Much of the railway embankments and railway lines have to be constructed on the loose deposits of the Indo-Gangetic belt. In the present situation, ground improvement using vibro techniques seems to be the feasible option for the DFCCIL to strengthen the loose deposits along the proposed route. As vibro stone columns are more complex to install, it is very high time to demonstrate a new technique as an alternate to the vibro techniques. Reinforcing the soil with geocells could be one such alternative option as they distribute the load laterally. In addition, geocells are more amenable to the field applications as it is cheaper and better compared to vibro techniques. Hence, research work has been taken up with the objective of evaluating the suitability of geocell reinforcement for the construction of foundations along these railway lines.

Since last two decades, geocell reinforcement has been showing its efficacy in the field of highways and embankments. Due to its three dimensional nature, geocell offers all-round confinement to the encapsulated soil and hence leads to the improvement in the overall performance of the foundation bed. Several researchers have reported the beneficial use of 3D-reinforcements in the construction of foundations. "Broms and Massarach (1977)" adopted the metallic grid mat consisting of rectangular and triangular cells for different offshore structure. "Rea and Mitchell (1978)" and "Mitchell et al. (1979)" carried out the study on footings supported on sand beds reinforced with square shaped paper grid cells through a series of small-scale laboratory tests and observed the different modes of failure. "Guido et al. (1989)" studied the influence of number of layers of geoweb cells on bearing capacity of sand bed using laboratory model tests. Similar studies were carried out "Dash et al. (2001a)" on strip footing, "Sitharam and Sireesh (2005)" on circular footing and "Madhavi Latha and Somwanshi (2009)" on square footing by using laboratory prepared geogrid cells. "El Sawwaf and Nazer (2005)" used Unplasticized Polyvinyl Chloride (UPVC) cylinders of different diameters to study the soil confinement on circular footing. "Tafreshi and Dawson (2010)" used strips of thermo welded non-woven geotextiles as 3D cells to study the response of sand bed under static and dynamic loading.

Review of the literature reveals that the majority of the researchers have used the laboratory prepared geogrid cells instead of commercially available geocells. Since commercially available geocells are the ones, going to be used in the field, the experimental findings cannot be directly correlated with the field conditions. In the present investigation, new commercially available geocells made of polyethylene are used; which is known for its high strength and durability. Sand

collected from the Indo-Gangetic belt itself was used in the experimental program to prepare the foundation bed. The test results of the static plate load tests and the numerical simulations are discussed in this paper.

2. LABORATORY MODEL TESTS

2.1 Design of Experiments

Footing sizes were arrived as per the scaling laws suggested by “Wood (2004)”. The prototype footing was a square raft with thickness 0.5 m and width 4.5 m made up of concrete with Young’s modulus 25 GPa. For the sake of convenience, the steel footing with Young’s modulus 200 GPa was selected for the experimental studies. Considering the scaling down factor of 10, the flexural rigidities of the model and prototype footings were equated to obtain the dimensions of the model footing. The arrived size of the model footing was 150 mm width and 20 mm thickness. The sufficiently bigger size of the tank was chosen, i.e. 6 times the size of the footing (900 mm x900 mm in plan area) to keep the boundary effect minimal.

2.2 Experimental Setup

The experiments were conducted in the cast iron test tank of size 900 mm length x900 mm width x 600 mm height. The tank was fitted to the loading frame and which was connected to manually operated hydraulic jack. A square shaped steel plate with 20 mm thickness and 150mm sides was used as the model footing. The bottom of the footing was made rough by a coating thin layer of sand with epoxy glue. The load was applied on the footing through the hand operated hydraulic jack and a pre-calibrated proving ring was placed between the footing and hydraulic jack to measure the applied load. To prevent the eccentric application of the load, the ball bearing arrangement was used. Figure 1a-b represents the photographic and schematic view of the test setup.

Figure 1. Test setup: (a) photographic view; (b) schematic view

2.3 Materials Used

Sand used in the investigation was dry sand with specific gravity 2.64, effective particle size (D_{10}) 0.26mm, coefficient of uniformity (C_u) 3.08, coefficient of uniformity (C_c) 1.05, maximum void ratio (e_{max}) 0.81, minimum void ratio (e_{min}) of 0.51 and angle of internal friction was (ϕ) 30° . According to Indian Standard Soil Classification System (ISSCS) the soil can be classified as poorly graded sand with symbol SP. The geocell used in the study was made up of polyethylene with a density of 0.95 g/cm^3 . The cells are 250 mm in length, 210mm in width and 150mm in depth. The thickness of the strip is 1.53 mm with cell-to-cell seam strength is 2150 N. Biaxial geogrid made up Polypropylene with aperture size 35 mm x 35 mm was used. Ultimate tensile strength of the geogrid was 20 kN/m. Figure 2 represents the tensile load-strain behavior of both geocell and geogrid used in the experiments.

2.4 Preparation of Test Bed

Firstly, the sides of the tank were coated with Polythene sheets to avoid the side friction. Pluviation technique was used to prepare the sand bed of 500 mm thickness. Before the start of the actual test, a series of trials were conducted to determine the height of fall required to achieve the desired relative density. In each trail, small aluminum cups with

known volume were placed at the different locations of the tank. A calibration chart was prepared by knowing the maximum and minimum void ratios of the sand. All the tests were conducted at a constant relative density of 65%. The height of fall required to achieve 65% relative density was directly obtained from the chart. The average density achieved in the sand bed during the pluviation was 16.08 kN/m^3 and the less than 1% difference was observed in the densities measured at the different locations of the bed. Reinforcement was placed at the predetermined depth and sand was used as the infill material. Sand was filled into the geocell pockets using the pluviation technique itself to maintain the relative density same as that of foundation bed.

Figure 2. Tensile load-strain behavior of geocell and geogrid

2.5 Testing Procedure

Reinforcements were placed at the predetermined depth during the pluviation of sand into test tank. After preparing the sand bed of 500 mm thickness, the fill was leveled using a trowel without disturbing the density of the bed. Footing was placed at the pre-determined alignment at the surface of the sand bed. A recess was made on the top surface of the footing and a ball bearing arrangement was placed on it. The concentrated vertical load was applied on the footing with the help of ball bearing arrangement. Through the precise measurements, the footing was placed exactly at the center of the test tank in order to avoid the eccentric loading. The load applied to sand bed was measured through the pre-calibrated proving placed between the footing and the hydraulic jack. Two dial gauges (D_1 and D_2) were placed on the either side of the centerline of the footing to record the footing settlements. Another set of dial gauges (S_1 and S_2) was placed at the distance of $1.5B$ (B is the width of the footing) from the centerline of the footing to measure the deformation underwent by the fill surface. The footing settlement (S) and the surface deformation (δ) were normalized by footing width (B) to express them in non-dimensional form as S/B (%) and δ/B (%). In all the plots, settlements are reported with the negative sign and heave with the positive sign.

3. RESULTS AND DISCUSSION

3.1 Bearing Pressure-settlement Curve

Figure 3 represents the pressure settlement response for the different test conditions. For unreinforced case, failure was occurred at footing settlement of 8% of footing width. Clearly defined failure was observed in case of unreinforced bed. In case of geocell reinforcement, no clear-cut failure was observed in the pressure settlement behavior even up to the large settlement of 35% of footing width. There was a slight reduction in the slope of the pressure settlement curve at the settlement range of 22% to 24% of the footing width and after which again the slope has become constant. This nature of the curve can be attributed to the beam effect of the geocell mattress; due to its high bending and shear stiffness, geocell mattress can support the footing even after the failure of soil. The interconnected cells form a panel that acts like a large mat that spreads the applied load over an extended area, leading to an overall improvement in the performance of the foundation beds. Post test exhumation of geocell has shown the deformation in the vertical and horizontal ribs. The reason for this could be, once the soil below footing underwent the shear failure, the footing might have rested directly on the ribs of the geocell. Figure 4a-b represents photograph of the geocell before and after the tests. It was observed that the provision of the additional geogrid layer at the base of the geocell mattress further

increase the load carrying capacity as well as the stiffness of the sand bed.(i.e. flattened pressure settlement curve). Similar trends were also observed by “Dash et al. (2000 b)”.

Figure 3. Variation of bearing pressure with footing settlement

(a)

(b)

Figure 4a-b. Photograph of the geocell: (a) before the test; (b) after the test

3.2 Surface Deformation

Surface deformation (settlement/heave) profiles of sand bed reinforced with different forms of reinforcement are discussed in this section. Surface deformation measurements were made through the dial gauges placed at the distance of $1.5B$ from the centerline of the footing. “Chummar (1972)” observed that the surface heaving extends up to $2B$ from the centerline of the footing for unreinforced case and with maximum heaving at a distance of $1.5B$. Generally, surface heaving can be attributed to the general shear failure of the soil mass. Figure 5 quantifies the maximum surface deformation for the different combination of reinforcements. The solid and dotted lines represent the deformation measured at the left and right side of the footing centerline. One can observe from the figure that the large difference between the solid and dotted lines. This difference is due to the rotational failure of the footing. The extent of rotation and amount of heaving was reduced in the case of the geocell reinforcement and further reduction in rotation was observed in the presence of the planar geogrid below the geocell. Interestingly, no surface heaving was observed with additional basal geogrid. From the above observation, it is evident that the combination of geocell and basal geogrid completely arrest the surface heaving and reduces the footing rotation. In addition, the planar geogrid contributes to improve the overall performance of the foundation bed by resisting the downward movement of soil due to the footing penetration. Hence, it is always beneficial to use planar geogrid layer at the base of the geocell matress.

Figure 5. Variation surface deformation with footing settlement

3.3 Bearing Capacity Improvement Factor (I_f)

The increase in the bearing capacity due to the provision of the reinforcement can be measured through a non-dimensional parameter called bearing capacity improvement factor (I_f), which is defined as,

$$I_f = \frac{q_r}{q_0} \quad [1]$$

Where, q_r is the bearing pressure of the reinforced soil at the given settlement and q_0 is the bearing pressure of unreinforced soil at the same settlement. "Binqet and Lee (1975)" reported the improvement factor is similar to the bearing capacity ratio. When the ratio is beyond the ultimate bearing capacity of the unreinforced soil, the ultimate bearing capacity (q_{ult}) is used instead of q_0 . Bearing capacity improvement values for different tests are listed in Table 1.

Table 1. Bearing capacity improvement factors

Avg.S/B	Bearing capacity improvement factors (I_f)	
	Only Geocell	Geocell+Geogrid
2%	1.10	1.48
4%	1.12	1.55
6%	1.14	1.57
8%	1.25	1.83
10%	1.28	2.12
12%	1.37	2.43
14%	1.49	2.67
16%	1.63	2.88
18%	1.78	2.96
20%	1.92	3.08

3.4 Percentage Reduction in Footing Settlement (PRS)

The performance improvement of the foundation bed due to geocell reinforcement can also be quantified in terms of the reduction in the settlement of the footing using the parameter called percentage reduction in settlement (PRS), which can be defined as,

$$PRS = \left(\frac{S_0 - S_r}{S_0} \right) \times 100 \quad [2]$$

Where, S_0 is settlement of the unreinforced foundation bed corresponding to its ultimate bearing capacity (which is determined using the double tangent method), was found out to be 15% of the footing width ($S/D=15\%$). S_r is settlement of reinforced foundation bed corresponding to the footing pressure equal to the ultimate bearing pressure of unreinforced foundation bed. In the present investigation, the PRS value of 53 % was observed with only geocell case and 73% was observed with additional planar geogrid at the base of the geocell.

4. NUMERICAL STUDY

The aim of this section is to demonstrate the simplistic approach of modeling the 3-dimensional nature of geocell in 2D finite difference software called FLAC^{2D} (Fast Lagrangian Analysis of Continua in 2D). In this approach, the geocell filled with sand is modeled as an equivalent composite layer with improved strength and stiffness parameters (“Madhavi Latha and Somwanshi, 2009”). Various investigators have reported that the geocell confinement of sand induces the apparent cohesion while the friction angle remains constant (“Bathurst and Karpurapu, 1993”; “Rajagopal et al., 1999”). The induced apparent cohesion of the equivalent composite layer was calculated using the Equations (3) and (4) given by “Rajagopal et al. (1999)”. The Equation (3) is originated from the rubber membrane theory proposed by “Henkel and Gilbert (1952)”. The increase in the confining pressure ($\Delta\sigma_3$) on the soil due to the presence of geocell is given by,

$$\Delta\sigma_3 = \frac{2M\xi_c}{d} \frac{1}{1-\xi_a} = \frac{2M}{d_0} \left[\frac{1-\sqrt{1-\xi_a}}{1-\xi_a} \right] \quad [3]$$

Where, M is the secant modulus of the geocell material at axial strain ϵ_a , which is obtained from the tensile load-strain response of the geocell material at 2% axial strain and d_0 is the equivalent diameter of the geocell pocket. The increment in the apparent cohesion (C_r) due to the increase of the confining pressure is given by,

$$C_r = \frac{\Delta\sigma_3}{2} \sqrt{K_p} \quad [4]$$

Where, K_p is the coefficient of passive earth pressure. In the present study, the equivalent diameter of the geocell pocket is 0.258 m and the secant modulus (M) corresponding to 2% strain obtained from the load–strain response of the geocell material (Figure 2) was 435 kN/m. The additional confining pressure ($\Delta\sigma_3$) was calculated from Equation (3) as 34.4 kPa. Then from the Equation (4), the apparent cohesive strength of the soil composite was obtained as 30 kPa. The C_r value calculated is valid only for a single cell. Due the presence of many interconnected cells, the apparent cohesion value reduces. Rajgopal et al. (1999) observed that the reduction in C_r value is in the range of 50% to 72% of the calculated value depending upon the number of interconnected cells. In the present study, the 70% reduction in C_r value i.e $C_r=21$ kPa was used for numerical simulations. Same value of the friction angle ($\phi=30^\circ$) as that of the sand used in the experimental study was used in the simulation of sand bed and the dilation angle value of $2/3\phi$ was considered.

Elastic-perfectly plastic Mohr Coulomb model was used to model the behavior of soil. Analyses were carried out under controlled velocity loading of $2.5 \times E-5$ m/step. Only half portion of the test bed was modeled using symmetry to reduce the computational effort and the time. The FLAC^{2D} model with the details of loading and the boundary conditions are shown in Figure 6. The size of the mesh was kept same as that of the test bed used in the experimental studies. The displacement along the bottom boundary was restricted in both horizontal as well as vertical direction. The side boundaries were restrained only in the horizontal direction, while the displacements were allowed in the vertical direction. Roughness of the footing was simulated by restraining the surface nodes representing the base of the footing in the horizontal direction.

The elastic properties were obtained from the experimental pressure settlement behavior using the method proposed in the “Appendix D of the Engineering Manual: 1110-1-1904, U.S Army Corps of Engineers (1990)”. The method uses the relationship involving the slope of the pressure settlement curve, Poisson’s ratio, and equivalent diameter of the footing to determine the elastic modulus of the bed. The values found to be underestimating the ultimate bearing pressure by large extent and hence the sensitivity analyses were carried out to determine a suitable value of the elastic modulus. Table 2 presents the details of the various material properties used in the analysis. Comparisons of the pressure settlement behavior of experimental and numerical studies are presented in the Figure 7. There exist a good match between the experimental and the numerical results. However, it was found that the FLAC^{2D} overestimates the bearing pressure at higher settlements.

Figure 6. FLAC^{2D} model with details of loading and boundary condition

Table 2: Material properties used in the analysis

Properties	Unreinforced	Geocell reinforced	Geocell+Geogrid reinforced
Shear modulus, G(MPa)	3.1	1.25	6
Bulk modulus, K (MPa)	6.6	2.6	13
Poisson's ratio, μ	0.3	0.3	0.3
Cohesion, C (kPa)	0	21	21
Friction angle, $\phi(^{\circ})$	30	30	30
Dilation angle, $\psi(^{\circ})$	20	20	20

5. CONCLUSIONS

This paper has investigated the suitability of new commercially available geocells in the constructions of foundations subjected to heavy loads through stress controlled static plate load tests. In addition, the study has demonstrated the simplistic approach of modeling the 3D nature of geocell in 2D finite difference package called FLAC^{2D}. Test results suggest that the provision of geocell increases the ultimate bearing capacity of the sand bed by 4 times. Due to its high bending and shear stiffness, geocell mattress can support the footing at larger settlements and even after the failure of soil. Provision of the additional planar geogrid at the base of the geocell arrests the surface heaving and prevents the footing from undergoing the rotation failure. Hence, it is always beneficial to use planar geogrid layer at the base of the geocell mattress. By using the scaling laws suggested by “Butterfield (1999)” the results of the small-scale models tests can be extrapolated to full-scale cases. Thus, the initial studies in static condition suggest that the combination of the geocell and basal geogrid can be successfully used for the construction of foundations subjected to heavy loads. Moreover, geocells are cheaper and faster compared to vibro stone columns and hence more amenable for field applications. However, further studies are necessary to understand the behavior of geocells under repeated dynamic loadings to ascertain the suitability of geocells in the construction of foundations for railway lines. In this direction, the process of establishing the dynamic plate load test setup is in progress in the Department of Civil Engineering, Indian Institute of Science, Bangalore.

ABSTRACT

This paper deals with soil-geogrid interaction under pullout loading conditions. The main interaction mechanisms affecting the pullout resistance of geogrids embedded in compacted granular soils are the skin friction, between soil and reinforcement solid surface, and the bearing resistance, which develops against transversal elements.

In particular, regarding to the bearing resistance mobilized at the soil - geogrid interface, plays an important role the interference phenomena which could occur when the spacing between transversal bearing members is lower than a fixed limit, depending on the extensions of active and passive surfaces mobilized on transversal bearing members.

In order to investigate the interference phenomena, a wide CRD (constant rate of displacement) pullout test program on several extruded bi-oriented geogrids characterized by different geometry, thickness of the transverse elements and mesh size (in terms of spacing between elements) have been carried out.

Based on the pullout test results a simple theoretical method to predict the peak pullout resistance, taking into account the interference phenomena, is proposed.

1. INTRODUCTION

The use of geogrids to improve the soil mechanical behaviour has become increasingly common practice in geotechnical engineering applications. In order to analyse the internal stability of reinforced earth structures, it is necessary to evaluate the pullout resistance of reinforcement, mobilized in the anchorage zone.

The main interaction mechanisms affecting the pullout resistance of extruded geogrids are the skin friction, between soil and reinforcement solid surface, and the bearing resistance that develops against transversal elements.

Nevertheless, it is important to define the role of all the design (and test) parameters on the mobilisation of the interaction mechanisms (frictional and passive) in pullout condition, including geosynthetic length, tensile stiffness, geometry and shape, vertical effective stress (acting at the geosynthetic interface) and soil shear strength.

Experimental results carried out by the authors (Calvarano et al. 2011, Calvarano 2012) show the existence of an optimum spacing between the transversal elements which maximizes the peak pullout resistance (Figure 1).

In order to study the interference phenomena, which could occur when the distance between the bearing members decreases, the authors performed a series of pullout test on several bi-oriented geogrids (tested in transversal direction), characterized by different spacing and thickness of the bearing members, by removing some transversal bars from the same specimens.

In particular, Figure 1 shows the peak pullout resistance envelopes, in the same test conditions ($L_R = 0.90$ m and $\sigma'_v = 50$ kPa), for GGEB2 geogrid obtained varying the spacing between the transverse elements.

Therefore, when the transverse bars spacing is below the "optimum" value, the pullout response appears to be detrimentally affected by the interference phenomena between the transversal bearing members. On the other hand, when the transverse bars spacing is above the "optimum" value, the pullout resistance decreases because of the less number of bearing members that provide the passive resistance contribution to the overall pullout resistance. These

results clearly demonstrate the significant effect of the spacing between the transversal bearing elements on the peak pullout resistance of the extruded geogrids.

In the present paper, on the basis of the test results obtained by the authors (Moraci and Recalcati 2006; Moraci and Giofrè 2006; Calvarano et al. 2011, Calvarano 2012, Cazzuffi et al. 2011), in order to take into account also the interference phenomena, an extension of the theoretical method developed by Moraci and Giofrè (2006) to determine the peak pullout resistance of extruded geogrids embedded in a compacted granular soil was developed.

Figure 1. Effect of the transversal bars spacing on peak pullout resistance for bi-oriented geogrid specimens (Calvarano et al. 2011, Calvarano 2012).

2. EXPERIMENTAL STUDY

2.1 Test Apparatus

The test apparatus is essentially composed by a rigid steel large pullout box (1700 mm × 680 mm × 600 mm), a vertical load application system, a horizontal force application device, an internal special clamp with sleeve system, and all the required control and data acquisition instruments (Moraci and Montanelli 2000; Moraci et al. 2003; Moraci and Recalcati 2006; Giofrè and Moraci 2006).

The test apparatus is capable to produce confined failure of the geosynthetic specimen using a clamp placed inside the soil, well beyond the sleeve in order to keep the geosynthetic specimen always confined in the soil for the test duration. Friction between the soil and the side walls of the box is minimized by use of smooth Teflon films.

The equipment incorporates two sleeves near the slot at the front of the pullout box in order to avoid front wall effects as recommended by a number of researchers (Moraci and Montanelli 2000; Palmeira and Milligan 1989).

The specimen displacements are measured and recorded using inextensible steel wires connected to at least six different points along the geogrid specimen. The wires are connected to displacements transducers (Rotary Variable Displacement Transducers - RVDT) fixed to the external back side of the box. All the measurements are digitally recorded on a personal computer at defined constant time intervals.

2.2 Test Materials

The pullout tests have been performed on three PP extruded bi-oriented geogrids (named GGEB1, GGEB2 and GGEB3), tested in the transverse direction (TD) along which the geogrids carry the higher mechanical characteristics. The three geogrids show similar geometrical characteristics, in plan view, but they have different number of tensile elements, per unit width, different longitudinal rib pitch and different cross sectional shape, with main differences in rib and bar thickness.

A more detailed analysis of the transversal bar geometry has also shown a non-uniform shape with greater thickness at the rib intersection. The passive interaction mechanisms develop both at the node embossments and at the transversal bars. Therefore, the node embossment and the transversal bar geometry have been carefully determined to calculate the effective passive resistance surfaces.

Figure 2. Schematic cross section of a generic transversal geogrid bar (Moraci and Recalcati 2006).

Figure 2 shows a schematic cross section of a geogrid bearing members that are placed transversely to the direction of pullout force. Table 1 shows the geometrical characterization of the geogrids, where W_r and B_r are the node width and thickness, respectively; S is the spacing between transversal bars in the pullout direction; W_t and B_t are the width and thickness of the bar portion between two nodes, respectively (Figure 2); A_b is the area of each rib element (including the node embossment and the bar portion between two nodes, A_t+A_r) where the bearing resistance can be mobilized. Also, per unit area of reinforcement, A_p and A_a are respectively the bearing and frictional surfaces.

Table 1. Geometrical geogrid characteristics (about symbol see Figure 2).

