTRODUCTION

1.1 Geographic Location

A large producer of iodine, lithium, nitrates and potassium salts, our company operates in various locations of the Atacama Desert - the driest in the world - in the northernmost region of Chile, South America. Many of these operations include brine evaporation ponds, as well as temporary brine storage ponds.

Figure 1: Small dots show location of operations using ponds in the Atacama Desert. Ponds at each location are exposed to different environmental conditions, and present different construction, configuration, and brine composition.

1.2 Brines Origin and Composition

Brines contained in the ponds operated by the company have two major sources:

- a) Naturally-occurring brines, pumped from deposits beneath the Salar de Atacama. A significant source of lithium, potassium and nitrates, these brines are pumped to the surface for treatment and subsequent solar evaporation in ponds. Salar brines are saturated in NaCl, have a high content of Na₂SO₄, KCl and LiCl, and contain a wide gamut of other salts.
- b) Brines generated by aqueous leaching (irrigation) of caliche, a sedimentary, highly water-soluble ore, exploited as a source of iodine, nitrates and potassium. The brines are channeled and stored in HDPE ponds, treated for iodine extraction and finally pumped to evaporation ponds. These solutions are saturated in NaCl or Na₂SO₄, and have a high content of NaNO₃, KCl, MgCl₂, and a large number of other salts. Total salt content in the solutions ranges from 480 gpl when recently generated, to upwards of 720 gpl in the final stages of the evaporation process.

Table 1: Chemical analysis of leaching brines, in grams per liter (gpl).

NaCl	Na ₂ SO ₄	Other
245	145	~130

Brines generated from leaching of caliche ore may present some acidity, in which case a neutralization of the solutions is necessary before entering the evaporation pond circuit. Salar brines are mostly neutral.

From the moment they are generated at the different leaching operations, or pumped from beneath the salar, saturation in NaCl and/or Na₂SO₄ produces continuous, uninterrupted precipitation of salts during the entire process, with a wide array of chemical and mass transport equilibria. Precipitation rates and type of precipitate vary according to the composition of each solution, and are also affected by ambient temperature. This precipitation produces a floor of salts that covers the HDPE liner in every brine-holding pond in operation. The salt floor is not a continuous solid, but a porous aggregate of different salt crystals and trapped solutions.

This presence of saturated solutions, salt precipitates, mass transfer between solids and liquid, as well as ionic transport and convective flow caused by concentration and thermal gradients, produce high levels of noise that make it difficult to apply normal levels of voltage and current in electrical leak detection surveys.

1.3 Ponds

The ponds in operation vary in location, age, size, design, construction, state of repair, and attached equipment - pumps, tubing, sinks, etc.- covering a total area of 42,000,000 m² (450,000,000 ft².)

The most common characteristics of these ponds are:

- a) The liner in contact with the brines in every pond is HDPE, 1 mm thick.
- b) Most ponds have a geotextile layer under the HDPE liner.
- c) Many of the ponds have service ground wiring underneath, for use in leak detection surveys. Older ponds have no wiring.
- d) The subgrade under the geotextile layer is the desert terrain, which can be composed of 40-60% water-soluble salts.

1.4 Pond Operation

During construction, the welded seams in the HDPE liner of every pond are subject to standard quality assurance practices, such as vacuum tests. Water lance leak detection tests are also performed on recently constructed ponds, where the liner is still exposed.

After construction, most ponds are filled with different types of highly saline, chemically diverse solutions (see Table 1). Solutions are pumped from one pond to another according to their concentration, distributed in an ordered sequence, going in general from more diluted to more concentrated. This results in a sequential series – or “train” -- of ponds, interconnected by HDPE pumping lines and pumping equipment. Equipment generally includes a cement sink within the ponds.

The final result in production ponds is a low-moisture salt aggregate, which is then removed (“harvested”) by bulldozers and trucked to other facilities for further refining. Non-production ponds, which also accumulate precipitated salts, must

be cleared of salts periodically in a similar manner. Machinery movement on the salt floor during harvesting or cleaning of the ponds often damages the underlying HDPE liner.

Electrical leak detection techniques are applied in recently cleaned or harvested ponds. After the majority of the solids are removed, a salt floor always remains, and water is pumped to the pond so it covers the salt floor, in order to allow submerged-probe surveys. Most of the adjustments in equipment and technique have been made here. Surveying over the salt floor, with no added water would be preferable, but has been impracticable as of yet.

2. SURVEYING

2.1 History

Electrical leak detection surveys have been performed at our company by an external contractor – the only local provider of this service until recently – for more than a decade. A project was started in 2008 to internalize these services, involving acquisition of necessary knowledge, equipment, training and testing.

Early testing stages using standard training, equipment and technique for submerged-probe surveys were unsuccessful. Although the available equipment was adequate for use in water, with sufficiently moist subgrade (permitting ~200 V and 2 A,) it was not capable of generating usable signals in production ponds. Extensive testing was conducted to determine the magnitudes required in order to have usable readings.

2.2 Feasibility testing

It was readily apparent that the aridness and high solubility of the soil, combined with the high conductivity of the solutions, would impose electrical requirements greater than those typically sufficient during tests in training ponds filled with water. It was also apparent that the significant chemical activity within the ponds (concentration gradients, thermal convection flow) would be cause for considerable levels of noise. Thus, the first steps were measuring total resistivity of the pond/solution system, and determining the level of voltage and amperage needed in order to overcome the noise levels.

Injecting current with our power supplies yielded a voltage much lower than expected, due to the low resistivity of the system. Noise level was 1.5-1.6 V, and this high level of noise was found to distort the readings of the leak sensor.

Figure 1. Component location in system, where PG1: Point Ground 1, SG1: Service Ground 1, SG2: Service Ground 2.

In order to surpass noise levels, the current applied to the system must be increased through an increase in applied voltage. Stability of the system if current is increased must be analyzed observing terrain and system resistivity. Thus, a series of voltages were applied and the resulting current was observed.

By Ohm's Law, apparent resistivity is found by:

$$R = \frac{V}{I} \quad [1]$$

Resistivity of the system with respect to the Service Ground 1 behaves linearly, which allows us to infer a constant resistivity between solution and subgrade.

Figure 2. Observed current between Injector and SG1.

The data obtained gives an average resistivity of $R_{E-SG1} = 12.8 \Omega$.

Figure 3. Observed current between Injector and SG2.

With the injector at the same position, and this time measuring between the former and service Ground 2, a linear response was also obtained, with an average resistivity of $R_{E-SG2} = 13.9 \Omega$.

A free ground point (PG1) was installed 32 m away from SG1, as shown in Figure 1, in order to determine terrain resistivity.

Figure 4. Observed current and voltage between PG1 and SG2.

Apparent resistivity obtained was $R_{PG1-SG2} = 492.6 \Omega$ for a 32 m distance. PG1 simulates a leak in an arbitrary point of the liner. Also relevant is to observe the resistivity between the wires under the liner.

Figure 5. Observed current and voltage between service grounds1 and 2.

It was observed that resistivity is linear between service grounds, with an average $R_{SG1-SG2} = 19.3 \Omega$ at 32 m. Therefore, an external analysis of voltage and current can give the approximate location of a leak.

Low subgrade resistivity allows for high current given a relatively low potential. Of course, applying higher voltages will produce even higher currents.

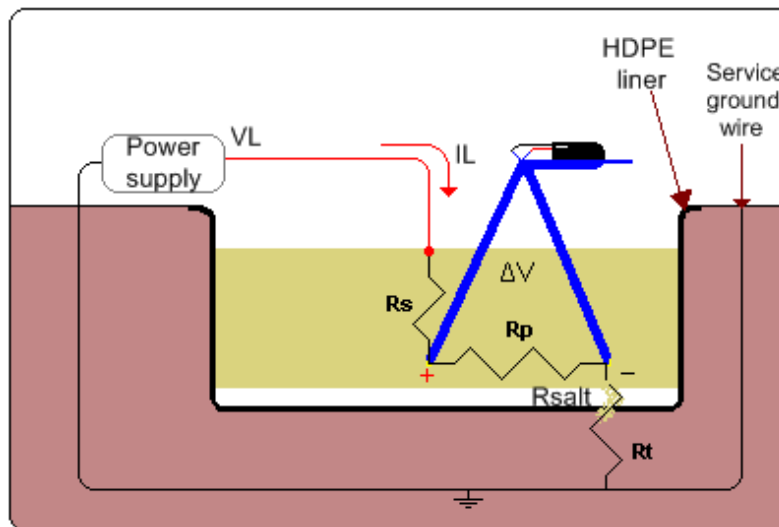

Figure 6. Electric equivalence of the system.

With data readings from the tested pond, apparent resistivity for the subgrade + solution + salt system can be calculated. We know that $R_{\text{salt}} < R_p < R_s$, and thus the leak is not detected.

From the collected data at $V_L = 20 \text{ V}$, and $I_L = 1582 \text{ mA}$:

$$R_t = 9.13 \ \Omega$$

$$R_{\text{salt}} + R_p + R_s = 3.51 \ \Omega$$

Since R_s increases with the distance from leak to positive pole of the power supply, we have:

Figure 7. Schematic circuit representing the pond system.

Resistivity between probe points is dependent on solution properties, and in this case it is estimated at $0.45 \ \Omega\text{-m}$.

Therefore, applying Ohm's Law for an established current of 1582 mA and the resistivity between the electrodes, we obtain the voltage that the sensor should be reading:

$$\Delta V = R \cdot I = 0.45 \cdot 1.582 = 0.712 \text{ V} \quad [2]$$

Voltage determined in Equation 2 is within the order of the noise level detected in the tested ponds ($0.065 - 1.69 \text{ V}$). In order to surpass the noise level, a greater current is needed in the system, thus requiring a power supply capable of withstanding currents greater than 1.6 A . A larger generator, power supply and wiring were assembled, capable of producing and withstanding currents greater than 20 A .

2.3 New Equipment and Results

Tests analog to those presented in section 2.2 - resistivity of subgrade, pond/solution system and measurement of the current established between service ground wires – showed that 100 V was the voltage most adequate for stable, easily recognizable signals using the leak detector in the submerged-probe surveys. Current levels reached during surveys average 4 A , but can reach nearly 10 A in certain conditions, such as large leaks, or badly insulated cement sinks within the ponds. Power supply and wiring of the equipment used originally proved unable to withstand these amperages.

Generator, voltage regulator, AC power supply and DC converter were assembled from off-the-shelf components, with specifications adequate for sustaining currents greater than 20 A . Leak detection equipment originally acquired, including wiring and electrode rods, was replaced by the new components. Only probe electrodes and leak detector (voltmeter) were kept as part of the system.

With equipment now able to withstand the high current, signals were clearly distinguishable from the noise in the ponds, and leaks could be reliably detected, with greater success than the contracted surveyors, in less time.

Table 3: Company vs. Contractor detection leak detection results.

Voltage (V)	Current (A)	Contractor	Company	Actual
50	4.2	2	2	2
100	7	1	3	3
100	8	3	1	1
100	10	0	3	3
100	7.5	18	18	18
100	16	6	6	6

The high amperages at 100 V introduced a concern for corrosion in the stainless steel rods, and possible dissociation of the solution contained in the probe electrodes. Corrosion was detected in the rods – a reduction of 3 mm in radius for a rod originally 5 mm in radius, for 100 hours of operation at 4 to 8 A (See Figure 8). Although gasification was not detected in the solution contained in the probe's electrodes, safety procedures were implemented in order to minimize the risk of electrode explosion.

Figure 8. Corrosion in stainless steel electrode rod.

3. STILL-STANDING CHALLENGES

Modifications in equipment and technique presented here have allowed satisfactory results in submerged-probe leak detection surveys, with more accuracy and speed than previous methods.

However, submerged-probe surveys after cleaning or harvesting of ponds requires that water be pumped into the pond before the survey, over the salt floor, a time-consuming operation that would be completely avoided if the soil-probe method could be applied. However, the latter has yet to yield readable signals, and no electric current level tried with the new equipment has been able to overcome the noise. We attribute this to the highly saturated solutions trapped within the salt floor, generating an extremely conductive layer that, with the methods reported here, would require excessively high currents in order to surpass the noise levels.

4. CONCLUSIONS

Accurate, fast leak detection surveys are possible using the submerged-probe method in evaporation ponds containing highly saline brines. The current levels required to overcome noise - produced by ion transport and convective flows - surpass the capacity of "normal" electrical leak detection kits, but are achievable by carefully-assembled equipment. Leak detection on soil-over-liner is still an unsolved problem.

Elevated Temperature Effects on Smooth Geomembrane – Geotextile Interfaces

Tanay Karademir, GSI Fellow, Maltepe University, Istanbul, Turkey, tanaykarademir@maltepe.edu.tr
David Frost, F.ASCE, PE, PEng, Georgia Institute of Technology, Atlanta, USA, david.frost@ce.gatech.edu

ABSTRACT

The mechanical properties of geosynthetic materials are strongly temperature dependent. Historically, most laboratory geosynthetic interface testing has been performed at room temperature. Information today is emerging that shows how temperatures in the liner systems of landfills can be much higher due to seasonal temperature variations as well as exothermic reactions occurring in the waste body. As part of an extensive research study undertaken to investigate temperature effects on interface shear behavior, a three-component study involving surface hardness tests, single filament tensile strength tests and interface shear tests between NPNW polypropylene geotextiles and both HDPE and PVC smooth geomembranes was undertaken. A temperature controlled chamber was utilized to simulate field elevated temperature conditions. The laboratory interface shear program included tests under a normal stress level of 100 kPa and a range of test temperatures from 21 to 50 °C. Complementary geotextile single filament tensile tests were performed over the same temperature range using a dynamic thermo-mechanical analyzer to evaluate the tensile strength properties of single geotextile filaments at these elevated temperatures. The surface hardness of smooth HDPE and PVC geomembrane samples was also determined at different temperatures in this range to evaluate how temperature change affected the surface hardness as well as the interface shear behavior and strength of smooth geomembranes in combination with geotextiles. The study showed that while the tensile properties of the geotextile filaments and the geomembrane surface hardness are both reduced, the interface strength increases. Quantitative measurements provide insight into the mechanisms dictating this behavior.

1. INTRODUCTION

The behavior of an interface is a combination of the interaction behavior between the counterface materials as well as the state of the interface. In addition to mechanical surface properties such as surface roughness, the relative hardness of the counterface materials impacts the interface shear response that develops. In addition, the interaction of a material surface with that of another is also influenced by the physical and chemical properties of the materials themselves. Consequently, it is essential to thoroughly evaluate the mechanical characteristics of the materials including micro and/or macro tensile strength as well as hardness properties of counterface materials to understand their effect on interface behavior and to identify the factors controlling the shear stress-displacement response of common interfaces such as geotextile-geomembrane (Dove, 1996). Interface shear behavior at different ambient temperature conditions is not a single attribute, but a collection of performance attributes of the counterface components which requires a suite of tests to assess the engineering strength properties of the components both independently and collectively. The performance of geosynthetic layered systems during their service lifetime in terms of interface shear behavior and strength properties is of major importance in selection of geosynthetic materials (i.e. geotextiles, geomembranes) for certain geotechnical applications such as landfills.

2. THEORETICAL BACKGROUND

One of the more common composite systems that has found widespread application in geotechnical projects are those involving geotextiles and geomembranes. They are generally used as composite systems rather than as stand-alone solutions in practice due to their complimentary advantages (Koerner, 2005). The interaction behavior between geotextiles and geomembranes is a critical component in defining the interface strength governing the integrity of the overall structure as well as the stability of the constructed system. Over the past few decades, fiber-texture (i.e. geotextile-geomembrane) interaction has become an increasingly important consideration in geotechnical engineering design. Non-woven geotextiles are porous and fibrous materials that consist of irregularly oriented long filaments which vary in terms of spatial distribution, curvature, orientation, size, and mass density. Geomembranes are continuum materials which depend on properties such as tensile strength, hardness, surface roughness, and chemical constitution. Both are made from polymeric material resins and temperature has a significant effect on the physical and mechanical engineering properties such as tensile strength, modulus and hardness of polymers.

The use of geotextiles, which are fibrous pervious materials, particularly in conjunction with geomembranes which are impervious continuum materials has increased since 1980s from operating landfill examinations carried out in the past.

The employment of a geotextile layer to protect the geomembrane from damage caused by the drainage layer has been adopted as the preferred solution (Martin et al., 1984; Giroud 1984). Although these composite geosynthetic interfaces are routinely employed in landfill liners and are exposed to high elevated temperature conditions, there is very little information published in the literature to date on the influence of higher temperatures on interface shear behavior and strength characteristics of geotextiles in contact with geomembranes. The results for smooth geomembrane-NPNW geotextiles presented herein are part of a larger study aimed to fill this gap in knowledge and to show how the developed shear mechanisms and interface resistance changes with elevated temperatures. This research study in particular focused on the most common geosynthetic materials used in current North American practice when placing geotextiles in combination with geomembranes. Additionally, complementary geotextile single filament tensile tests as well as geomembrane surface hardness tests at different temperatures which provide important insight into the role of temperature in the observed behavior differences will also be summarized and discussed. These latter tests are critical for microscale analysis of elevated temperature effects on shear behavior of smooth geomembrane – geotextile interfaces.

3. MATERIALS, TESTING PROGRAM AND EQUIPMENTS

A multi-phase research study was undertaken in an effort to investigate temperature effects on interface shear behavior between (a) needle punched nonwoven (NPNW) polypropylene (PP) geotextiles and both smooth high density polyethylene (HDPE) as well as smooth polyvinylchloride (PVC) geomembranes. A unique temperature controlled chamber (TCC) was developed to be utilized to simulate the field conditions at elevated temperatures and evaluate shear displacement failure mechanisms at these higher temperatures. The physical laboratory testing program consisted of multiple series of interface shear tests between aforementioned material combinations which have found widespread use in landfill applications. The two smooth geomembranes produced from different base polymers (HDPE, PVC) were tested in combination with a single staple type NPNW geotextile (mass per unit area of 270 g/m² (8 oz/yd²) per ASTM D 5261) and apparent opening size of 0.18 mm (per ASTM D 4751). High density polyethylene (HDPE) produced from formulated polyethylene resin is the most widely used geomembrane material due to its high tensile properties at low strain levels. On the other hand, polyvinylchloride (PVC) geomembranes are selected for use in infrastructure projects which require more flexibility in three dimensional performances as well as having less hardness of the geomembrane itself which can lead to enhancement of interfacial properties for combined and layered applications consisting of different material types. Force-displacement failure mechanisms developing at geotextile-geomembrane interfaces at higher temperatures were determined by imitating elevated temperature field conditions in the insulated and temperature controlled environment of the TCC. The geomembrane liner samples were sheared against the geotextile fabric specimens under a normal stress level of 100 kPa and at one of three different temperatures (21°C, 35°C and 50°C). The large displacement direct interface shear device enclosed by the TCC (Figure 1a) was utilized to measure the interface shear resistance between geotextiles and geomembranes at different elevated temperatures. In all tests, the specimens were sheared at a constant rate of displacement of 1 mm per minute over a displacement range of 60 mm.

Complementary geotextile single filament tensile tests were performed at the same temperatures as the interface shear test temperatures (21°C, 35°C and 50°C) using a dynamic thermo-mechanical analyzer (DMA) (Figure 1b) to measure the micro-tensile strength properties of single NPNW-PP geotextile filaments at different elevated temperatures. A total of 45 micro-mechanical thermo-tensile tests on single geotextile filaments were conducted consisting of 15 tests at each test temperature to observe the repeatability of the developed tensile force-extension behavior as well as to see the reproducibility of filament tensile strength response at each test temperature. Single geotextile filament specimens were tested to failure using a constant-rate-of extension (CRE) type tensile testing of a predetermined gage length (i.e. initial sample length) of 12.5 mm and rate of extension of 0.125 mm/sec at different temperatures for filament specimens having an average diameter of 0.035 mm (35 µm). Using the force extension (elongation) curve (i.e. force-displacement, stress-strain), tensile strength properties including tensile strength (T_{MAX}), Young's modulus (E) (i.e. Modulus of Elasticity) were determined and their variation with temperature were evaluated.