Geogrid	S [mm]	W_r [mm]	W_t [mm]	B_r [mm]	B_t [mm]	B_{eq} [mm]	A_b [mm ²]	A_p [mm ² /m ²]	A_a [mm ² /m ²]
GGEB1	64.54	14.98	44.34	5.73	3.88	4.43	224.3	68530	250000
GGEB2	39.48	14.81	25.84	3.76	2.90	3.29	107.1	83359	310000
GGEB3	56.92	16.24	59.49	4.95	3.72	4.02	269.7	70598	230000

A granular soil was used in these tests. The soil was classified as uniform medium sand (SP according to USCS classification system, A-3 according to CNR-UNI 10006 classification system), with grain shape from sub-rounded to rounded, uniformity coefficient U equal to 1.96, and average grain size D_{50} equal to 0.32 mm. The Standard Proctor compaction test performed show a maximum dry unit weight $\gamma_{dmax}=16.24$ kN/m³ at an "optimum" water content $w_{opt}=13.5\%$.

Direct shear tests, performed at an initial unit weight equal to 95% of γ_{dmax} (obtained at a water content of 9.3%) yield very high single values of the peak shear strength angle ϕ'_p , in the range 48° to 42° where the higher and the lower values refer respectively to the lower ($\sigma'_v=10$ kPa) and the higher ($\sigma'_v=100$ kPa) confining pressure. The shear strength angle at constant volume ϕ'_{cv} results equal to 34°.

2.3 Analysis Tests Results

Pullout tests have been carried out varying the specimen length ($L_R = 0.40, 0.90, 1.15$ m) and the applied vertical effective pressures (σ'_v was equal to 10, 25 and 50 kPa). All the tests have been performed at controlled rates of displacement (CRD) equal to 1.0 mm/min until geogrid rupture or until a total horizontal displacement of 100 mm was achieved. For all the tests, the geogrid specimens remained confined within the soil for its whole length.

The test results were analysed to define the influence of the different parameters studied (reinforcement geometry, embedded length and vertical stress) on the pullout behaviour of extruded geogrids analysed in the transverse direction (TD) and embedded in a granular soil.

The results of pullout tests for shorter and longer reinforcements are reported in Figure 3 that shows the trend of the pullout resistance versus vertical effective stresses.

Figure 3. Peak pullout resistance envelopes varying the normal effective confining stresses for extruded bi-oriented geogrids.

When the geogrid tensile failure doesn't occur, for all bi-oriented geogrids studied and for all test conditions (L_R and σ'_v) the experimental data show a comparable values of the peak pullout resistance.

These experimental results are particularly interesting because they disagree with the comparison between the values of the overall frictional and passive surfaces on which it is possible to mobilize the interaction mechanisms. In particular, the GGEB2 geogrid is the reinforcement that has the higher values of frictional and passive surfaces when compared with the values corresponding to the GGEB1 and GGEB3 geogrids. Therefore we would expect that the GGEB2 geogrid can mobilize congruent greater values of peak pullout resistance. On the other hand the GGEB2 geogrid exhibits the lower spacing values between the transversal bearing members compared to the values measured for the GGEB1 and GGEB3 geogrids. Therefore, the comparable values of the peak pullout resistance, under the same test conditions, are due to the interference phenomena between the passive failure surfaces, that are generated in front of each bearing members, and the active failure surfaces that are generated in the unloading stress areas at the back of these bars (Palmeira 2004 and 2009).

In this case, the theoretical model developed by Moraci and Giofrè (2006) in order to determine the peak pullout resistance of extruded geogrids embedded in a compacted granular is not applicable.

3. THEORETICAL STUDY

The model proposed by Moraci and Giofrè (2006) to predict the peak pullout resistance, that takes into account the non-linearity of the envelope of rupture of fill soil and extensibility of the reinforcement, is herein modified in order to take into account the interference phenomena between transversal bearing elements.

In the proposed model is introduced a reduction factor on the passive component to take into account the interference phenomena between the extensions of active and passive surfaces mobilized between transversal bearing members. Therefore, the new theoretical expression becomes:

$$P_R = 2 \cdot C_{\alpha S} \cdot \alpha_S \cdot L_R \cdot W \cdot \sigma'_n \cdot \tan \delta + C_{\alpha b} \cdot n_t \cdot n_{tb} \cdot A_b \cdot \sigma'_b \quad [1]$$

where the symbols mean: $C_{\alpha S}$ is the reduction coefficient of geogrid area where skin friction develops (Moraci e Giofrè 2006); n_t is the number of geogrid bearing members; n_{tb} is the number of nodes in a transversal element; $A_b = A_t + A_r$ is the area of each singular module (the node embossments and portion of the adjacent transversal bar) on which the bearing resistance can be mobilized. The bearing stress σ'_b was evaluated by equation proposed by Matsui et al. (1996). Previous studies (Jewell 1985 and 1990, Dyer 1985, Palmeira and Milligan 1989; Palmeira 2004 and 2009; Calvarano et al. 2011, Calvarano 2012, Cazzuffi et al. 2011) have shown that the coefficient $C_{\alpha b}$ is primarily dependent on the geometric characteristics of the mesh reinforcement, such as the spacing and the equivalent thickness (B_{eq}) of the bearing member (Figure 4).

Figure 4. Assumed equivalent geometry transversal rib (Moraci and Giofrè 2006).

Palmeira and Milligan (1989), Dias (2003) and Palmeira (2009) showed that the coefficient $C_{\alpha,b}$ decreases with decreasing of the normalized spacing and suggest that the interference phenomenon can be considered negligible or absent only if the ratio $S/B > 40$. In this case, each bar of the geogrid will behave as if it were isolated. However, Palmeira and Milligan (1989) and Palmeira (2009) showed, moreover, that the interaction coefficient decreases as the number of the bars increase, and therefore decreases with the geogrid length.

Based on the above considerations $C_{\alpha,b}$ is considered as the product of two contributions:

$$C_{\alpha,b} = C_{\alpha,b1} \cdot C_{\alpha,b2} \quad [2]$$

where: $C_{\alpha,b1}$ is the of passive interference coefficient calculated in function of the spacing between bearing members, the equivalent thickness B_{eq} and in function of applied confining stress; $C_{\alpha,b2}$ is the passive interference coefficient calculated in function of the reinforcement length.

In this preliminary study $C_{\alpha,b1}$, in the range of normalized spacing studied, has the following law of variation:

$$C_{\alpha,b1} = a \cdot e^{[b \cdot (S/B_{eq})]} \quad [3]$$

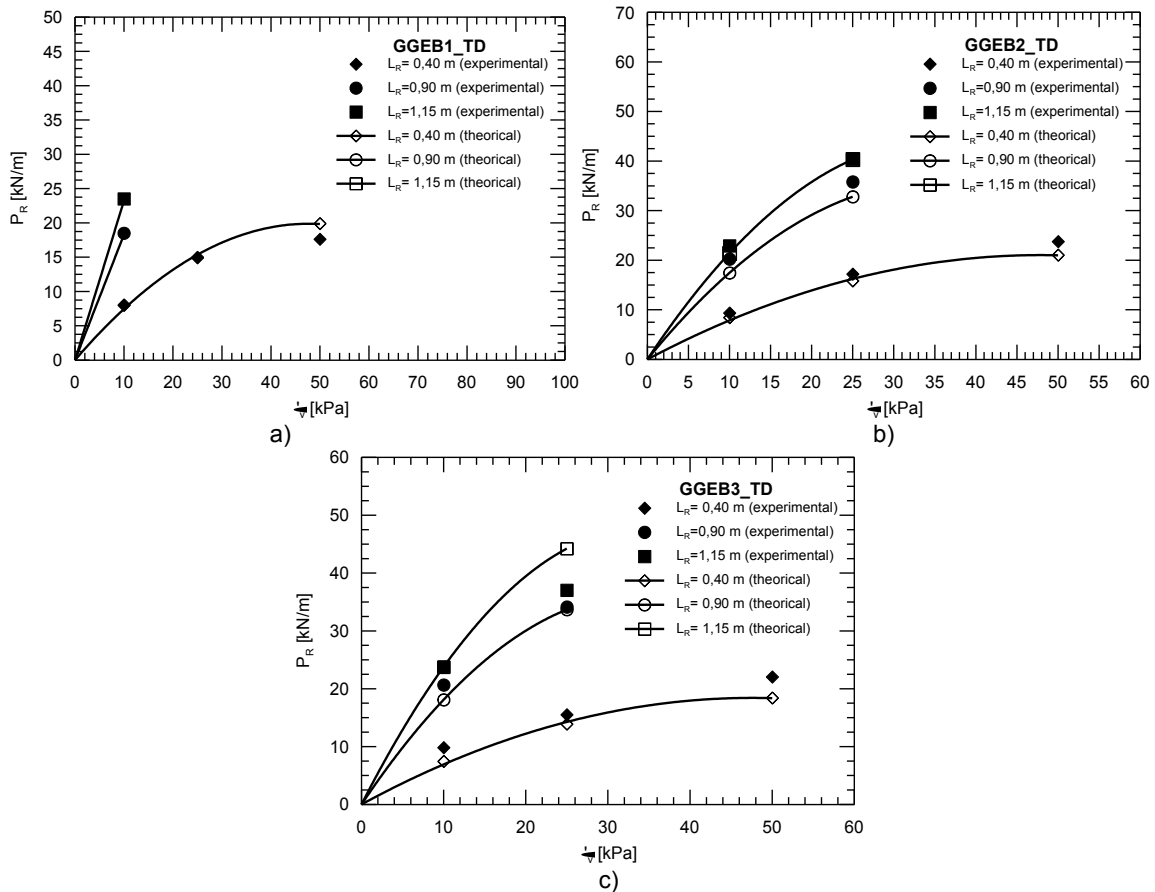

Figure 5. Comparison between experimental and theoretical values of peak pullout resistance regarding extruded bi-oriented geogrids: a) GGEB1, b) GGEB2 and c) GGEB3.

Table 2. Theoretical and experimental peak pullout resistance, P_R (kN/m), for geogrid GGEB1, GGEB2 and GGEB3.

Geogrid	Length [m]	Normal Stress σ'_v								
		10 kPa			25 kPa			50 kPa		
		P_R^{Exp} [kN/m]	P_R^{Theor} [kN/m]	P_{RS}^{Theor} [kN/m]	P_R^{Exp} [kN/m]	P_R^{Theor} [kN/m]	P_{RS}^{Theor} [kN/m]	P_R^{Exp} [kN/m]	P_R^{Theor} [kN/m]	P_{RS}^{Theor} [kN/m]
GGEB1	0.40	7.99	8.05	1.00	14.92	14.96	1.37	17.62	21.06	2.62
	0.90	18.50	18.30	1.29	-	-	-	-	-	-
	1.15	23.50	23.23	1.65	-	-	-	-	-	-
GGEB2	0.40	9.39	8.45	0.71	17.24	15.85	1.70	23.78	21.06	3.24
	0.90	20.25	17.45	1.60	35.82	32.81	3.82	-	-	-
	1.15	22.92	21.42	2.04	40.35	40.31	4.88	-	-	-
GGEB3	0.40	7.09	7.47	0.53	15.54	13.92	1.26	22.06	18.44	2.41
	0.90	20.67	18.11	1.19	34.16	33.69	2.84	-	-	-
	1.15	23.72	23.79	1.52	37.06	44.23	3.62	-	-	-

with a and b constants of the exponential function which assume different values varying σ'_v . The above constants were calibrated considering the results of the experimental tests and as upper bound $C_{\alpha b1}=1$ when $D/B_{eq} \geq 40$, the condition in which each cross bar behaves as isolated bar and therefore the interference phenomenon is irrelevant.

In particular, respectively for vertical confinement stresses of 10, 25 and 50 kPa, the constant "a" is equal to 0.1425, 0.1382 and 0.1089, while the constant "b" takes on the values of 0.0505, 0.0497 and 0.0527.

The passive interference coefficient $C_{\alpha b2}$, in the range of the lengths investigated, is a function of L_R , with the following expression:

$$C_{\alpha b2} = c \cdot L_R + d \quad [4]$$

with c and d constants of the law of linear regression equal to -0.0005 and 1.0221.

The presented comparisons (Table 2) clearly illustrate the application of the above formulation. The proposed method, for all extruded bi-oriented geogrids studied, predicts the peak experimental pullout resistances well, both for different applied vertical effective confining stresses and for different reinforcement lengths.

Table 2 reports the comparison between the peak experimental (P_R^{Exp}) and theoretical (P_R^{Theor}) pullout resistances and Figure 5 shows the comparison between experimental (closed symbols) and theoretical values (open symbols and continuous lines) of the peak pullout resistances, evaluated for the different applied vertical effective confining stresses.

In particular, where rupture confined didn't occur, for "short" reinforcements (0.40 m), the values vary between 1% and 13%, between -8% and -11% and between -24% and -13%, respectively for the GGEB1, GGEB2 and GGEB3; for the "long" reinforcements (0.90 m and 1.15 m), these differences vary about -1%, between -14% and 0% and between 0% and 19%, respectively for the GGEB1, GGEB2 and GGEB3.

On the basis of the theoretical analysis, the skin friction component P_{RS}^{Theor} represents less than 15% of the peak pullout resistance respectively for all the bidirectional geogrids.

Therefore, the comparison between theoretical and experimental results was favourable, thus confirming the suitability of the proposed approach.

4. CONCLUSIONS

The experimental results presented in this paper have shown clearly the influence of the geogrid geometry on the mechanical response of different geosynthetic reinforcements in interaction with compacted granular soil, in pullout loading condition.

Particularly, when the spacing of bearing members is lower than a fixed limit, the extensions of active and passive surfaces mobilized on transversal bearing members produce a reduction on bearing component of pullout resistance.

On the basis of experimental results, the following conclusions could be drawn:

- the increases in the bearing surface are not directly associated with increases of the mechanical response parameters if interference phenomena occur;
- the coefficient of passive interference C_{ob} proposed in the paper allows extending the previous theoretical model developed by Moraci and Giofrè (2006) also when interference phenomena, due to the proximity of the transverse bars, occur.
- the theoretical values of peak pullout resistance obtained by the proposed model are in agreement with the experimental data.
- in the case of extruded geogrids embedded in compacted uniform medium sand, the skin friction component of the peak pullout resistance is small in comparison with the bearing one. For the interfaces analysed in the research and in the test conditions used in the pullout tests the skin friction component represents less than 15% of the peak pullout resistance.

Failures of Geomembrane Liners for Agricultural Waste Storage Ponds

B. Doerge, P.E., G.E., USDA-NRCS, Fort Worth, TX, ben.doerge@ftw.usda.gov,
C. Lafleur, P.E., USDA-NRCS, Fort Worth, TX, cherie.lafleur@ftw.usda.gov

ABSTRACT

The USDA-Natural Resources Conservation Service (NRCS) provides technical and financial assistance for thousands of conservation practices annually, including agricultural waste storage ponds. This paper is the outgrowth of several failures involving exposed geomembrane liners on NRCS-assisted agricultural waste storage ponds. The main points to be covered include: 1) factors responsible for failure of the liners; 2) unique requirements of agricultural waste storage facilities compared to municipal wastewater facilities and solid waste landfills; and 3) recommendations for designing constructable, cost-effective, yet robust liners for agricultural waste storage ponds.

1. INTRODUCTION

The USDA-NRCS assists with the design and construction of numerous agricultural waste storage ponds (AWSP's), primarily under its Environmental Quality Incentives Program (EQIP). A variety of pond liners are used to limit the seepage losses from the ponds, including compacted soil liners, amendment-treated soil liners, geosynthetic clay liners, and covered and exposed geomembrane liners. While most liners function satisfactorily, a number of exposed geomembrane pond liners have failed in recent years, due to a variety of causes. These failures reflect on both the harshness of the conditions which can be encountered in the setting of a commercial agricultural operation and the climbing of the learning curve associated with the implementation of a new technology.

Lessons learned from structure failures are valuable in pinpointing where improvements need to be made. To that end, this paper presents four case histories of failures of exposed geomembrane liners in AWSP's. Particular emphasis is given to the causes of failure in each case. Based on these experiences, recommendations are presented for the investigation, design, construction, and operation of AWSP's with geomembrane liners. These recommendations reflect the unique requirements and challenges associated with agricultural waste storage facilities.

2. FAILURES CASE HISTORIES

The four case histories presented below occurred on NRCS-assisted projects over the last fifteen years. All references to names and locations are omitted out of privacy considerations.

2.1 Case History No. 1

2.1.1 Project Details

Capacity of pond: 23,000 cubic meters

Liner material: Reinforced, slit-film, woven polyethylene geomembrane, 0.6 mm thick with 0.05 mm coating.

Date of construction: 1998

Time to failure: 1 year

Nature of Failure: Numerous large gas bubbles and tears in liner,

Drainage system: None.

Gas venting system: None.

The geomembrane liner was a last-minute substitution for a compacted clay liner when a suitable source of clay borrow material could not be found. The particular liner material was selected because it had been pre-approved by NRCS for use in clear water ponds, provided a pre-qualified contractor performed the installation. No quality control/quality assurance testing of the seams was performed during construction. The expertise of the installer was relied upon for quality. The seams were welded with a hand-held hot air gun and a hand roller.

During the first filling of the pond, a small bubble was observed to rise with the liquid level in the pond. It was suspected to be filled with water and dissipated as the pond filled. About nine months later, large gas-filled bubbles under the liner began to appear shortly after the pond contents were agitated for the first time (see Figure 1). Tears in the liner and floating pieces of geomembrane were also observed. Large streams of gas bubbles were observed to be escaping from

holes in the liner. The entire liner had to be removed and replaced. Inspection of the failed liner revealed numerous poorly adhered seams, burn-through, and holes along the seams.

2.1.2 Causes of Failure

Primary cause: Poor quality seams and damage to the liner during construction, leading to leakage of manure under the liner and formation of biogas bubbles.

Contributing causes: 1) inappropriate liner material used; 2) designer had no previous experience with geomembrane liners; 3) no agitation ramps or pads included in the design; 4) no quality assurance performed during construction; 5) damage to liner during agitation operations.

Figure 1. Large gas bubbles under geomembrane liner (Case History No. 1).

2.2 Case History No. 2

2.2.1 Project Details

Capacity of pond: 2,550 cubic meters
Liner material: Non-reinforced EPDM, 1.1 mm thick.
Date of construction: 2003
Time to failure: 2 years (initial problems); 5 years (total failure)
Nature of Failure: Numerous large gas bubbles under liner,
Drainage system: None
Gas venting system: None.

Immediately following construction, the landowner installed a series of fence posts through the liner along the top edge of the pond side slopes. Later, the landowner observed a fox scratching at the liner. It was suspected that the fox was pursuing mice that had gained access behind the liner through the holes at the fence posts. Small holes were observed in the liner and were presumably made by the fox. One of these holes was below the maximum operating level of the pond. Liquid manure is believed to have entered through this hole and accumulated behind the liner. After the first two years of operation, a single small bubble formed in the middle of the pond. The bubble was presumed to be from biogas generated by the manure that had leaked underneath the liner. The bubble went away when the pond was emptied during the summer for the following two years. The landowner apparently did not consider the bubble to be significant enough of a problem to report it to the designer. The following season, multiple bubbles appeared (see Figure 2). During the fifth year of operation, the liner was cut by the impellor of an agitation pump, presumably because it was "floating" above the bottom of the pond. The agitation and pumping were performed by a custom operator hired by the landowner. After the liner was cut, manure could flow freely under the liner and it could not be salvaged.

2.2.2 Causes of Failure

Primary cause: Animal damage, which allowed manure to leak beneath the liner and generate biogas bubbles.

Contributing causes: 1) puncturing of liner to install fence posts; 2) failure to recognize significance of gas bubbles and attempt corrective actions early on; 3) no gas venting system included in design; 4) damage to liner by agitation equipment operated by outside contractor.

Figure 2. Gas bubbles in manure storage pond Case History No. 2).

2.3 Case History No. 3

2.3.1 Project Details

Capacity of pond: 16,700 cubic meters

Liner material: Non-reinforced EPDM, 1.1 mm thick.

Date of construction: 2007

Time to failure: 1 year

Nature of Failure: Gas/water bubbles under liner,

Drainage system: Perimeter drain tile

Gas venting system: 136 g/m² nonwoven geotextile under liner with 2 percent bottom slope; flap vents on top of slope.

Design phase geologic investigations identified a perched water table in the pond area, based on redoximorphic features (mottling). The ground water level was estimated from test pits, but the pits were not left open to obtain the 24 hour water levels. A perimeter drain was included in the design to control the perched water table. During construction, sloughing occurred on portions of the pond slopes due to wet soil conditions. This wet area appeared to be a deeper seep that was separate from the upper perched water table. Air lance testing was performed to check seam quality, at the recommendation of the manufacturer. No destructive tests were run to determine the shear and peel strengths of the seams.

Approximately one year after construction, a number of large bubbles formed beneath the liner. Some bubbles were filled with liquid, as indicated by a sloshing when touched. Gas bubbles were also observed to be escaping from under the liner. After the pond was drained, an inspection of the liner revealed holes, split seams, and bubbles, along with soft, spongy soils under the liner. Three separated seams were noted.

Following the failure, twelve observation wells were installed to monitor the groundwater level fluctuation at the site. The upper perched table was found to reach levels far higher than indicated by the redoximorphic features. The perimeter drain, with a 49 m span in the narrow direction, was not capable of controlling the groundwater level under the pond.

2.3.2 Causes of Failure

Primary cause: High groundwater pressures under liner as well as split seams and holes in liner.

Contributing causes: 1) inadequate geologic investigation to determine the groundwater levels in the pond area, particularly the seasonal fluctuations; 2) inadequate drainage system under liner; 3) inadequate gas venting system under liner; 4) no destructive testing of seams was performed during construction.

2.4 Case History No. 4

2.4.1 Project Details

Capacity of pond: 7,800 cubic meters

Liner material: Non-reinforced EPDM, 1.1 mm thick.

Date of construction: 2008

Time to failure: 1.5 months

Nature of Failure: Gas bubbles under liner and tearing of liner by agitation equipment.

Drainage system: Perimeter drain tile.

Gas venting system: 0.5 m wide strips of geocomposite at 15 m spacing with 271 g/m² nonwoven geotextile under liner with 1.5 percent bottom slope; PVC pipe vents and flap vents on top of slope.

Geologic investigations identified a perched water table in the pond area, based on redoximorphic features (mottling). The ground water level was estimated from test pits, but the pits were not left open to obtain the 24 hour water levels. A perimeter drain was included in the design to control the perched water table.

The design included a gas venting system, consisting of strips of geocomposite underlain by a geotextile. The geocomposite strips were supposed to have been recessed to be flush with the ground surface, but they were not recessed, and the geotextile was laid on top of the geocomposite strips instead of underneath. The flap vent outlets for the geocomposite strips were not installed for at least a week after the liner was installed.