A durometer with a constant loader test stand composed of a flexible joint system and an air damper was utilized in this study to perform surface hardness measurements of smooth geomembrane samples. This type of constant load stand maximizes repeatability of hardness tests by providing a variable speed control and a flexible joint on the load shaft to ensure complete contact with the sample material as well as to ensure consistent measurements by applying a consistent force throughout all the measurements. To investigate the variation of this index value with changing temperature for smooth HDPE as well as smooth PVC geomembranes, the Durometer with the Constant Loader Test Stand was placed in the vertical configuration of the Temperature Controlled Chamber (TCC) (Figure 1c). A total of 240 measurements were performed on HDPE as well as PVC geomembrane samples. In order to maintain consistency in measurements and to obtain accurate test results, it is required to conduct all the hardness measurements with the same speed for all the materials tested. A total of 120 measurements were taken on smooth HDPE geomembrane samples. It is recommended as good practice to take several readings and average the results by showing the variability in measurement data. A similar procedure was followed for smooth PVC geomembrane as well in which a total of 120

surface hardness measurements were made on geomembrane samples. The readings, in general, indicated that the variability in measurements was consistent for all the samples tested. Shore hardness measurement is a very common method used to determine surface hardness of rubber and plastic materials (i.e. polymeric materials such as geomembranes). The Shore D scale is used for relatively harder plastics and is an appropriate way of measuring surface hardness of geosynthetics (i.e. Smooth HDPE and Smooth PVC Geomembranes). Shore D Hardness (H_D) provides an index of the material surface hardness which can then be correlated to the interface friction characteristics of geosynthetic materials. As such, Shore D hardness scale, (H_D) ranging from 1 to 100 on Type D durometer gauge was an appropriate scale to attain an index value for surface hardness of these aforementioned geomembranes at different temperatures. Shore D Hardness measurements were performed according to ASTM D 2240-05 at different ambient temperatures.

a) Interface Shear Device enclosed by TCC

b) Dynamic Thermo-Mechanical Analyzer (DMA)

c) Durometer with Constant Loader Test-Stand enclosed by TCC (Vertical Configuration)

Figure 1. Testing Device and Equipments

In summary, the effects of higher temperature conditions on geosynthetic interface performance were quantified through laboratory interface shear tests at elevated temperatures in the temperature controlled chamber (TCC), fibrous material

single filament micro-mechanical tensile tests using a thermo-dynamic mechanical analyzer (DMA), and additionally through continuum material surface hardness measurements. The laboratory testing program was conducted over a range of temperature (21 °C – 50 °C) to capture variations in behavior as a function of ambient temperature.

4. TEMPERATURE EFFECTS ON SMOOTH GEOMEMBRANE – GEOTEXTILE INTERFACE SHEAR BEHAVIOR

The results of laboratory tests carried out to investigate the factors controlling the interface shear behavior and strength between smooth geomembranes and geotextiles in particular to examine the role of temperature on the interface performance developed and filament-continua interaction will be presented. The research study specifically involved in smooth high density polyethylene (HDPE) as well as smooth polyvinylchloride (PVC) geomembranes in combination with needle punched nonwoven (NPNW) fabrics. It is noted that a geomembrane liner with relatively high rigidity (smooth HDPE) as well as the one with relatively low rigidity and high flexibility/softness (smooth PVC) were selected to quantify the effects of continuum material surface hardness on the shape of the shear-displacement curve and on the magnitude of interface strength mobilized in combination with fibrous materials (geotextiles).

4.1 HDPE Smooth Geomembrane/NPNW Geotextile

The typical behavior of HDPE smooth geomembranes when sheared against NPNW polypropylene (PP) geotextiles is brittle in nature with a sharp peak and rapid transition to post-peak behavior. The stress-displacement responses of HDPE smooth geomembranes, at all temperatures tested and at 100 kPa normal stress representative of in-situ stresses typical of landfill liners, were essentially an elastic-perfectly plastic response (Figure 2a). Some post-peak softening was observed followed by a near constant large strain or residual shear stress value. The displacement required to mobilize the peak interface shear strength ranged from approximately 1 to 2 mm for the tests at temperatures ranging from 21 °C and 50 °C. The behavior of smooth HDPE geomembrane versus NPNW-PP geotextile interface can thus be described as an initial rapid increase in shear stress as soon as displacement starts followed by a peak shear stress at relatively low displacement of order of 1 to 2 mm. Additional shear displacement produced negligible to moderate reduction in shear stress. Further, the peak and post-peak (i.e. residual) interface strength values in terms of coefficient of friction, ($\tan(\delta)$) is presented in Figure 2b to display the trend with changing temperature. The post-peak strength values computed were based on shear stress values averaged over 2 mm range from 57 to 59 mm horizontal displacement. Both peak and pseudo-residual interface shear strength values increase with temperature.

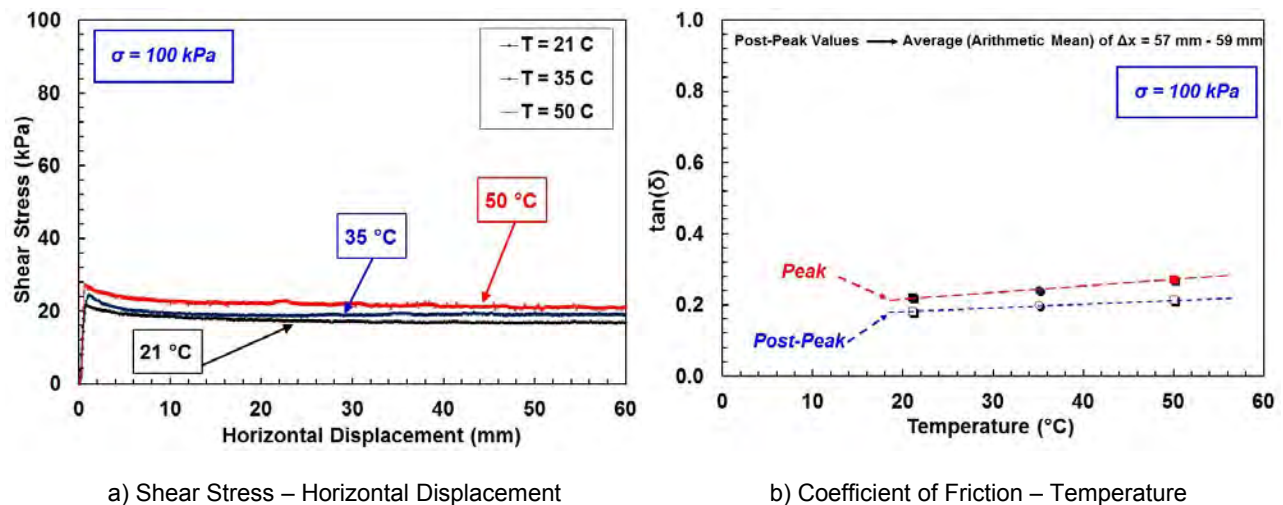

Figure 2. Smooth HDPE Geomembrane – NPNW PP Geotextile Interface

4.2 PVC Smooth Geomembrane/NPNW Geotextile

PVC geomembranes in general offer higher deformation response and increased interfacial strength and improved resistance to stress cracking as a result of their more plasticized and flexible nature. Figure 3a presents the stress-displacement responses between PVC smooth geomembrane and NPNW-PP geotextiles at 100 kPa normal stress under different ambient temperature conditions ranging from 21°C up to 50°C, and additionally, the change in peak as well as residual coefficient of friction with temperature for PVC smooth geomembrane – NPNW PP geotextile interface is shown in Figure 3b. The interface tests carried out at different elevated temperatures conditions showed similar responses in which shear displacement hardening behavior occurred after yielding in contrast to the behavior observed

with smooth HDPE geomembranes where a post-peak strain softening response developed. The tendency of PVC smooth geomembrane – geotextile interfaces to behave in this fashion was completely dependent on the differing material properties compared with HDPE liners. Additionally, the hardness reduction at higher temperatures contributed to some very minor increase in strength with increasing temperature level compared to HDPE.

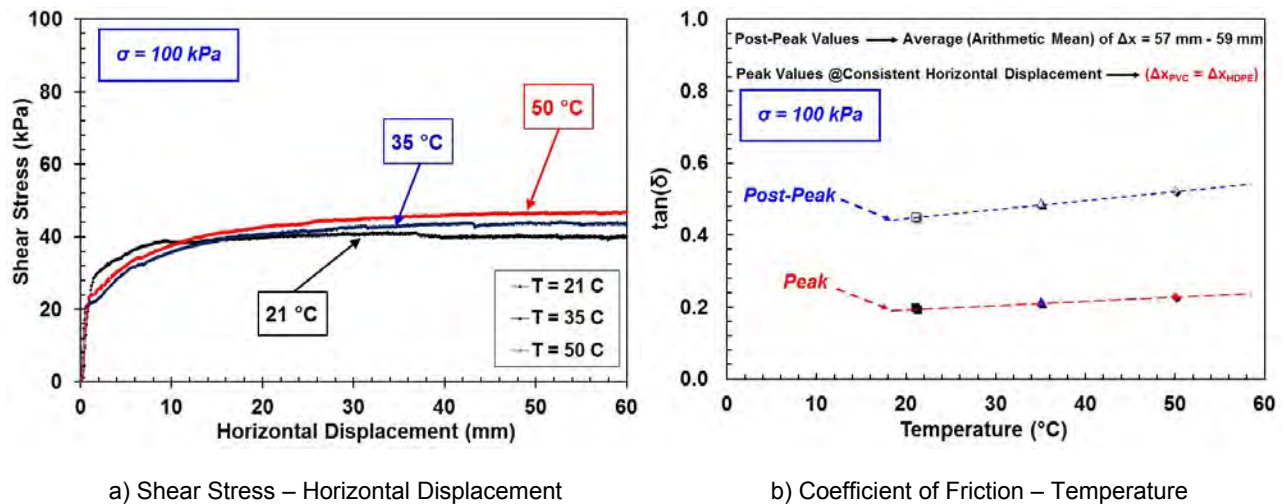

Figure 3. Smooth PVC Geomembrane – NPNW PP Geotextile Interface

As seen in Figure 3a, it is not feasible to determine distinct peak strength from the stress-displacement curve for the typical interface behavior of PVC geomembranes against NPNW geotextiles. After a rapid increase in shear stress at very small displacement (< 2 mm), a yielding type pattern occurs with displacement up to 8 mm to 10 mm displacement, and later a plastic response in terms of a slight strain-hardening behavior is observed regardless of ambient test temperature. For this reason, in the analysis of the interface results at every test temperature, the shear stress values that correspond to the shear displacements of the mobilized peak strength values of the smooth HDPE geomembrane tested were selected for the determination of the peak interface strength. Similar to the analysis process performed on the smooth HDPE test results, post-peak strength values were taken as the average of the values at shear displacements from 57 mm to 59 mm. As the interface response of the smooth PVC is plastic at different ambient temperatures, the residual shear resistances mobilized at the interface are larger than the peak strength values and results from the slight strain-hardening shear behavior observed in the smooth PVC interfaces with NPNW geotextile. In light of this, the resulting coefficient of friction values (both peak and residual) as a function of temperature were presented in Figure 3b. From the stress-displacement relationships for different ambient temperatures, the residual (post-peak) shear strengths of the PVC interface at all test temperatures were larger than the peak values. It is noted that the higher frictional resistance and the larger interface shear response in terms of stress – displacement failure envelope is related to the physical properties of the geosynthetic layered systems including hardness, stiffness, and temperature dependency which tend to alter the shear strength mobilized at the interface.

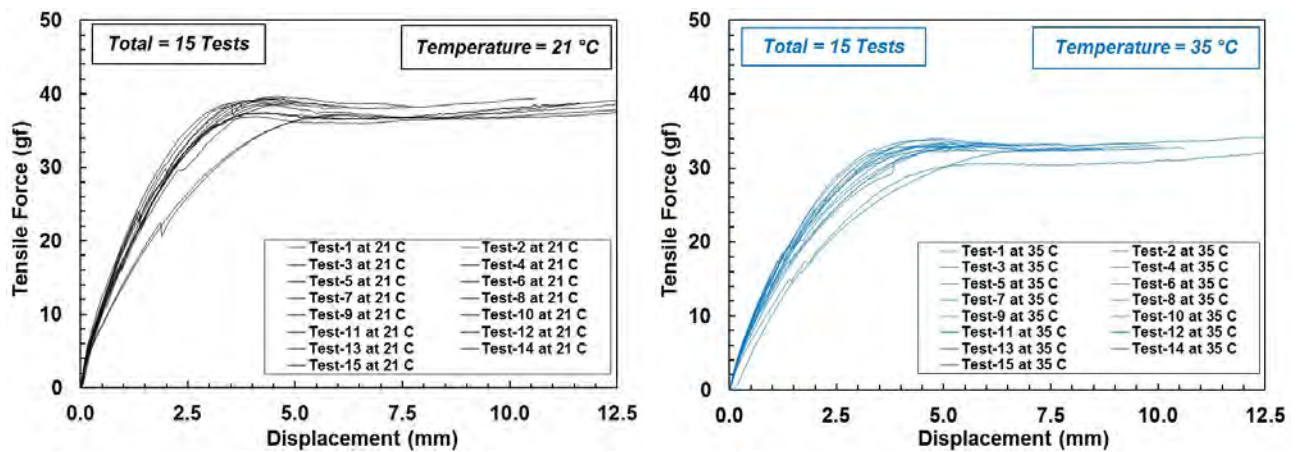

5. TENSILE PROPERTIES OF SINGLE GEOTEXTILE FILAMENTS

The single filament studies are important since the interface strength between geotextiles and geomembranes is controlled by the fabric global matrix properties as well as micro-scale characteristics of the geotextile such as filament strength and how it interacts with the geomembrane macro-topography. To this end, complementary geotextile single filament tensile tests provide insight into the role of temperature in the observed behavior differences of the individual materials. Therefore, tensile strength properties of geotextile filaments at elevated temperatures were evaluated to further understand the influence of temperature on post-peak interface shear behavior and strength. The strength of the NPNW geotextiles is related to the amount of entanglement produced by the needling and the inter-fiber friction. As such, the geotextile samples utilized in the experimental program are produced from polypropylene (PP) fibers that have more frictional surface to facilitate inter-fiber-friction leading to a relatively strong geotextile macro-structural matrix. The tensile response of the fibrous nonwoven geotextile is governed by the micro-scale (filament) and/or global-level (fabric matrix) tensile and elongation properties. In order to investigate tensile behavior and the developed “micro-scale” stress-strain response of single geotextile filaments at different temperatures, laboratory tests were performed in this study by measuring filament thermo-mechanical properties using DMA. The test temperatures between 21 °C and 50 °C were chosen to simulate the elevated temperature range expected in the field for geotechnical applications such as landfill liners.

5.1 Micro-Mechanical Thermo-Tensile Tests on Geotextile Single Filaments

The filaments from NPNW-PP 8 oz/yd² (270 g/m²) geotextile resulted in a similar trend of tensile load-elongation response at all test temperatures such that the tensile force-displacement curve has a nonlinear elasto-perfectly plastic form in terms of stress-strain relationship (Figures 4a, 4b and 4c). The general pattern in force-elongation behavior of polypropylene filaments in tension tests can visually be portrayed in two segments: i) sharp increase to peak; and then, ii) leveling off at higher strain levels. The filaments exhibited nearly constant resistances after yielding until they reached rupture at elongations of between 70% and 120%. Before experiencing yield, the elastic portion of the curves develops with a relatively constant rate of change in tensile force with respect to displacement. The resulting force-displacement curves for lower temperature tests are located on the upper part of the load-extension space compared with force-displacement curves from higher temperature tests. In other words, the tension failure envelopes for the tested filaments diminished as the ambient temperature increased. Figure 4 presents these 45 tests in which the 15 replicate tests at each test temperature are shown in the same graph starting from the room temperature of 21 °C up to the elevated temperature of 50 °C. There is an apparent trend which can be observed in the series of graphs in Figures 4a, 4b and 4c of the tension force-displacement failure envelopes for polypropylene filament specimens diminishing as the temperature is increased. This variation in tension versus extension behavior shows the influence of temperature on force-displacement response of geotextile single filaments at micro-level.

Figure 4d presents the mean force-displacement plots during extension loading as a function of the temperature at which they were obtained. These mean curves are typical and descriptive in illustrating how the tensile behavior of single geotextile filaments at various test temperature conditions takes form. The filaments from NPNW-PP 8 oz/yd² geotextile resulted in a similar trend of tension load-elongation response at all test temperatures such that the tensile force-displacement curve has a nonlinear elasto-perfectly plastic form in terms of stress-strain relationship. The shapes of force-displacement curves for all the tests performed on filament specimens at various temperatures were in good agreement and indicated that plastic elongation behavior occurs in polypropylene filaments under tension load prior to failure of the fibers. In the tests, the tensile force increases with increasing axial extensional displacement, then, it remains almost constant during inelastic deformation of the polymeric material after passing through yielding deformation. The inelastic portions of the stress-strain curves are essentially parallel.

a) Force – Displacement Curves (T = 21 °C)

b) Force – Displacement Curves (T = 35 °C)

c) Force – Displacement Curves (T = 50 °C)

d) *Mean* Force – Displacement Curves

Figure 4. Tensile Force versus Elongation (Tensional Extension) Behavior for NPNW-PP Geotextile Single Filaments

One of the most important mechanical properties of polymeric materials is its tensile strength under extension force that shows the toughness and indestructibility of the material employed in the field. Since a polymer type (i.e. PP) is used as a base material to produce geotextile fibers, they do not retain tensile strength and robustness properties with temperature change to which many geotechnical engineering applications are exposed (i.e. 21 °C – 50 °C). It was observed as a result of micro-scale thermo-tensile tests on geotextile single filaments that tensile strength, (τ) for PP filaments decreased with increasing temperature with lower strength measured at higher elevated temperatures. In the experimental program temperature range (21 °C – 50 °C), the micro-tensile test at room temperature exhibited the largest toughness under extension and gave the largest tension strength value. Figure 5a shows the variation of the mean tensile strength as temperature changes.

The observed elasto-perfectly plastic force-extension behavior of PP filament specimens indicated that the fibers become stronger and stiffer as temperature decreases under tensile load application. The elastic portion of force-displacement curve rotates “clockwise” demonstrating the reduction in stiffness; hence, modulus with increasing temperature. The slope of initial linear portion of the force-displacement curves was used to compute elastic modulus (Young’s modulus). The major impact of temperature on this tensile strength property of the polymeric filaments was a reduction in stiffness (elasticity modulus) (Figure 5b).

a) Tensile Strength – Temperature

b) Modulus of Elasticity – Temperature

Figure 5. Tensile Strength Properties and Temperature (NPNW-PP Geotextile Single Filaments)

For the consequences of the thermo-mechanical tensile strength behavior of single geotextile filaments at different ambient temperatures to the global matrix level response, the total contact area involved during shearing of the

geomembranes against geotextiles depends heavily on the development of tension in the fiber and the tendency of the filament to elongate. As such the frictional resistance mobilized at geotextile versus geomembrane interfaces is heavily governed by the magnitude of the embedding of the geomembrane into the fabric matrix. This facilitates stronger interlocking between the counterface materials due to the presence of larger contact stresses at contact points at the micro-level due to reduced contact area between the different individual filaments subjected to tensional elongation. To this end, this study reported on the characterization of the tensile behavior of NPNW-PP single geotextile filaments at the “micro-scale” level to be taken into account in evaluating the interface shear behavior of fabrics (i.e. geotextiles) with continua (i.e. geomembranes) under varied temperatures. At the “micro-scale”, the tensile failure takes place due to breakage of filaments whereas at the global scale, the slippage between filaments and the structural deformation due to inherent internal geotextile void space that is governed by fabric manufacturing and fiber processing type, dominates.

6. SURFACE HARDNESS OF GEOMEMBRANES

Hardness which depends on stiffness and viscoelastic properties of the material is defined as the resistance of a plastic material to indentation (ASTM D 2240 – 05). The peak interface strength for geotextile-geomembrane interface is mainly attributed to the geomembrane micro-texture and depends particularly on the geomembrane properties such as hardness and surface roughness. The mobilized frictional strength and the developed interface shear behavior at fabric (geotextile) – continua (geomembrane) interfaces are influenced by the surface hardness of the geomembrane, and additionally, the change in geotextile-geomembrane interface shear behavior with a change in temperature results from the relatively higher temperature dependency of geomembrane properties such as hardness (Figures 2 and 3). Geomembranes, which are polymeric continuum sheet materials comprised of a specific polymer resin, are manufactured uniformly to possess homogeneity in terms of physical and mechanical properties as well as a uniform distribution of material characteristics throughout a large lining sheet. The amount of shear resistance developed at the interface is mainly attributed to geomembrane surface pliability governed by the material hardness which can vary as a function of the ambient temperature. To this end, hardness measurements on geomembrane samples were performed to study the effect of temperature on surface hardness and interface friction of smooth high density polyethylene (HDPE) as well as smooth polyvinylchloride (PVC) geomembranes. Figures 6a and 6b present Shore D, (H_D) surface hardness measurements for both HDPE and PVC geomembranes, respectively, at temperatures ranging from 21 °C to 50 °C in 10 °C increments based on 30 readings at each test temperature to observe the repeatability of the measured surface hardness variation and material firmness behavior with increasing ambient temperature. The 30 repeat measurements at each test temperature are more than sufficient to constitute a sample population to evaluate the surface hardness change of HDPE and PVC geomembrane liners at each temperature.

Figures 6c shows the mean values for surface hardness of both smooth HDPE and smooth PVC geomembranes measured at different temperatures (21 °C – 50 °C) with error bars showing the range and the variation in measurement data, and additionally, the change in their surface hardness with temperature. The hardness of PVC liners at all test temperatures is 0.4 – 0.5 times of the surface hardness of HDPE geomembranes; and this ratio continues in this range (0.4 – 0.5) even with increasing temperature as both the liner materials get softer and more malleable as their hardness values are reduced.

a) Repeated Hardness Measurements (HDPE)

b) Repeated Hardness Measurements (PVC)

Figure 6. Surface Hardness and Temperature for HDPE and PVC Geomembranes

7. DISCUSSION AND CONCLUSIONS

The interface shear test results reported herein over a range of elevated temperature conditions are to capture variations in NPNW-PP geotextile – smooth HDPE or smooth PVC geomembrane interface shear behavior as a function of ambient temperature variation (T (°C)). These results were intended to provide insight into smooth HDPE or smooth PVC geomembrane – geotextile fabric interaction mechanisms at elevated temperature conditions in the field, and thus, the development of interface shear response at different temperatures.

The interface frictional resistance of both smooth HDPE or PVC geomembranes and NPNW geotextile interfaces increased with increasing ambient temperature owing to a decrease in material hardness, and hence, an increase in surface pliability of the geomembranes. It is considered that the acceleration of the polymer relaxation at elevated temperatures resulted in quick dispersion of the concentrated stresses over the interface contact area after the application of load leading to more uniform stress distribution over the entire contact surface at the interface during shear displacement. An increase in ambient temperature results in softening of the polymer and a reduction in stiffness as the temperature increases leading to greater flow of the polymeric material under a load application and greater interaction with the counterface. The peak and residual (post-peak) strength values as defined using the quantitative strength parameters including coefficient of friction, ($\tan(\delta)$) showed an increase with temperature. This is consistent with previous observations made by others of the change of frictional resistance between polymers under increasing temperature. The change of $\tan(\delta)$ over the entire range of test temperatures from 21°C up to 50°C only applies to the particular geosynthetic combinations utilized in this study.

The softer nature of PVC assists the overlying/underlying interface component to embed into the geomembrane body by forming a more intimate interface interaction as shearing progresses at each elevated temperature. As shearing progresses, the higher surface pliability of the PVC lining materials possessed at all temperatures tested, allows it to get roughened by being embedded by the counterface geotextile owing to the malleable nature of the PVC liner and this results in a larger shear resistance. The stiffer and harder nature of HDPE liners does not facilitate the counterface filament embedment into the geomembrane surface as much as the softer PVC liner. This also prevents the frictional resistance of the smooth HDPE from reaching that of the smooth PVC.

The mechanical properties of polypropylene fibers do not remain constant within the range of temperatures found in typical civil engineering applications. It was seen in the result of micro-scale thermo-tensile tests on single geotextile filaments that all filament specimens tested at different temperatures exhibited nonlinear elasto-perfectly plastic tensile behavior under extension. The tensile strength was largest at room temperature and decreased with increasing temperature. Similarly, the modulus of elasticity for polypropylene filaments decreased with increasing temperature. For the test temperatures evaluated in this study, the initial elastic modulus was the largest at room temperature.

The effects of temperature on the friction properties of geotextile versus geomembrane interfaces were examined based on surface hardness measurements at different temperatures and showed that the mobilized frictional strength at geotextile – geomembrane interfaces at different temperatures is primarily influenced by the surface hardness of the

geomembrane. In this context, the measured index value of hardness of the geomembrane surface based on a standard scale (i.e. Shore D in this case) at various temperatures provided a useful quantitative value to evaluate the shear resistance being generated at the interface of fabric – continua. Due to the differences in surface hardnesses of HDPE and PVC geomembranes, the smooth PVC exhibited higher shear stress – displacement curves than those of the smooth HDPE at all temperatures tested although both lining sheet material possess similar surface roughness characteristics. The interface tests carried out at elevated temperatures conditions for PVC liner showed similar responses in which shear displacement hardening behavior occurred after yielding in contrast to the behavior observed with smooth HDPE geomembranes where a post-peak strain softening response developed. The tendency of PVC smooth geomembrane – geotextile interfaces to behave in this fashion was completely dependent on the differing material properties compared with HDPE liners. Additionally, the hardness reduction contributed to some very minor increase in strength with increasing temperature level compared to HDPE. However, the smooth HDPE geomembrane showed a higher increase in strength with temperature for same normal stress level tested.

The experimental results and discussion presented herein have important implications for practice. In predicting the behavior of geosynthetic interfaces that are an important component of composite layered systems widely designed and employed in geotechnical applications, it is critical to consider the significant influence of operational temperature conditions on this behavior. In light of the experimental tests performed in this study and the analyses and discussion included herein, the frictional shear capacity of interfaces between geomembranes and other polymeric materials is not just influenced by the effect of temperature on the individual materials but also the effect of temperature on the combination of materials. In this context, the measured index value of hardness of the geomembrane surface based on a standard scale (i.e. Shore D in this case) at various temperatures can provide insight into how interface shear strength may change (i.e. increase or decrease) at different ambient temperature conditions compared to those determined in conventional laboratory tests conducted at standard room temperatures.

ACKNOWLEDGEMENTS

The research study reported herein was conducted in part with support from the Geosynthetic Institute through a GSI Fellowship to the first author. This support is gratefully acknowledged.

ABSTRACT

River bank erosion is a natural process that results in the formation of the productive floodplains and alluvial terraces common to many of river systems. Events like flooding can trigger dramatic and sudden changes in rivers and streams. However, land use and stream management can also trigger erosion. Many anti-erosion techniques are used as engineered solutions to the problems. The Farakka Barrage Project (FBP), 2245 m long barrage across the River Ganga and 213 m long barrage across the River Bhagirathi, is designed to serve the need of preservation and maintenance of Calcutta Port by improving the regime and navigability of the Bhagirath-Hoogly river system. The river banks at the Farakka Barrage Project on River Ganges have been experiencing erosion, especially during floods. The protection works carried out by FBP has successfully restored the eroded banks. The paper describes the anti erosion works carried out along the banks of River Ganges and restorations of damaged banks.

1. INTRODUCTION

Rivers and their flood plains are dynamic geologic systems. Ever-changing patterns of erosion and deposition occur during the evolution of a river, especially when it begins to meander and shift its course across the cut bank of the bend, while deposition of sediment builds point bars on the inside of the meander. The shifting of meander paths occurs at varying rates, but it is generally most rapid during periods of high water. Erosion of the cut bank may attain a magnitude of centimeters or even meters per day, and streams occasionally shorten their courses dramatically by cutting across the necks of meanders. Therefore, it is unwise to build on surficial materials close to an active stream meander, even though the building sites may be higher than the flood plain.

Floods are recurrent phenomena in India from time immemorial. Almost every year some parts of the country or the other are affected by floods of varying magnitude. It is also experienced that while some parts are suffering under devastating floods, another part is suffering under drought. With the increase in population and developmental activity, there has been tendency to occupy the flood plains which has resulted in more serious nature of damage over the years.

The erosion of banks by the rivers and the consequent loss of life and property are major problems. Rivers tend to erode their beds and banks in the hilly regions resulting in the deepening and widening of rivers. When a river enters the flood plains, it shows a tendency to braid and develop number of channels causing silting of the riverbed, change in course and bank erosion. In the plains, a river shows a meandering tendency with meanders moving downstream causing erosion on the concave and deposition on the convex side and cut offs. The meanders also show a tendency to move downstream. This causes large-scale bank erosion. In deltaic reaches near the outfall into sea, the river divides itself into a number of branches resulting in bank erosion. Thus bank erosion and consequent loss of land and properties is a constant phenomenon all along the course of the river. The study of the problem and remedial measures for training of the river into the defined channel has gained importance due to increase in population pressure and want of alternative sources of livelihood for the people whose land and properties are lost to rivers.

Anti-erosion works are normally taken up only for protection of towns, industrial areas, groups of thickly populated villages, railway lines and roads where re-location is not possible on socio-techno-economic grounds, long lengths of vital embankments benefiting large areas in case retirement is not technically or otherwise feasible and agricultural lands where the cost-benefit ratio justifies such works.

Bank erosion can be minimized by adopting measures that aim at deflecting the current away from the river bank or which aim at reducing the current along the bank of the river and induce silt. The anti-erosion measures in the form of revetment or pitching along with launching apron and spurs of earth protected by armor of stones or spurs of loose stones or stones in wire-mesh crates aim at increasing resistance of the bank to erosion and deflecting the current away from the bank. These generally shift the problem in the upstream or the downstream and necessitate further works to safeguard the land against erosion.

Measures such as permeable spurs, porcupine spurs made of bamboos or of reinforced cement concrete elements reduce the velocity of flow and thus prevent erosion and induce siltation in the vicinity of the bank. Geosynthetic material

(woven geo-textile) available in various forms like big bags and tubes etc. can be filled in-site with riverbed sand to form the groynes, spurs and revetments. The dredging of the channels in the selected reaches which have silted up can be tried. Geo-web filled with concrete overlaid on geo-fabric filters in lieu of stone revetment and launching apron is also a new development.

2. EROSION CONTROL TECHNIQUES

The processes of sediment erosion, transport, and deposition may cause local and system-wide adjustments in the bed and banks of the river channel, including the migration of a river channel across the flood plain. In a natural setting, undisturbed by anthropomorphic impacts or cataclysmic events, the river is dynamic and changes occur over time as a result of these sediment processes. However, when viewed over the long term, these changes tend to fluctuate about an equilibrium condition, known as dynamic equilibrium. Disturbances to the river corridor often affect these sediment processes, and the channel may become unstable (i.e. no longer in a state of dynamic equilibrium). With time, the disturbed channel may achieve a new state of dynamic equilibrium, but viable water management activities or appropriate aquatic habitat for fish and wildlife may not be sustainable during this period of transition. Disturbances to rivers and streams can be caused by dams, water diversions, levees, roads, bridges, bank protection, removal of vegetation and woody debris, logging, grazing, gravel mining, urbanization, and recreation. There are numerous ways to control these disturbances in the river corridor and to restore fully or partially the natural processes and the dynamic equilibrium. Soil conservation practice, check dams, sediment bypass devices, and sluicing are often used to reduce sediment inflow or remove sediments from a reservoir to prolong the useful life of a reservoir.

Bank stabilization has historically been constructed on a reactionary basis in response to lateral erosion of banks from floods. The impact of bank stabilization on natural processes depends on the location of the bank relative to the channel migration zone boundaries, the rate of natural channel migration, and the material that composes the bank stabilization.

Traditional bank stabilization uses hard, angular rock that protects against the high velocities and shear stress against the bank. There are three general approaches of bank stabilization: live planting, bioengineering, and hard armoring. The best technique will depend on the size and location of the eroded bank, and the cause and severity of the erosion.

3. FARAKKA BARRAGE PROJECT

Farakka barrage was constructed across river Ganga at Farakka to divert 1135 cumecs of water into Bhagirathi River to revive it. The Bhagirathi River is one of the important spill channel, taking off from Ganga and feeding the Hoogli system which is the lifeline of this region where a large industrial complex has developed. The diverted water of 1135 cumecs to Bhagirathi – Hoogli system preserves the Kolkata Port. The Farakka Barrage Project, commissioned in the year 1975, is thus of national importance.

3.1 Meandering Behavior of River Ganges Near Farakka

River Ganges has been meandering through ages like all other alluvial rivers. Bank erosion is a common feature during the process of meandering. Ganges with its large mean discharge and a flat slope of about 1 in 20000 near Farakka, flows in a meandering state exhibiting typical behavior of a large river flowing in alluvial plains. Due to the phenomenon of meandering, the river course keeps on changing, resulting in bank erosion at different places. The comparison of the river courses in the seventies and nineties clearly indicates the progressive meandering of the river Ganges and swinging of banks causing bank erosion in the nearby regions such as Gopalpur, Aswintola, Khaskal, Panchananadpur etc. River Ganges has been meandering towards the right bank downstream of Farakka, even much before the construction of the barrage.

3.2 Anti Erosion Measures Adopted in the Past and their Efficacy

The problem of bank erosion was attempted to be tackled by construction of bull headed spurs, lowering of dip trees, construction of boulder bars during the years seventies and eighties. But none of these measures withstood the ferocity of bank erosion and got damaged after facing two or three flood seasons. The dip trees induced siltation during low floods, but during high floods, all the silt deposits were completely washed away along with dip trees.

3.3 Design Philosophy of Anti Erosion Works

The design philosophy includes the estimation of scouring potential of river which is a function of the discharge intensity and Lacey's scour depth. The fineness of river bed material is indicated in terms of silt factor which along with discharge intensity governs the Lacey's scour depth. The thickness of sloped bank pitching is determined on the basis of velocity of

flow along the bank. Similarly the thickness of launching apron is determined once the scour depth, High Flood Level and Low Water Level are known. A suitable filter is also provided below the sloped pitching and launching apron.

The design philosophy is simple but the phenomenon of bank erosion is very complex. A variety of factors and their possible combinations play a major role in causing the bank erosion. These parameters among others include river curvature, reverse/cross flows, composition of bed / bank material etc. It is for this reason the scour factor near the nose of guide builds and spurs and along the curved bends of river is taken as more as compared to that of straight reach of river.

It has been observed during bank erosion on the banks of Ganga that the whirling action of water during the flood causes the scooping out of bed material near the banks and huge landmasses on the banks just sink vertically downwards. This whirling action is an outcome of the reverse flows due to river bank curvature. Once the bed material near the bank gets scooped out because of whirling action of water, the bank becomes unstable and the soil properties of the bank material are of such type that the bank sinks vertically downwards. Hence the problem lies in identification of those places along the bank where the whirling action of water takes place so that the designed length and thickness of launching apron is suitably increased there. The eroded bed material can also be prevented from getting lifted up provided that a suitable filter is placed in position. Selection of filter material and its opening size is very important considering that at a given place on the river bed the different layers of river bed may have different soil particle size and type. When the apron gets launched then there are chances of the filter being torn apart if it does not have sufficient tensile strength. These are some of the practical difficulties in the selection of the filter material.

3.4 Farakka Barrage

The Farakka Barrage Project is designed to serve the need of preservation and maintenance of Calcutta Port by improving the regime and navigability of the Bhagirath-Hoogly river system. The increased upland supplies from Ganga at Farakka into Bhagirathi also reduces salinity in the system and ensures sweet water supply to Calcutta and surrounding areas. The rail-cum-road bridge built across the river Ganga at Farakka establishes direct road and rail communication link to the North-Eastern States. The Bhagirathi, the Feeder Canal and the Navigation Lock at Farakka form part of the Haldia-Allahabad Inland Waterway (National Waterway No. 1).

3.4.1 Principal Components of Farakka Barrage Project

The principal components of the Project are:-

- A 2245 metre long barrage across the River Ganga with rail-cum-road bridge, necessary river training works and a Head Regulator on the right side.
- A 213 metre long barrage across the River Bhagirathi at Jangipur.
- Feeder canal of 1133 cumec (40000 cusec) carrying capacity and 38.38 km. long, taken off the head regulator on the right of the Farakka Barrage.
- Navigation works such as Locks, Lock channels, Shelter basins, Control tower building, navigational lights and other infrastructure.

The jurisdiction map of the Farakka barrage project is presented in Figure 1.

Figure 1. Jurisdiction map of the Farakka barrage project

3.4.2 Activities of the Project

JURISDICTION MAP OF FARAKKA BARRAGE PROJECT

- Maintenance of Barrage and appurtenant structures.
- Anti erosion works in the original jurisdiction.
- 12.5 km u/s & 6.9 km d/s of barrage axis in the main Ganga
- 16 km d/s of Jangipur Barrage along Ganga/Padma near Moya
- Anti erosion works in the extended jurisdiction of 40 km u/s & 40 km d/s of barrage axis in the main Ganga/Padma since 2004.

3.4.3 Anti Erosion Works Executed So Far

Up stream of Farakka barrage along left bank of river Ganga:

Simultola & Birnagar area	-	Length -300m
Panchanandapur	-	Length - 4000 m
Just u/s of left guide bundh	-	Length - 220 m

3.4.4 Anti Erosion Works Being Executed Now

During the current working season, Farakka Barrage Project is presently executing the following anti erosion works.

At Birnagar – Simultala	:	870 m
At Maniakchak Ghat	:	1700 m
At Ramrampur/Arjunpur/Dhuliyani	:	700 m

Figure 2 shows a typical section of the anti-erosion work carried out at these locations.

Figure 2 Typical design section of anti erosion works

3.4.5 Sequence of Anti Erosion Works

- Fixing of the Geotextile on tarza mat
- Laying of the Geotextile-tarza mat composite on the river bed
- Anchoring the Geotextile on the river bank
- Laying of two layers of boulder filled wire crates on the Geotextile-tarza mat composite

Fixing of the Geotextile on Tarza mat

Tarza mat being laid in river bed

Anchoring the Geotextile on the river bank

Laying of two layers of boulder filled wire crates on the Geotextile-Tarza mat composite

The anti-erosion works mainly involve lying of geosynthetic fabric filter under Tarza mat in water as well as on the land depending on site conditions and over that boulder filled GI wire crates of 1.6 m thickness in 34 m long apron laid/dumped to arrest scour due to high discharge intensities.

4. INVESTIGATIONS CARRIED OUT

The materials used for the protection works against the river bank erosion needs to be tested for their quality. Therefore, the Geotextiles and the GI wires which were used for the protection works at the Farakka barrage were tested at Central Soil and Materials Research Station (CSMRS).

CSMRS is a premier institute in India located at New Delhi, which deals with field and laboratory investigations, basic and applied research, and problems in geomechanics, construction materials and allied fields relevant to river valley projects within and neighboring countries viz. Nepal, Bhutan, Afghanistan etc. A well established geosynthetics material testing laboratory at CSMRS has the capability of testing woven and nonwoven geotextiles, geogrids, geonets, geomembranes, and geocomposites that are used in drainage, earthwork, erosion control, and soil reinforcement applications.

The geosynthetics laboratory is equipped with equipments that are used for evaluating the properties such as tensile strength, tearing resistance, thickness, apparent opening size, permeability, interface friction and the pull out resistance.

The Farakka barrage project authorities approached CSMRS for testing the materials used at the protection works of the eroded river banks at Farakka. A large number of Geotextile fabrics and GI wires were received at CSMRS for further testing at the laboratory.

4.1 Laboratory investigations on Geotextiles

The laboratory tests such as apparent opening size, mass per unit area, tensile strength (warp), tensile strength (weft), permeability, etc., were carried out on the geotextiles received from the projects. All these tests were carried out in accordance with ASTM standard test methods. The tests results are presented in the following table.

Table 1 Laboratory Testing on Geotextile Fabric from Farakka Barrage Project, West Bengal

Field Sample No.	Lab. Sample No.	Apparent Opening Size, Micron	Mass per Area, g/m ²	Tensile Strength (warp), kN/m	Tensile Strength (weft), kN/m	Permeability, lit/m ² /sec at 10cm head
S-3/GT	GS/2008/1	150	240.4	55.3	45.7	30.1
S-4/GT	GS/2008/2	150	241.2	55.8	44.7	30.0
S-5/GT	GS/2008/3	150	240.6	55.2	45.3	30.3
S-6/GT	GS/2008/4	150	242.5	55.5	45.1	30.6
S-7/GT	GS/2008/5	150	240.6	55.2	45.3	32.8
S-8/GT	GS/2008/6	150	242.1	55.0	45.2	31.0
S-9/GT	GS/2008/7	150	240.9	55.6	45.2	31.1
S-10/GT	GS/2008/8	150	241.3	56.1	45.5	30.5
S-11/GT	GS/2008/9	150	241.7	55.4	45.6	30.4
S-12/GT	GS/2008/10	150	242.2	55.9	46.1	30.9
S-13/GT	GS/2008/11	150	241.1	55.7	45.9	31.8
S-14/GT	GS/2008/12	150	240.8	55.1	45.4	31.5

4.2 Laboratory Investigation on GI Wire

The GI wire which is used to prepare the boulder filled wire crates, to be placed on the Tarza mat supported geotextile was subjected to the laboratory tests such as evaluation of the wrap strength of the wire, evaluation of the quantity of the zinc coating on the GI wire, evaluation of the tensile strength, , etc., as a quality control measure. This test was performed on five specimens of each 3.15 mm diameter GI wire and the average value is reported as the test value. The test results are in accordance with IS: 280-2006

4.3 Evaluation of the Quantity of the Zinc Coating on the GI Wire

The mass of zinc coating is determined as per IS: 6745-1998. The minimum zinc coating on wire of 3.15 mm diameter is taken as 80 g/m² as per IS: 4826 -1979 for light coated wire.