During the initial filling of the pond, gas accumulated in the geocomposite strips and caused them to float to the surface of the pond (see Figure 3). The PVC pipe vents were in place at this time. The presence of several larger bubbles suggested that at least some of the gas was from sources other than just the air contained within the geocomposite strips. After the bubbles had formed, the liner was cut by the agitation equipment. After the pond was drained, several seam failures were noted. Two seams in the bottom of the pond were able to be pulled apart easily by hand. Additional large bubbles under the liner were observed in the empty pond (see Figure 4). Ultimately the damaged liner was removed.

Figure 3. Gas accumulation in venting system (Case History No. 4).

2.4.2 Causes of Failure

Primary cause: inadequate gas venting system as well as leakage through seams.

Contributing causes: 1) inadequate drainage system; 2) inadequate quality control/quality assurance on seaming operations during construction; 3) gas venting system not installed as designed; and 4) damage to liner by agitation equipment.

Figure 4. Large bubbles under liner visible after emptying (Case History No. 4).

2.5 Summary – Causes of Liner Failures

The four case histories illustrate that many factors can contribute to liner failure and that multiple causes are frequently involved in a given failure. Problems can arise during all phases of the design process, including investigation, design, construction, and operation. Problems common to many of the case histories presented above include:

- Inadequate geologic investigations to determine the seasonal fluctuation of ground water in the pond area.
- Inadequate drainage and/or gas venting systems.
- Inadequate quality control/quality assurance during construction.
- Improper operation procedures.

3. UNIQUE REQUIREMENTS OF LINERS FOR AGRICULTURAL WASTE STORAGE PONDS

The design and operation of geomembrane-lined AWSP's pose unique challenges. First, geomembrane liners are much thinner than other lining materials (e.g., concrete and compacted soil) and geomembranes can be damaged relatively easily, both during and after construction. Furthermore, Koerner (2005) points out that geomembranes are more "unforgiving" than other geosynthetics in that even a small leak can produce alarmingly high leakage rates. Excessive leakage from geomembrane-lined AWSP's is an environmental concern because of the potential for pollution of ground water. It is also a functional concern. Leakage of liquid manure underneath the liner poses a serious threat to the integrity of the liner because of manure's ability to generate large amounts of biogas. Because of geomembranes' low

weight, any accumulation of gas under an exposed liner will result in harmful gas bubbles unless the liner is equipped with well functioning drainage and gas venting systems. Any error or omission in the design of these protective features can lead to rapid and total failure of the liner system. Once large gas bubbles form under the liner, it is generally considered to have failed and must be removed and replaced.

At the same time, the conditions under which AWSP's are operated can be very harsh and unpredictable. Loading, agitation, and clean-out operations can place large stresses on the liner, and these operations are typically performed by a variety of individuals who may not be fully aware of the limitations and vulnerabilities of the liner. Animals, both domesticated and wild, can also damage the liner if they have access to it.

Another major challenge relates to the economics of AWSP's. The control of seepage from AWSP's is typically mandated by state and federal regulatory agencies, and the cost of complying with these regulations is borne solely by the landowner/operator. With municipal waste water facilities and soil waste landfills, the cost of the required engineered systems can be spread out over a relatively large pool of end users. This is not the case with private farmers where the prices they receive for the commodities they produce are outside of their direct control. Therefore, it is important that the cost and complexity of liner systems for AWSP's be kept to a minimum. Elaborate, multi-layer systems like those often used in landfills are likely not economically feasible for many agricultural producers. On the other hand, liner systems for AWSP's must be sufficiently robust so that they can stand up to the operating conditions they will face over their economic life. These opposing requirements for economy and robustness must be successfully balanced to make the use of geomembranes liners for AWSP's attractive.

4. RECOMMENDATIONS FOR INVESTIGATION, DESIGN, CONSTRUCTION, AND OPERATION OF AGRICULTURAL WASTE STORAGE PONDS

Based on the insights gained from failure case histories like those presented in this paper, the following recommendations are offered for designers of AWSP's. The recommendations are separated into the followings areas: investigation, design, construction, and operation.

4.1 Investigation

Geologic investigations should be performed to characterize all subsurface conditions that could impact the performance of the liner. Such conditions include the presence of coarse-grained materials and the proximity of bedrock. It is also critical that ground water conditions be identified, including the seasonal variation of the ground water level. This information is needed to design the drainage system under the liner so that the liner will not be subjected to excess hydrostatic pressure at any time. Rising groundwater can also displace air in the soil pores and produce bubbles under the liner. Determining the seasonal high water level from redoximorphic features (mottling) alone is not adequate. The water level in boreholes and test pits should be noted, and if possible, the holes should be left open at least 24 hours to allow the water level to stabilize. Undisturbed soil samples can also be used to determine the degree of saturation. It should be noted that these water levels only show the conditions at the time of investigations. Seasonal fluctuations can be significant and may require the installation of observation wells with one or more years of monitoring.

Significant subsurface conditions are not always discovered during geologic investigations. Therefore, the designer should be present during any foundation excavations in case any differing conditions are encountered. Other inspection personnel may not be able to recognize significant changes in conditions compared to what was assumed in design. Any seepage observed within the excavation must be critically evaluated.

4.2 Design

The design of geomembrane liner systems is complex and requires specialized training and experience. Koerner (2012) states that designing pond liner systems using geosynthetics requires that the designer "buy into the whole package." This means that a number of components besides just the geomembrane are required for a geosynthetic liner system to function satisfactorily. Therefore, a geomembrane cannot simply be substituted for, say, a compacted clay liner. Other features, such as a drainage system and a gas venting system are also required, along with a full complement of quality control/quality assurance inspection and testing during construction. The case histories presented above demonstrate that incomplete understanding of these complexities on the part of the designer can result in the omission of critical features and ultimately failure of the liner. Training, expert reviews, and contracting out should be considered until in-house expertise in liner design can be brought up to an acceptable level. Designers should develop their own expertise rather than rely too heavily on manufacturer's recommendations or "experienced" installers. Manufacturers are a good source of information on their respective products, but they may not be aware of all site-specific details that may impact the overall design.

As stated above, all geomembrane liner systems should include drainage and gas venting systems. These systems should be designed assuming that some leakage will occur through the membrane. For example, Giroud and Bonaparte (1989) recommend designing the drainage system for a geomembrane based on a frequency of one 100 mm² hole per 4,000 m² of surface area. The drainage system must also be designed to maintain the ground water level below the liner. The capacity of the gas venting system should consider both gas coming from the foundation as well as gas generated by the assumed manure leakage. The gas generation potential of manure is not well defined in the technical literature and further study would be helpful. It is recommended that a continuous gas collection and transmission medium be installed under the liner, such as a nonwoven geotextile or a geocomposite (geotextile-geonet-geotextile). Closely spaced vents should be provided to facilitate the evacuation of the gas. The gas venting system should be configured so that no high spots exist where gas can be trapped.

4.3 Construction

Construction inspection personnel need to be experienced in geomembrane installation. Detailed quality control/quality assurance requirements should be developed for each project. If in-house inspection personnel do not have the required expertise, then the use of outside specialists should be considered. Seam quality should not be evaluated solely by non-destructive tests such as the air lance. Destructive samples and test strips should also be used to document seam strength. Quality assurance should also insure that all components of the project are installed as designed. Leak testing of the completed system may also be considered.

4.4 Operation

Geomembrane liners of AWSP's are subject to harsh conditions during operation which the designer must thoroughly consider during the design process. Protective features such as curbs, ramps, agitation aprons, and fences should be incorporated into the design as needed to reduce the potential for damage to the liner. The vulnerabilities of the liner should be clearly communicated to the landowner/operator in the form of a detailed operation and maintenance plan. The consequences of damage to the liner must be clearly understood all involved in the operation of the facility. The operator should be educated to be able to recognize the early signs of problems so that the designer can be notified in a timely manner and corrective action can be taken before total failure of the liner occurs. In some cases, the manure management system of the operator may make the use of an exposed geomembrane liner unadvisable, such as when the solids and liquids are not separated before storage in the pond. In such cases, an alternate lining system should be used.

ABSTRACT

Expanded Polystyrene (EPS) - block geofoam has been successfully used in many civil engineering applications such as lightweight fill in roadway embankments over soft ground and in landslide stabilization and repair. Seismic loading can affect both external and internal stability of an embankment containing EPS-block geofoam. The geofoam dynamic parameters required to perform seismic analysis are the shear wave velocity, shear modulus and damping ratios. Currently, these parameters are obtained predominantly from laboratory testing such as resonant column and cyclic triaxial tests. However, laboratory tests are typically performed on small specimens and not on full-size geofoam blocks. Additionally, it is difficult to reproduce the field stresses and strains in conventional dynamic laboratory testing. Techniques such as Spectral Analysis of Surface Waves (SASW) are commonly used in geotechnical practice to measure the shear wave velocity of soils. MASW (Multi-Channel Analysis of Surface Waves) tests were performed on full-size EPS blocks to evaluate the feasibility of using geophysical techniques to measure the dynamic parameters of geofoam for use in seismic analysis. Results of the feasibility study suggest that MASW tests may be a reliable and economical procedure for determining the shear modulus of geofoam blocks.

1. INTRODUCTION

Expanded Polystyrene (EPS) - block geofoam has been successfully used in many civil engineering applications such as lightweight fill in roadway embankments (Stark et al., 2004, Arellano and Stark, 2009) over soft ground and in landslide stabilization and repair (Arellano et al., 2010; 2011b). The National Cooperative Highway Research Program Project 24-11(02), "Guidelines for Geofoam Applications in Slope Stability Projects," includes a recommended design guideline for the use of EPS-block geofoam in slope stabilization and repair and an overview of the design procedure is included in Arellano et al. (2010; 2011a&b). Figure 1 depicts the major components of an EPS-block geofoam slope system. Seismic loading can affect both external and internal stability of a slope stabilized with EPS-block geofoam. Design for external stability of the overall EPS-block geofoam slope system considers failure mechanisms that involve the existing slope material as well as failure mechanisms that involve both the fill mass and the existing slope material. Failure mechanisms that are considered for external seismic stability analysis include overall slope instability, horizontal sliding of the entire EPS-block geofoam fill mass, overturning of a vertical sided embankment, bearing capacity failure of the existing foundation earth material, and settlement of the existing foundation material. Design for internal stability considers failure mechanisms within the EPS-block geofoam fill mass. Failure mechanisms that are considered for internal seismic stability analysis include horizontal sliding between layers of blocks and/or between the pavement system and upper layer of blocks and load-bearing failure of the EPS blocks.

Figure 1. Major components of an EPS-block geofoam slope system (Arellano et al. 2010).

The geofoam dynamic parameters required to perform seismic analysis are the shear wave velocity, shear modulus and damping ratios. Currently, these parameters are obtained predominantly from laboratory testing such as resonant column and cyclic triaxial tests. However, laboratory tests are typically performed on small specimens and not on full-size geofoam blocks. Additionally, it is difficult to reproduce the field stresses and strains in conventional dynamic laboratory testing. Athanasopoulos et al. (1999, 2007), Duskov (1997), Trandafir et al. (2010), Athanasopoulos and Xenaki (2011), Ossa and Romo (2011) performed cyclic triaxial tests and Ossa and Roma (2011), Athanasopoulos and Xenaki (1999, 2011) performed resonant column tests to measure the dynamic properties on geofoam specimens.

The literature of the laboratory test results, indicated above, revealed that the shear modulus of EPS material is sensitive to specimen size. Duskov (1997) performed a series of cyclic uniaxial tests on cylindrical EPS specimens with a diameter of 100 mm and height of 200 mm and with a diameter of 150 mm and height of 300 mm to measure the dynamic modulus of elasticity (E_{dyn}). Dynamic modulus of elasticity is approximately twice the shear modulus based on an assumed Poisson's ratio of zero (Trandafir et al. (2010)). The density of the EPS specimens was 20 kg/m^3 . The dynamic modulus of elasticity on the smaller 100 mm diameter specimens ranged between 6.1- 8.3 MPa based on static loads ranging from 15 to 30 kPa and cyclic loads of 30 and 35 kPa. A higher modulus of 9 MPa was obtained on the larger 150 diameter mm specimen based on a test static load of 15 kPa and cyclic load of 30 kPa. Therefore, these laboratory test results indicate that the dynamic modulus of elasticity and corresponding shear modulus is dependent on specimen size.

Athanasopoulos and Xenaki (2011) developed the empirical relationship shown by Equation 1 between the shear modulus (G_0) and density (ρ) of EPS based on the results from unconfined resonant column tests on cylindrical EPS specimens with a diameter of 36 mm and height of 80 mm and with densities ranging from 10 to 30 kg/m^3

$$G_0 = 0.32\rho - 1.4 \quad (1)$$

Equation 1 provides a shear modulus of 6.28 MPa for EPS with density of 24 kg/m^3 which is significantly smaller than the shear modulus of 10.5 MPa measured by Ossa and Roma (2011) based on unconfined resonant column tests on the same EPS density, albeit with a cylindrical specimen with the same diameter but with a larger height of 89 mm. These resonant column tests results also indicate that shear modulus is dependent on the specimen size. Field or laboratory tests on full-size EPS blocks can minimize the effect of specimen size on the measured shear modulus.

Another issue with dynamic laboratory tests is the uncertainty in estimating the field stresses and strains such as estimating the in situ horizontal confining stress to incorporate in conventional dynamic laboratory tests. The confining stress used in dynamic lab tests has an influence on the shear modulus of EPS material. Ossa and Roma (2011) performed a series of resonant column tests on EPS specimens with densities ranging between 24 to 32 kg/m^3 on cylindrical samples with a diameter of 36 mm and a height of 89 mm under confining horizontal stresses of 0, 30, and 60 kPa. A higher shear modulus of 14.5 MPa was obtained under zero confining stress and a lower shear modulus of 12 MPa was obtained under a confining stress of 60 kPa based on test performed on EPS specimens with density of 30 kg/m^3 . Test results show that the shear modulus (G_0) decreases as the confining stress increases. Field tests on EPS blocks under actual field embankment configurations eliminate the need to estimate in situ stresses.

In summary, the effect of specimen size and confining stresses on shear modulus values obtained from laboratory tests can be minimized by in situ geophysical tests such as the MASW (Multi-Channel Analysis of Surface Waves) method. Geophysical techniques such as Spectral Analysis of Surface Waves (SASW) and MASW are used in geotechnical practice to measure the shear wave velocity of soils. Utilizing the Geophysical technics to evaluate the properties of different materials such as PCC slab (Bay and Stoke 1990), mortar cement (Cho 2003 and Cho & Lin 2000 & 2005), asphalt pavements (Ryden et al. 2004) have been reported several times. In this paper the feasibility of MASW testing on estimating the shear modulus of full scale EPS blocks are presented herein. A summary of the MASW procedure is subsequently provided followed by a summary of the test results and conclusions from the test.

2. MASW PROCEDURE

MASW is a geophysical test procedure which is typically used to evaluate the small strain shear wave velocity of subsurface soils. The MASW test is performed by placing geophones (typically 24) on the ground surface that record the time histories of propagating waves from an active or passive seismic source located at various distances (offset) from the sensors. Active seismic source waves are generated by hitting the ground at a specified location with a source such as a sledge hammer whereas, passive seismic source waves are generated from random sources such as nearby vehicle traffic.

In MASW testing, the seismic source is chosen based on the survey depth desired. Seismic sources with large impact energy such as the use of heavy weights can be used for deep investigations (Park (2011)). Seismic sources with lower impact energy such as the use of small balls can be used for shallow investigations (Cho and Lin (2005)). An active

seismic source consisting of a tennis ball, approximately 6.7 cm (2.64 inch) in diameter, was utilized in testing a full-size EPS block. Forty-eight 4.5 Hz geophones similar to the one shown in Figure 2(a) were placed on top of the 0.96 × 1.22 × 7.32 m (3.17×4× 24 ft) EPS block at 15.24 cm (0.5 ft) intervals as shown in Figure 3. Time histories of propagating waves were collected by dropping the ball used as the active seismic source from a height of approximately 15 cm (5.9 inch) onto the surface of the EPS block at 48 different locations or stations. At each station, the test was repeated five times, i.e., the ball was dropped five times, and for each test, the geophones recorded time histories of propagating waves.

The time histories recorded by the geophones are digitized by Geodes (Figure 2. (b)) and the digitized data is transferred to a portable laptop that contains the Geometric Seismodule Controller software™ package. The time histories of propagating waves were recorded at time intervals of 0.125 milliseconds for a duration of 2 seconds. In order to initiate the start of data collection of each test in the software, one of the following two alternatives must be specified: automatic triggering or manual triggering. In automated triggering, the start of the test is recognized by the software automatically from a trigger which is installed on the head of a sledge hammer that is used as an active seismic source and connected to the laptop computer. In manual triggering, the start of test data collection for each test is manually triggered by the person that is monitoring the data acquisition software in the laptop during the test. Since a tennis ball was used as a seismic source, the automatic triggering was not an option and the manual triggering method was used.

Figure 2. (a) 4.5 Hz geophone, (b) Geode

One objective of MASW testing is to obtain shear wave velocity profile at various locations along the block length. A shear wave velocity profile is obtained at the centerline of a series of 24 geophones aligned as shown in Figure 3. The centerline of the 24 geophones is called midsection as shown on Figure (3). Shear wave velocity profiles at other locations of the EPS block can be obtained by moving the 24 geophone series to another location along the block length to change the midsection of the 24 geophones and repeating the test. In testing the full-size EPS block, 48 geophones were utilized instead of 24 to incorporate geophones along the full length of the block to minimize the number of tests needed to obtain shear wave velocity profiles throughout the length of the block. Therefore, 48 geophones were utilized instead of 24 to obtain a two- dimensional (2D) image of shear wave velocity of the block by choosing different 24 geophones series combinations having different midsection locations along the block. The use of 48 geophones expedited the time needed to obtain shear wave velocity profile along the block compare to the time needed to obtain shear wave velocity profiles with only 24 geophones because the use of 24 geophones would require physically moving the 24 geophones after each test, which would have damaged the block as well.

Figure 3. Source-receiver configuration for active MASW test

Noise effects such as vibrations of the data acquisition components and vibrations from random noise sources not related to the specific active seismic source used in the test, can introduce random errors in the test data.

In order to minimize noise from vibration of any data acquisition system components such as the geophone cables, connection cables and Geodes, the data acquisition system is kept away from contact with the EPS block during the tests.

In order to minimize random ambient noises that typically occur during the day the tests were also performed in the evening. Figure 4 shows the test set up for the full-size EPS22 with measured density of 20.9 kg/m³. The density was obtained from the measured weight of full-size block and the dimensions of the block. EPS 22 is designated by ASTM D6817 – 11.

The analysis used to obtain the shear modulus of the EPS block from the recorded time histories is presented next.

3. ANALYSIS

Analysis of MASW data consists of two primary steps: 1) dispersion analysis and 2) inversion analysis. An overview of each of these steps is subsequently provided.

3.1 Dispersion Analysis

The purpose of dispersion analysis is to develop a dispersion curve from the time histories recorded by the geophones. A dispersion curve is a plot of phase velocity versus frequency as depicted in Figure 5. Dispersion curves can be dispersive or non-dispersive. In dispersive curves, different frequency components of surface waves travel with different velocity and create a dispersive curve (Figure 5 (a)). For example, in soils, longer wave length (lower frequency (f_1)) penetrates greater depths which is usually in higher densities and therefore travels with higher velocity ($V_1 > V_2$) (Figure 5. (a)). If all the frequency components travel with the same velocity, the dispersion curve will be non-dispersive as a straight line (shown in Figure 5.(b)) (Park(2012)).

Figure 4. Large scale EPS block under MASW test at the University of Memphis Geotechnical Lab.

Figure 5. Phase Velocity vs Frequency for (a) dispersive curve, (b) Non- dispersive curve.

As described previously, each geophone records the time history of propagating waves for each test. Therefore, 24 time histories (traces) are recorded for each test. In order to create a dispersion curve for each test, the recorded time histories (set of 24 traces) are transformed to the frequency domain by utilizing the Fast Fourier Transformation (FFT). A band pass filter with desired corner frequencies is used to filter data for each frequency range. The filtered time histories are plotted beside each other in manner where vertical axis represents time and horizontal axis represents the offset at which, each geophone is located. By connecting the normalized peak amplitudes of all traces together, an inclined line can be drawn with a specific slope. It is possible to measure the cumulative values of time history amplitude along the slope. The slope of each line represents a unique velocity by which each frequency is travelling and is called phase

velocity. By repeating this procedure for the range of desired frequencies, a contour (dispersion curve) which represents the variation of phase velocity with frequency is generated.

Surfseis software package developed by Kansas Geological Survey is used to generate dispersion curves from the recorded time histories. The test setup configuration details, such as source location, geophone spacing, and number of tests performed at a given seismic source location, are the required software input parameters to generate the dispersion curves. In addition to the provisions previously described to minimize noise effects, the following two additional procedures were also incorporated in the analysis to minimize noise effects:

1) As described previously, at each active seismic source station, the test is repeated 5 times. A dispersion curve is developed for each test repetition at each midsection of a set of 24 geophones and the dispersion curves from the 5 repetitions of the test are stacked (summed) together to obtain a single dispersion curve to minimize noise effect that tends to influence the individual dispersion curves from each individual test.

2) As previously noted, a dispersion curve is obtained at the midsection of a set of 24 geophones for a given offset of the seismic source. Therefore, multiple dispersion curves are obtained at a given midsection location from tests that are performed at various offset locations. For example, Figure 6 provides the various test offset locations and the associated midsection location of a set of 24 geophones located at Station 11.75, which is at the center of the EPS block. Table 2 provides the offset location of each seismic source. Each offset location listed in Table 2 represents a single test. Therefore, as listed in Table 2 and as depicted in Figure 6, 13 different test offset locations are associated with the midsection location at Station 11.75. Therefore, 13 dispersion curves, one for each test offset location, are developed at Station 11.75.

Figure 6. Geophone and test offset used to create a dispersion curve at the middle of EPS block (Station 11.75).

Table.2. Source offset combination for midsection at Station11.75

Source Location (hit) from one edge of block		Offset from the source as shown in Figure (3)	
ft	m	ft	m
0.25	0.08	6.00	1.83
0.75	0.23	5.50	1.68
1.25	0.38	5.00	1.52
1.75	0.53	4.50	1.37
2.25	0.69	4.00	1.22
2.75	0.84	3.50	1.07
3.25	0.99	3.00	0.91
3.75	1.14	2.50	0.76
4.25	1.30	2.00	0.61
4.75	1.45	1.50	0.46
5.25	1.60	1.00	0.30
5.75	1.75	0.50	0.15
6.25	1.91	0.00	0.00

Figure 7 shows the total number of dispersion curves after the two previously described procedures were performed. As shown in Figure 7, between 5 to 125 stacked dispersion curves were developed from all the tests performed on the EPS block. The stacked dispersion curves provide improved phase velocity data at various frequencies than the dispersion curves obtained from a single test.