4.4 Evaluation of the Warp Strength of the Wire

The warp strength test was performed on five specimens per sample of the wire. The test is performed in accordance with IS: 1755-1983 and IS: 280-2006

5. CONCLUSION

The figures below show the geotextiles and GI wires used for the protection works of the river banks at Farakka barrage project.

Protection work using Geotextiles and GI wires

Slope Pitching by sand bags

Nylon Crate being dumped by boat

The protection works carried out for the river bank erosion at the river Ganges around the Farakka barrage project are somewhat simple and a highly engineered solution. While designing the protection works and choosing the products, due care has to be taken for proper design, structural integrity of the system, experienced designer and contractors who installs the system in order to avoid negative criticism.

By carrying out these protection works, the Farakka barrage project authority has restored the damaged banks of the river Ganges successfully and has imbibed a sense of security in the minds of the inhabitants of the area.

ACKNOWLEDGEMENT

Enhancing the Performance of HDPE Geomembranes with Flexible Polypropylene

F. Ceccarani, LyondellBasell, USA; P. Goberti, LyondellBasell, Italy; M. Grazzi, LyondellBasell, Italy

ABSTRACT

Thermoplastic polyolefins (TPOs) are utilized by many industries for the production of materials that go into a variety of applications including flexible packaging, automotive components, single ply roofing membranes, and geomembranes. They are known in the geomembrane industry as “flexible polypropylene” (fPP). They are used in geomembrane applications because of their unique combination of mechanical toughness, flexibility, barrier properties, dimensional stability, and environmental resistance. Recent studies show that flexible polypropylene can be used as a HDPE/MDPE modifier to improve important properties such as flexibility, impact resistance, and environmental stress cracking resistance (ESCR). Although HDPE is widely used in a number of geomembrane applications, an improvement in certain specific properties (flexibility, impact, dimensional stability, ESCR) is often desired.

1. INTRODUCTION

1.1 Flexible Polypropylene: A Reactor-TPO

Thermoplastic polyolefins (TPOs) are polypropylene (PP) based copolymers that contain greater than 40% of a rubbery phase. In addition to being manufactured as post-reactor mechanical blends of PP and an ethylene-propylene rubber (EPR), TPOs can be produced directly in the polymerization reactors using a unique production process known as the *Catalloy* process technology. “Reactor-TPOs” produced with such technology have a unique morphology with the rubber domains very finely and uniformly dispersed within the polypropylene backbone, resulting in enhanced physical properties. These reactor-TPOs are specialty materials known in the geomembrane industry as “flexible polypropylene” (fPP). They are used due to their outstanding flexibility, puncture resistance, and impact resistance as well as their very good dimensional stability and environmental stress cracking resistance (ESCR). Being PP based materials, they have a relatively high melting point (above 140°C) and the high percentage of amorphous polymer in the composition allows these materials to maintain flexibility and impact resistance at very low temperature. Therefore fPP can often be used when very high or very low operating temperatures are expected during service life.

1.2 Typical Polyethylene Materials Used For Making Geomembranes

The three types of polyethylene (PE) that are traditionally used for producing geomembranes have different chemical structures and, consequently, different densities. High density polyethylene (HDPE) resins have densities greater than or equal to 0.941 g/cm³, medium density polyethylene (MDPE) resins have densities in the range of 0.926 to 0.940 g/cm³, and linear low density polyethylene (LLDPE) resins have densities in the range of 0.9125 to 0.925 g/cm³. HDPE is manufactured using either only ethylene as a monomer for the polymer chains (HDPE Homopolymer) or using low amounts of co-monomers (normally butene or hexene), and linear polymer chains with short-chain branches are obtained. MDPE and LLDPE are similar to HDPE but by copolymerizing the ethylene monomer with higher amounts of an alky-branched co-monomer (butene, hexene, or octene), a copolymer PE is produced in which hydrocarbon branches replace some of the hydrogen atoms bonded to the carbon atoms. The distinction between MDPE and LLDPE is a result of the degree of copolymerization, ultimately affecting the density of the polymer (the higher the short-chain branching, the lower the density), with LLDPE being significantly more flexible than MDPE and HDPE.

1.3 Weaknesses of HDPE/MDPE in Geomembrane Applications

HDPE and MDPE are widely used all over the world in a number of geomembrane applications due to their relatively low cost, good property balance, good chemical resistance and UV weathering performance, and easy processability in the blown film and flat die extrusion processes used for making geomembranes. However, an improvement in certain specific properties (flexibility, impact resistance, dimensional stability, ESCR, temperature resistance) is often desired. In fact, HDPE and MDPE are quite stiff polymers and geomembranes made with such materials tend to lack flexibility and impact resistance, especially in cold climates (for instance the Northern US and Canada) and cold environments (for instance mountainous areas), leading to potential membrane handling, installation, and durability issues. Also, polyethylene materials tend to be prone to environmental stress cracking, which is a key property in geomembrane applications.

1.4 HDPE/MDPE Property Improvement with Flexible PP

This paper investigates the properties of HDPE-fPP and MDPE-fPP blends to understand if fPP can significantly improve the weak points of HDPE/MDPE in geomembrane applications. Typical properties that are meaningful in geomembrane applications are examined for HDPE-fPP blends and compared to the properties of a 100% HDPE control and those of HDPE-LLDPE blends. In particular, test results are presented for physical properties, ESCR, weldability window, and UV weathering performance of HDPE and MDPE blended with the following two materials at both 20 percent by weight (20 wt%) and 40 percent by weight (40 wt%) incorporation levels: commercial *Catalloy* Reactor-TPO produced by LyondellBasell and commercial LLDPE produced by Polimeri Europa.

2. EXPERIMENTAL

2.1 Materials Used in this Study

2.1.1 Base HDPE and MDPE Materials

The following HDPE and MDPE commercial grades produced by LyondellBasell were used as the base PE materials for this study:

HDPE -- *Lupolen* 5021DX (density = 0.950 g/cc);

MDPE -- *Lupolen* 3721C (density = 0.937 g/cc).

2.1.2 Modifiers

The following commercial grades were used as the HDPE/MDPE modifiers:

fPP -- *Hifax* CA10A (Reactor-TPO having high EPR level; density = 0.89 g/cc);

LLDPE -- *Clearflex* FG106 (ethylene-hexene copolymer; density = 0.918 g/cc).

2.1.3 Blend Preparation

Blends were extruded using a Berstorff ZE2525 mm twin screw extruder with a strand pelletizing system. Each modifier was blended with each base PE material at levels of 20wt% and 40wt%. In order to simulate commercial geomembrane formulations and provide UV stability during the accelerated weathering test, a suitable amount of Carbon Black and UV stabilizers (HALS) were also included in each formula along with additional primary and secondary antioxidants.

2.2 Physical Property Characterization

2.2.1 Compression Molded Specimens

The physical properties listed below were measured using compression molded specimens (typical of PE materials, whereas for PP materials injection molded specimens are normally used). Specimens were molded on a COLLIN 200M press according to the ISO 293 standard.

- Melt Flow Rate (190°C/2,16kg) (ISO 1133)
- Density (ISO 1183-2)
- Coefficient of Linear Thermal Expansion (CLTE) (Internal Method)
- Flexural Modulus (ISO 178)
- Vicat Softening Point (ISO 306)
- Notched Izod Impact (ISO 180)
- Environmental Stress Cracking Resistance (ESCR) (ASTM D1693)

2.2.2 Sheet Specimens

The physical properties listed below were measured using specimens that were die cut from 1mm (40 mil) thick sheet.

- Tear Resistance (ASTM D1004)
- Puncture Resistance (ASTM D4833)
- Impact Resistance at Low Temperature (ISO 6603)
- Tensile Properties (ISO 527-3; 500 mm/min)
- Weldability Window (Internal Method)
- Accelerated UV Weathering (Internal Method)

3. RESULTS

3.1 Mechanical/Thermal Properties on Compression Molded Specimens

Test results obtained by testing compression molded specimens are reported in Table 1 and Table 2.

Table 1. Properties of HDPE-fPP and HDPE-LLDPE Blends (Compression Molded Specimens)

Physical Property	Test Method	Unit	fPP	HDPE	HDPE + 20% fPP	HDPE + 40% fPP	HDPE + 20% LLDPE	HDPE + 40% LLDPE

Vicat Soft. Temp. (9.81 N)	ISO 306	°C	55.2	118	111	91.5	116	112

3.1.1 Melt Flow Rate

All materials used in this study have low melt flow rate (MFR), as is typical of extrusion and blown film grades. The flowability of all the materials being fairly similar, the MFR was not significantly impacted by blending either modifier with HDPE or MDPE. Fractional MFR values were obtained and no impact on processability is expected.

3.1.2 Density

The density of the blends decreased upon modifier addition since both fPP and LLDPE have lower density than HDPE and MDPE. fPP has an even lower density than LLDPE and, therefore, a more significant decrease in density was obtained using fPP (about 3%). A lower density is beneficial because less material is needed to produce the same membrane.

3.1.3 Coefficient of Linear Thermal Expansion (CLTE)

fPP has significantly lower CLTE than PE based materials, which is why fPP is often the material of choice to minimize wrinkles when there are high temperature fluctuations during the installation of the liner. Thermal excursions can be significant between day and night or between summer and winter installation. Unfortunately, HDPE/MDPE blends with 20% or 40% fPP maintained the original CLTE with no decrease obtained. The lower a material's coefficient of linear thermal expansion, the greater its dimensional stability.

3.1.4 Izod Impact Resistance at Low Temperature

The low temperature Izod impact strength of fPP is approximately 20 times higher than that of HDPE or MDPE. Therefore a large improvement in low temperature Izod is obtained by blending in 20% and especially 40% fPP. Much smaller improvements in impact resistance are obtained by using LLDPE at either 20% or 40% as modifier.

Impact testing determines a material's toughness and resistance to puncture by impact. Impact strength is used to evaluate how much energy is required to break the impacted specimen. As geomembranes are often exposed to low temperature during servicelife (for instance, if they are installed at high altitudes or in cold climates), it is important to determine the impact performance at lower than ambient temperature.

3.1.5 Flexural Modulus

fPP is a softer and much more flexible material than either HDPE or MDPE. Test results for the materials used in this study show that fPP is about 14 times more flexible than HDPE and about 8 times more flexible than MDPE. The reduction in stiffness obtained by blending fPP at 20% is already significant (a reduction of approximately 33%), but with 40% fPP an even greater improvement is achieved (65% reduction blended with HDPE and 54% reduction blended with MDPE). While the addition of LLDPE also provides an improvement in flexibility, it is not as efficient as fPP. The stiffness reduction obtained by blending in 40% LLDPE is less than the reduction obtained by blending in only 20% fPP. The flexural modulus of the membrane material affects the ability to prefabricate large sections in the manufacturing environment. Also, a more flexible membrane will better conform to the substrate surface when the geomembrane is deployed and will be easier to install in cold climates.

3.1.6 Vicat Softening Temperature

The Vicat softening temperature of fPP is lower than that of HDPE or MDPE due to the large amount of amorphous polymer in fPP (EPR). HDPE/MDPE blends with fPP, therefore, tend to have a decreased softening temperature, which can help to broaden the material's heat welding window.

3.2 Mechanical Properties on Sheet Specimens

Test results obtained by testing sheet specimens are reported in Table 3 and Table 4.

Table 3. Properties of HDPE-fPP and HDPE-LLDPE Blends (Sheet Specimens)

3.2.1 Tensile Properties

The HDPE and MDPE materials used in this study have very good tensile properties, as confirmed by the tensile stress at yield and tensile stress at break test results obtained on the sheet specimens. Although fPP has lower tensile stress at yield than either HDPE or MDPE, a higher elongation at break can be obtained with fPP because of its high level of EPR. Thus, HDPE/MDPE blends with fPP have lower tensile stress at yield (between 2% and 30% lower with the addition of 20% fPP) but higher elongation at yield. fPP has tensile stress at break similar to HDPE (slightly higher) and lower than MDPE. It is interesting that for tensile stress at break, there seems to be a synergistic effect between HDPE and fPP since their blends have higher tensile stress at break than either the HDPE or the fPP alone. This could be due to a strain hardening effect. Similar results are obtained with LLDPE blends.

The tensile properties of a membrane provide practical indications about the behavior of the material when it is stretched during installation or in its service life. High tensile elongation at break demonstrates the polymer's ability to be stretched prior to break and is a key property in geomembrane applications.

3.2.2 Tear Resistance

Tear resistance is higher when the polymer has a higher degree of crystallinity, as indicated by the high tear strengths exhibited by HDPE and MDPE. As expected, tear resistance of HDPE and MDPE decreases when those materials are blended with fPP or LLDPE. Laboratory tear tests can be useful to predict a material's ability to resist tear forces and tear propagation in service.

3.2.3 Puncture Resistance

Puncture resistance of the HDPE and MDPE materials used in this study is surprisingly high-- even higher than that of fPP. Therefore, when fPP is blended in at 20%, the puncture resistance decreases a little but not significantly (about 4% with HDPE and about 10% with MDPE). Puncture resistance is especially important during installation since workers can damage the geomembrane during deployment. Also, sharp rocks can perforate the membrane from underneath and affect the integrity of the liner if the soil is not perfectly prepared.

3.2.4 Low Temperature Impact

Test results aimed at understanding the puncture impact resistance behavior of the polymers and blends used in this study were quite surprising, indicating very similar puncture impact strength for HDPE, MDPE, fPP, and their blends. Also, all samples showed ductile failure. This could be due to the specific test method that was used (ISO 6603) in which the test specimen is punctured at its center using a lubricated striker that impacts perpendicularly to the specimen surface and at high speed. This test was designed for rigid plastics and does not seem capable of discriminating between the performances of the flexible materials used in this study.

3.3 Environmental Stress Cracking Resistance (ESCR)

Test results for Environmental Stress Cracking Resistance (ESCR) according to ASTM D 1693 are reported in Table 5.

Table 5. ESCR of fPP, MDPE, HDPE, and HDPE-fPP Blends

Property	Test Method	Unit	fPP	MDPE	HDPE	HDPE + 20% fPP	HDPE + 40% fPP	HDPE + 20% LLDPE	HDPE + 40% LLDPE
ESCR (10% Igepal)	ASTM D 1693	hours	>1600	>1600	52	>1600	>1600	740	>1600
ESCR (100% Igepal)	ASTM D 1693	hours	>1600	>1600	185	>1600	>1600	>1600	>1600

Unlike PE based materials, fPP is not prone to environmental stress cracking, as confirmed in this study (ESCR > 1600 hours). The particular MDPE selected for this study also performed very well (ESCR > 1600 hours). However, the HDPE showed quite poor results at both 10% Igepal concentration (52 hours) and 100% Igepal concentration (185 hours). The addition of fPP at the 20% level was enough to dramatically improve the ESCR performance of HDPE, bringing it to the same level as 100% fPP or 100% MDPE (ESCR > 1600 hours). The addition of LLDPE also had a positive effect but not as great as fPP, since 40% addition of LLDPE was necessary to achieve the same effect as 20% fPP.

3.4 Weldability

In general fPP has a much broader welding window than PE based material due to the presence of amorphous polymer, which tends to soften and melt at lower temperatures than PE. In order to have a preliminary indication regarding whether the introduction of fPP affects the weldability of HDPE and MDPE, some sheet samples were welded with a hot wedge welding procedure using commercial equipment. Hot wedge welding is carried out by a hot wedge, which is

normally heated to a temperature of 300-500°C and pulled between the overlapping lower and upper geomembranes that need to be seamed. A system of guide rollers provides a complete surface contact between the membranes and the two separate tracks of the dual hot wedge. The surface layers of the geomembranes are melted and the two melt layers are pressed together by a squeeze roller system immediately behind the wedge. Basically, the membrane surfaces are united by the wedge-shaped arrangement and pressed together by the squeeze rollers immediately behind the wedge nose, realizing the seam. Hot wedge temperature, roller force and welding speed as well as process engineering and welding parameters can be independently controlled and adjusted to the correct values needed for the particular plastic material being used.

Seam integrity and strength were evaluated according to ASTM D 6392. This test method requires that welded specimens are subjected to both T-peel and shear tests:

- Shear tests on welded coupons can verify if there is proper elongation of the material immediately adjacent to the weld. This is useful to check if the material was adversely affected by excessive heat, scoring or over-grinding. For the materials used in this study, the shear test was considered complete once the specimen reached 50% elongation.

- The T-peel test verifies the degree of proper bonding of the weld. It was performed at a speed of 50 mm/min (as prescribed for HDPE membranes).

Pass requirements vary depending on the project and the material specification and are often determined per GRI GM19.

Based on the limited testing that was performed in this study, it is possible to summarize the results of the welding test as follows:

- fPP can be successfully welded at lower temperatures and higher speeds than HDPE/MDPE (HDPE/MDPE showed adhesion failure when welded at 400°C, while fPP could be successfully welded at high speed even at 360°C).

- The weldability window of HDPE seems to shift to lower temperatures when blended with fPP or LLDPE (HDPE could be successfully welded at 400°C when 40% fPP or 20% LLDPE were added).

- Typical HDPE welding conditions might have to be adjusted if fPP or LLDPE is blended in as a modifier.

A more thorough study would need to be executed to map the welding windows of selected HDPE-fPP blends.

3.5 Accelerated UV Weathering

Accelerated QUV aging was performed on 1 mm thick sheet specimens using an ATLAS UV 2000 apparatus and the following conditions:

- 20 hours of UV exposure with an uninsulated black panel temperature set point of 75°C (167°F), alternating with 4 hours condensation at 60°C (140°F) uninsulated black panel temperature set point.

- Irradiance level of 0.78 W/(m² nm) at 340 nm

- Exposure duration = 1000 hours

Weathering conditions were in accordance with the following two standards, which are often used for accelerated weathering tests of geomembrane formulations:

- ASTM D7238 - Standard Test Method for Effect of Exposure of Unreinforced Polyolefin Geomembrane Using Fluorescent UV Condensation.

- GRI Test Method GM13 - Standard Specification for Test Methods, Test Properties and Testing Frequency for High Density Polyethylene (HDPE) Smooth and Textured Geomembranes.

Due to equipment availability issues, the test was stopped after 1000 hours of exposure (as opposed to the 1600 hours required by GM13). For the evaluation of changes in material properties, tensile strength retention was measured, while it was not possible to measure HP-OIT retention. Test results are reported on Table 6 and Table 7.

Table 6. Tensile Stress At Break Retention after QUV Weathering of fPP, HDPE, HDPE-fPP, and HDPE-LLDPE Blends

Physical Property	Exposure Time (Hours)	Test Method	Unit	fPP	HDPE	HDPE + 20% fPP	HDPE + 40% fPP	HDPE + 20% LLDPE	HDPE + 40% LLDPE
Tensile Stress at Break	0	ISO 527	MPa	22.4	15.8	16.5	23.2	21.8	30.7
Tensile Stress at Break	500	ISO 527	MPa	21.3	16.3	14.9	24.6	17.3	32.8
Tensile Stress at Break	1000	ISO 527	MPa	20.3	16.6	14.7	19.8	16.0	17.0

Table 7. Tensile Stress At Break Retention after QUV Weathering of fPP, MDPE, MDPE-fPP, and MDPE-LLDPE Blends

Physical Property	Exposure Time (Hours)	Test Method	Unit	fPP	MDPE	MDPE + 20% fPP	MDPE + 40% fPP	MDPE + 20% LLDPE	MDPE + 40% LLDPE
Tensile Stress at Break	0	ISO 527	MPa	22.4	32.4	24.8	24.7	32.3	29.5
Tensile Stress at Break	500	ISO 527	MPa	21.3	34.2	24.2	24.1	34.7	33.0
Tensile Stress at Break	1000	ISO 527	MPa	20.3	32.6	25.1	23.1	30.9	30.8

With the exception of HDPE-LLDPE blends, all samples have good tensile strength retention. It seems, therefore, that the addition of fPP does not significantly affect the UV weathering performance of HDPE/MDPE. It must be underlined,

however, that the performance of polyolefins during the accelerated UV weathering test is highly dependent on the presence of Carbon Black in the formula, and especially on the type and amount of specific antioxidants and UV stabilizers (Hindered Amine Light stabilizers, UV Scavengers, others). The selection of a suitable stabilization package is fundamental for achieving good results during the accelerated weathering test and long-term durability during service life.

4. SUMMARY

Test results for HDPE-fPP blends and MDPE-fPP blends are presented in this paper alongside test results for HDPE-LLDPE blends and MDPE-LLDPE blends. It seems that the addition of fPP to either HDPE or MDPE provides benefits in terms of increased flexibility, improved impact resistance at low temperature, and better ESCR. While no positive effect was found on CLTE and little detrimental effect on either tear or puncture resistance was noted, a synergistic effect on tensile stress at break for HDPE-fPP blends was indicated by the data. Weldability tests seem to show that fPP addition can offer an improvement in this regard as well, but a more thorough study is needed to confirm these findings. Finally, the accelerated UV weathering test indicated that the introduction of fPP does not have a negative effect on durability if a proper stabilization package is chosen.

ABSTRACT

A carbon footprint is a measure of the impact that our activities have on the environment, and in particular climate change. It is the measurement of all the greenhouse gases generated by human activity including construction works, measured in units of tonnes of carbon dioxide equivalent. The lower the carbon footprint, the lesser the impact construction works have on the environment. Engineering solutions are not just compared purely on economic terms, but are beginning to be compared on carbon footprint as well. Therefore engineering solutions that protect and improve the environment are increasingly favored as opposed to those that have a negative impact to the environment. This paper describes and compares the carbon footprint of geotextile tubes alternatives versus conventional engineering solutions.

1. INTRODUCTION

Carbon footprinting as an approach is relatively new and has been developed from Life Cycle Assessment (LCA), which has been around since the late 60s. Both methods take a systematic view of the supply chain from raw material extraction through to the final disposal of the product. This approach crucially prevents decisions being made which may shift the environmental burden up and down the supply chain. The impact can be quantified as a total or can be broken down to present the results as its constituent sub-systems. The latter can be used to identify priority areas for improvements.

A product carbon footprint is an assessment of the global warming potential of a product and is also known as embodied carbon. This is often measured as a cradle to gate assessment, which includes all greenhouse gas (GHG) emissions up until the point where the product leaves the factory gate. For example raw material extraction, transportation at all stages, refining, processing and fabrication up to the product leaving its final factory gate. The boundaries of cradle to site also include the transportation up to the site of use for the product. Finally the boundaries of cradle to grave are the most holistic and include all lifecycle stages. This covers the cradle to site, usage (including operation and maintenance) and finally the end of life stage (recycling, reuse, and disposal). This study considered the cradle to grave carbon footprints of breakwater systems and sludge dewatering systems.

2. GEOTEXTILE TUBE SOLUTIONS

A geotextile tube is a closed ended tubular formed fabric unit tailored with regular filling ports. Its circumference and length may be sized specific for each project and are limited only by constraints of handling practicalities and site conditions. The geotextile tube contains the slurry mixture of solids and water that is pumped in, allows water to dissipate through the permeable fabric skin and retains solids within the geotextile tube. Geotextile tube solutions include use as structural units for marine and hydraulic engineering applications and use as containment and dewatering units for municipal, industrial, mining, agricultural and environmental dewatering applications.

2.1 Marine and Hydraulic Engineering Applications

A geotextile tube is filled with sand to form structural unit as replacement for rock in marine and hydraulic engineering applications. Typically sand is specified as fill material for geotextile tube because it can be mixed with water to form slurry for hydraulic filling of the tube and the high permeability of sand allows the geotextile tube structural unit to be constructed rapidly with acceptable or negligible post construction deformations. Figure 1(a) shows the use of geotextile tube to replace the core of a coastal breakwater.

2.2 Dewatering Applications

Dewatering is a process operation used to reduce moisture content of sludge for a few reasons; reduction of volume to reduce cost of transportation and landfilling, reduction of excess moisture to increase the calorific value and processing cost during incineration, etc. Effectiveness is measured by percentage solids capture, dewatering rate and achievable solids content of dewatered material. Effluent water quality is also a measured success criteria, especially when in a

proposed application there is no further water treatment prior to the effluent water being released. Conventional dewatering techniques include mechanical dewatering (centrifuges, belt presses, etc.) which require high capital investment cost and natural dewatering (drying beds and sludge lagoons) which require large area of land and can be very time consuming. The performance of natural dewatering techniques is subject to the weather and the exposed sludge can emit foul odor as well as attract airborne vectors which are negative factors to the environment. Geotextile tube dewatering technology has the advantages of being able to handle very large sludge volumes, achieving very high solids capture rate, requiring low capital investment and the sludge is effectively concealed from the environment. Figure 1(b) shows the use of geotextile tube for dewatering applications.

Figure 1. Geotextile tube applications

3. CARBON FOOTPRINTING METHODOLOGY

The carbon footprint was calculated by collecting data from the supply chain (primary data) and combined with literature sources (secondary data). Data was collected throughout the lifecycle which covered:

- Production of raw materials
- Transport of raw materials
- Manufacturing of the geotextiles
- Transportation to final customer
- Use
- Transport to disposal
- End of life

End of life was determined to be negligible in this study. The method used is called QuickSteps and is built upon the PAS 2050:2011 method of carbon footprinting, which is the most robust carbon footprint method to date. The main difference between these two methods is the different requirements to collect primary data from the supply chain and first tier suppliers. However the underlying principles and method requirements are otherwise the same.

The carbon footprint is measured in CO₂ equivalents (CO₂e) and all IPCC direct GHGs were included in this assessment and converted to CO₂ equivalents (CO₂e) using the latest IPCC (2007) global warming potentials (GWP). These include carbon dioxide, methane, nitrous oxide, hydrofluorocarbons (HFC), perfluorocarbons (PFC) and sulfur hexafluoride.

The exclusion from the carbon footprint is in line with accepted international standards (ISO 14040:2006 and ISO 14044:2006, and the PAS 2050:2011). This study excludes:

- Capital goods (e.g. manufacturing of vehicles, roads, buildings, machinery etc.)
- Human energy inputs to processes
- Transport of employees to and from the place of work
- Animals providing transport services
- Offsetting of emissions

The most recent data for primary data collection were used, covering a period of the calendar year in 2010. The period of GHG assessment (i.e. the temporal boundary) is 100 years, which is in line with PAS 2050:2011 and all global warming potential factors are based on a 100 year timeline.

4. CARBON FOOTPRINT COMPARISONS

Carbon footprint calculations are project specific. In many instances, geotextile tube options result in lower carbon footprints when compared with conventional solutions. A proprietary Carbon Footprint Calculator was developed for the purpose of calculating carbon footprint of and comparison between conventional and geotextile tube solutions. One comparison between geotextile tube option against conventional rock solution in marine and hydraulic engineering application and one comparison between geotextile tube option and belt press operation in dewatering application each are provided. A project case study is also described whereby the geotextile tube solution resulted in significant carbon footprint savings over the conventional solution.

4.1 Breakwater Example

In this hypothetical example a comparison is made between a breakwater built using only rock material and a breakwater built using a core consisting of stacked geotextile tube construction covered with rip-rap. This example is based on conditions applicable to the Netherlands. Figure 2(a) shows the conventional rock breakwater while Figure 2(b) shows the breakwater option with geotextile tube replaced core. Both have the same overall geometrical cross-sectional dimensions. The breakwater height is assumed as 3.3 m, with a base of 16.2 m, crown of 3 m and side slopes of 1:2. This breakwater geometry is not untypical of an inland breakwater application in the Netherlands. In Figure 2(b) three identical geotextile tube filled to height of 1.5 m are used as the core of the breakwater, replacing rock. A geotextile protection layer is used to cover the geotextile tubes before rip-rap is placed on. Both design options involved the use of a basal geotextile layer for the breakwater.

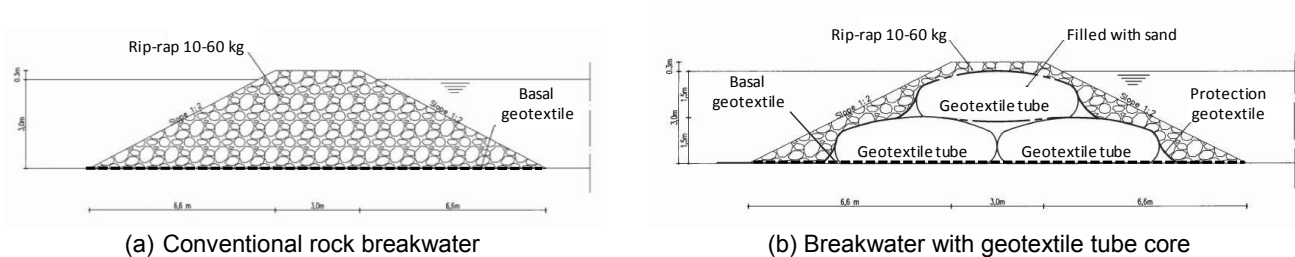

Figure 2. Breakwater details

Table 1 shows the materials, transport quantities and quantities per 100 meter of breakwater for the conventional rock only system and the alternative geotextile tube core system. The carbon footprints for both systems were determined using the proprietary Carbon Footprint Calculator. Figure 3 shows the summary of the carbon footprints per 100 meter of breakwater for the conventional rock breakwater and geotextile tube alternative. Figure 3 also shows a savings of 95 tonnes of CO₂e in carbon footprint per 100 meter when the geotextile tube system is used in replacement of the conventional rock breakwater system.

These results show that, in the context of this example, the carbon footprint of the geotextile tube solution was lower because of the lower transport emissions. This is largely a result of the lower quantity of rocks used when compared with the conventional total rock solution, due to replacement of core with geotextile tubes filled with sand. The sand was dredged onsite for this case example and the pumping energy from this operation has been included in the study. However if the sand was imported to the site the transport distance would likely be small. This is because sand is typically sourced from a local resource.

Table 1. Materials, transport distances and quantities for conventional and geotextile tube solutions for a hypothetical inland breakwater in the Netherlands.

Materials	Transport distance	Quantities per 100 meter of breakwater	
		Conventional	Geotextile Tube
Geotextile tube (4 m diameter)	150 km by road	N.A.	300 m
Sand to fill geotextile tube	Site available	N.A.	4600 tonnes
Riprap (10 – 60 kg)	1200km by sea + 50km by road	7300 tonnes	1800 tonnes
Protection geotextile (200 g/m ² nonwoven)	150 km by road	N.A.	2300 m ²
Basal geotextile (300 g/m ² nonwoven)	150 km by road	1650 m ²	1650 m ²

Breakwater Carbon Calculator Results

Figure 3. Summary output using proprietary Carbon Footprint Calculator

4.2 Dewatering Example

The dewatering example chosen involved a dredging project of a lake in Germany. A total of 30,000 m³ of lake sediment had to be dredged, dewatered and transported to a landfill. Two dewatering options were considered. The first option involved dewatering using a belt press system. The second option involved dewatering using geotextile tubes. The lake sediment had an in-situ solids concentration averaging 22%. Based on tests the dewatered solids concentration of 48% would be achieved for both options. In the comparison the dredging operation was not taken in account as this was similar for both options. For the geotextile tube dewatering option a dewatering platform had to be constructed first. The dewatering platform consisted of a geomembrane and a 100 mm thick layer of gravel above the liner and both materials were sourced locally within a 10 km zone. The source of energy for operating the belt press system was based on a 0.3 litre diesel generator. After the dewatering process the dewatered sludge needed to be hauled away over a distance of 30 km using 17 tonne trucks. The geotextile tube dewatering option was chosen based on both economic and carbon footprint competitiveness. The carbon footprints for both systems were determined using the proprietary Carbon Footprint Calculator. Figures 4(a) and 4(b) shows the boundaries of study for the dewatering carbon calculator of geotextile tube dewatering option and belt press dewatering option respectively. Figure 5(a) shows the carbon footprint breakdown for the geotextile tube dewatering option. Figure 5(b) shows the carbon footprint breakdown for the belt press dewatering option. For both options compared, the use of polymer as well as all related transportation activities were considered.

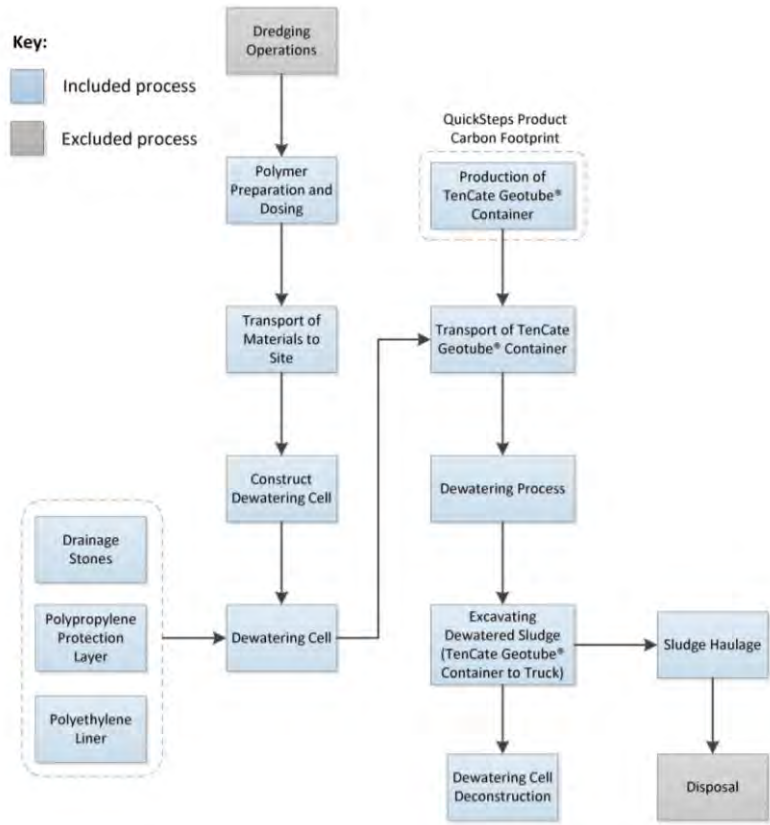

The geotextile tube dewatering option required 72 geotextile tubes of length 30.2 m and circumference of 13.7 m. The geotextile tube dewatering option had a higher cradle to site carbon footprint which comes in the form of the embodied carbon to manufacture the geotextile tubes. However the carbon footprint of the mechanical dewatering system in operation was significantly higher as a result of the electricity consumption of the mechanical system.

4.3 The Zutphen Case Study – A Combination of Dewatering and Hydraulic Engineering

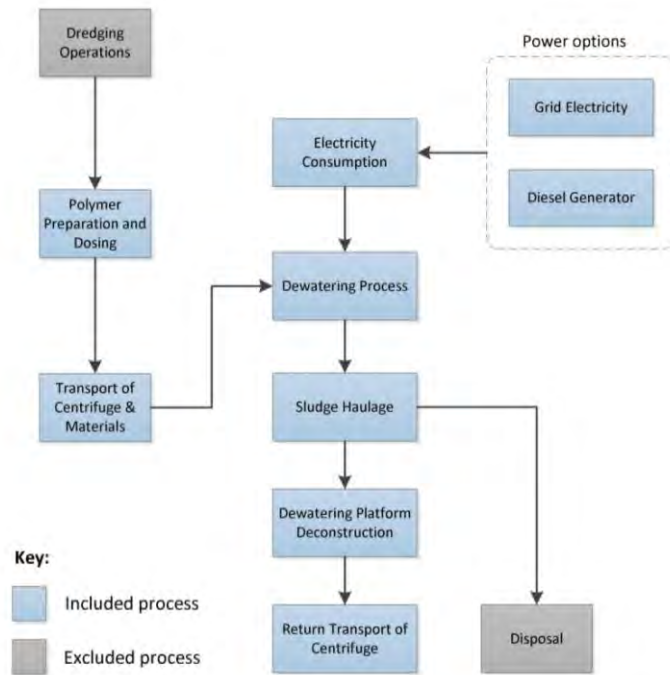

4.3.1 Background of Zutphen Project

The city of Zutphen in the Netherlands is located on River IJssel, a tributary of River Rhine. The old industrial harbour De Mars is being refurbished as part of a restoration plan of the entire industrial area. The harbour and its entrance have been neglected for many years. Fully loaded ships could only enter at high tide without grounding on the bottom of the harbour. To meet future requirements calling for access of ships with a draught of 2.8 meters, the port and the harbour entrance had to be dredged to the original depth and the riverbanks had to be restored. Without the riverbank

restoration, the harbour would again be filled with sand and sludge within a few years. Figure 6 shows the map of the Netherlands and location of Zutphen Project.

4.3.2 The Geotextile Tube Solution

There has been a shift in strategy for the maintenance of waterways and harbours in the Netherlands in recent years. In the past the main question had been on 'how to get rid of dredged materials'. Currently, the question is more on 'where and how materials can be re-used in the most cost effective way'. In the Netherlands, contaminants in dredged materials are benchmarked by a series of designated values (Bray et al. 2001), as follows:

- Target Value (indicates the level below which risks to the environment are considered to be negligible, at the present state of knowledge)
- Limit Value (refers to the concentration at which the water sediment is considered relatively clean)
- Reference Value (is the concentration level indicating whether the dredged sediment is still fit for discharge in surface water or not)
- Intervention Value (indicates that remediation may be urgent, owing to increased risks to public health and the environment)
- Signal Value (is the concentration level of heavy metals above which the need for cleaning up should be investigated)

Dredged materials are then classified with disposal recommendations (Bray et al. 2001), as follows:

- Class 0 (below Target Value) can be spread over the land without restrictions
- Class 1 (exceeds Target Value, but is below the Limit Value) allowed to be disposed unless the soil quality is not significantly impaired
- Class 2 (does not meet the Limit Value, but is below the Reference Value) can be spread in surface water or on land, under certain conditions
- Class 3 (does not meet the Reference Value, but remains below the Intervention Value) should be stored under controlled conditions, specific requirements can be set, depending on the storage location
- Class 4 (does not meet the Intervention Value) should be contained in isolation in deep pits or on land, in order to minimise the influence on the surroundings

The Zutphen Project required both dredging and riverbank works. For the Zutphen Project, a total of 6,000 m³ of Class 2 sediment and 12,000 m³ of Class 3 sediments had to be dredged. The Class 3 contaminated sediment would have required placement in confined disposal facilities, which would have been a costly operation. The geotextile tube solution was able to solve both problems in an economical and green manner. Geotextile tube units filled with dredged sediments from the harbour were dewatered and used as replacement of imported fill material to raise the embankments to the required level. The final structure had to fulfil the geotechnical stability requirement as well as withstand the forces of River IJssel, the fastest flowing river in the Netherlands.

4.3.3 Works Execution

Figure 7 shows the aerial view of dewatering works along the riverbank. This riverbank restoration is adjacent to the harbor entrance where dredging works were carried out to increase the draught for improved navigation. Four work compartments were created, defined by sheet piles as its boundary. The compartments, each 100 m by 100 m, are aligned along the 400 m length of riverbank to be restored. The reasons for doing so were as follows:

- the sheet piles formed a barrier in which the compartments could be prepared for works,
- the sheet piles formed a barrier against River IJssel, creating a safety margin for rising water levels,
- the sheet piles contributed to the geotechnical factor of safety of the restored river bank,
- the compartments formed enclosures to serve as dewatering platforms, and
- effluent water from the tubes could be collected in the adjacent compartments and tested before it was discharged to the river in a controlled way.

The geotextile tubes were laid out and filled within within the confines of the work compartments. In each of the compartments, 4 tubes were filled on a flat surface. The geotextile tubes were sized such that they fit the confines of the compartments but at the same time maximum dewatering capacity is achieved. Figure 8 shows the filling of geotextile tube with dredged contaminated sediment within the sheet pile compartments. The tubes were filled in pairs of two with dredged material having a solids concentration of about 10%. Chemical accelerant was injected into the incoming slurry stream. The in-tube material consolidated to 65% solids concentration within 4 days. Figure 9 shows the backfilling of soil over the consolidated geotextile tube.

Figure 7. Aerial view of geotextile tube dewatering works along the riverbank.

Figure 8. Filling of geotextile tube with dredged contaminated sediment.

Figure 9. Backfilling over dewatered and stabilized geotextile tube.

4.3.4 Carbon Footprint Savings Using Geotextile Tube Solution

For the Zutphen Project a comparison of carbon footprint is made between the geotextile tube solution and that of a conventional solution. For the comparison we are only looking at the process or processes that are different between the two solutions. The conventional solution would have involved two processes, namely:

- Transportation of 12,000 m³ of Class 3 dredged contaminated sediment to the storage depot IJsselooog in the IJsselmeer for disposal
- The importation of 12,000 m³ of suitable backfill, spreading and compaction as part of the riverbank restoration works (this is the extra quantity of fill that would equal the space occupied by the dewatered sludge in the geotextile tube used for the riverbank restoration works of the adopted solution)

The geotextile solution adopted for the Zutphen Project involved only one process that was different from the conventional solution ie. use of geotextile tube and polymer as chemical accelerant for the dewatering of 12,000 m³ of Class 3 dredged contaminated sediment. Table 2 shows the carbon footprint comparisons between the geotextile tube solution and the conventional solution. These comparisons were conducted based on published carbon footprint rates (DEFRA 2010). It can be seen that an estimated savings of 83 tonnes of eCO₂ (equivalent carbon dioxide) was achieved with the adoption of the geotextile tube solution. In the context of only the compared equivalent processes, the savings for the geotextile tube solution was about 55%.