Figure 7. Total Number of stacked dispersion curve after two stacking procedures (step1 and 2) (Graphic fold)

For example, the final dispersion curve from stacking steps for Station 5.75 is shown in Figure 8. This figure shows the variation of phase velocity by frequencies and the shading represents the dominance of each phase velocity on results. Since EPS material are homogenous material, as described before, the dispersion curve are non-dispersive and show an approximately straight line. As shown in Figure 8, the dispersion curve is nearly horizontal line at frequencies greater than 70 Hz. Figure 9 shows a magnified image of the dispersion curve at frequencies greater than 70 Hz. As shown in Figure 9, the dispersion curve represents a non-dispersive wave with phase velocity constant with frequency as defined by Figure 7(b).

Figure 8. Dispersion curve from Surfseis for station # 5.75.

The phase velocities for various frequencies are obtained from the non-dispersive portion of the dispersion curve by connecting the highest amplitudes in this portion as shown as marked points in Figure 9. Table 3 represents the extracted phase velocities versus frequencies for this section.

Figure 9. Extracted dispersion curve from Surfseis for station # 5.75.

This procedure is repeated for all the sections between 1.75 m (5.75 ft) and 5.41 m (17.75 ft) of EPS blocks. The dispersion curves for each station are stacked (summed) together and a combined dispersion curve for each station is used to extract the phase velocity and their corresponding frequencies.

Table 3. Extracted dispersion results.

109.65	221.78	727.61
119.01	223.21	732.32

3.2 Inversion Analysis

Inversion analysis is a procedure to find the shear wave velocity profile from the experimental dispersion curves. In general the inversion is an iterative process to find a shear wave velocity profile for the experimental dispersion curve with the minimum error between theoretical dispersion curve of inverted velocity profile and experimental. In this research since the dispersion curves show a nearly straight line, the iteration to find a profile velocity is not required and the results can be estimated from the available equations related to propagating waves in homogenous media. The relationship between phase velocity (surface wave velocity (V_R)) and shear wave velocity (V_S) can be estimated from Equations (3&4) (Bay and Stokoe (1990)):

$$V_s = \frac{1+\nu}{0.862+1.14\nu} V_R \quad (3)$$

For Poisson's ratio (ν) between 0.1 and 0.3, shear wave velocity can be approximated by:

$$V_s = 1.11V_R \quad (4)$$

Figure 10. 2-D Shear wave velocity profile of EPS block (m/sec)

Phase velocity is converted to shear wave velocity for all the tested sections of EPS block by utilizing the Equation 4. Figure 10 depicts a 2D shear wave velocity variation within EPS block (between 1.75 m (5.75 ft) and 5.41 m (17.75 ft) of EPS blocks). This plot shows the variation of shear wave velocity by depth of EPS blocks. As shown in Figure 10, the shear wave velocity obtained from the inversion analysis varies within the block. The shear wave velocity should be the same throughout a homogenous material. However, density variations occur with a full size EPS block because of the molding process (Stark et al. 2004), which can contribute to variations in shear wave velocity within the block.

A second factor that can contribute to the variation of shear wave velocity within the block is the used inversion technics which is just based on equations related to Rayleigh wave propagation in homogeneous media. Further works to improve the inversion analysis such as utilizing the Lamb waves (Ryden et al., 2003) is recommended.

Shear modulus of material, under the small strain condition, can be calculated from the shear wave velocity from the Equation 5:

$$G = \rho V_s^2 \quad (5)$$

where,

V_s is the shear wave velocity and ρ is the density of EPS material. Measured shear wave velocities were used to calculate the shear modulus at all the section between 1.75 m (5.75 ft) and 5.41 m (17.75 ft) of EPS block by utilizing the Equation (5). Results show a shear modulus with a range of 10 to 13 MPa (1450 to 1885 psi) and an average of 12.2 MPa (1770 psi). This measured shear modulus is in the range of the shear modulus measured by Ossa and Roma (2011) from resonant column tests (10 to 16 Mpa (1450 to 2320 psi) for EPS material with density range of 24 to 32 kg/m³ (1.5 to 2 lb/ft³)) but is far from the results from resonant column tests reported by Athanasopoulos and Xenaki (2011) (2 to 8 Mpa (290 to 1160 psi) for EPS material with density range of 10 to 30 kg/m³ (0.6 to 1.9 lb/ft³)). Table 4 provides an example of calculated shear wave velocity and shear modulus at the section 5.75 with 1.75m (5.75 ft) distance from the one edge of EPS block. Results show an average shear wave velocity of 240 m/sec (787 ft/sec) and shear modulus of 11.81 MPa.

Table 4. Shear wave velocity and Shear modulus at station #5.75

4. CONCLUSIONS

Performance evaluation of EPS embankments under dynamic loading, such as earthquake analysis of slope stabilized with EPS blocks, depends on their dynamic properties. Shear modulus and shear wave velocity are geofam dynamic parameters required to perform seismic analysis. Understanding the behavior of EPS material under dynamic loading is a key issue in the seismic design of EPS embankments. This paper proposes the use of the MASW method to evaluate the large scale dynamic properties of EPS material. Results show an average shear modulus of 12.2 Mpa (1770 psi) for the EPS 22 with the measured density of 20.9 kg/m³ (1.3 lb/ft³).

The shear modulus measured by the MASW test shows a higher value than the reported results for EPS blocks with densities close to the tested block (20.9 kg/m³ (1.3 lb/ft³)). However, the MASW result is still in the range of the shear modulus measured by Ossa and Roma (2011) from resonant column tests (10 to 16 Mpa (1450 to 2320 psi) for EPS material with density range of 24 to 32 kg/m³ (1.5 to 2 lb/ft³)). MASW results vary greatly from the shear modulus reported by Athanasopoulos and Xenaki (2011) measured by resonant column tests (2 to 8 Mpa (290 to 1160 psi) for EPS material with density range of 10 to 30 kg/m³ (0.6 to 1.9 lb/ft³)). Further investigation by performing the resonant column test on the tested EPS block in this research is in progress.

This method can be extended to be performed on projects with EPS blocks in the field to measure the dynamic properties of the EPS material under the in-situ condition (confining and vertical pressure). Utilizing the MASW method in evaluating the dynamic properties of EPS material can provide the following potential advantages: (1) eliminate the effect of the small scale sample size on the results, (2) provide a capability to test EPS material under in-situ condition (3) provide an image of integrity of EPS blocks (4) utilize fast and economically procedures.

ACKNOWLEDGEMENTS

The authors would like to give their sincere thanks to Drew Foam Companies and Mr. Charles Tyner for providing the EPS block to The University of Memphis.

Finite Element Mesh Generation for Drainage Geocomposites

Dhani Narejo, Ph.D., P.E., GSE Environmental LLC, USA, dnarejo@gseworld.com.

ABSTRACT

Landfill cover systems invariably include a drainage layer which is most often a drainage geocomposite. The drainage design is typically based on either Darcy's Law or a combination of the law with a mass balance analysis as expressed in the "mounding equations". However, these types of analyses do not consider several site conditions including multiple soil types, anisotropy and evapotranspiration. This paper illustrates the use of a commercially available finite element software with drainage geocomposites. Simple methods, based on the published equations, were found to provide similar maximum pressure head on the liner as the finite element analysis. The pressure head was found to be very different when more than one material was involved in the drainage. The pressure head distribution along the slope and the variation of the pressure head over time were found to be of practical interest for a practicing design professional. Construction lines, drawn at 1 mm spacing, were used to define the mesh for the drainage geocomposite and a thin soil layer immediately above it. This technique appears to have resolved convergence problems for all the analyses presented in this paper. The software was found to provide an excellent representation of the sharp change in the material properties at the soil-geocomposite interface. A limited sample of conditions analyzed for this paper indicates that the finite element method can be used to solve most landfill cover seepage problems within a few hours of computer time.

1. INTRODUCTION

Landfill covers consist of a relatively thin layer of soil over an impermeable barrier. Approximately 1/2 a meter of soil, placed on a long slope, is underlain by a geomembrane and/or a geosynthetic clay liner. Stability of the cover soil is an important design concern especially with regards to the seepage and erosion resulting from rainfall. Simple methods exist for landfill cover design, and when properly implemented, are known to result in an acceptable cover system. The simplest and most popular of these methods is a veneer stability analysis that includes the effect of a maximum pressure head on the liner after a design rainfall event (Giroud et al. 1995). The pressure head is often obtained from the mounding equations of which the most popular for landfill covers are those presented by Giroud et al. (2000). Alternatively, many engineers obtain pressure head based on Darcy's Law, which yields the same results as the limit cases of the mounding equations. Such pressure head calculations are a simplified form of the reality in the field and do not consider such factors as evapotranspiration, multiple soil types, three-dimensional slopes, unsaturated flow and boundary conditions. However, the simple equations are practical and popular, as experience has shown that an acceptable landfill cover design can be obtained from these within a short time.

The finite element method of seepage analysis can also be used to obtain the pressure head distribution over the liner. Most problems can be analyzed within a few hours of computing time thanks to the power of personal computers. The finite element method does not require the simplifying assumptions of the exact solutions and, therefore, gives a more accurate prediction of the pressure head. On the other hand, certain material properties, necessary for the finite element analysis, are not required for the simple procedures. Methods do exist, however, for an estimate of the material properties based on gradation and density, and a few inexpensive tests (Th. van Genuchten et al. 1991). It is likely that in some cases a finite element seepage analysis based on even an estimate of the material properties gives more and better information than an estimate of the pressure head based on simple solutions. This paper demonstrates this by analyzing a few simple slopes with a commercially available software Hydrus 2D/3D (Simunek, et al. 2011). The problems are taken from the published literature as it is much easier and less time consuming to further explore an analysis that has been performed by others than to commence a new problem or project. The methodology presented here can be easily extended to an actual landfill cover project.

The finite element seepage analysis of unlined slopes has been reported in numerous publications (Ng & Shi, 1998; Kai & Ugai, 2004). The emphasis in this paper is on the use of drainage geocomposites in the finite element analysis as the published literature on this topic is minimal to none. Drainage geocomposites are very thin materials - only a few millimeters - with a very high hydraulic conductivity. The actual landfill cover slopes vary in dimension and can be as long as 100 meters in extreme cases. The thickness and hydraulic conductivity of drainage geocomposites is so different from the underlying and overlying materials that entering the geometry and obtaining a convergence can be difficult. The purpose of this paper is to specifically represent the geocomposite as a material - not a boundary condition - and compare the results with exact solutions. Drainage geocomposites are sometimes represented as a seepage face boundary (Iryo & Rowe, 2005) or as a drainage boundary condition. Representing drainage geocomposites as a

material, rather than a boundary, is necessary in order to obtain a pressure head distribution throughout the slope.

Based on mass conservation and Darcy's Law, Giroud et. al. (2000) derive the following equation for unconfined flow in a soil layer on a slope underlain by a barrier:

$$\lambda x = \frac{t \cos^2 \beta}{\sin \beta} - \frac{\cos^4 \beta}{\sin^2 \beta} t \frac{dt}{dx} \quad (1)$$

Where λ is a dimensionless parameter that defines the shape of the liquid surface and is given as:

$$\lambda = \frac{q_h}{k \tan^2 \beta} \quad (2)$$

In the above equations, q_h = liquid supply rate (LT^{-1}), k = coefficient of hydraulic conductivity (LT^{-1}), t = thickness of liquid (L), x = distance along x-axis (L), and β = slope angle (degrees). The authors present two limit cases of Equation 1: Equation 3 for $\beta = 0$ (i.e., $\lambda = \infty$) and Equation 4 when q_h is very small or k is very large (i.e., λ is very small).

#

$$t_{\max} = \sqrt{\frac{q_h}{k}} L \quad (3)$$

$$t_{\max} = \frac{q_h L}{k \sin \beta} \quad (4)$$

Equation 4 is the most common expression that is used to determine the required transmissivity of drainage geocomposites. For general case, where equations 3 and 4 do not apply, the authors present an approximate solution of Equation 1 as follows:

$$t_{\max} = j \frac{\sqrt{\tan^2 \beta + \frac{4q_h}{k}} - \tan \beta}{2 \cos \beta} L \quad (5)$$

Where j is defined by the authors as follows:

$$j = 1 - 0.12 \exp \left[- \left[\left(\frac{\log \frac{8q_h}{k}}{5 \sin^2 \beta} \right)^{\frac{5}{8}} \right]^2 \right] \quad (6)$$

In the above equations, t_{\max} = maximum liquid thickness, (L). Maximum pressure head, h_{\max} , is related to the maximum liquid thickness as $h_{\max} = t_{\max} \cos \beta$. Equations 3, 4 and 5 represent the expressions that are typically used in the current state-of-the-practice for the design of the landfill cover liquid collection layer. Equation 4 applies to the case of a drainage geocomposite as k is often very high for these materials resulting in a very small value of λ . Equation 5 applies to a soil drainage layer for which j value can be obtained either from Equation 6 or from a graph given by the authors. The maximum pressure head obtained from the above expressions – based on Darcy's Law and mass balance - can be compared to the maximum value obtained from a finite element analysis.

2. PROBLEM DESCRIPTION, SOFTWARE AND METHODOLOGY

The paper presents a finite element seepage analysis of several variations of a problem originally analyzed by Iryo and Rowe (2005). The published problem was first modeled exactly as described in the journal paper to ensure that the output from the software was matched the published values. Having confirmed this, four important changes were made to the model: i) the depth of the cover soil was changed to 600 mm to model a typical landfill cover soil, ii) a 5 mm thick geosynthetic drainage layer, i.e., a drainage geocomposite, was placed under the cover soil, iii) the bottom boundary

condition was changed from seepage face to no-flow to represent a geomembrane, and iv) horizontal slope length was varied from 2500 mm to 10000 mm. Iryo and Rowe modeled the original 5000 mm long by 300 mm deep slope with Seep/W software. They performed virtual experiments (no physical experiments were performed) by changing the slope angle and impingement rate (flux entering the top boundary). A 3 mm thick geotextile was modeled under the soil with a seepage face boundary under the geotextile representing flow into a geonet. The adaptation of the Iryo and Rowe problem for this paper is shown in Figure 1. It consists of a 600 mm thick soil layer underlain by a 5 mm thick drainage geocomposite which is underlain by a geomembrane. The present analysis uses the same properties for the soil and drainage material as those used by Iryo and Rowe for their soil and geotextile, respectively. Slope angle is varied between 0 and 18.4 degrees to cover a range of conditions encountered in real life landfill covers.

Hydrus 2D/3D software, version 2.01 (www.pc-progress.com) was used for the seepage analysis. The software considers both saturated and unsaturated flow and has an environmental boundary condition option that is ideal for landfill covers. For the present problem, only rainfall with no evapotranspiration was considered. The software numerically solves the Richards' equation for saturated-unsaturated flow and can be used with one-, two- and three-dimensional problems. The volumetric water content formulation of the Richards' equation is as follows:

$$\frac{\partial \theta}{\partial t} = \frac{\partial}{\partial x_i} \left[K \left(K_{ij}^A \frac{\partial h}{\partial x_j} + K_{iz}^A \right) \right] - S \quad (7)$$

Where θ is the volumetric water content (L^3L^{-3}), h is the pressure head (L), S is a sink term (T^{-1}), x_i ($i=1, 2$) are spatial coordinates (L), t is time (T), K_{ij}^A are components of a dimensionless anisotropy tensor \mathbf{K}^A and K is the unsaturated hydraulic conductivity function (LT^{-1}) given by $K(h,x,y,z) = K_s(x,y,z)K_r(h,x,y,z)$.

Figure 1 – Problem Modeled in the Finite Element Software.

With known boundary and initial conditions, the software solves Richards' equation using a Galerkin type linear finite element method applied to a network of triangular elements. Integration in time is achieved using an implicit finite difference scheme for both saturated and unsaturated conditions. The van Genuchten-Mualem equations with the assumption that $m=1-1/n$ were used to define water characteristic curve and the hydraulic conductivity functions. Table 1 presents the basic properties and van Genuchten parameters assumed for the materials based on the paper by Iryo & Rowe (2005). Sand and loam represent two materials with a comparatively high and low hydraulic conductivity, while the drainage geocomposite is a low transmissivity drainage geocomposite with properties similar to a thick nonwoven needlepunched geotextile.

Table 1. Basic material properties and van Genuchten parameters.

Parameter	Sand	Loam	Drainage Geocomposite
Saturated volumetric water content, θ_s , (-)	0.38	0.40	0.92
Residual volumetric water content, θ_r , (-)	0.04	0.06	0
Saturated hydraulic conductivity, K_{sat} , mm/hour	360	3.6	82800
van Genuchten parameter, a , (1/mm)	0.0072	0.00216	0.029
van Genuchten parameter, n , (-)	3.16	1.47	3.0

An environmental boundary condition with a precipitation, zero evapotranspiration and instant run-off was used for the top of the slope. The instant run-off implies that the water that does not enter the soil runs off without any head buildup at the surface. A no-flow boundary condition was used at the right and bottom of the model. The no-flow condition at the bottom represents a perfect liner with no leakage while at the right it represents a divide with a slope in the opposite direction. On the left side, a seepage face boundary condition was used. Physically, a seepage face boundary condition can be interpreted as a highly porous stone, such as in gravel drains. A uniform pressure head of -1000 mm was used for the entire domain as the initial condition representing a dry material.

The discretization of the problem of Figure 1 in the finite element software is presented in Figure 2. Construction lines parallel to the slope were used to divide the drainage geocomposite into 1 mm thick regions. Three regions of the same thickness (i.e., 1 mm) were entered immediately above the geocomposite in the cover soil. Then a triangular mesh size of 20 mm was entered for the entire domain. The result was a mesh of uniform size for the entire domain except for 8 mm thickness at the bottom of the domain where one side of the triangles was forced to be 1 mm. This mesh scheme was used after trials with several mesh refinement methods that did not work as well as the method of the construction lines. Most refinement methods resulted in a very large number of mesh elements. Very thin regions of one mm thickness were found to improve convergence significantly but convergence problems persisted nonetheless. Pressure head was found to be sensitive to the size of the mesh in the vicinity of the geocomposite.

Figure 2 – Mesh Discretization Used for Geocomposite and Cover Soil (Triangle Side = 20 mm).

3. RESULTS

Table 2 presents the results of all the virtual experiments conducted for this paper. The first column represents categories, indicating the purpose of the experiments included in a specific class. For example, in Category A, the

purpose was to determine the rainfall rate that will result in a steady state pressure head of less than the thickness of the drainage geocomposite. Series C is a confirmation of the results with two different finite element software. The second column represents a sequence number of each of the runs. A total of 17 runs were performed. The third column is the slope angle which ranged from zero to eighteen degrees. Most landfill slopes are less than or equal to 3H:1V and, therefore, this was the maximum slope modeled. The fourth column represents slope length, i.e., L in Figure 1. Slope lengths were chosen arbitrarily to be 2500, 5000 and 10000 mm. Slope lengths for actual projects vary over a broad range. This paper considers slope lengths shorter than those found in practice for most projects.

Rainfall rates of 0.2, 5.9 and 30.3 mm/hour in the sixth column were determined by increasing the rainfall rate in small increments until the maximum steady state pressure head was approximately equal to the thickness of the geocomposite. Drainage is, therefore, taking place only within the geocomposite. This makes it possible to compare the results with solutions from published equations. For the last six runs, a rainfall rate of 30 mm/hour was used. Runs 1 through 8 were long enough to achieve a steady state output, referred to as SS in column 7. The last 9 runs were for 6 hours representing a 30 mm/hour probable maximum precipitation for a duration of 6 hours. Column 8 gives the maximum pressure head obtained for each of the runs. For runs 15, 16 and 17, wetting front did not reach the geocomposite. The last column shows the software used for the analyses. All runs, except #8, were performed with the software referenced above (Simunek, et al. 2011). Run 8 was performed with a different software that is often used by geotechnical engineers for seepage analysis and that was used by Iryo and Rowe for their analysis. The second software does not have an environmental boundary condition; therefore a constant flux was used for this purpose, as no evapotranspiration was considered in the analyses. This second software was used to confirm the values obtained with the primary software used in this paper.

Notes: GM= geomembrane; GC = geocomposite; Max. = maximum, SS = steady state, Hor = horizontal, * = wetting front did not reach the drainage geocomposite in 6 hours

Design engineers typically use equations based on Darcy's Law and mass-balance to select a suitable drainage geocomposite. Some of these equations were presented in Section 1 and other similar equations are available in the literature. Equation 4 is the most popular method for calculating the required transmissivity of drainage geocomposites placed on slopes less than 90 degrees. Most of the runs presented in Table 2 were repeated with the published equations. The results are summarized in Table 3. In Table 3, the first column corresponds with the second column in Table 2 and the 2nd column corresponds to the third column in Table 2. The third and fourth columns give hydraulic conductivity of the drainage geocomposite and the cover soil, respectively. The fifth column is the effective infiltration

rate which is the lower of the hydraulic conductivity and rainfall rate. Lambda in column 6 is obtained from Equation 2. Column 7 represents the maximum pressure head obtained from equations 4, 5 or 6.

4. DISCUSSION

Runs 1 through 3 of Series A in Table 2 present pressure heads at a steady state for the rainfall rates indicated. Several iterations were performed to obtain the rainfall rate that gave the maximum pressure head approximately equal to the thickness of the drainage geocomposite. The rainfall rate required to achieve an approximate pressure head of 5 mm increases with increasing slope angle, which is to be expected. The corresponding solution with the equations is presented in Table 3 in rows runs 1 through 3. There appears to be excellent conformance between the solution obtained with the equations and that obtained with the finite element analysis. A few mm of pressure head, as represented in tables 2 and 3, does have important practical significance. The selection of the thickness of a drainage geocomposite is practically based on the pressure head, and the goal of keeping the head within the geocomposite represents real cost. The author was relieved to find this fine a conformance without much effort on the analysis. However, the comparison is based on a very small set of conditions and needs to be extended to additional slope and material characteristics. For the conditions analyzed in this paper, it is seen that the simple equations yield the same pressure head as the finite element analysis for steady state conditions when positive pressure head is within the geocomposite.

The runs in Series B show that the pressure head obtained without a drainage geocomposite is very high compared to that with the drainage geocomposite. Again, this result is as expected and the software appears to be handling the geocomposite correctly. A 5 mm thick geocomposite in the cases analyzed is found to be effective in reducing the pressure head to approximately the thickness of the drainage geocomposite. In Table 3, rows 4, 5 and 6 give the corresponding solution with the equations. The equations generally give a higher pressure head than that with the finite element analysis. The difference may be due to the unsaturated flow with the finite element analysis or approximations inherent in the exact solutions. For a uniform cover soil with no geocomposite, the current state of the practice appears to be conservative.

Table 3. Maximum pressure head above the geomembrane with published equations.