It should be noted that the storage of dredged contaminated sludge at IJsselooog involved a further carbon footprint that has not been included in the calculations. The construction, operation and final closure of the storage depot IJsselooog has a footprint and therefore the storage of 12,000 m³ of dredged contaminated sediment there would have involved a specific share of that carbon footprint. It was not possible to calculate this carbon footprint for this study due to a lack of data on the history and the future fate of the storage depot. It was therefore neglected. However this would have further tipped the balance in favor of the geotextile tube option.

Table 2. Carbon footprint comparisons between geotextile tube and conventional solutions for Zutphen Project.

Activity	Tonnes of eCO ₂	
	Conventional	Geotextile Tube
Transportation of 12,000 m ³ of Class 3 dredged contaminated sediment to IJsselooog	38	N.A.
Importation of 12,000 m ³ of suitable backfill, spreading and compaction	110	N.A.
Use of geotextile tube and chemical accelerant, and dewatering of 12,000 m ³ of Class 3 dredged contaminated sediment	N.A.	65
Total	148	65

5. CONCLUSIONS

This paper described the methodology for carbon footprinting of geotextile tube solutions and the conventional systems they replace. Two comparison examples have been given, one for marine and hydraulic application and one for dewatering application. A dredging and dewatering case study was also presented. Geotextile tube solutions appear to have more favorable carbon footprints over conventional systems in the cases presented.

Estimating the Lifetime of Exposed Geomembranes Using Thin-film Samples and Accelerated UV Aging

Daniel C. Bratton, GSE Lining Technology, LLC, Houston, TX

ABSTRACT

As polyethylene geomembranes are increasingly used in exposed applications it is ever more important to quantify the lifetime of a geomembrane under these conditions. When exposed to UV radiation, free radicals are formed in the polyethylene matrix which react with the polymer chain and cause degradation. UV stabilizers and antioxidants are added to the polymer to intercept free radicals and neutralize them.

The relative concentration of additives within the polymer can be measured using the oxidative induction time (OIT). Using the Arrhenius methodology, an OIT depletion rate can be calculated. It is hypothesized that when two samples of identical formulations but different thicknesses (such as 1.5 mm against 0.125 mm) are subjected to the same accelerated UV weathering conditions that the thinner sample will have a higher OIT depletion rate. A model is proposed to quantify the acceleration factor based solely upon the difference in sample thickness.

1. INTRODUCTION

As polymer technology advances forward and plastic formulations are continuously improved, polyethylene has become increasingly practical to use in exposed engineering applications. These applications include landfill caps, solar ponds, wastewater treatment and other engineering projects that require the geomembrane to be exposed to the sun while in use. It is well established that without the proper protection, polyethylene will readily degrade when exposed to ultraviolet radiation (UV) from the sun. Extensive research has been done to discover the degradation mechanisms and the chemical reaction kinetics of degradation (Wiles and Carlsson 1980, Singh and Sharma 2007, Suits and Hsuan 2003). Moreover, practical studies have been performed to estimate the lifetime of exposed geomembranes with the use of accelerated aging (Hsuan and Koerner 1998, Sangram and Sharma 2002, Hsuan et al. 2008, Rowe et al. 2001, Accorsi 1999, Koerner et al. 2005). This study has focused primarily on the development of an empirical model that can be used to estimate the lifetime of a geomembrane using its thin-film equivalent during accelerated UV aging. The use of this model in other accelerated aging applications is discussed. The main goal is to significantly decrease the amount of time it takes to estimate the lifetime of an exposed geomembrane. Although it is not recommended to depend solely on the results of a thin-film aging test, this method can provide a lifetime estimate in a reasonable amount of time for research and product development purposes. Only by testing a full thickness sample can the prediction by the model be verified.

1.1 The Role of Antioxidants and UV Stabilizers

For the most part, it is accepted that the degradation of polyethylene when exposed to UV radiation is initiated by the formation of free radicals (Hsuan et al. 2008). These free radicals will react with oxygen to produce hydroperoxide (ROOH) groups. The formation of the ROOH group is the primary trigger for degradation. As the concentration of ROOH increases it will eventually reach a critical point where it can readily degrade with the aid of energy. The products of the ROOH degradation will then react with the polymer chain to cause degradation. Antioxidants and UV stabilizers are added to the polymer in small amounts to prevent degradation by (1) converting the free radical species to stable molecules and (2) decomposing hydroperoxides (ROOH) into stable groups rather than free radicals (Hsuan and Koerner 1998). However, antioxidants are consumed whenever they interrupt the oxidation cycle. In addition, antioxidants can migrate through the polymer and ultimately be removed by diffusion before they can serve their protective purpose. It is for this reason that the rate of antioxidant depletion is important to researchers and product developers.

The rate of the chemical reactions involved with oxidation and the formation of free radicals are increased with temperature. As the service temperature (or testing temperature) is increased, the molecules are more excited, there are more collisions, and the chance of there being sufficient activation energy for the reactions is increased. An increase in temperature also increases the antioxidant's ability to diffuse out of the geomembrane. If the temperature is increased sufficiently enough to approach the softening temperature of the polymer, then the diffusion of antioxidants out of the polymer will increase even more due to the additional amorphous regions in the polymer. An effective additive will readily react with free radicals and/or decompose hydroperoxides while also resisting diffusion out of the polymer.

1.2 Phases of Degradation

During accelerated UV aging, polyethylene geomembranes will degrade in three stages according to Hsuan and Koerner (1998): (1) depletion of antioxidants, (2) induction time, and (3) polymer degradation phase or acceleration period. The additives are in place to delay the occurrence of stages 2 and 3 and maximize the length of stage 1. Once the additives are depleted, the induction period begins. It is during this step that the concentration of ROOH begins to steadily increase until it reaches a critical point and can readily degrade. The degradation of ROOH signifies the end of the induction period and the beginning of the acceleration phase as shown in Figure 1 (Hsuan and Koerner 1998).

Figure 1. Phases for the oxidation and degradation of polyethylene (Hsuan and Koerner 1998)

The beginning of the induction phase can be measured by the oxidative induction time (OIT). As the OIT approaches zero it is an indication that the concentration of additives in the sample are also approaching zero. Following the end of the induction phase, the sample's progress through the acceleration phase can be measured by the change in mechanical properties, the change in rheology (melt index), or by the detection of certain functional groups that are formed by the degradation mechanisms. This study utilizes the OIT to measure the sample's progress through the antioxidant depletion phase.

1.3 Previous Aging Studies

This study was largely inspired by a previous investigation by Keegan and Ramsey (1998) which investigated the use of thin-films to compare the UV aging of samples with different levels of antioxidants and different types of UV screeners. The primary goal of Keegan and Ramsey's study was to investigate any differences during UV aging between formulations while this study was focused on deriving a relationship between the aging characteristics of thin-films and their geomembrane-thickness equivalents.

There have been a number of studies conducted on polyethylene to investigate its behavior in both accelerated aging and under field conditions. Hsuan and Koerner (1998) discussed types of antioxidants and their effect on the OIT and high pressure OIT (or HPOIT) in addition to outlining the stages of degradation as shown in Figure 1. Their study also supplied a method for antioxidant lifetime extrapolation using the OIT depletion rate which has been used in many studies since then (Sangram et al. 2002, Hsuan, et al. 2008, and Rowe, et al. 2010) and is used in this study as well. It is typically used to generate antioxidant depletion rates at several temperatures in order to extrapolate to a field temperature and estimate the time to complete antioxidant depletion under those conditions. However, these studies have mainly focused on the aging of samples of identical thickness and usually thicknesses that are typical for geomembranes such as 1.0, 1.5, or 2.0 mm. Rowe, et al. (2010) observed that the antioxidant depletion rate is not only dependent on the testing conditions, but also the thickness of the geomembrane.

1.4 The Effect of Sample Thickness

A previous study by Rowe, et al. (2010) has shown that when samples of varying thickness are exposed to identical aging conditions the OIT depletion rate increases with decreasing sample thickness. As expected, there is a strong relationship between sample thickness and the OIT depletion rate as depicted in Figure 2 below. In Rowe et al.'s study, samples of three different thicknesses (1.0, 1.5, and 2.0 mm) were immersed in a synthetic leachate at four different temperatures. For more than 12 months the samples were routinely tested for their OIT and an OIT depletion rate was calculated for each sample. Using this data, plots of the antioxidant depletion rate against the testing temperature for three sample thicknesses were produced. Figure 2 displays this same data presented in a different way. Instead of

plotting the antioxidant depletion rate against temperature at various thicknesses, the antioxidant depletion rate is plotted against the sample thickness at various temperatures and a strong linear trend is observed (R^2 was exceeding 0.94).

Figure 2. Data from Rowe, et al. (2011) plotted with thickness against OIT depletion rate.

Figure 2 demonstrates that the antioxidant depletion rate is strongly related to the sample thickness under identical testing conditions. This also suggests that OIT depletion rate of a thin-film could be used estimate the OIT depletion rate of a geomembrane-thickness sample. The use of thin-films is advantageous to product developers and researchers because it takes considerably less time to collect OIT depletion data.

The results published by Rowe et al. (2011) can only be used to predict the OIT depletion rate of samples that undergo the identical test method used. In order to compare the results from Rowe et al.'s test method to others, the OIT depletion rate ratio $\frac{s_H}{s_h}$ and the thickness ratio $\frac{H}{h}$ are introduced where s_H is the OIT depletion rate of a geomembrane-thickness sample, s_h is the OIT depletion rate of a thin-film sample, H is the thickness of the geomembrane-thickness sample, and h is the thickness of the thin-film sample. This way, the magnitude of difference between samples of different thicknesses is investigated and the differences between testing methods is eliminated. This is a key assumption of this study.

The thickness ratio can be compared to the OIT depletion rate ratio using the power law as shown in Equation 1 below. The constant k and power α can be determined by taking the natural log of Equation 1 and plotting $\ln \frac{s_H}{s_h}$ against $\ln \frac{H}{h}$. The slope of the resulting line is the power α and the y-intercept is the natural log of the constant k as shown in Equation 2.

$$A = kB^\alpha \text{ or } \frac{s_H}{s_h} = k \frac{H}{h}^\alpha \quad [1]$$

$$\ln \frac{s_H}{s_h} = \ln k + \alpha \ln \frac{H}{h} \quad [2]$$

The data from Rowe, et al.'s study (2010) can be used to generate values of $\frac{s_H}{s_h}$ and $\frac{H}{h}$. Three thickness ratios and OIT depletion rate ratios can be generated for the four temperatures as shown below in Table 1.

Table 1. Values used to determine the values of k and α in Equations 1 and 2 using data from Rowe, et al. (2010).

Testing Temperature (°C)	$\frac{H}{h}$	$\frac{s_H}{s_h}$
22	1.67	0.64
	1.33	0.79
	1.25	0.82
55	1.67	0.73
	1.33	0.84
	1.25	0.88
70	1.67	0.59
	1.33	0.70

By taking the average of the values of $\frac{s_H}{s_h}$ for each value of $\frac{H}{h}$ for each temperature and then plotting the values according to Equation 2, Figure 3 is produced. The 95% confidence interval for each point is shown as error bars in Figure 3. The resulting linear trend line is shown in Equation 3 following Figure 3. Equation 4 displays the resulting power law. Theoretically, the value of k should be one (1) because two samples of identical thickness and formulation will exhibit the identical OIT depletion rate under the identical testing conditions. It is expected that the value of α be negative because the OIT depletion rate will decrease with increasing thickness. The analysis of Rowe et al.'s (2010) data yielded a value of 1.00 ± 0.13 for k and -0.86 ± 0.35 for α .

Figure 3. Linear trend line derived using Equation 2 and data from Rowe et al. (2010).

$$\ln \frac{s_H}{s_h} = (0.0046 \pm 0.13) + (-0.83 \pm 0.35) \ln \frac{H}{h} \quad [3]$$

$$\frac{s_H}{s_h} = (1.00 \pm 0.13) \frac{H}{h}^{-0.83 \pm 0.35} \quad [4]$$

Because this study utilizes the ratio between the OIT depletion rates and the ratio between the thicknesses, it is applicable across different test methods. Although samples will age differently depending on their testing conditions, the ratio between the OIT depletion rates should be the same as long as the samples are of the identical formulation and are tested in the exact same testing conditions.

In this study, UV aging was chosen because it is one of the more complex testing scenarios used for geomembranes. In addition, there is limited research published regarding the UV aging of geomembranes and it has become an increasingly important topic to the industry.

2.0 EXPERIMENTAL METHODOLOGY

2.1 Sample Preparation

All UV aging was performed in a QUV Basic ultraviolet fluorescent device which gives an irradiance of approximately $0.78 \text{ W/m}^2\text{nm}$. The UV aging was performed according to GRI GM13 (Geosynthetic Institute 2011) at a temperature of 70°C . This method incorporates a 24 hour cycle with 20 hours of UV exposure followed by a 4 hour condensation period at 60°C .

All of the samples were prepared using a lab scale calendaring line and there was some observed thickness variation in the samples (see Table 2 under thickness). Each sample was prepared according to ASTM D7238 which is shown in Figure 4. In order to avoid any interaction between the aluminum backing and the thin-film samples, a non-stabilized sample of 1.5mm HDPE was placed behind the thin-film sample.

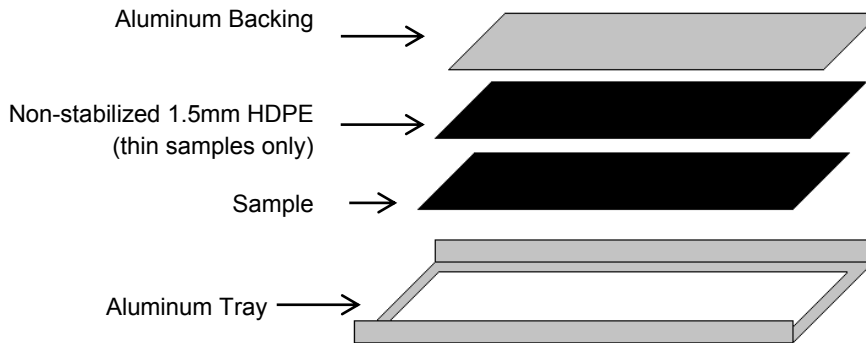

Figure 4. Sample preparation for the UV accelerated aging.

2.2 Sample Testing

Each sample was periodically taken out of the UV device and tested for its OIT according to ASTM D3895. Once an OIT value was below 10 minutes, it was assumed that the antioxidant depletion phase had ended. Each time the samples were removed from the UV device for testing they were placed back into the device randomly such that they were routinely rotated.

2.3 Calculation of the OIT Depletion Rate

As discussed in section 1.3, there are many studies that calculate an OIT depletion rate using Equations 5 and 6 below (Hsuan and Koerner 1998, Hsuan et al. 2008, Sangram and Sharma 2002). When plotting the log of the OITs against their exposure time, a linear trend is observed. The slope of the resulting line is the OIT depletion rate, s . This line can be expressed according to Equation 5 below where OIT_t is the OIT at a testing time t , OIT_0 is the initial OIT value, and s is the OIT depletion rate.

$$OIT(t) = OIT_0 e^{-st} \quad [5]$$

$$\ln OIT_t = \ln OIT_0 - st \quad [6]$$

Although the values of s have usually been calculated at various testing temperatures to extrapolate an OIT depletion rate at a desired temperature (usually a field temperature), this study used values of s calculated at two different geomembrane thicknesses in order to extrapolate and OIT depletion rate at a desired thickness.

2.4 Comparison of the Antioxidant Depletion Rates

As discussed in section 1.4, the OIT depletion rate ratio was related to the thickness ratio according to Equation 1. The OIT depletion rates of the thin-film and geomembrane-thickness samples were used to generate a value of power α . This value was compared to the value derived from data collected by Rowe, et al. (2010).

3.0 RESULTS AND DISCUSSION

3.1 Samples

Table 2 below displays the samples that were used during this study. The samples consisted of two different resins all of which had some level of thermal and UV stabilization. Two different master batches were utilized to provide four different formulations. All of the samples had 2.0 – 3.0% carbon black content. Samples with identical formulation IDs have identical formulations. There was some observed variance in the initial OIT of samples with identical formulations and it is believed that this was caused by variation in the resin lots used from sample to sample.

Table 2. Sample thickness and initial OIT information for both the thin-film and geomembrane-thickness samples.

Sample ID	Formulation ID	Initial OIT (mins)	Thickness (mils)
1	A	184	5.0±0.4

3.2 OIT and Calculated OIT Depletion Rates

Tables 3 and 4 display the OIT results of the samples over UV exposure time. All thin-film samples reached an OIT of 10 minutes in less than 1,678 hours. The OIT depletion rates calculated using Equation 6 for each sample are shown in Table 5.

Table 3. Measured OIT values for thin-film samples during UV exposure.

*Indicates geomembrane-thickness samples.

Figures 5-8 display the measured OITs during UV aging for the thin-film and geomembrane-thickness samples for each formulation. As expected, the OIT depletion rates for the thin-film samples are much greater than the OIT depletion rates of the geomembrane-thickness samples.

Figure 5. Measured OIT values during UV aging for formulation 1.

Figure 7. Measured OIT values during UV aging for formulation 4.

Figure 8. Measured OIT values during UV aging for formulation 5.

3.3 Calculated Values of α During UV Aging

Values for α can be calculated for each of the four formulations that were evaluated during accelerated UV aging. The value for k cannot be determined because only one value of $\frac{H}{h}$ and $\frac{s_H}{s_h}$ was produced for each formulation. As discussed in section 1.4, k is expected equal to one (1). Values for α can be calculated using Equation 7 below using a value of 1.00 for k . Table 6 displays the calculated values for α for each formulation.

$$\frac{s_H}{s_h} = (1.00) \frac{H}{h}^\alpha \quad [7]$$

Table 6. Calculated values of α for the UV aging samples using a value of 1.00 for k .

Formulation ID	α
A	-1.23
B	-0.91
C	-1.14
D	-0.92

The average value of α between the four formulations listed in Table 6 was -1.05 ± 0.34 which is comparable to the value of α that was previously calculated with Rowe et al.'s data (2011): -0.86 ± 0.35 . A preliminary F-test was conducted for the equality of variance and indicated that the variance is not statistically different between the two values of α ($P=0.0515$). A t-test assuming equal variances confirms that there is no significant statistical difference ($P=0.0621$) between the values of α calculated from Rowe et al.'s data and the data from this study.

Because the value of P (0.0515) was very close to indicating there was a significant difference between the sample variance, a t-test assuming that the variance was not equal was performed and also indicated that there was no statistical difference between the two values of α ($P=0.0688$).

A more simplified form of Equation 7 uses a value of -1 for α and a value of 1 for k and is shown below in Equation 8. Table 7 displays the estimated values of the OIT depletion rate of the geomembrane-thickness samples (s_H) using Equation 8. Table 8 displays the estimated OIT value of the geomembrane-thickness samples after 1,600 hours of UV exposure compared to the observed results.

$$\frac{s_H}{s_h} = \frac{h}{H} \quad [8]$$

By incorporating Equation 6 into Equation 8, the OIT at a desired time can be calculated directly as shown in Equation 9 where t is the desired time, h is the thin-film thickness, s_h is the OIT depletion rate of the thin-film, H is the desired thickness, OIT_t is the OIT value at time t for the desired thickness, and $OIT_{H,0}$ is the initial OIT value of the desired thickness (which can be substituted for $OIT_{h,0}$, the initial OIT of the thin-film sample, if the formulation is identical to the geomembrane-thickness sample).

$$OIT_t H = OIT_{H,0} e^{\frac{-(t)(h)(s_h)}{H}} \quad [9]$$

Table 7. Values of s_H predicted using Equation 8 for geomembrane-thickness samples.

Formulation ID	Measured values of s_h (10^3 , 1/hr)	Measured values of s_H (10^3 , 1/hr)	Estimated s_H Using Equation 8 $\alpha = -1.0$ (10^3 , 1/hr)	Percent Difference Between s_H Values $\alpha = -1.0$ (%)
A	3.75	0.170	0.306	79.5
B	3.17	0.343	0.273	20.3
C	3.31	0.274	0.372	36.0
D	2.32	0.250	0.205	18.2

Table 8. OIT values at 1,600 UV hours predicted using Equation 9 for geomembrane-thickness samples.