Drain = drainage geocomposite; k = hydraulic conductivity, h_{max} = maximum pressure head

In design practice the author has used software B in the past, as its results can be easily imported into slope stability analysis software. Case 8 was run only as a check on the finite element software A utilized in this paper. For software B run, a rectangular grid was used instead of the triangular grid in software A. All other model conditions were exactly the same as that with software A. The results show that both software programs give essentially the same value of maximum pressure head for the comparison case. Note that software B does not have an environmental boundary condition as

additional software must be purchased for that from the suppliers. However, a constant flux condition was used for the top boundary as no evapotranspiration was included in any of the analyses. An attempt to model the drainage geocomposite with software B resulted in convergence problems. However, with some additional practice, the author is hopeful that a drainage geocomposite can be considered as a material (not as a boundary) even within software B.

The hydraulic design of drainage layers for landfill covers is generally based on a 6-hour probable maximum precipitation (Soong and Koerner, 1997). The PMP curves are available on the Internet for the entire United States. For the rain event to be only 6 hours, the finite element analysis time discretization must be limited to six hours. Alternatively, one can apply precipitation for six hours followed by no-precipitation for some additional time. Runs in series D in Table 2 are the same as the runs in series A except that a transient condition of only 6 hours is considered. At the end of a 6-hour rainfall, the pressure head is found to be very different from that under the steady state conditions. Therefore, although the equations and the steady state finite element analyses results show good agreement, the two are very different for transient conditions. Moreover, the equations are not always conservative when the positive pressure head extends up into the cover soil. Notice a maximum pressure head of 226 mm in Run 14 in Table 2 versus 10.9 mm with equations in Table 3. Actually, a steady state pressure head of 400 mm is obtained by the finite element analysis for Run 14. The positive pressure head is now above the geocomposite and two materials are involved in drainage: sand and geocomposite. Simple equations cannot handle such a case and may significantly under-predict the pressure head if the hydraulic conductivity of the geocomposite is used in the equations. The drainage is occurring through both sand and the geocomposite and the pressure head represents this in the case of the finite element analysis. An equivalent hydraulic conductivity can be calculated and used in Equation 4. Doing this leads to a maximum pressure head of 1500 mm. Although a conservative value, this significantly over-predicts the geocomposite requirement that may be necessary to obtain a pressure head that is low enough for an adequate factor of safety against instability.

For the case of LOAM/GC/GM, the conventional design methods would indicate that a very thin drainage layer of less than 1 mm is necessary. However, the finite element analysis shows that a 6-hour storm of 30 mm/hour will not require a geocomposite as the geocomposite does not have any effect on the pressure head. A steady state analysis was not carried out for the LOAM/GC/GM cases. Cover soils with low permeability may build up significant pressure head within the cover soil while the geocomposite may stay completely dry. For example, one can review the development of the pressure head with time for Run 7 in Figure 3. The figure shows pressure head on the liner with time at about 4000 mm horizontal distance down the slope. The maximum pressure head of 250 mm occurs at about 3 hours and the steady state pressure head of 100 mm is significantly lower than this value. Depending on the storm event and material properties, maximum pressure head may occur sooner than what a steady state analysis or exact solution may show. The finite element analyses offer a valuable tool as one can track the water pressure buildup with time and adjust the design to address this.

A very important advantage of using the finite element analysis is the pressure head distribution along the liner. Figure 4 shows the steady state pressure head distribution over the liner for Run 3. It is seen that a positive pressure head is limited to only about 500 mm length of the slope which is only 1/10th of the total slope length. For the design methods currently in practice, a uniform or linear pressure head distribution is assumed over the liner for the entire slope length. The figure shows that although the maximum pressure head is nearly equal to the thickness of the geocomposite, most of the geocomposite is dry. The actual pressure distribution could have a significant effect on the factor of safety against veneer instability. In some cases, the cover soil can get saturated at the toe while rest of the slope is dry. In other cases, it may be possible for the positive pressure head to move up into the cover soil with little or no effect on the stability. Moreover, the pressure distribution can have a significant effect on the selection of the type of the geocomposite. For example, one can use a thicker or more permeable drainage geocomposite at the toe while using a thinner material farther from the toe. The finite element analysis presents an opportunity to optimize the placement of a drainage geocomposite on a slope.

5. CONCLUSIONS

A very small matrix was used to look into the possibility of the use of finite element software – The software – for seepage analysis of slopes with drainage geocomposites. The following conclusions can be drawn based on this very limited effort:

- It was seen that drainage geocomposites can be entered into the software as a material rather than a drainage boundary condition. Construction lines were used to obtain 1 mm thick triangular mesh elements for the geocomposite and a thin soil layer immediately above the geocomposite. This improved convergence significantly but convergence problems persisted.
- Convergence problems occurred when the wetting front reached the geocomposite. Additional work is necessary to develop a method to solve convergence problems so that it is very easy for a practicing geotechnical engineer to perform the analysis for a typical project.

- Simple cases showed good agreement between the finite element analysis and the published equations for the case of thin materials like drainage geocomposite. Published equations over-predict pressure head with drainage within thick cover soils. No agreement was found when more than one material was involved, such as

Figure 3 – Pressure Head with Time on the Liner at a Point about 1000 mm from the Toe for Run 7.

Figure 4 – Pressure Head Distribution on the Liner at Steady State for Run 3.

sand and geocomposite, or when transient conditions were analyzed, for example 6-hour rainfall.

- The pressure head distribution along the liner and with time was found to be of a significant importance for a practicing geotechnical engineer as it may affect the slope stability analysis and the material selection. Although a maximum pressure equal to the geocomposite thickness was reached, most of the geocomposite remained dry.

6. LIMITATIONS

This paper is not a comprehensive evaluation of a broad range of conditions that may occur in real life projects. Neither is it meant to be a detailed comparison of conventional design methods and finite element analysis. The objective was to see if a drainage geocomposite can be represented as a material in a finite element analysis software. This is of a significant interest for a practicing geotechnical engineer. Drainage geocomposites have a very high hydraulic conductivity and very low thickness (only a few mm). It is often difficult to include these materials in a finite element analysis. The software was found to provide consistent results. Yet only a very small range of conditions was analyzed. Moreover, no laboratory verification of the results is possible as actual physical experiments were not performed for this paper.

Drainage geocomposite was represented as a thick geotextile with properties obtained from Iryo and Rowe (2005). Real drainage geocomposites consist of a geotextile bonded to one or both sides of a geonet. A more refined representation of the drainage geocomposite with soil water characteristic curve obtained from laboratory testing is necessary. The author has initiated work on this topic but this information was not available at the time this paper was written. A more realistic soil water characteristic curve for drainage geocomposites may significantly affect the results. However, it is very likely that the software will successfully analyze a seepage problem over a broad range of conditions provided convergence problems are resolved. Convergence problems occurred in some of the cases and changing the mesh size and initial conditions resolved the problems, but it is likely that a better method exists for improving the convergence.

Flexible Pavement Performance with and Without Geosynthetics: Nine Year Follow-Up

B. A. Lacina, P.E., TenCate Geosynthetics, USA, b.lacina@tencate.com

F. S. Dull, P.E., TenCate Geosynthetics, USA, s.dull@tencate.com

ABSTRACT

A project case study was undertaken to evaluate the differential performance of asphalt surfaced flexible pavement sections in a suburban community of Raleigh, North Carolina, USA nine years after being placed in service. Pavement sections that utilized a moderate strength reinforcement geotextile at the base course - subgrade interface showed a marked improvement in durability and performance compared to other pavement sections constructed without geosynthetics in the same subdivision during the same time period. These flexible pavement sections were examined using both destructive and nondestructive evaluation methods to assess the physical differences between the geosynthetically enhanced and non-geosynthetic pavement sections.

The results of pavement coring, ground penetrating radar (GPR), falling weight deflectometer (FWD) and surface roughness measurements are presented herein. Pavement coring tests show the thickness of the pavement system layers and evaluate the layer boundaries. GPR testing results provide a larger surface cross sectional perspective into the pavement system layers in the reinforced and unreinforced sections. FWD results are presented using AREA parameters for both reinforced and unreinforced pavement sections. Pavement surface roughness assessments are presented using the mean international roughness index (MIRI) for reinforced and unreinforced pavement sections. A summary and conclusions of the pavement testing and analyses are provided at the conclusion of this report.

1. INTRODUCTION

The project site is the Cornerstone subdivision which is located approximately 16 miles to the northwest of downtown Raleigh, NC, USA (Figure 1) and is located in the Piedmont geophysical province. Soils in the Piedmont can exhibit a loss of pavement support due to the presence of mica in the typically silty or clayey sands, which causes the subgrade soils to lose strength when exposed to moisture in roadway and other geotechnical engineering applications (Christopher, *et al*, 2009). Portions of the asphalt surfaced flexible pavements named Marvino Lane and Country Trail and their intersection were constructed January, 2003 and the contractor was required by the City of Raleigh to use a biaxial strength geosynthetic and an additional 2 inches (50 mm) of aggregate base course (ABC) material for pavement support due to the poor construction conditions at the site. It was originally thought that the thickness increase was required, but the coring evaluation completed for this study indicated that this was not the case. Construction of approximately 1500 feet (460 m) of Marvino Lane and Country Trail needed to be completed during this time. Marvino Lane and Country Trail are the main collector roads that service the 300+ home subdivision and the surrounding commercial retail developments.

The contractor placed approximately 13,000 square yards (10,900 m²) of TenCate Geosynthetic's woven Mirafi® HP370 base reinforcement geotextile (Figure 2) as the biaxial strength geosynthetic required by the City. The wider roll widths than typical biaxial geogrids used in this application allowed the contractor to place the rolls over the subgrade three panels wide using the appropriate overlap on the wide collector road entering the subdivision. Use of the wider roll widths allowed the contractor to easily complete construction of the roadways on schedule. The geotextile reinforced areas of Marvino Lane and Country Trail that used the geotextile showed much less pavement distress after four years of service life than the other areas of flexible pavement completed during the prior phase without the use of a reinforcement geotextile. In addition, the traffic counts on the geosynthetic reinforced roadways are significantly higher than the traffic counts on the older roadways that showed early surface deterioration.

When the original project case study was completed in February of 2007, after approximately four years of trafficking, photos were taken of a representative area on Country Trail where the geotextile reinforcement was used as well as a section of Parkstone Drive constructed without the benefit of a geosynthetic about 6 months prior to the Country Trail section. In February of 2011, these same areas were investigated and new photos were taken noting any changes that had occurred. The sections of Country Trail and Marvino Lane where the reinforcement geotextile was installed showed no major pavement deterioration. The asphalt showed very minor surface abrasion and nothing that would indicate a deteriorating subgrade or any loss of pavement support.

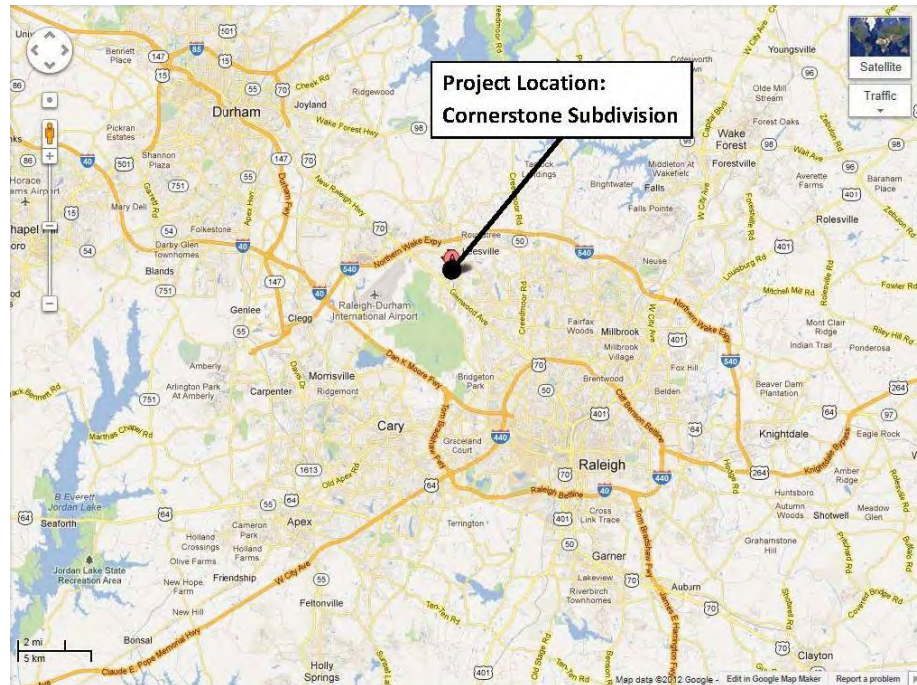

Figure 1. Project location near Raleigh, NC, USA (Google, 2012)

The Parkstone Drive area constructed without a geosynthetic had continued to deteriorate. It appeared as though a section of the pavement had been patched with a repair and areas adjacent to the repair were starting to show major signs of pavement fatigue. Another area of pavement with signs of premature deterioration was observed further into the development on Country Trail, beyond where the geotextile reinforcement was used. This part of Country Trail was constructed approximately one year after the first pavement areas that incorporated geosynthetics.

Figure 2. Pavement construction in 2003 showing placement of the woven base reinforcement geotextile.

It was also evident that the pavement sections that used the geotextile reinforcement provided a much quieter ride (less road noise) and smoother driving experience than the other pavement areas throughout the Cornerstone subdivision that did not use geosynthetics in their construction. These observations were initially considered to be significant, but were not fully understood and took some consideration to determine the appropriate analysis method(s) and their

resulting conclusions. There were some obvious difference between the geotextile reinforced pavement surfaces and the unreinforced pavement surfaces due to signs of pavement distress.

Figure 3. Conditions in 2011 on Country Trail with reinforcement geotextile and Parkstone Drive without geosynthetics.

2. ROADWAY INVESTIGATION AND EVALUATION PROGRAM

2.1 Pavement Coring Evaluation Destructive Testing on Country Trail Road: 2 Roadway Sections; 6 Cores

Six, 6 inch (150 mm) diameter pavement layer coring evaluations, including coring into the subgrade soil and to verify the existence or absence of geosynthetics in the pavement cross section, were performed by ECS Carolinas, LLP. Core testing was performed at two different locations of Country Trail Road. One location was found to have the reinforcement geotextile at the subgrade – base course interface, while the other was found to be unreinforced. A plan of the core testing locations is shown in figure 4.

A summary of the results from the coring testing report at each test location is shown in Table 1. It is evident from this testing summary that the asphalt layer thickness varied from 2 inches (50 mm) to 5 inches (125 mm) with an average of 3.4 inches (85 mm) for the unreinforced pavement areas and a uniform 2.6 inches (65 mm) for the geotextile reinforced pavement areas. Ignoring the base course thickness in the pavement repair area in coring location 1, the in-service ABC thickness varied from 4.5 inches (113 mm) to 8.5 inches (213 mm) with an average of 6.7 inches (166.7 mm) for the unreinforced pavement areas and 6.3 inches (156 mm) for the geotextile reinforced pavement areas. The unreinforced pavement areas showed much more variability in their layer thickness which is unexpected.

The pavement areas in coring locations 1 through 4 were originally constructed with no geosynthetics but coring location 1 which showed significant rutting in 2011 had a repair performed at sometime in its past, and that repair included the use of two layers of geosynthetics. This section then showed fatigue prior to the city accepting the project and the contractor had to remove and replace the failed section. The core testing shows that a light weight slit-tape woven geotextile was placed at the bottom of the repair undercut, about 22 inches (550 mm) below the pavement surface, and approximately 9 inches of compacted gravel was placed over this geotextile. Next a punched and drawn biaxial geogrid was installed and approximately 9 inches of additional compacted aggregate was placed on the geogrid. This was followed with approximately 4 inches (100 mm) of compacted hot mix asphalt (HMA). This is a repair scenario that utilizes various geosynthetic products to stabilize the gravel base aggregate represents a common repair technique used for flexible pavements constructed in the Piedmont range that show early fatigue or loose subgrade support and the results are sometimes ineffective.

Figure 4. Pavement layer core testing location on Country Trail Road in both geotextile reinforced and unreinforced pavement areas (Google 2012).

Table 1. Pavement layer summary from core testing on Country Trail Road in both geotextile reinforced and unreinforced pavement areas.

Layer Thickness (in)	Core Test Location					
	1	2	3	4	5	6
HMA	3.88	2.00	2.75	5.00	2.63	2.63
ABC	17.50	4.50	8.50	7.00	6.00	6.50
Notes	Unreinforced	Unreinforced	Unreinforced	Unreinforced	Reinforced	Reinforced
Subgrade	MH Mica	CH Mica	CH Mica	CL	ML Mica	ML Mica
Geosynthetics	Separation Geotextile at bottom of ABC				Reinforcement Geotextile	Reinforcement Geotextile
	Biaxial Geogrid at mid-gravel layer thickness					

The pavement areas in coring locations 5 and 6 were constructed with the reinforcement geotextile at the interface between the subgrade and base course as shown in Figure 2. These test locations show a good consistency between the compacted ABC thickness and HMA layers between each location. This trend of consistent layer thickness is commonly observed when flexible pavements are constructed using geotextiles. A visual summary of the layers and total thickness is shown in Figure 5.

Figure 5. Pavement layer core testing result summary on Country Trail Road in both geotextile reinforced and unreinforced pavement areas.

2.2 Ground Penetrating Radar (GPR) Nondestructive Testing: Country Trail Road

GPR was performed by ECS Carolinas, LLP on two different areas of Country Trail in an attempt to verify the existence of a clear boundary created by the geotextile within the pavement cross sections. One location was found to have the reinforcement geotextile at the subgrade – base course interface, while the other was found to be unreinforced. A plan of the GPR testing locations is shown in figure 6.

Figure 6. Pavement GPR testing locations on Country Trail Road in both geotextile reinforced (Location 1) and unreinforced (Location 2) pavement areas.

Ground Penetrating Radar (GPR) nondestructive testing is a fairly straightforward technique of emitting radio waves into a substrate and measuring the reflected, refracted or absorbed waves at a receiver at the surface of the substrate. The measurements can be used to assess the subsurface materials or layers by analyzing the time taken for signals to be reflected back to the receiver. This information can then be used to determine the depth to a reflective feature or detect the absence of reflective features below the ground.

The GPR test results were obtained using Sensors and Software, Inc, Ontario, Ca Conquest GPR unit containing a 1000 MHz antenna. The GPR scans show a cross sectional image of subsurface conditions derived from reflected energy of high frequency electromagnetic waves. Reflections of these waves occur where a variation in material properties take place. For this survey, this may include the transition from the different flexible pavement system layer such as HMA to ABC, ABC to subgrade, ABC to reinforcement geotextile and reinforcement geotextile to subgrade soils.

A review and analysis of the GPR data for Location 1 on Country Trail for the pavement areas with the reinforcement geotextile are displayed in Figure 7. The results from the GPR scans display a very clear separation of layers at the transition between the HMA and ABC layers and also depth of approximately 12 inches (300 mm) that is consistent throughout the width of the roadway. We believe this layer separation is the reinforcement geotextile located between the ABC and the subgrade soils since it coincides with the approximate total flexible pavement thickness above the subgrade elevation. We are unaware of previous GPR surveys being able to locate this boundary so clearly in the past.

The significance of this result is that it shows that the pavement layers above the subgrade have maintained their as-designed thickness over the service life of the pavement to date. Early AASHTO flexible pavement design methods accounted for the lower portion of the base course aggregate intermixing with the subgrade over time (*Special Report 73*) and reducing the structural integrity of the pavement by adding approximately 2 inches (50 mm) to the final base course layer thickness. Without any consideration for reduction of tensile forces or strains at the bottom of the base course, the simple function of separation of the base course and subgrade soils has maintained the as-designed structural integrity of these reinforced pavement areas (Lacina, 2011).

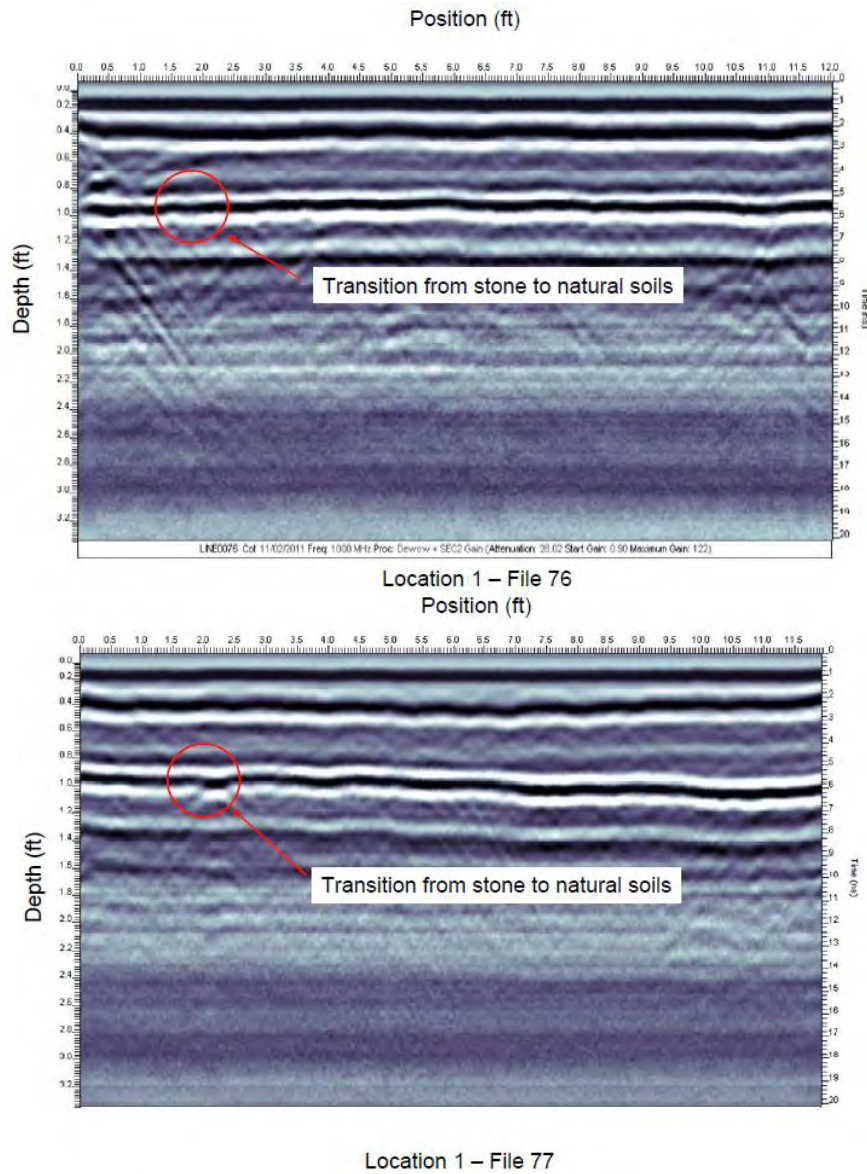

Figure 7. GPR testing image results for Location 1 on Country Trail with geotextile reinforcement.

A review and analysis of the GPR data for Location 2 on Country Trail for the pavement areas without any reinforcement geotextile shows entirely different cross sections than those in Location 1. The cross sections represented by Figure 8

show a potential separation between the ABC and subgrade soils around a depth of approximately 2.2 feet (660 mm), which transitions to a depth of approximately 12 inches (300 mm) at approximately 15 feet (4.6 m) from the curb and stays consistent along to the pavement area where the road was previously repaired.