Formulation ID	Measured OIT value at 1,600 UV hours ¹ (mins)	Predicted OIT value at 1,600 hours UV exposure using Equation 8 (mins)	Percent difference between OIT values (%)
A	196	158	19.5
B	142	158	14.6
C	166	142	-11.8
D	177	190	-7.53

¹The value was extrapolated from measured OIT data using equation 5.

Using a value of -1 for α and a value of 1 for k , the OIT at 1,600 hours of UV exposure was predicted within 13.3% on average. In half the samples, the OIT was under predicted. For a more conservative approach, the value for α can be increased to -0.9. Using this value for α , the OIT after 1,600 hours of UV exposure is predicted within 14.7% on average and was under predicted in all four samples.

4.0 CONCLUSION

Using thin-films to estimate the OIT depletion rate of geomembrane-thickness samples can significantly reduce testing time and enable product developers and researchers to quickly estimate the aging performance of a geomembrane sample.

A strong relationship was found between the thickness of the sample and the OIT depletion rate. The OIT depletion rates are highly dependent on the test environment; therefore, a method was devised to eliminate the differences between test methods by introducing the ratio between the OIT depletion rates ($\frac{S_H}{S_h}$) and the ratio of the thicknesses $\frac{H}{h}$. By relating these two ratios using the power law as shown in Equation 1, the results can be compared across different testing methods. This study compared aging results generated by Rowe et al. (2011), which immersed samples in synthetic leachate at various temperatures, to the results of accelerated UV aging. The resulting values of α from the analysis of both data sets are statistically the same. By analyzing data from Rowe et al.'s (2011) study, α was -0.83 ± 0.35 . The α calculated in this study was -1.05 ± 0.34 .

The value of alpha can be used to estimate the OIT depletion rate of a sample of a desired thickness in any testing environment when the OIT depletion rate of a thin-film sample is known. Equation 1 can be simplified by assuming a value of -1.0 for α and 1.0 for k . When using this estimation, the OIT values after 1,600 hours of UV exposure of the geomembrane-thickness samples were estimated within 13.3%. For more conservative estimates, a value of -0.9 should be used for α . Using -0.9 for α yielded OIT estimates within 14.7% of the measured values after 1,600 hours of UV aging for the geomembrane-thickness samples.

The first 400 hours of UV aging performed on the geomembrane-thickness samples in this study was at a slightly elevated temperature from their thin-film equivalents (75°C instead of 70°C) and could be a source of error. Other sources of error include the difference in extruder residence time of the thin-film and geomembrane-thickness samples during processing. Additionally, the UV radiation is not believed to completely penetrate the geomembrane-thickness samples.

Any future work should incorporate at least three thicknesses so that a value for α and k can be estimated with a 95% confidence interval. Additional thicknesses will provide a more accurate calculation of α and k . Additionally, future studies should include several different testing methods such as oven aging and aging while immersed in liquids to confirm this study's applicability across various test methods. Multiple OITs should be taken for each formulation at each time interval to account for any error in the OIT test.

The use of thin-films could also be used to study the induction time and the acceleration phase (see Figure 1). Although this was outside of the scope of this study, thin-films could allow researchers to not only monitor the OIT depletion rate, but also the degradation of the mechanical properties. This could shed light on, as an example, the UV screening effect of different particle sizes of carbon black.

Evaluating Wind Uplift for Exposed Geomembranes Using Computer Modeling

Keaton Botelho, P.E., Geosyntec Consultants, USA, kbotelho@geosyntec.com,
Oliver Heynes, PhD, MMI Engineering, USA, ohaynes@mengineering.com,
Jean-Pierre Giroud, PhD, JP Giroud, Inc., USA, jpg@jpgiroud.com

ABSTRACT

The accurate calculation of wind uplift forces on an exposed geomembrane is essential for generating design requirements for the anchorage system. These requirements often largely dictate construction costs, so inaccuracies in the uplift calculation may have significant economic repercussions. Inaccuracies may occur when using generic suction factors rather than a site specific assessment using Computational Fluid Dynamics (CFD) technology. This paper presents preliminary research conducted to determine whether potential cost savings warrant more complex CFD modeling. Preliminary results comparing a two-dimensional case of an exposed geomembrane (which was used to develop generic suction factors commonly used to evaluate wind uplift) indicate the wind uplift forces calculated from a CFD model resulted in tensions that were significantly less than those using generic suction factors. Preliminary research was performed with the intention of employing CFD modeling to refine the simple prescription of generic suction factors on a site-specific basis.

1. INTRODUCTION

1.1 Objective

Giroud et al. (1995) developed and published a comprehensive analytical methodology for the various aspects of design of geomembrane exposed to wind, such as calculation of tension and strain in the geomembrane, evaluation of geomembrane deflection, and sizing of anchor trenches and benches. The methodology has been completed and refined in subsequent papers (Zornberg & Giroud 1997, Giroud et al. 1999, Giroud et al. 2006, Giroud 2009). Giroud et al. (1995) conservatively proposed that generic suction factors be used with their methodology. These generic suction factors were derived from small-scale wind tunnel testing published by Dedrick (1973, 1974a, 1974b, 1975). The wind tunnel testing was intended to replicate a reservoir with different orientations with respect to wind direction.

Herein, the analytical methodology, which is widely accepted and used, is not discussed. The purpose of this paper is essentially to show that the generic suction factors can be overly conservative and that Computational Fluid Dynamics (CFD) can be used as a method to evaluate the suction directly for a variety of different slope inclinations, orientations, lengths, and other parameters which may affect the magnitude of suction for exposed geomembranes. The paper shows that CFD modeling allows designers to predict the suction exerted by wind on an exposed geomembrane system more accurately than generic suction factors, which makes it possible to efficiently design a cost effective anchorage system.

1.2 Comparison

For the purpose of this paper, the suction was evaluated using both CFD and the generic suction factors derived by Giroud et al. (1995) from Dedrick small-scale tests. The same parameters were assumed for both approaches to provide an equal comparison of the results using both approaches. The model assumes the condition of a reservoir (negative slope inclination) located at sea level for simplification. The slope length and wind velocity were held constant and the slope inclination was adjusted from 2:1 (horizontal:vertical) to 4:1 (H:V) in 0.5:1 (H:V) increments.

2. APPLICABILITY OF CFD MODELING TO EXPOSED GEOMEMBRANES

Unlike empirical methods which are based upon relationships derived from experience, CFD is a technique that is based on the solution of Navier-Stokes equations. These equations were obtained by combining basic principles (equilibrium and continuity) with Newton's constitutive law of viscosity. Therefore, Navier-Stokes equations are the fundamental equations for analyzing the motion of Newtonian fluids. Examples include air flows over aircraft, water flow in rivers and lakes, wind dynamics on sites and many others. In all cases the fluids are governed by the same general principles which are satisfied in a CFD simulation. As computational power has increased, the use of CFD in engineering has also increased. CFD is now widely used in many industries and has been in some for almost 40 years.

A distinct advantage of CFD is the collection of data available once a simulation is complete. Contour plots of velocity, pressure, temperature or any number of variables may be produced, together with velocity vectors and streamlines. Figure 1 shows an example of a typical output from a CFD model, showing wind flow over a site. The modeling domain is approximately 1500 (length) x 900 (width) x 150 m (height) (5,000 x 3,000 x 500 ft) and the wind direction is in the length direction. The contour plot shows wind velocity magnitude, red indicating high velocity and blue low velocity. The effects of obstructions (in this case, a porous windbreak just upstream of dust piles) can be observed. In addition to the visual output which is useful for gaining general insight into flow patterns, spot measurements may also be taken anywhere in the domain of the CFD model. This is particularly useful where certain variables are critical to design – in this case, suction pressure.

Figure 1. Example CFD Modeling Output

It is clear that the air flow over an exposed geomembrane may therefore be modeled using CFD (assuming that air behaves as a Newtonian fluid, which is a common assumption), and the output may be processed to derive the suction pressure. However, to the authors' knowledge and extent of their literature search, there are no published articles that have attempted this analysis. Application of CFD in closely related fields is common. Air flows over two- and three-dimensional hills and escarpments have been studied by Bergeles (1985), Paterson & Holmes (1993), Kim et al. (1997) and Carpenter & Lock (1999) to name a few, where the focus is often the dispersion of pollutants or the suitability of sites for wind farms. In civil engineering and architecture, CFD is often used to evaluate wind loads on buildings (see Murakami et al. (1992), Delauny et al. (1995) and Mikkelsen & Livesey (1995)), a similar problem but one where the critical parameter is not a negative uplift pressure but instead a positive face pressure. In many cases these studies include comparisons to experimental data from wind tunnels to validate the CFD model.

3. SUCTION EVALUATION

3.1 Interpretation by Giroud et al. of Wind Tunnel Tests

The generally accepted method for designing exposed geomembranes and anchorage systems has been presented in Giroud et al. (1995) and the subsequent papers mentioned above. The critical parameter is the suction factor λ which is calculated by the following equation:

$$\lambda = \frac{S}{\Delta P_{ref}} \quad [1]$$

where S is the suction pressure (positive if the pressure on the geomembrane is negative, i.e. inducing an uplift force) and ΔP_{ref} is the reference pressure, which is simply the dynamic pressure of the wind, calculated from the air density ρ and the mean wind velocity U :

$$\Delta P_{ref} = \frac{\rho U^2}{2} \tag{2}$$

Data from wind tunnel tests on small scale models of reservoirs by Dedrick (1973, 1974a, 1974b, 1975) for both windward and leeward slopes were summarized by Giroud et al. (1995) (see Figure 2, for example). These data were then simplified by Giroud et al. (1995) to be conservatively applicable to a generic slope regardless of its orientation with respect to wind direction. For the sake of simplicity, the generic slope and the adjacent horizontal areas were divided into three distinct zones, with the suction factor given at each of the three zones as:

- $\lambda = 1.0$ at the crest
- $\lambda = 0.7$ on the slope if the entire slope is considered; or $\lambda = 0.85, \lambda = 0.7, \lambda = 0.55$ for the top, middle and bottom thirds of the slope, respectively, if the slope is decomposed into three sections.
- $\lambda = 0.4$ on the bottom of the slope.

These generic suction factors are summarized in Figure 3. It is important to note that the generic suction factors given in Figure 3 are intended to be used regardless of the wind direction.

Figure 2. Pressure variation due to wind blowing past a reservoir (solid line for wind perpendicular to slope direction and dashed line for the worst case of wind at an angle) based on the work of Dedrick (1973, 1974a, 1974b, 1975). (Figure reproduced from Giroud et al. 1995)

Figure 3. Generic suction factors for the worst case of wind direction as conservatively recommended by Giroud et al. (1995).

While the strength of the generic suction factors is their simplicity and conservatism, their weakness is that they do not account for parameters that are likely to have a significant impact on wind-generated suction such as slope inclination and wind direction. Furthermore, the generic suction factors do not account for other parameters that may have an

impact such as surface roughness, presence of obstructions, and complex geometries (such as benches and swales on slopes). It will be seen that the CFD method makes it possible to determine the influence of a variety of parameters on suction.

3.2 Computational Fluid Dynamics

Almost any geometry can be used with a CFD model. In this preliminary research, a two-dimensional slope was used and the slope inclination was varied from 2:1 (horizontal:vertical) to 4:1 (H:V) in 0.5:1 (H:V) increments. A view of the domain and computational mesh for the 2:1 simulation is shown on Figure 4. The computational mesh is a critical component of a CFD simulation, as the discretization of space into smaller cells on which the conservation principles are enforced provides the basis of an accurate simulation. It should be noted that the cells become smaller near the bottom boundary to accurately resolve the high velocity gradients. The labels in the figure at the mesh boundaries indicate the types of boundary conditions that were used in the simulations. A logarithmic wind velocity profile was set at the upwind (“inlet”) boundary, with the mean wind vector from left-to-right as shown in the figure. On the bottom boundary, a “wall” type boundary condition was used which enforces the no-slip condition and calculates the shear stress. The top and downwind boundaries were both set to “pressure opening” type boundaries. At these boundaries, the pressure was set to zero relative to the atmospheric pressure. This combination of boundary conditions is typical for CFD simulations of external wind flows.

Figure 4. Typical computational mesh for a 2:1 leeward slope, with the boundary conditions marked. The mean wind vector is from left to right.

Figure 5. Contours of wind velocity for the case defined in Figure 4, showing high wind velocity (red) away from the ground and low wind velocity (blue / green) downwind of the slope.

Figure 6. Contours of differential pressure (e.g. relative to atmospheric pressure) for the case defined in Figure 4.

Figure 5 shows the results from the CFD simulation for air velocity over a 2:1 leeward slope. The reference wind velocity in the simulation was set to 100 km/h. The red areas in the figure indicate air flowing at this velocity, while the blue and green areas show areas of low velocity just downstream of the slope (the wind in the figure is from left to right).

Pressure is also calculated in a CFD simulation. However, it is more useful to report the differential pressure relative to atmospheric pressure because suction is a differential pressure. For example, in Figure 6, the blue areas indicate pressures of -100 Pa or less. This is relative to atmospheric pressure, so for example if the atmospheric pressure was 101325 Pa, then the absolute pressure in the blue areas would be $101325 - 100 = 101225$ Pa.

The blue areas in Figure 6 show that a negative pressure (suction) appears on the entire face of the slope, with a greater value near the crest and gradually reducing near the bottom.

There is a quantitative difference between the results of the CFD modeling and the generic suction factors. The reference pressure ΔP_{ref} in the CFD simulation is 500 Pa (as calculated using Equation 2 with $\rho = 1.29 \text{ kg/m}^3$ and $U = 27.78 \text{ m/s} = 100 \text{ km/h}$). Therefore, suction pressures of around 60 Pa in the middle and lower thirds of the slope translate into suction factors of just over 0.1 compared to 0.70 and 0.55 for the generic suction factors recommended by Giroud et al. (1995) and shown in Figure 3. The suction pressure near the crest in the CFD simulation is approximately 100 Pa (i.e. $\lambda = 0.2$), which is far lower than the value in Figure 3 of 0.85 or 1.0.

The difference between CFD modeling and generic suction factors is even more marked when the slope inclination is reduced. The total data set from the CFD simulations is summarized on Figure 7, where the values of suction factor are plotted for the upper, mid and lower thirds of the slope. The 2:1 line (red) shows suction along the entire face, while at shallower slopes the suction on the mid-third is approximately zero and is negative on the lower third (e.g. the pressure is downwards).

Figure 7. Comparison of Suction Factor Values

This unusual, non-linear behavior can be explained with reference to the velocity vectors on Figure 8. On the left sub-figure, the vectors for a 2:1 slope are shown. Notice that, in the low velocity areas (blue) near the ground, the vectors are pointing in the *opposite* direction to the mean wind vector – the flow has *reversed*. This is not the case for the 4:1 slope case shown on the right sub-figure on Figure 8. Here, the flow vectors all point from left to right. The two flow regimes are very different and distinct. For steep slopes, the flow is “separated” while at the shallower slopes the flow remains “attached”. Separated flow results in suction all along the face of the slope, while for attached flow the suction pressure is positive at the crest (uplift) and negative at the bottom (downward pressure).

It should be noted that the CFD results plotted in Figure 7 were obtained for wind perpendicular to the crest line since the model used was two-dimensional. In contrast, the generic suction factors (the top curve in Figure 7) correspond to the worst case for all wind orientations based on Dedrick’s tests. It is possible that part of the difference between the generic suction factors and the CFD results is due to three-dimensional effects in Dedrick’s tests where the small-scale models replicated square reservoirs with four dikes. Further investigation is needed, in particular with three-dimensional CFD models. Nevertheless, it is clear that the generic suction factors derived from the Dedrick’s experiments are extremely conservative. To assess whether a computational analysis is an economically feasible option to reduce the conservatism, we have calculated the cost impacts in the following sections.

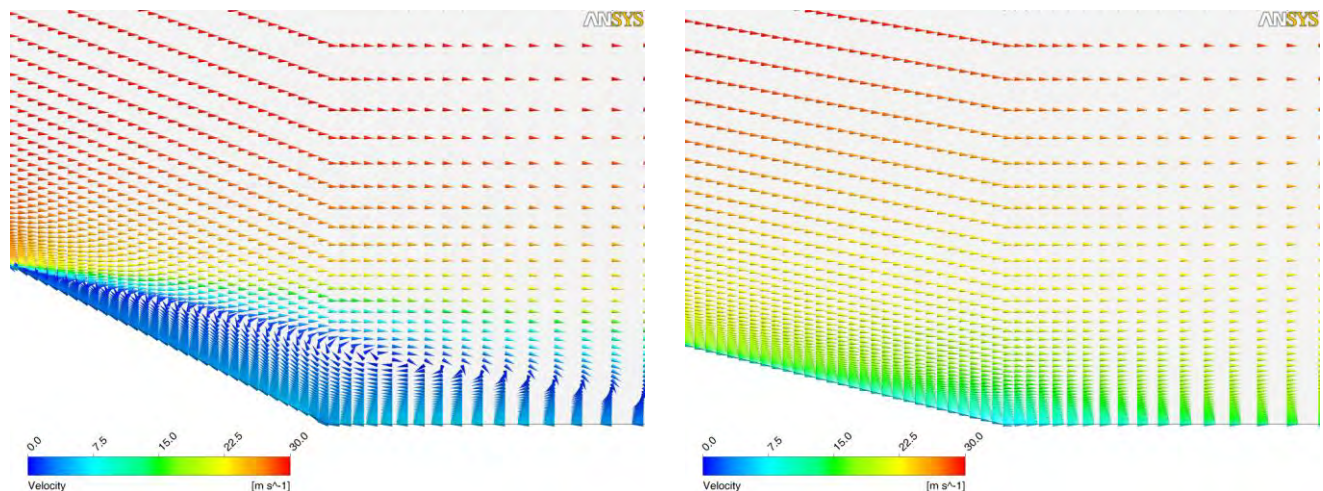

Figure 8. Contours of differential pressure (e.g. relative to atmospheric pressure).

4. TENSION COMPARISON

4.1 Objective

The suction values calculated using CFD modeling and the generic suction factors recommended by Giroud et al. (1995) were used with the analytical method by Giroud et al. (1995) to compare potential anchorage for a simplified uplift condition. The following assumptions were made to compare the two methods:

- Slope inclination = 2:1 (H:V)
- Slope height = 15 m
- Wind velocity = 100 km/h
- Elevation above sea level = 0 (i.e. assumed at sea level)
- Geomembrane mass per unit area = 1 kg/m^2
- Geomembrane assumed to have a tension-strain curve linear in its initial portion with a stiffness modulus of 450 kN/m
- Geomembrane allowable strength = 7.7 kN/m
- Suction evaluated at the crest of the slope (i.e. $\lambda = 1.0$)

The above geomembrane properties are typical properties of geomembranes that can be used in applications where the geomembrane is exposed to wind.

Figure 9. Tension Comparison Model

4.2 Tension Evaluation

Tension and strain in the geomembrane are linked by the following relationship, which is applicable in the initial portion of the tension-strain curve of the geomembrane which has been assumed to be linear:

$$T = J \varepsilon \quad [3]$$

Where:

- T = Tension (kN/m)
- J = Stiffness (kN/m)
- ε = Strain (%)

In the paper by Giroud et al. (1995), a simplified analytical methodology is presented for the case where the tension-strain curve of the geomembrane can be assumed to be linear. This methodology uses the normalized tensile stiffness, $J/S_e L$, where S_e is the effective suction calculated as the suction minus the weight per unit area of the geomembrane and L is the length of exposed geomembrane between two anchor trenches (also called “unsupported length”). Table 1 was generated using this simplified methodology:

Table 1. Tension Evaluation

Suction evaluation	Effective Suction $S_e^{(1)}$ (P_a)	Unsupported Length L (m)	Geomembrane Strain ϵ (%)	Geomembrane Tension T (kN/m)
Generic suction factors	416	5	1.0	4.5
	416	6	1.1	5.0
	416	7	1.3	5.9
	416	8	1.4	6.3
	416	9	1.5	6.8
	416	10	1.6	7.2
	416	11	1.7	7.7
	416	12	1.8	8.1
	416	13	1.9	8.6
	416	14	2.0	9.0
CFD	89	45	1.6	7.2
	89	46	1.6	7.2
	89	47	1.6	7.2
	89	48	1.6	7.2
	89	49	1.6	7.2
	89	50	1.7	7.7
	89	51	1.7	7.7
	89	52	1.7	7.7
	89	53	1.7	7.7
	89	54	1.8	8.1
89	55	1.8	8.1	

¹The effective suction is calculated as the suction minus the weight per unit area of the geomembrane.