The significance of the unclear boundary between the ABC and subgrade layers is that the current level of pavement support and structural capacity in these areas is unknown and has apparently deviated greatly from the original pavement design layer thickness. This observation is also supported by the findings of the pavement cores in test locations 2 through 4. While this GPR data supports the early AASHTO flexible pavement design recommendations to add additional base course thickness to the pavement design to compensate for aggregate loss into the subgrade over time, the actual additional thickness needed to create this compensation is unclear and would most likely be much greater than two inches.

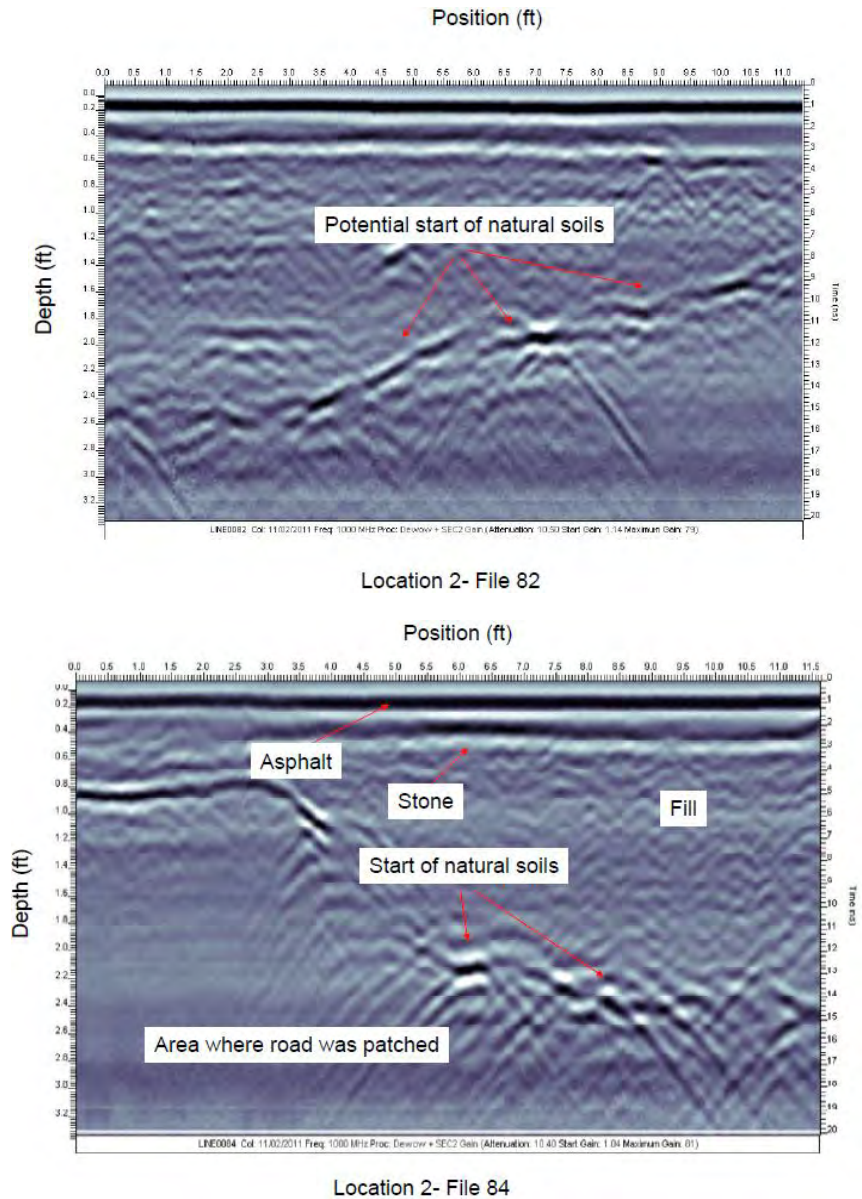

Figure 8. GPR testing image results for Location 2 on Country Trail without geotextile reinforcement.

2.3 Falling Weight Deflectometer (FWD) Nondestructive Testing: Country Trail Road and Marvino Lane

FWD tests were performed at 3 locations by TriMat Materials Testing, Inc on sections of Marvino Lane and Country Trail Road as shown in Figure 9. The presentation of testing results on Country Trail Road will be broken up into its northern

and southern portions for this FWD section of the report and in following surface roughness measurement section. The northern section of Country Trail Road was constructed without geosynthetics while the majority of the southern section was constructed using the geotextile reinforcement placed below the ABC layer.

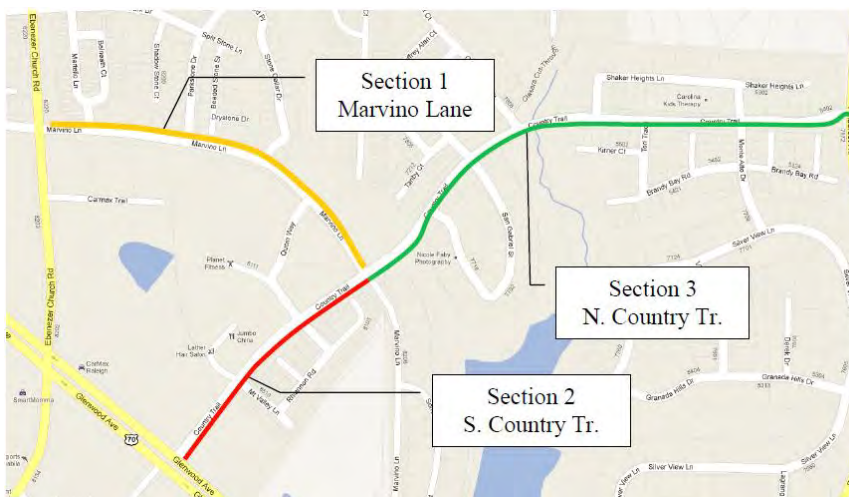

Figure 9. Falling Weight Deflectometer (FWD) nondestructive testing on Marvino Lane (Section 1); South Country Trail Road (Section 2); North Country Trail Road (Section 3).

Falling weight deflectometer (FWD) testing is a method for measuring the surface deflection of pavement surfaces and results in measurements that illustrate the deflection basin shape at the pavement surface. Deflections are measured at the center of the applied load and radially outward from the load. Deflections can be associated to pavement performance or can be used to determine the material characteristics of the in-situ pavement layers. FWD output is often presented in the form of subgrade moduli. Although layer moduli are meaningful, it can be more useful to utilize a single number as an indicator of the deflection shape.

One indicator method known as the AREA parameter characterizes the normalized area of a vertical slice taken through a deflection basin between the center of the test load, and 36 inches (0.9 m) away from the test load. Dividing the slice area by the deflection measured at the center of the test "normalizes" the AREA Parameter. The AREA is calculated using deflection measurements at 0, 12 inches (300 mm), 24 inches (600 mm) and 36 inches (0.9 m). The maximum AREA value is 36 inches and would occur when all four deflection measurements were equal, indicating that the pavement being tested would be extremely stiff (i.e. rigid pavement or thick, full-depth HMA).

The least expected AREA value is 11.1 inches (282 mm). This condition could occur only if all the pavement layers have the same elastic moduli and the pavement structure does not contribute any additional stiffness to the underlying subgrade. A low AREA value suggests that the pavement structure is not much different than the underlying subgrade material (i.e. a very stiff subgrade soil). Typical AREA values for pavements are shown in Table 2:

Table 2. AREA values for paved "Typical" roadways, North County Trail, South Country Trail and Marvino Lane.

Pavement	AREA Value (in)
Rigid	24 - 33
Thick Flexible (> 4 in, 100 mm)	21 - 30
Thin Flexible (< 4 in, 100 mm)	16 - 21
S. Country Trail, Reinforced (6,200 lb-f)	18.8
Marvino Lane, Reinforced (6,200 lb-f)	17.9
N. Country Trail, Unreinforced (6,200 lb-f)	15.3
S. Country Trail, Reinforced (8,300 lb-f)	18.9
Marvino Lane, Reinforced (8,300 lb-f)	17.5
N. Country Trail, Unreinforced (8,300 lb-f)	17.2
S. Country Trail, Reinforced (12,300 lb-f)	19.6
Marvino Lane, Reinforced (12,300 lb-f)	19.5
N. Country Trail, Unreinforced (12,300 lb-f)	17.2

As shown in Table 2 and Figure 10, the geotextile reinforced pavement areas show a higher AREA value for all three impulse loadings and this FWD testing was performed at or near the core test locations discussed in Section 2.1. All of the AREA values appear to be in the normal range for thin pavement sections and these flexible pavements have an average HMA layer thickness of = 3.2 inches (81 mm) as determined by the core testing results (Table 1). The scatter of the data points and the very low R values would indicate that the thickness of the ABC stone and pavement layer (HMA) have very little effect on the FWD deflection measurements and the AREA calculations. The core testing shows that the soil conditions encountered under the ABC layer were all similar: moist red silty-clay with trace mica. Based on the core test data, it can be assumed that the soil subgrade in all of these areas provided the same support to the overlying layers, indicating that the primary variable effecting the FWD deflection measurements is the presence of the geotextile reinforcement fabric.

Figure 10. Correlation of AREA vs. Layer Thickness.

2.4 Surface Roughness (IRI) Nondestructive Testing: Country Trail Road and Marvino Lane

Surface roughness tests were also performed at 3 different locations at the project site by TriMat Materials Testing, Inc on sections of Marvino Lane and Country Trail Road as shown in Figure 9. The profilograph used for surface roughness testing of the pavement surface was an Ames Engineering Model 8200 high speed laser profiling device and utilizes two LMI technologies Roline 3 KHz lasers. Sampling at more than 16,000 times per second, the laser profilometers are capable of creating an exact reproduction of the road surface in digital form. Combined with on board accelerometers, the lasers are capable of producing data for any known standard of ride quality.

IRI is the International Roughness Index and measures pavement smoothness. The measurement of IRI is required for data provided to the United States Federal Highway Administration, and is covered in several standards from ASTM International: ASTM E1926 - 08, ASTM E1364 - 95(2005), and others. IRI is also used to evaluate new pavement construction, to determine penalties or bonus payments based on smoothness. The lower the calculated IRI, the smoother vehicles will ride on the pavement. The higher the IRI value, the rougher the pavement will ride.

Based on the data presented in Figure 11, the mean IRI (MIRI) ride quality on the reinforced sections of South Country Trail and Marvino Lane is better than the unreinforced section of North Country Trail. It appears that the numerous water valves located in the travel lanes on Marvino Lane affect the measured ride quality, thus yielding higher MIRI values than South Country Trail. As a reference, North Carolina Department of Transportation specifies a range of acceptable IRI values of 55-70 in/mile on new construction for US routes and Interstates.

Figure 11. Mean IRI (MIRI) values for South Country Trail Road (reinforced); Marvino Lane (reinforced); and North Country Trail Road (unreinforced).

3. CONCLUSION

Flexible pavement construction was permitted by the City of Raleigh, NC over winter provided a biaxial reinforcement geosynthetic was used over the subgrade during construction. Pavement construction was made easier and proceeded faster utilizing the reinforcement geotextile. Pavement deterioration in unreinforced areas was evident early on, after only a few years in-service, which resulted in increased maintenance costs for the unreinforced pavement areas. Use of the reinforcement geotextile has increased the service life and reduced maintenance costs of the reinforced flexible pavement.

Pavement core testing showed consistent layer thickness for the HMA and ABC layers after 9 years of pavement service life in areas using the reinforcement geotextile. Core testing showed large variability in the layer thickness for HMA and ABC layers in pavement areas without geosynthetics. It also showed the presence of micaceous silt and clay subgrade soils, typical of Piedmont Geophysical Province. The stability of these unpredictable soils as subgrade material benefits greatly from the use of a reinforcement geotextile.

The GPR results from the geotextile reinforced roadway sections display a clear separation of layers at approximately 10 to 12 inches (250 – 300 mm) depth, which is consistent across the width of the roadway. The unreinforced pavement sections displayed entirely different layer thickness results and show no clear transition between the ABC and subgrade layers. They show a potential separation around a depth of approximately 2.2 feet (670 mm), which transitions to a depth of approximately 10 to 12 inches at approximately 15 feet (4.6 m) from the curb.

The FWD testing and subsequent calculated AREA values results show that the test sections constructed with the reinforcement geotextile appear to be stiffer than the unreinforced sections. The reinforced sections also appear to be performing better based on the visual evaluation as well. The use of the reinforcement geotextile has provided a stiffer roadway cross section than the comparable unreinforced pavement sections.

The average IRI measurements show that the ride quality on the reinforced section of South Country Trail is much better than the unreinforced section of North Country Trail. The average IRI measurements on the reinforced section on Marvino Lane shows a slight improvement over the unreinforced section of Country Trail and it is apparent that the measured improvement is skewed by the presence of numerous water valves in the travel lanes on Marvino Lane that can have a drastic effect on ride quality measurement. The use of the reinforcement geotextile has provided the unexpected benefits of a smoother roadway surface, which in turn improves tire rolling resistance (i.e. improved fuel economy) and improves driver comfort (i.e. improved level of service).

Flexural Behavior of Concrete Beams Reinforced with Different Types of Geogrids

F. El-Meski, Ph.D. Lecturer, Lebanese American University of Beirut, Lebanon, fme09@aub.edu.lb

M. Harajli, Prof., American University of Beirut, Lebanon, mharajli@aub.edu.lb

ABSTRACT

The objective of this study is to investigate the performance of three geogrids of different aperture shapes and properties as reinforcement in Portland cement concrete (PCC) beams. The results from this study serve as a foundation for further investigation of using geogrids as reinforcement in thin concrete overlays. The experiment comprises of four-point bending tests conducted on unreinforced PCC beams and those with one layer of geogrid-reinforcement. The flexural behavior of the unreinforced geogrid reinforced beams for the various geogrids tested are compared. Results confirm the reinforcing benefit from the geogrids as evidenced from the load-deflection response in terms of post-cracking behavior, load capacity, crack mouth opening displacement (CMOD) and failure mode. Results also reveal a correlation between the concrete strength and the mechanical properties of the geogrid.

1. INTRODUCTION

Geosynthetics had been for long used as reinforcement and stabilization elements in various earthwork construction applications^[1]. More recently, their use as reinforcement elements has expanded into pavement systems, particularly as reinforcing elements in asphalt layers^[2,3], and as interlayers in overlay applications^[4]. Little research, however, has been conducted on their use as reinforcement in PCC overlays^[5] in pavements and other elements where steel reinforcement cannot be placed.

Geogrid has longitudinal and transverse ribs, which form apertures; a new type is launched which has triangular aperture with ribs in more directions. There are three types of geogrids used for reinforcement and interlayers: uniaxial, biaxial and triaxial (

Figure 1). Uniaxial geogrids exhibit high tensile strength in their uni-directional ribs; while biaxial geogrid ribs have tensile strengths in two directions. Tests conducted on biaxial geogrids^[1] showed that it cannot provide a uniform tensile strength when subjected to tension in different directions. It is believed that this deficiency led to the development of geogrids consisting of triangular ribs.

Figure 1. Uniaxial, biaxial, and triaxial geogrids

2. RESEARCH OBJECTIVE AND SCOPE

The objective of this research is to fully understand the structural behavior of reinforced beams with geogrid materials. Understanding such behavior aids in evaluating the potential of using the geogrids as reinforcement in PCC elements such as pavement overlays and identifying critical geogrid properties that impact the reinforcement effectiveness. The structural behavior will be evaluated for normal strength concrete subjected to monotonic loading. Simply supported beam specimens reinforced with one layer of either uniaxial, biaxial or triaxial geogrids are subjected to four-point bending until failure. The structural response of each is compared to that of an unreinforced

plain concrete specimen to quantify the benefits gained from geogrid reinforcement. Aspects of the behavior evaluated include the maximum load capacity, the load deflection response, crack mouth opening, flexural strength, accumulated energy absorption and mode of failure.

3. EXPERIMENTAL PROGEAM

A total of twelve beam specimens composed of 35 MPa PCC were tested. Specimen dimensions and loading details are shown in Figure 2. Specimens have a span length of 53 cm, with a triangular groove of 8 mm wide and 4.5 mm deep in the middle of the span to induce flexural failure close to the mid-span of the beam. The beams are divided into four categories: three unreinforced plain specimens used as control, three with one layer of uniaxial geogrid, three with one layer of biaxial geogrid and three with one layer of triaxial geogrid.

Figure 2. Typical longitudinal section showing loading position and reinforcement layout

3.1 Geogrid Properties

All three rigid geogrids used consisted of geosynthetic material but different aperture geometry and dimensions, and different mechanical properties as reported by the manufacturer, and presented in Table 1. The uniaxial type is made of high density polyethylene, while the two other types are made of polypropylene.

Table 1. Physical and mechanical properties of the geogrids used

Component (Uniaxial)	Description	Unit
Aperture Size MD	220	mm
Aperture Size TD	13/20	mm
Mass Per Unit Area	400	g/m ²

3.2 Specimen Fabrication

For concrete beams reinforced with one layer, a 5-cm concrete layer was first poured and compacted in the beam mold with a vibrator (Figure 3), and then the geogrid layer was carefully installed followed by layer of concrete mixture. The mixtures were consolidated to the extent possible to ensure intermixing between the concrete layers above and below the geogrid. No separation or surface voids were observed after de-molding the specimens.

Figure 3. Placing of the geogrid layer after pouring and compacting of the 5 cm concrete layer

3.3 Loading and Measurement Instrumentation

The concrete beams were subjected to flexural testing according to ASTM C78. Monotonic loading is applied through a closed-loop 100-ton servo-hydraulic universal testing machine at a constant displacement rate of 0.002 mm/sec. A 16-bit data acquisition system was used to collect data of applied actuator load, horizontal and vertical displacement at midspan, in addition to crack mouth opening displacement throughout the test until failure.

An Epsilon Model 3541 clip-on gage with 7-mm range was used for measuring the crack mouth opening displacement (CMOD). Additionally, a spring loaded LVDT was placed horizontally on one face of the beam as an added means of measuring horizontal displacement across the notch as loading was applied. A vertical spring-loaded LVDT was fixed to the bottom of the loading plate with its tip touching the specimen's bottom face at the center adjacent to the crack. The loading and instrumentation setup can be seen in Figure 4.

Figure 4. Testing and measurement instrumentation setup

4. RESULTS AND ANALYSIS

4.1 Load versus Vertical Displacement

The load versus vertical displacement plots for plain and reinforced concrete specimens are shown for the various geogrid types in Figure 5 through Figure 7. Figure 5(a) through Figure 5(d) present plots of the load-deflection curves for all four beam categories. Curves corresponding to the three replicates of each category are plotted separately on one graph. As seen in Figure 5(a), all three replicates of unreinforced beams fail in a brittle manner once peak load is reached, at which sudden drop in the load and eventual failure of the whole beam occur. This is expected due to absence of any reinforcement. For all reinforced specimens, both concrete and the geogrids absorb the tensile stress due to bending of the beam. Once the stress in the concrete reaches its strength value, a crack initiates in the bottom concrete layer. This leads to the inability of the concrete layer to carry any more tensile load and thus the sudden drop in load that is witnessed in the load-deformation curves. Since the geogrids' tensile strength exceeds that of concrete the load is redistributed such that it is absorbed totally by the geogrids. The slope of the load-deformation curve is now lower than the initial slope since geogrids are more ductile than concrete. Once the load reaches the strength of a rib or multiple ribs, the rib is torn and that is where a sudden drop in the load-deformation curve occurs. The load is then redistributed to other ribs and so on until all ribs are torn. At that point total failure of the specimen occurs. This phenomenon can be clearly demonstrated in Figure 6 and Figure 7, where the load-deformation curves of a representative sample for each of the geogrid-reinforced beams (uniaxial, biaxial, and triaxial) are plotted.

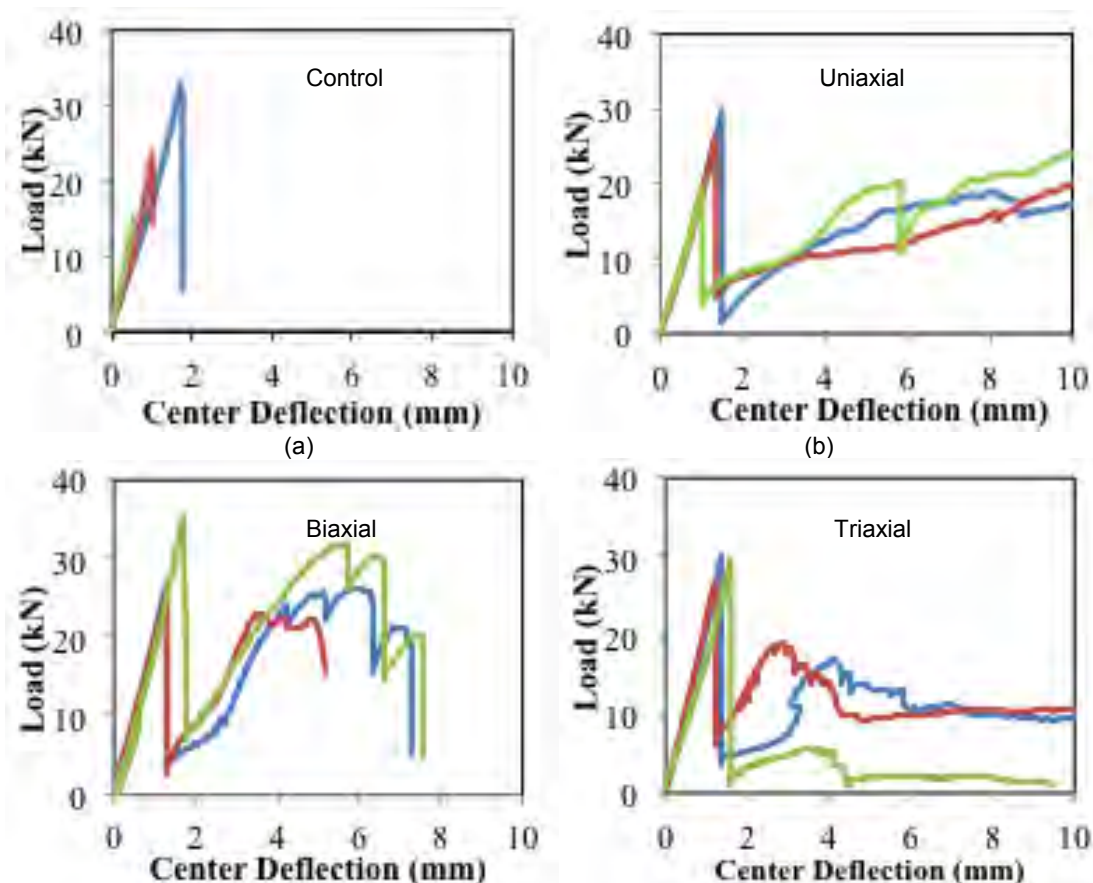

Photographs of beams during loading and after failure provide more information on the reinforcing mechanism and response of the beam under loading.