Looking at the values in Table 1, the unsupported length required to develop the allowable geomembrane strength of 7.7 kN/m is approximately 5 times greater when using the suction values computed with CFD compared to the generic suction factors derived by Giroud et al. (1995) from the small-scale wind tunnel studies by Dedrick.

Figure 10. Example of exposed geomembrane anchorage (Courtesy of K. Perera, HDR)

5. POTENTIAL COST IMPACTS

A decrease in spacing for anchorage can translate to cost savings during construction. If we assume that the exposed geomembrane on a side slope is simply anchored using trenches along the slopes as shown in Figure 10, we can estimate potential cost savings by making some simple assumptions.

Table 2. Potential Cost Evaluation

Analysis Method	Trench Cost \$/m ⁽¹⁾	Slope Length m	Slope Width m	Trench Spacing m	Total Cost \$	Modeling Cost \$	Design Cost	Effective Cost \$
Generic suction factors	\$13.50	35	300	11	\$53,000	\$0,000	4,000	\$57,000
CFD	\$13.50	35	300	50	\$12,000	\$10,000	4,000	\$26,000

¹Rates for trench cost are based on experience.

The cost evaluation is overly simplified and is not intended to include all costs associated with constructing the anchor trenches or cost associated with geomembrane material. Also, the cost evaluation and the resulting cost savings would vary if some parameters (such as slope inclination) were different. This information is provided for discussion purposes and is only intended to highlight how potential cost savings can be realized. The evaluation assumes the exposed geomembrane is only anchored on the side slopes (four sides) and no horizontal or top deck anchorage is included. In reality, some horizontal anchorage could be required as well as anchorage on the top deck. Example methods for horizontal anchorage are shown in Figure 11.

Figure 11. Example of Horizontal Anchorage (Yeo et al. 2011)

Table 2 shows a cost savings of approximately 50 percent using the simple scenario described above. Different, but still significant, cost savings would be obtained with different scenarios. Cost savings during construction would increase as the proposed project size increases. Larger projects require more anchorage than smaller projects and therefore provide more potential for cost savings when compared to the additional modeling cost associated with CFD. Cost benefits may not be realized for small and simple projects.

6. SUMMARY AND CONCLUSION

Preliminary research indicates that wind uplift forces calculated using CFD modeling produce significantly lower values of wind-generated suction than those computed using the generic suction factors recommended by Giroud et al. (1995). The CFD modeling can more accurately predict wind uplift forces allowing for less conservancy and more efficient design resulting in lower construction cost while satisfying regulatory requirements as a no method for evaluating uplift on exposed geomembranes is prescribed. However, smaller projects may not warrant more complex CFD modeling where the potential cost savings do not outweigh the additional modeling cost. Additional investigation will be undertaken to

evaluate the influence of parameters such as wind direction, presence of typical obstructions (e.g. benches), three-dimensional geometries (e.g. slopes with non-straight crest line), geomembrane surface condition, wind gusts and atmospheric turbulences. In conclusion, the analytical method published in Giroud et al. (1995) and subsequent papers for all aspects of design of exposed geomembranes (tension and strain in the geomembrane, deflection of the geomembrane, sizing of anchorages) can be used to its full potential with suction determined using CFD rather than with generic suction factors.

Evaluation of Ethylene Vinyl Alcohol (EVOH) for Containment of High Concentrations of Volatile Organic Compounds in Geosynthetics

Robert Armstrong, Kuraray America Inc., USA, robert.armstrong@kuraray.com

ABSTRACT

Geosynthetic liner systems, particularly in concrete liner applications are intended to control migration of liquids and vapor into the surrounding environment. The chemical resistance of existing geomembranes comprised of polypropylene (fPP), polyethylene (HDPE or LLDPE) could be significantly improved through use of Ethylene Vinyl Alcohol copolymer (EVOH), a random copolymer of ethylene and vinyl alcohol, which has extremely high resistance to the migration of gases, hydrocarbons and organic solvents. In select concrete liner applications the use of EVOH as part of a high barrier geomembrane (HBGM) would significantly increase the level of environmental protection and reduce potential remediation costs due to failure of liner systems. An evaluation of the performance of EVOH in containment of concentrated aromatic hydrocarbon and chlorinated hydrocarbon solvents shows EVOH can improve the volatile organic compound (VOC) barrier properties of polypropylene or polyethylene geomembranes significantly.

1. INTRODUCTION

Ethylene Vinyl Alcohol copolymer (EVOH) is a random copolymer of ethylene and vinyl alcohol, widely used to as a minor component of thermoplastic polymer composites to protect materials from oxidation and for containment of volatile organic hydrocarbons because of its outstanding barrier to gases, solvents and hydrocarbons (Lagaron et al. 2001). Typically these multilayer composites are formed by the coextrusion of multiple layers of thermoplastics into a sheet or film. Inclusion of EVOH in co-extruded geomembranes increases the capability of geomembranes to minimize the migration of gases, hydrocarbons and solvents without causing any significant changes in existing form and functionality of geomembranes (Armstrong & Chow, 2012). The use of EVOH in concrete liner solvent containment applications offers potential for significant increases in service life of the concrete liner and reduced losses of solvent from a process into the surrounding environment.

2. BACKGROUND

2.1 Use of Concrete Liners to Contain Hydrocarbons and Solvents

The majority of geosynthetic concrete liners in use are installed in relatively benign environments, such as municipal drinking water, storm water or waste water treatment systems. In certain cases however a concrete liner is challenged to contain concentrated solutions of hydrocarbons or acids. A specific example is the solvent extraction process utilized for heap leach mining of copper, in which the aqueous pregnant leach solution (PLS) is vigorously mixed with an organic solvent and selectively recovers copper from the PLS. The organic solvents used commercially in the solvent extraction step include dialkylphosphoric acids and hydroxyoximes, often in conjunction with benzene, ethylbenzene, and toluene. Effective containment of organic solvents within the solvent extraction system and prevention of offsite contamination by dilute solvents is a critical aspect of the heap leach mining process. The use of geomembranes to line concrete tanks used for solvent extraction as an alternative to stainless steel tanks has been reported, as have several failures of liners due to inadequate chemical and solvent resistance.

2.2 Properties of Ethylene Vinyl Alcohol

Several alternatives exist to improve the barrier of polypropylene and polyethylene geomembranes to organic solvents, including laminations with aluminum foil or fluorination of HDPE (Sangram & Rowe 2005), and coextrusion with polymers such as nylon or EVOH. The barrier of EVOH to a wide range of VOC's is so great that a very thin layer of EVOH within a polyethylene or polypropylene geomembrane significantly reduces diffusive migration of volatile organic compounds. A high barrier geomembrane structure containing a layer of EVOH is presented below in Figure 1. Incorporating EVOH in a HBGM would require at least three layers in a coextrusion, although five or seven layer structures would allow for optimizing the amount of EVOH at perhaps no more than 2 to 4% of the total thickness of a geomembrane. Designing and manufacturing a commercial scale multilayer cast or blown geomembrane line capable of producing a coextruded HBGM is an engineering exercise that does not require any fundamental changes or break through in coextrusion technology or practice

Figure 1 Model of High barrier Geomembrane (HBGM) with EVOH

EVOH has extremely good resistance to the migration of volatile organic compounds (VOC's), hydrocarbons and organic solvents, with the rate of solvent diffusion in EVOH orders of magnitude lower than in polyethylene. A large number of polymers also exhibit softening, swelling or environmental stress cracking when exposed to solvents, while EVOH retains key physical properties in the presence of organic solvents and non-ionic surfactants. As has been described by others (Park & Nibars 1993, Sangram & Rowe 2001) the migration of organic solvents through polymers such as HDPE or EVOH is a three step process of absorption or partitioning of the solvent from solution into the polymer, diffusion of the solvent through the polymer and then desorption into environment. The relationship between the mass flux due to diffusive migration and the solubility, diffusive and permeation coefficients (S_{gf} , D_g and P_g) can be stated as:

$$f = -S_{gf} D_g \frac{d_{c_f}}{d_z} = -P_g \frac{d_{c_f}}{d_z} \quad [1]$$

Where c_f = solution concentration and z = position through membrane.

Published data shows that the barrier property of EVOH to aromatic and chlorinated hydrocarbons is extremely good. Table 1 compares the permeation coefficients of a select number of solvents in EVOH and HDPE. (McWatters and Rowe, 2011 and in publication). Even under the worst case conditions for EVOH (monolayer film at 100% relative humidity), the permeation coefficients of hydrocarbon in EVOH was at least two orders of magnitude lower than LLDPE or HDPE. In previous tests of a commercial geomembrane with EVOH the permeation coefficients of the HBGM were typically three to four orders of magnitude lower than HDPE (McWatters and Rowe, 2010).

Table 1 Permeation coefficients ($\times 10^{-14}$ m²/s) of select solvents through EVOH and HDPE*

Solvent	44mol% EVOH	HDPE
benzene	3.0	1000
toluene	3.6	3000
ethyl benzene	4.4	5000
m&p xylene	5.3	6000
trichloroethylene	6.6	3400
1,2 dichlorethane	2.3	480

*Permeation coefficients in m²/s at 25ppm solvent concentration in water and 24°C

3. EXPERIMENTS

3.1 Experiment – Barrier and Physical Properties of HDPE and HDPE/EVOH Coextrusions

One litre (L) monolayer and coextrusion blow molded bottles were prepared as model solvent containment vessels, intended to mimic the function of geomembranes used as concrete liners. The bottles had a diameter of 75mm and height of 200mm, resulting in overall surface area of approximately 0.0515 sq.m. The HDPE used in the bottles was a fractional melt, high molecular weight HDPE resin typically used for agricultural chemical containers. The EVOH used was EVAL F101A, a 32 mol%, 1.6 melt Index (190°C/2160grams) EVOH supplied by Kuraray America Inc. There were three different bottle types, including a monolayer HDPE control, a six layer bottle with EVOH in the centre of the composite and finally a four layer bottle with EVOH on the inside of the bottle in contact with the solvent. The average wall thickness of the bottle was 1500 microns (60 mil) which is a typical geomembrane thickness. Table 2 below

describes the structure of each sample. The test matrix consisted of the three different bottle constructs described in Table 2 and exposed to three different solvent systems. A set of 6 bottles from each construct was filled with the three solvent solutions, sealed with a foil lined cap and exposed to a temperature of 60°C to simulate a harsh process environment.

The 3 different chemical solutions will be identified as follows:

F1 = BTEX 25 ppm = 25ppm each benzene, toluene, ethyl benzene and xylene in water

F2 = BTEX 25% = 25% by weight of benzene, toluene, ethyl benzene and xylene

F4 = TCE = 100% Trichloroethylene

The trial plan called for the weight loss of the bottles to be checked periodically for a period of two years, and that three bottles were to be removed from test between 300 and 360 days for evaluation of physical properties.

Table 2 Construction of monolayer and coextrusion blow molded bottle samples – typical sidewall thickness

Layer	6 layer coex (B1)		4 layer coex (B2)		Monolayer Control (B3)	
	Polymer	Thickness (µm)	Polymer	Thickness (µm)	Polymer	Thickness (µm)
1	HDPE	250	HDPE	900	HDPE	1500
2	HDPE regrind	400	HDPE regrind	500		
3	Adhesive Tie	50	Adhesive Tie	50		
4	EVOH	50	EVOH	50		
5	Adhesive Tie	50				
6	HDPE	700				
Total		1500		1500		1500

Throughout the balance of this paper the monolayer and coextrusion blow molded bottles that model geomembrane liners will be referred to as “B1”, “B2”, and “B3”.

The weight loss data reported is the average weight loss in grams of a set of bottles and common solvent on a given day. The weight loss experiments were conducted in a mini SHED (evaporative emissions test unit) by Intertek Inc. The experimental setup was comprised of an environmental chamber maintained at a temperature of 60°C within ±0.5°C. Each average value reported is at least four bottles (some bottles developed leaks at cap liner and were excluded from the data set). Samples were analyzed repeatedly the first month and thereafter, analysis occurred one to two times per month. The physical testing conducted to evaluate changes in physical properties of the bottles follows the general guidelines of GRI Test method GM-13 and ASTM D5747 – Standard Practice for Tests to Evaluate Chemical Resistance of Geomembranes to Liquid. Tensile testing was conducted according to ASTM D6693 Standard Test Method for Determining Tensile Properties of Non-reinforced Polyethylene Geomembranes.

4. RESULTS & DISCUSSION

4.1 Barrier Properties

After 280 days the weight loss from all bottles containing then F1 BTEX 25ppm solution was insignificant. The total weight loss for each set of samples was less than 20 grams or 2% of the average filling weight of 900 grams of aqueous BTEX solution. In the case of the F2 (25% BTEX) and F4 (100% TCE) solvents the results were significantly different. The monolayer B3 bottles failed to contain the F2 and F4 solvents, with total loss of these solvents in less than 140 days for the F2 BTEX and less than 60 days for the TCE. The weight loss data to 280 days for the F2 solvent is in Figure 2 and for the F4 solvent is in Figure 3. The weight loss from the B3 monolayer samples plateaued at just over 900 grams for the 25% BTEX solution and 1400 grams for the TCE at the point that the solvent ceased diffusing from the bottle. Based on weight loss data and surface area of the bottles, the average permeation rate of F2 BTEX was 128 grams/m².day and 485 grams/m².day for the F4 TCE from the B3 monolayer HDPE bottle. The B1 and B2 bottles with EVOH barrier showed only small weight loss over the entire 280 day period, with part of the weight loss of F2 and F4 solvents attributed to leakage at the cap liner. After 280 days the permeation rate of F2 BTEX and F4 TCE was less than 2 grams/m².day. The results of the weight loss test were as expected, with significant improvement in diffusive barrier and effective containment of concentrated solvents observed in both types of EVOH bottles. The position of the EVOH layer did not appear to have a significant effect on the barrier properties of the B1 and B2 bottles.

Figure 2 Weight Loss vs. Time - 25% BTEX solvent from B1, B2, B3 bottles

Figure 3 Weight Loss vs. Time - 100% TCE solvent from B1, B2, B3 bottles

4.2 Physical Properties

A limited evaluation of the structure and physical properties of the bottles was conducted on 3 bottles removed from each set of samples at 280 days. The physical testing was conducted as described in the experimental section and a summary of the results is presented in Table 3. A set of samples that had been reserved prior to the weight loss test were used as a control. These bottles had been stored at 20°C and 65%RH while the balance of the samples was in test. In addition to the standard GM-13 tensile properties, the modulus of each sample was measured.

The first significant result is that for the control samples the addition of EVOH to the HDPE reduces the yield strength and modulus slightly. In addition the elongation at break was significantly reduced, to a level below that required for smooth geomembranes, but still higher than that specified for textured geomembranes. It should be noted that the modulus, break and yield strength of all samples versus the control was not significantly affected by the solvents through 280 days. The second observation was the effect of moisture, solvents and position of EVOH layer on physical properties of the samples. In the case of the 25ppm BTEX solution, the B2 bottle with EVOH exposed to an aqueous solution had a high elongation at break versus the B1 bottles with EVOH layer separated from the aqueous solution by HDPE. This effect is often observed when EVOH is exposed to moisture. In the case of the 25% BTEX solution the B2

sample with EVOH layer exposed to the solvent had the lowest elongation at break, with the B2 sample showing some reduction in elongation strength, but not to the same degree. In this case the BTEX solvent mixture contained very little moisture, which caused moisture level in the EVOH layer of the B2 sample, immediately adjacent to the solvents, to drop to a lower level than that of the B1 sample, with EVOH layer separated from the solvent by a layer of HDPE. The trichloroethylene (F4) solvent had a major effect on the elongation to break of the EVOH coex samples, with elongation to break of the B1 and B2 samples exposed to TCE approaching that of the monolayer HDPE control.

To investigate the effects of the F2 and F4 solvents on the polymer structure of the samples, they were examined using Differential Scanning Calorimetry (DSC) to observe changes in melting point, Thermal Gravimetric Analysis (TGA) to detect changes in degradation temperature and Fourier Transform Infrared Spectroscopy to confirm effects of solvents on EVOH structure. The DSC analysis of melting point and enthalpy of melting showed a consistent trend of reduced melting point of the HDPE by 2 to 3°C after exposure to the F2 and F4 solvents from an average melting point of 133°C. The EVOH melting point did not change significantly after exposure to the F2 BTEX solvent mixture, but did reduce from 182°C to 178°C in samples exposed to TCE. The enthalpy of melting of the EVOH was also reduced after exposure to TCE. Observations by FTIR showed that the mol% of vinyl alcohol in the EVOH had not been reduced, so the reduction in melting point is explained by the TCE affecting the weak crystalline structure of the EVOH layer. Despite this effect on the physical properties of the EVOH, the barrier to TCE remained extremely high through 280 days at elevated temperatures.

Table 3 Physical properties of B1, B2 and B3 bottles after 280 days exposure to solvents

Properties	GM1-3	Control – No solvent			F1 – 25ppm BTEX			F2 – 25% BTEX			F4 – 100% TCE		
		B1	B2	B3	B1	B2	B3	B1	B2	B3	B1	B2	B3
Modulus (MPa)		453	400	483	499	446	476	334	445	469	367	468	482
Yield Strength (KN/m)	22	141	134	149	161	145	152	136	146	147	141	146	148
Break Strength (KN/m)	40	140	132	232	162	141	254	132	141	250	165	156	242
Yield Elongation (%)	12	15	17	16	16	17	16	21	17	17	19	17	16
Break Elongation (%)	700	180	250	660	364	380	700	110	60	710	550	550	700

*Results are the average of 5 replicates of a sample, all tested in the machine direction (MD)

In these and other tests including EVOH in a geosynthetic is observed to have a slightly negative effect on the physical performance of the geomembrane, particularly elongation to break. Further investigation of these effects and development of modified forms of EVOH is underway.

5. CONCLUSION

The barrier to dilute and concentrated aromatic and chlorinated hydrocarbons of monolayer HDPE and coextruded HDPE and EVOH model solvent containment vessels, intended to mimic the function of geomembranes used as concrete liners was evaluated over 280 days at elevated temperatures, with testing ongoing to 3 years. The diffusive barrier of monolayer HDPE to concentrated hydrocarbons was found to be practically nonexistent, while the coextruded HDPE-EVOH samples had barrier properties at least an order of magnitude lower. A limited evaluation of the key physical properties showed a reduction in elongation at break tensile properties of the HDPE-EVOH samples, which is dependent upon EVOH moisture content. EVOH offers the potential of improved VOC barrier with limited effect on key form and functional performance characteristics of concrete liners. The primary function of a geosynthetic liner is an advective and diffusive barrier to contain liquids and vapor that should not migrate into the environment. The inclusion of EVOH by coextrusion into select concrete liners intended for use with aggressive aromatic and chlorinated hydrocarbons would greatly reduce diffusive migration of VOC's, and offers potential for extended service life of concrete liner systems in aggressive environments.

ACKNOWLEDGEMENTS

The author acknowledges the contributions of Ron Rose and Edgard Chow in experiment design and execution and Steven Trener, Al Gongora and Joe Vasquez for completing the physical testing of samples.

ABSTRACT

Indian Railway has taken up the ambitious project of constructing 3300 km of new track across eastern and western corridors. The majority of these tracks will pass through the regions with poor soils including loose sands of the Indo-Gangetic belts. Hence, the experimental and numerical studies are undertaken to evaluate the suitability of geocell cellular confinement as a foundation technique for this project. This paper presents the results of the 1-g model tests performed on geocell reinforced sand bed supporting the square footing. Results show that the provision of geocell increases the ultimate bearing capacity of the sand bed by 4 times. Introduction of planar geogrid at the base of the geocell mattress not only enhances the load carrying capacity but also arrests the surface heave and prevents the footing from undergoing the rotational failure. In addition to the experimental studies, numerical study was also carried to demonstrate the simplistic approach of modeling of the geocells in FLAC^{2D}.

1. INTRODUCTION

Indian economy is one of the largest as well as the fastest growing economy in the world. In a last decade or so, India's growing economy has experienced the rise in the demand for additional transportation, infrastructure, and services. Until these days, Indian railway was playing a pivotal role in the transportation sector and was contributing to the economic success of the country. However, since last few years, Indian Railway has been facing the serious challenge to keep up the pace with country's continued economic growth and the rising demand, since all the country's high-density rail corridors are facing severe capacity constraints. Hence, to enhance the capacity, Railway ministry has undertaken the construction of Dedicated Freight Corridors across the heavy traffic networks in India. As part of this initiative, DFCCIL (Dedicated Freight Corridor Corporation of India) is constructing two corridors along western and eastern routes spanning a total length of about 3300 km (Courtesy, <http://dfccil.org>).