Figure 8 shows that the unreinforced beam separated into two parts directly upon failure of the concrete, while the reinforced beam remained intact as the crack initiated and cracked all the way to the top of the specimen. This is in agreement with the post-peak behavior witnessed in the load-deflection curves of reinforced beams, where load remains to be resisted after the sharp drop in load due to the concrete failure.

Figure 9 shows the extent of stretching of the uniaxial geogrid after crack opening, which explains the significant ductility observed in the load-deflection curve. **Error! Reference source not found.** reveals an excellent illustration as to why the beams reinforced with uniaxial geogrids exhibit multiple post-peaks in the load deflection curve compared to one post-peak for the biaxial and triaxial reinforced geogrids. **Error! Reference source not found.** (a) shows that failure of the geogrid occurs in the ribs, unlike the biaxial and triaxial geogrids where the failure occurs at the interface of the junction and the ribs. Hence, for the uniaxial geogrid each peak corresponds to the break of one or more ribs and hence the multiple peaks; whereas, the single peak observed for the biaxial and triaxial case corresponds to the break of the junction-rib interface.

Although all the geogrid reinforced beams had ductile post-cracking behavior, each, however, exhibited a different post-peak behavior. The beams reinforced with uniaxial geogrids exhibited the most ductility and largest load capacity. The increase in load capacity is about 30-60% compared to that of unreinforced beams, with a substantial increase in deflection ranging from 44 mm to 72 mm in compared to a deflection of 1.7mm for the unreinforced beam. The beams reinforced with biaxial geogrid showed an increase in load capacity by about 10-15% and a deformation ranging from 5 to 8 mm. On the other hand, the beams reinforced with triaxial geogrid showed an increase in load capacity by about 28% and an increase in the deflection by 10 to 20 mm.

The difference in the behavior between the three types of geogrid reinforced beam categories is attributed to the difference in the geogrids themselves, particularly: number and direction of ribs, junction characteristics, such as rigidity, width and thickness of ribs, tensile strength and stiffness, and aperture shape. For instance, the uniaxial geogrid layer in the beam consisted of seven ribs in the direction of applied tensile stress (longitudinal), with a corresponding area of 29.4 mm², the biaxial geogrid layer consisted of five ribs, resulting in an area of 17.5 mm², while the triaxial geogrid layer consisted of six ribs which resulted in an area of 14.82 mm². In addition, the junction of the uniaxial type, which is relatively rigid, was coincidentally located in the middle of the span and that might also have contributed to delaying of the rupture of the geogrid.

4.2 Load versus CMOD Curves

Although all beams were notched at the mid span to force a flexural crack, the cracks in some of the specimens occurred within the middle third of the span length. For those specimens, the CMOD measurements do not offer adequate insight into the effectiveness of the geogrids. A sample of CMOD data for beams reinforced with uniaxial geogrids and that failed at midspan is shown in **Error! Reference source not found.** After the initial cracking, a sudden drop in load is accompanied by a significant increase in CMOD. Then, as load is redistributed to the geogrids, CMOD increases gradually as ribs elongate until either sudden or gradual rupture of the ribs occur.

Figure 11. Load versus CMOD for normal strength concrete beams reinforced with uniaxial geogrid

4.3 Flexural Strength

According to ASTM C78, the flexural strength, which is expressed as Modulus of Rupture R , is calculated from the following formula:

$$R = \frac{Pl}{bd^2} \quad [1]$$

where:

P is the maximum total load measured, units in kN;
 l is the span length, 43 cm;
 b is the specimen width, 15 cm;
 d is the specimen height, 15 cm.

Based on the average values of three replicates, the geogrid reinforcement provides an increase in flexural strength to the concrete beams by approximately 10 to 30% for uniaxial geogrids, by 10 to 15% for biaxial, and by 25-30% for triaxial geogrids.

4.4 Fracture Energy

The area under the load-deflection curve represents the fracture energy of the concrete beams. All types of geogrid reinforcement in concrete beams lead to an increase in the fracture energy, mostly the uniaxial type.

5. CONCLUSIONS

Based on the findings of the above tests, the benefits from the use of geogrid as reinforcement for thin concrete sections can be summarized as follows:

- 1- It was noted the lack of bond between the concrete matrix and the geogrid material, caused the failure of concrete first followed by rupture of geogrids ribs.
- 2- All types of geogrid reinforcement provide a ductile post-cracking behavior, high fracture energy, high flexural strength, and large deflection.

- 3- It is worth noted that the geogrid properties have a great impact on the post-peak behavior of reinforced beams in flexure. Uniaxial geogrids with ribs aligned in the longitudinal direction yielded better performance in comparison to other types of geogrid.
- 4- Deeper notch should have been used to enforce the crack initiation at mid span

6. RECOMMENDATIONS

The inclusion of different types of geogrid in concrete beams subjected to flexural loading reveal significant improvement in the response. However, more parameters still need to be investigated such as: methods to improve the interlocking between geogrids and coarse aggregates in the concrete matrix, use of multiple geogrid layers, effects of junction location especially for uniaxial type, and behavior under cyclic loading.

ABSTRACT

Segmental retaining wall (SRW) units are extensively practiced as a facing column to mechanically stabilized earth wall and bridge abutment because of its many fold advantages. Mechanical connectors are mainly used to help out unit alignment and control the wall facing batter, and it has a great effect on interface shear capacity of modular blocks. This study mainly focuses on interface shear capacity of newly and locally produced modular block units with and without shear pins. In this investigation, steel and plastic bars were used in the connection systems as shear connectors. The cavities of the blocks were not filled with gravel to minimize the number of parameters that could influence the test results. Geosynthetic inclusions were also not used at the block interface because of its influence on interface shear capacity. A series of direct shear tests were executed based on the existing ASTM and National Concrete Masonry Association (NCMA) test protocols to find out the effectiveness of steel and plastic shear pins under different normal loading conditions. Test results were outlined in the form of shear force-displacement relationship to compare the frictional performance of the blocks. Shear capacity envelopes were also plotted by using Mohr-Coulomb failure criterion to find out the angle of friction for each case. Test results revealed that the presence rigid shear pins reduce the shear capacity than a purely frictional condition and flexible shear pins increase the shear capacity.

1. INTRODUCTION

Dry-stacked columns of segmental retaining wall (SRW) units as the facing for geosynthetic reinforced mechanically stabilized earth (MSE) walls have been commonly used for about 30 years (Bathurst and Simac, 1994). Segmental retaining wall units are precast masonry concrete blocks manufactured using both types of wet and dry casting processes. The use of these types of precast concrete blocks has gained popularity in Malaysia.

Due to the discrete nature of the concrete units, facing stability is an important issue in the current design guidelines (NCMA, 1997; Elias et al., 2001) and it mainly depends on interface shear and connection failures.

Two different types of shear connection systems are mainly used in segmental retaining wall constructions to develop interlocking mechanism between successive vertical courses of units. One is built-in mechanical interlock in the form of concrete shear keys or leading/trailing lips and another one is the mechanical connector consisting of pins, clips, or wedges. Mechanical connectors are mainly used to help out unit alignment and control the wall facing batter. Bathurst and Simac (1997) reported that shear connectors (mechanical) or shear keys provide additional interface shear capacity of segmental concrete units. Ali et al. (2011) reported that the rigid (steel) and flexible (plastic) shear connectors on the interface shear capacity of segmental block system infilled with gravel.

In this investigation, steel and plastic bars were used in the connection systems as shear connectors. The cavities of the blocks were not filled with gravel to minimize the number of parameters that could influence the test results. Geosynthetic inclusions were also not used at the block interface because of its influence on interface shear capacity. To find out the performance parameters, a series of full scale laboratory tests were conducted with and without steel pins (NCMA SRWU-2, 1997; ASTM D 6916-03). Shear force-shear displacement graphs were drawn to compare performance of the infilled concrete units with and without shear pins. Shear capacity envelope graphs were also plotted by using Mohr-Coulomb failure criteria under peak and service state criteria.

2. EXPERIMENTAL PROGRAM

2.1 Segmental Concrete Unit

A newly designed segmental unit system is used in this research. The innovated concrete unit is named as I-Block due to its geometrical shape (Figure 1). The I-Blocks are wet cast masonry units made from 30N/mm² concrete, which consist of one centre web and a tail/rear flange that is extended beyond the web. The rear flange is tapered to allow the blocks to form curve walls.

I-Blocks are flat interface modular concrete blocks, which can be stacked with and without shear connectors. The maximum tapered angle of the I-Block is approximately 11.3°. I-Blocks are double open-ended units and provide a larger hexagonal hollow space in conjunction with two units, and the equivalent hole dimensions are about 450 mm in length, 257 mm in average width and 300 mm in height. Thus, I-Block promotes the increment of wall face area and also minimizes the use of concrete volume. The weight of the hollow block varies approximately 41 to 42 kg. Table 1 summarizes the physical and mechanical properties of the blocks.

2.2 Mechanical Connectors

Galvanized mild steel round bars were used in the study as a rigid mechanical connector that are generally known as shear connectors. According to the hole dimensions of the segmental concrete units, 12 mm diameter bars were selected, and the bars were cut into 125 mm in length. The physical and mechanical properties of the used round steel bars are illustrated in Table 2.

Ultrahigh molecular weight polyethylene (UHMWPE) plastic bars were used in this investigation as flexible connectors because of their toughness and flexibility. UHMWPE has also highest impact strength. White color UHMWPE round bars of 13 mm diameter were used and the parent bars of 1 m in length were cut into 100 mm in length. The physical and mechanical properties of the proposed plastic bars are given in Table 3.

2.3 Test Methodology

A general test setup for interface shear tests with I-Block system is illustrated in Figure 2. According to the test protocols (NCMA SRWU-2, ASTM D 6916-03), two layers/courses of modular block units were used for interface shear tests. The bottom course consisting of two I-Blocks was placed on platform to coincide running joint with the centerline of the horizontal actuator and braced laterally against restraining plate. The back of bottom course was fixed by using a back support beam, which was bolted with platform to stop bending of bottom course during shear testing.

Surcharge/Normal load was imposed by vertical actuator only over the top block through stiff rubber mat and simulated an equivalent height of stacked blocks. The shear/horizontal load was applied against the top course and immediately above the shear interface to minimize moment loading at a constant rate of 1 mm/min of horizontal actuator (ASTM D 6916-03). A steel plate with a gum stiff rubber mat was attached to geosynthetic loading clamp (Figure 4.9) to concentrate shearing load only over the centrally installed top block. A horizontal seating load of 0.22kN was applied to the top block to ensure close fitting of the block systems and after that the load and displacement devices were set to zero (NCMA, SRWU-2). The shear displacement and load/pressure reading were continuously measured and recorded during the tests by a data logger. The data were recorded at every 10 second interval.

Tests were continued until failure of shear resistance occurred. To check the accuracy of the test executions, three identical tests were performed at different normal loading conditions. For each test, new shear pins were used. As usually, the blocks used in the tests were new and free from any visual cracks. In order to minimize the use of new blocks for repeated tests, first time tested/used blocks (free from any damage) were reused by interchanging their positions to provide undamaged interface for subsequent testing. The used blocks were interchanged according to clockwise direction started from top block.

Mohr-Coulomb failure criterion (Eq. (1)) was used to find out interface shear capacity at ultimate strength criterion.

$$V = N \tan\lambda + \alpha \quad [1]$$

3. TEST RESULTS AND DISCUSSIONS

The curves of Figures 3 to 5 illustrate the frictional behavior of the hollow block system for different surcharge (normal) pressures and different types of shear pins of different rigidities. The variation in normal stress increments among the test series was due to the manual controlling of normal pressure by using a pressure adjustment knob.

For the purely friction condition (without shear connectors), the curves illustrate the rapid increase of shear stresses at the early stage of load application. It may be happened due to frictional resistance of plain concrete surfaces. After reaching the maximum shear resistance, it heads towards almost a constant value with the mobilization of block.

Although, the curves show abrupt rise and fall of shear stresses with displacement for high normal stresses that may be resulted from frictional interlocking of irregular contact areas at block's interface. At the time laboratory testing, it was also observed that sudden fall of shear stresses happens due to insignificant spalling of flanges (front and rear) of top block at the interface.

The increasing patterns of shear stress at the beginning for test with plastic pins show almost similar patterns as described for purely frictional conditions but shear strength heading towards a higher maximum value with the lateral displacement and then decrease gradually with the mobilization of block. Although, the initial shear resistance is controlled by concrete-to-concrete surface friction, the presence of flexible shear pins provides additional shear resistance to the block interface. From the curves for plastic pins, it is seen that shear resistance drops gradually after a significant amount of displacement and heading towards purely frictional shear resistance. It occurs due to the pure shear failure of flexible connectors after certain amount of displacement.

For the tests with steel pins, the curve shows a typical saw-tooth pattern of shear stress after a small amount of displacement. Due to the presence of rigid pins (steel), shear stress increases sharply to a lower maximum value and then drops insignificantly. It was observed that the small drop of shear stress corresponded to the initiation of cracks at the running joints and/or insignificant spalling at flanges and joints. Due to progressive failure patterns of blocks, shear stress reaches the higher maximum value and then drops significantly (Figure 4).

The cracks at the running joints of blocks occurred due to stress concentration generated by steel (rigid) pins and propagate with displacement. In some cases, it was observed that both joints do not fail together due the block setup and block geometry. As a result, after failure of one joint shear resistance increase again and dropped permanently after complete failure of both joints (Figures 3 and 5). Due to the high stiffness, steel pin does not fail in shear but just bends slightly at high shear force.

The plots presented in Figure 6 illustrate the peak (ultimate) shear capacity envelopes for different types of shear connectors with different flexibilities. It is clear from the Figure 6 that the shear capacities of blocks with shear connectors are higher than those without shear connectors (purely frictional interface). Bathurst and Simac (1997) and Bathurst et al. (2008) reported the similar effects of mechanical interlocks or connectors on interface shear capacity for different type of block geometries. The initial peak capacity of block with steel pins is relatively higher at low surcharge pressures but the capacity significantly reduced at high normal stress than those with plastic pins. This happened due to rigidity and strength of steel pins that caused the concrete to break at small displacement (<6 mm) and reduced the area of contact significantly at high normal stress although rigid pins provided a higher apparent cohesion (normal stress-independent shear strength) than flexible plastic pins.

Shear pins are one type of mechanical connectors used to align the blocks and to provide additional interlocking to the wall system as well. If they are too rigid and strong it can damage the block at relatively small displacement and consequently reduce the interface shear capacity.

It can be said that shear pins especially flexible pins deliver more effective shear connection than purely frictional interfaces and even rigid pins (steel).

4. CONCLUSIONS

Mechanical shear connectors have great influence on interface shear capacity of facing units although their principle purpose to help out unit alignment and control the wall facing batter (Bathurst and Simac, 1997 and Bathurst et al., 2008). This investigation divulges that the presence of connectors influence the interface shear capacity depending on the nature of the connectors i.e. rigid or flexible. In this study, two types of shear pins (steel and plastic) were used and the effects of the rigidity of those shear pins are summarized as follows:

- Shear pins increase the interface shear capacity of facing units by providing additional interlocking between the layers of those segmental concrete blocks.
- Steel shear pins initially increase the shear strength (initial peak capacity) than purely frictional capacity of empty block system and eventually decreased the shear strength after a small displacement.
- Flexible connectors provide higher interface shear capacity. Plastic shear pins allow the full mobilization of the interface shear capacity of the block system by failing itself in clear shear.
- The segmental block system with or without plastic shear pins easily follow serviceability criterion but the system with steel pins are unable to follow that criterion because these rigid pins breaks the block before serviceability deformation (6 mm for I-Block wall).
- Although, plastic and steel pin were used as shear transferring device in this study to provide additional interlocking for the empty block system but it is seen that plastic pin provides a better and effective shear connection to the block system in respect to shear strength and serviceability criterion.

Geocells Reinforced with Geogrids is the Winning Solution for Repairing Landslides in Hawaii

Todd D. Wentworth, P.E., L.G.

ABSTRACT

Six landslides occurred on military service roads during a 40-day rain storm in 2006. Surface water runoff on the roads triggered embankment failures in clayey silt fill soils and saprolite. When the USACE advertised the design-build project, their conceptual repair only considered structural walls supported with vertical piles.

The selected design-build team determined that mechanically stabilized earth (MSE) walls could be constructed less expensively, quicker, and more safely than cast-in place walls resting on steel piles. The project saved \$1.5 million (approximately 50% of the project cost) by constructing MSE walls with cellular confinement (geocell) facing and geogrid reinforcement, instead of the conceptual design provided with the Request for Proposal (RFP) documents.

Geocells were selected as the MSE wall facing due to their light weight, ease of installation with relatively small construction equipment, tolerance to differential settlement, and cost compared with traditional pre-cast products and cast-in-place construction methods. Additionally, the green geocell facing blended into the lush tropical vegetation of the ravine.

1. INTRODUCTION

This design-build contract managed by the US Army Corp of Engineers (USACE) included repairing six landslides along two roads that contour down both sides of a ravine within the Wheeler Army Airfield, located in the middle of the island of Oahu, Hawaii. The six landslides occurred during the winter of 2006, during what was known as the "40 day rainstorm." During the storm, surface water from the runway and adjacent areas flowed down the roads and overfilled the storm drain system. Uncontrolled surface water flowed over the roads and down into the ravine below the roads causing severe erosion at the six sites as well as other locations.

The RFP documents included site plans with limited topography, cross-sections, photographs, and some limited geologic information. The requested repairs included constructing retaining walls, restoring the paved driving surface, adding guard rails, replacing and improving stormwater drainage controls, and replacing damaged electrical lines.

2. SITE CONDITIONS

The landslides appear to have been debris avalanches that developed into debris flows (Turner and Schuster, 1996). The failures occurred in road fill, existing colluvium on the slopes, and erosion into the native soils. The primary cause of the damage was due to uncontrolled surface water runoff causing severe erosion and hydraulic excavation. Each of the landslides were located where surface water flowed over the side of the road causing severe erosion in the embankment fill. The landslide scarps at all six sites were similar. The vertical scarps were 1.5 meters (m) to 3.7 m deep directly below the road. Hydraulic excavation had created steep gullies that drained to the main ravine. The bottoms of the gullies were 6 m to 12 m below the road and had accumulations of colluvium and slide debris within them. Photograph 1 shows the landslide scarp at Site 4.

Photograph 1. Landscape Scarp at Site 4.

2.1 Exploratory Methods

The RFP documents provided preliminary topography, borings drilled near two of the six landslides, laboratory test results of soils collected from the borings, photographs of each site, and a geologic cross-section of each site based on visual observations during a site reconnaissance. Four additional explorations were drilled on the road near the landslides that had not been drilled previously.

Drilling at the toe of the slopes was considered, but it was determined to be too difficult to drill below the steep landslide scarps in a safe manner. The main goal of drilling below the scarps was to determine the thickness of loose slide debris that would need to be removed. Since this could not be determined prior to construction, the volume of excavation and export, as well as the subgrade elevation of the walls would need to be determined during construction. This, however, was acceptable, since this was a design-build project.

2.2 Soil Conditions

The site vicinity is characterized by pahoehoe lava flows from the Koolau Volcano, known as the Koolau Basalt. Weathering of the Koolau Basalt has developed two soil types classified as saprolite and residual soil. Saprolite is a soil that exhibits relic structure of the basalt. Vesicles and joints may be visible due to color differences in the soil. The saprolite consists of stiff to hard clayey silt with variations in color and mottling. Residual soils are the result of a greater degree of weathering of the basalt so that the rock structures are no longer present. The soil is stiff to hard, brown and red, clayey silts. The Koolau Basalt and the saprolite and residual soils derived from it are known for high shear strengths (Sherrod et al., 2007).

The borings drilled at each site and the soils observed in the scarps documented road fill, residual soils, and saprolite derived from vesicular basalt. Geotechnical laboratory tests revealed that the residual soils and saprolite are generally high plasticity silt with moisture contents near their plastic limit. The laboratory strength tests results showed large variations, at least partially due to the difficulty of collecting and testing very stiff soils. Based on observations of exposed soils, drilling and sampling results, and laboratory testing, the soils possess high shear strengths. Figure 1 is a geologic cross-section from Site 4 that illustrates AMEC's stratigraphic interpretations, which was similar to all six sites.

Figure1. Site 4 Geologic Cross-Section.

2.3 Groundwater Conditions

Explorations were drilled during both wet weather (January and February 2010 by others) and dry weather (October 2010) and none of the borings encountered groundwater. Groundwater was not encountered during construction (December 2011 and January 2012).

3. DESIGN

Three conceptual retaining wall options were included in the RFP for restoring the roads. The first concept used a cast-in-place concrete wall supported with micropiles; the second option used micropiles, a shotcrete wall face, and a cast-in-place concrete drive slab; and the third option used drilled shafts, steel H-beams as soldier piles, and pre-cast concrete panels for lagging (Figure 2).

The selected design-build team determined that pile structures were too expensive and too difficult to construct safely near the edge of the landslide scarps. Access would have been difficult for the large equipment needed for the steel pile and concrete wall concepts. The team decided that mechanically stabilized earth (MSE) walls could be constructed less expensively, quicker, and more safely. Rock slopes and reinforced soil slopes were also considered; however, the toe of the slopes would have extended beyond allowable construction limits into wetland areas for most of the sites. A rock slope was used to restore Site 6, the smallest of the landslides, with minimal site impacts. Gabion basket gravity walls were considered, but the baskets were not readily available on the island and they would have been susceptible to corrosion in the highly humid tropical environment. Stacked geocell facing with geogrid reinforcing layers were selected for their design advantages, constructability, and availability on the island for five areas.

The proposed walls were located close to the previous edge of the road shoulder due to the construction limits and access limitations. Furthermore, due to the depth of the landslides, a large amount of temporary excavation was necessary to access the base of the wall, allow room for the geogrid reinforcements and create a safe slope for workers (Photograph 2).

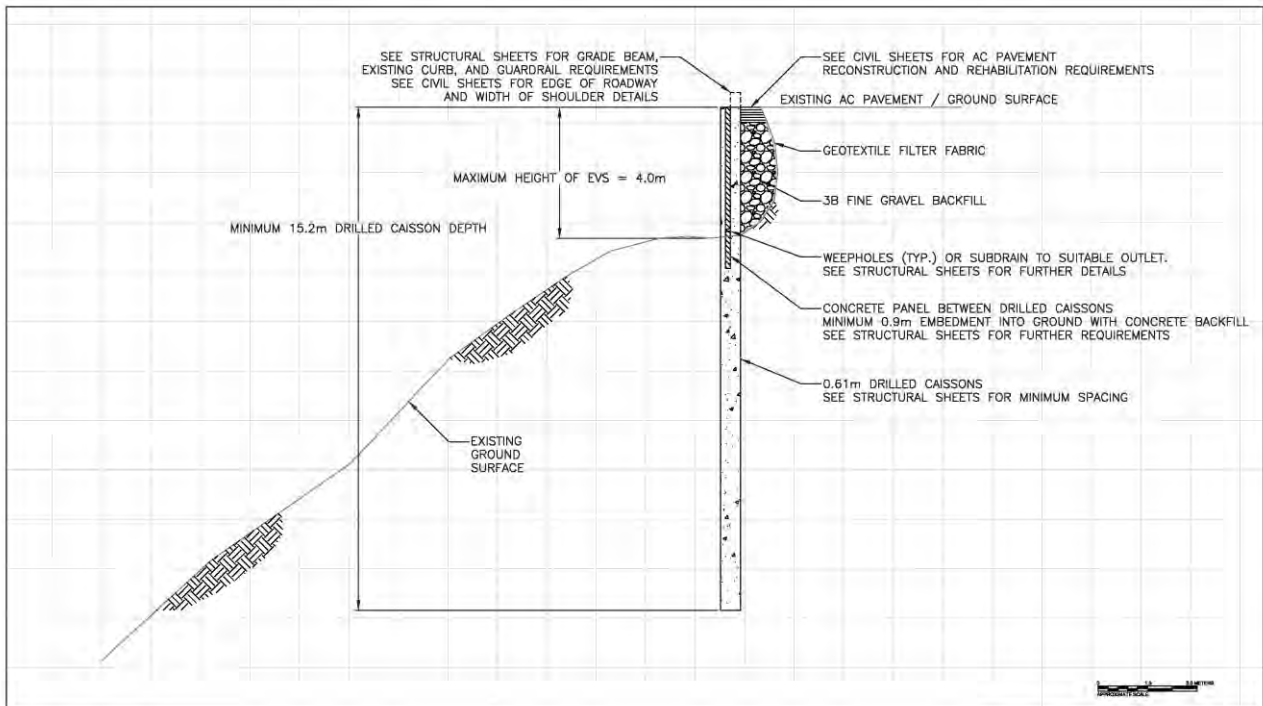

Figure 2. Conceptual Walls.

Photograph 2. Site 1 Excavation, Total Depth of 6.1 meters.

3.1 Slope Stability Analyses

The safety factors against sliding for trial failure surfaces were high for any deep-seated failures when the failed slopes were analyzed. Based on this evaluation, it appeared that the landslides that occurred at each of the six sites was the result of erosion, and there was no indication of deep-seated slope instability. This analysis gave the team confidence that the original concept of structural walls supported by piles was not necessary and an excessively costly repair given the site conditions. Our estimated values of internal friction angle, cohesion, and density for each soil layer are listed in Table 1 below. These conservative values are based on exploration information, laboratory testing, and slope stability calibration.

Table 1. Estimated Values of Internal Friction Angle, Cohesion, and Density for Each Soil Layer.

Geologic Name	Soil Type	Unit Weight (kN/m ³)	Internal Friction Angle (degrees)	Cohesion (kPa)
Fill, Colluvium and Slide Debris	Silt with gravel	16.5	28	0
Residual Soil	Highly plastic Silt	18	36	0
Saprolite	Highly plastic Silt	18	34	4.8

3.2 MSE Wall Design

Project specific external loads on the walls included a traffic live load on the road above the walls and seismic horizontal acceleration coefficient, as well as the lateral earth pressure from the retained soils. The traffic live load was modeled as an additional 0.61 m of soil (12 kPa) placed on the roadway, as specified by AASHTO (2002, 2010) and FHWA (2001) design manuals. A peak ground acceleration of 0.18g was used for the seismic stability analysis, as recommended by Hawaii Department of Transportation (HDOT, 2005). Global stability of the retaining walls determined the embedment depth of the wall and the minimum length of the geogrid reinforcement. Internal and external stability analyses determined the geogrid strength and spacing for the walls.

3.3 Wall Components

The geocells consisted of polyethylene, stabilized for ultraviolet light and corrosion, forming cells that were 27 cm long by 33 cm wide by 15 cm high when expanded. The geocells were delivered in sections 0.80 m wide by 2.6 m long. Each course of geocells were stacked with a 2.5 cm setback from the course below, to achieve a batter of 1H:6V. The geogrids consisted of polyester multifilament yarns woven in tension and finished with a PVC coating and had a long-term design strength (LTDS) of 45 kN/m. The LTDS is determined by reducing the ultimate tensile strength to account for potential material degradation. Both the geocell infill and the wall backfill material was a crushed and screened gravelly sand, meeting the HDOT 703.18 Filter Material specification (2005), which had a maximum grain size of 4 cm and less than 5 percent fines (Photograph 3).

Geogrid lengths were approximately 80 percent of the total wall height and spaced every 0.61 m (four stacked geocells), except for walls greater than 6 m tall, in which case the geogrid spacing was less for the lower portion of the wall.

The walls were embedded a minimum of 1 m into the intact soils. This embedment is deeper than typical installations due to the falling foreslope and desire to ensure global stability. The typical design cross-section (Figure 3) displays the wall components.

Photograph 3.Site 1 Backfilling.

NTS

Figure 3. Design Cross-Section.

3.4 Other Design Considerations

This paper is focused on the use of geogrid reinforced geocell retaining walls, however it should be noted that there were other design and construction tasks. Surface water drainage improvements were an important component of the project in order to reduce the risk of future erosion. The project also included repairing electrical service that had been lost due to the landslides.

4. CONSTRUCTION

The advantages of geogrid reinforced geocell walls quickly became evident during construction. The light-weight materials are easier to transport; less expensive to ship to Hawaii, and easier for laborers to carry and assemble at the wall location than typical precast blocks or cast-in-place construction. The light-weight, flexible facing tolerates settlement better than heavier, rigid facing elements. It is also very easy to adjust the facing during construction to accommodate actual site conditions and the specified wall position tolerances. Since the geocells are 15 cm high, the backfill lifts are always 15 cm thick, never more. The thin lifts ensured that sufficient compaction (95%) could be achieved with relatively small equipment.

There were several advantages over the conceptual steel pile and concrete walls including:

- All of the materials could be easily and cost effectively transported;
- No need for a drill rig and a crane, and the contractor did not need to provide access for a concrete truck. The heaviest equipment near the edge of the landslides was the bucket of the tracked excavator.
- Geosynthetics are not corrosive, which was an important consideration in a tropical environment.

- The outer edge of the geocells will eventually become vegetated blending the wall into the tropical environment. In addition, the green colored geocells initially blended in with the lush vegetation of the ravine, even without becoming vegetated (Photograph 4).

Photograph 4. Site 4 Near the End of Construction.

5. COMPARING COSTS

The engineer's cost estimate for the design-build RFP was approximately \$5 million, based on the conceptual steel pile and concrete retaining walls. The selected design-build team completed the project for approximately \$2.9 million by constructing geocell faced walls with geogrid reinforcing and drainage improvements instead of the conceptual walls presented in the RFP. Excavation costs were about \$970 per square meter of wall face, and the wall construction with imported gravel backfill was \$3,200 per square meter of wall face. These unit costs will appear high compared with typical reported construction costs for MSE walls, which is due to the following factors:

- The project was on Oahu, an isolated island with limited competition, a high cost of living, and where all supplies and equipment must be shipped ahead of time.
- The project was competed under a federal contract that required contractors to be experienced with additional procedures and reporting requirements.
- Site access constraints allowed only one wall to be constructed at a time resulting in reduced economies of scale and concurrent activity scheduling instead of simultaneous.
- The five walls were tall, ranging from 5.2 m to 7.6 m deep, but short in length. The total wall face area for each wall ranged from 49 m² to 93 m², for a total of 330 m² of wall facing.

6. CONCLUSIONS

This case history demonstrates the advantages of using geosynthetics for retaining wall components in difficult access conditions, and the advantage of the design-build contracting process. The design-build team repaired the landslides using safer, lighter, greener and less expensive materials than the original concept of steel pile supported concrete walls, saving approximately \$1.5 million in the process.

Geocells reinforced with geogrids were the winning solution for repairing the landslides at these difficult access sites.

- The lightweight materials were easy to transport to the project and were easy to carry and place in position.
- Only small, light-weight equipment was needed to construct the walls.

- The geosynthetic materials allowed for flexibility in the layout of the walls and tolerance to differential settlement.
- Geosynthetics were non-corrosive, important in tropical environments.
- The green geocell facing blended into the tropical vegetation surrounding the walls.
- The materials and construction methods allowed for a cost effective method of repairing the failed slopes.

ACKNOWLEDGEMENTS

We would like to acknowledge design-build team leader and general contractor, Hal Hays Construction, who deserves credit for selecting, bidding and constructing a different wall design than shown in the RFQ. The earthwork contractor Koga Engineering did a terrific job of constructing their first reinforced Geoweb retaining walls. Presto Geosystems were very helpful with design and construction support, and they supplied Geoweb cellular confinement system components. Last but not least, we acknowledge the rest of the AMEC Environment & Infrastructure staff who worked on this project.

ABSTRACT

Typical final cover systems can be damaged by differential settlement during postclosure, can suffer from slope veneer failures, and experience strain of the geomembrane beyond allowable yield with development of excessive landfill gas (LFG) pressure beneath geomembrane barrier layers.

Given the risks with standard final cover systems, additional design elements have been recommended for use in final cover systems. For example, use of sub-barrier layer LFG collection has been recommended by Thiel (1998) and Richardson (2000) to control LFG pressure beneath geomembranes to improve stability. Exposed geomembranes have been suggested for consideration by Koerner (2010) as a temporary final cover system until the deleterious effects of landfill differential settlement, and LFG generation with the attendant slope stability risks, have reduced in the initial postclosure period. In addition, geosynthetic material can be used in substitution for typical LFG control devices being used today.

This paper discusses a new alternate final cover system which can best be described as a geosynthetic final cover system. It consists of a sand ballast layer placed on a specialized HDPE artificial grass tufted into a double layered polypropylene woven geotextile. This assembly is deployed across a structured geomembrane that provides a sub drainage layer beneath the turf component. This hybrid Final Cover system (trade name "Closure Turf®") can provide designers with an alternative LFG collection system that can significantly reduce requirements for more costly and easily damaged vertical LFG extraction wells for energy recovery projects. In combination with two other geosynthetic based LFG collection systems, an Integrated LFG Collection System can be deployed at modern sanitary landfills with geosynthetic materials.

1. INTRODUCTION

This surficial LFG collection system can be combined with vacuum application to geosynthetic leachate collection and removal systems (LCRS), and placement of geosynthetic LFG strip collectors in the active landfill areas. These geosynthetic applications may be used in substitution for typical vertical LFG extraction well systems. The location of these applications is depicted in Figure 1. There are three general locations where geosynthetic materials could be applied as LFG collection layers:

1. A surficial collection layer beneath the geosynthetic final cover system.
2. Geosynthetic collection strips in active landfill areas.
3. Geosynthetic leachate collection and removal system (LCRS) layer at the landfill base.

Figure 1. Locations for LFG collection with geosynthetic materials

These applications are discussed below.

2. GEOSYNTHETIC FINAL COVER SYSTEM

The geosynthetic final cover system can be placed in combination with geocomposite collection strips to control LFG beneath the final cover system. This practice has been recommended by Thiel (1998) and others to reduce the negative effects on LFG pressure build-up beneath final cover geomembranes on slope stability. The concept of this system is depicted in Figure 2.

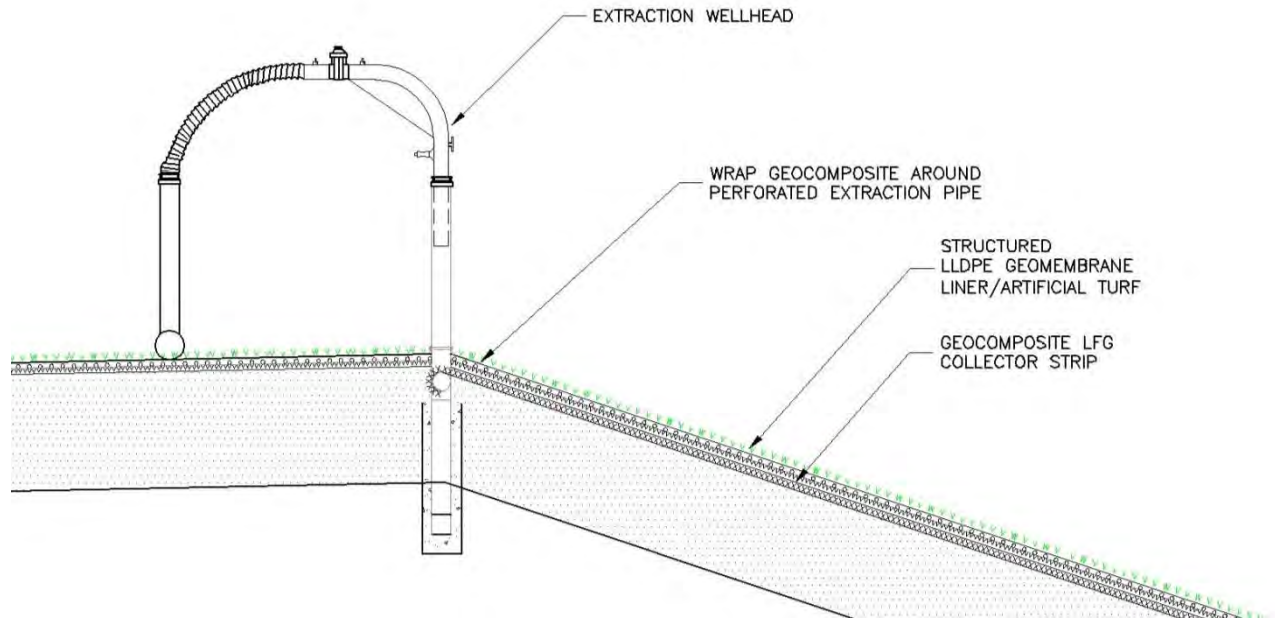

Figure 2. Surficial LFG collection beneath geosynthetic final cover system

In general, a geocomposite strip of an engineered width is placed along the length of the landfill slope. At the top of the slope, the geocomposite is connected to an extraction point - a typical LFG wellhead tapped to a perforated pipe manifold. The geocomposite is wrapped around the perforated pipe manifold and can be secured in place using a gravel backfill. The geosynthetic final cover system is then deployed over the geocomposite collector strip(s) to complete the surficial gas collection system. The configuration shown is proposed for incremental closure construction along the landfill sideslopes.

2.1 Geocomposite Collection Strip Spacing and Flow

Spacing of geocomposite collection strips can be determined based on allowable gas pressures beneath the final cover system. Using an interface shear strength accounting for gas uplift pressure (Equation 1), the allowable gas pressure ($u_{(g\text{-allow})}$) beneath the geosynthetic final cover system can be determined as 60 Pa (at $FS_{allow} = 1.5$).

$$u_{(g\text{-allow})} = h\gamma\cos\beta - \frac{FS_{allow}h\gamma\sin\beta - \alpha}{\tan\phi} \quad [1]$$

From Thiel, LFG flow to geocomposite collector strips can be estimated using Equation 2:

$$U_g x = \frac{Q_i}{A} \frac{1}{k_g t} \gamma_g Lx - \frac{x^2}{2} \quad [2]$$

Where,

- $U_{g(x)}$ = gas pressure, Pa (minimum applied vacuum in this scenario)
- Q_i = LFG flow rate, M^3/sec
- k_g = gas permeability of flow media, m/sec
- t = thickness of flow media, m
- γ_g = gas unit weight, N/m^3
- L = half distance between collection strips, m
- x = distance from collection strip, m

The LFG flow rate, Q_i , is related to the LFG generation rate and the volume of waste where gas is being generated. Q_i is estimated below.

$$Q_i = r_g(t \times L \times 1) \gamma_{\text{waste}} \quad [3]$$

Where r_g is the LFG generation rate and γ_{waste} is the unit weight of the in-place waste. Emcon (1980) estimated r_g at 7 ml/day/kg. Thiel recommended a value of 17 ml/day/kg. The variable t represents the depth of waste generating LFG to be collected by the geocomposite strip. The unit weight of waste can be taken 700 and 800 kg/m³.

The gas unit weight is essentially the combined unit weight of methane (6.54 N/m³) and carbon dioxide (17.9 N/m³). At a nominal mixture of 50/50 in a balanced extraction scenario, $\gamma_g = 12.2 \text{ N/m}^3$.

The gas permeability, k_g , of the flow media is derived from the refuse beneath the slope cover. Emcon reported an intrinsic permeability, k_s , for refuse between 13 and 20 Darcies. Intrinsic permeability is a function of the solid material structure. Gas permeability of the waste can be found by Equation 4.

$$k_g = ks(\gamma_g)/\mu_g \quad [4] \text{ (Kou)}$$

Converting to Darcies to SI units, and using a LFG dynamic viscosity, μ_g , as $1.15 \times 10^{-5} \text{ Ns/m}^2$ (Emcon), k_g can vary from $1.2 \times 10^{-5} \text{ m/sec}$ to $1.8 \times 10^{-5} \text{ m/sec}$.

The slope cover will be too variable in thickness to act as a gas relief layer with any reliability. A refuse thickness, t , of 5 meters is assumed as immediately affected by an applied vacuum from the geocomposite beneath the final cover system. Using an average landfill depth of 30 meters in sideslope areas, it can be assumed that half that depth is generating landfill gas that will be collected by the geocomposite strip before vacuum influence from an active area horizontal collector strip (Section 3), or the LCRS (Section 4 below) compete for the flow.

Substituting Equation 3 into Equation 2 and inserting the highest variable values, $U_g(x)$ every 1 meter along the collector strip can vary according to L as shown in Table 1

Table 1. Surficial LFG Collection System Pressure and Collector Spacing

Collector Strip Half-Distance L (m)	$U_g(x)$ (Pa)
5	3
10	28
15	93
20	220
25	430
30	743

Based on the estimated allowable gas pressure from Equation 1, geocomposite strips would be required every 20-30 meters for natural venting as was discussed by Thiel. For active extraction as considered here, the unit flow (per meter of strip length) towards geocomposite strips placed along a nominal 50 meter long slope spaced every 60 meters, can be calculated using Equation 3 as 71 ml/sec/m (with $r_g = 17 \text{ ml/day/kg}$, $t = 15 \text{ m}$). Or 7,080 ml/sec across the length of the strip (both sides) applying vacuum to an area of 3,000 m².

2.2 Actual Flow Conditions at an Active Landfill

In March 2011, the LFG surficial collection system described above was applied to a partial closure at an active landfill in Missouri. The partial closure area was approximately 40,490 m². The average slope (3H:1V) length in the closure area was 75 meters. A total of eight (8) 1.5-meter wide 5-mm thick single-sided geocomposite strips were placed on this slope at an average spacing of 60 meters. The strips were curled around a perforated pipe collector at the toe of the slope. The perforated pipe was connected to a typical LFG vertical well head as depicted in Figure 2. The well head delivered collected gas to a perimeter header pipe feeding an onsite flare. The lower end of LFG flow from this surficial LFG collection system was measure as of 4.1 ml/sec/m². Applied over an area of 3,000 m² as calculated above, this is equivalent to 12,250 ml/sec, or 1.7 times the estimated flow rate calculated above. Adjusting the calculation method by the actual data suggests applied vacuum from the geocomposite strip may reach as deep as 25 meters into the waste mass.

2.3 Laminar Flow within the Geocomposite Strip

As long as the Reynolds number for gas flow within the geocomposite strip is less than that for the equivalent of a pipe ($Re = 2,000$), laminar flow conditions are expected, therefore the equations above are expected to produce valid estimates. In the application at the Missouri site, the velocity for a 1.5 meter wide, 5-mm thick single-sided geocomposite (assuming very little geotextile intrusion due to the low overburden) is found from:

$$V = Q/A = 12,250/(1.5 \times .005) = 0.17 \text{ m/sec} \quad [5]$$

Reynolds number is then:

$$Re = \frac{\rho v d}{\mu} = (1.24 \text{ kg/m}^3)(0.17 \text{ m/sec})(.005 \text{ m})/(1.15 \times 10^{-5} \text{ N}\cdot\text{s/m}^2) = 92 \quad [6]$$

Use of these equations in the above scenarios is acceptable with this low of a Reynolds number.

3. HORIZONTAL COLLECTION STRIPS IN ACTIVE LANDFILL AREAS

The surficial collection system discussed above can also be expanded for use within the active landfill area to control surface emissions. Installation of horizontal LFG collection wells require landfill operations to move to another location in the landfill. The wells are excavated as trenches across the topdeck surface of the landfill. Excavation spoils and the trench itself release significant amounts of LFG exposing the construction workers and landfill operating staff to health risks that must be controlled with engineered controls and personal protective equipment. Horizontal collection wells can water in with leachate if the bottom of the trench is in contact with previous placed intermediate cover. To avoid these issues, geosynthetic collection strips could be used in lieu of vertical and horizontal LFG collection wells as shown in Figure 3.

A structured geomembrane is available for use in this application. The membrane is a 1.5 mm HDPE geomembrane with 3.3-mm studs on one side of the membrane sheet. The studs with a covering geotextile (underlying in this application) behave similar to a geocomposite collection layer. The horizontal collector strip would be placed over a completed daily refuse cell before daily or intermediate cover soil is placed. First a geotextile would be deployed to prevent fines intrusion into the drainage matrix of the structured geomembrane. The structured geomembrane would then be deployed with studs in contact with the geotextile strip to complete the horizontal collector strip. No seaming equipment would be needed. The materials would simply be rolled out by site labor crews before soil cover was placed. Site personnel would not be in contact with exposed waste as they would walk behind the rolls as they rolled them out.

This placement method would allow for the horizontal collector strip to draw LFG from the refuse lift below, out to a distance L , depending on the spacing of the strips and the refuse gas permeability. This construction technique also would reduce the potential for watering in the collector strip as percolating fluids from above lifts would be diverted to either edge of the collector strip and continue downward in contrast to fluid gathering in the gravel backfill of a horizontal collection well. No refuse excavation is required, and normal cover operations can be completed immediately after the geotextile and structured geomembrane collector strips are deployed.

Laboratory performance data for this material is typically reported only for hydraulic properties. This material has a tested hydraulic transmissivity value of $5.4 \times 10^{-3} \text{ m}^2/\text{sec}$ at an applied normal load of 250 KPa, and a flow gradient of 0.1 (applicable for a near horizontal application). The hydraulic permeability, k_w , of the material is simply the transmissivity divided by the stud height of 3.3-mm, or $k_w = 1.6 \text{ m/sec}$. The gas permeability of the structured drainage geomembrane can be found by Equation 7.

$$k_g = k_w \frac{\mu_w \gamma_g}{\mu_g \gamma_w} \quad [7]$$

With μ_w equal to $1.01 \times 10^{-3} \text{ N}\cdot\text{s/m}^2$ and γ_w at $9,797 \text{ N/m}^3$, k_g is found as 0.17 m/sec.

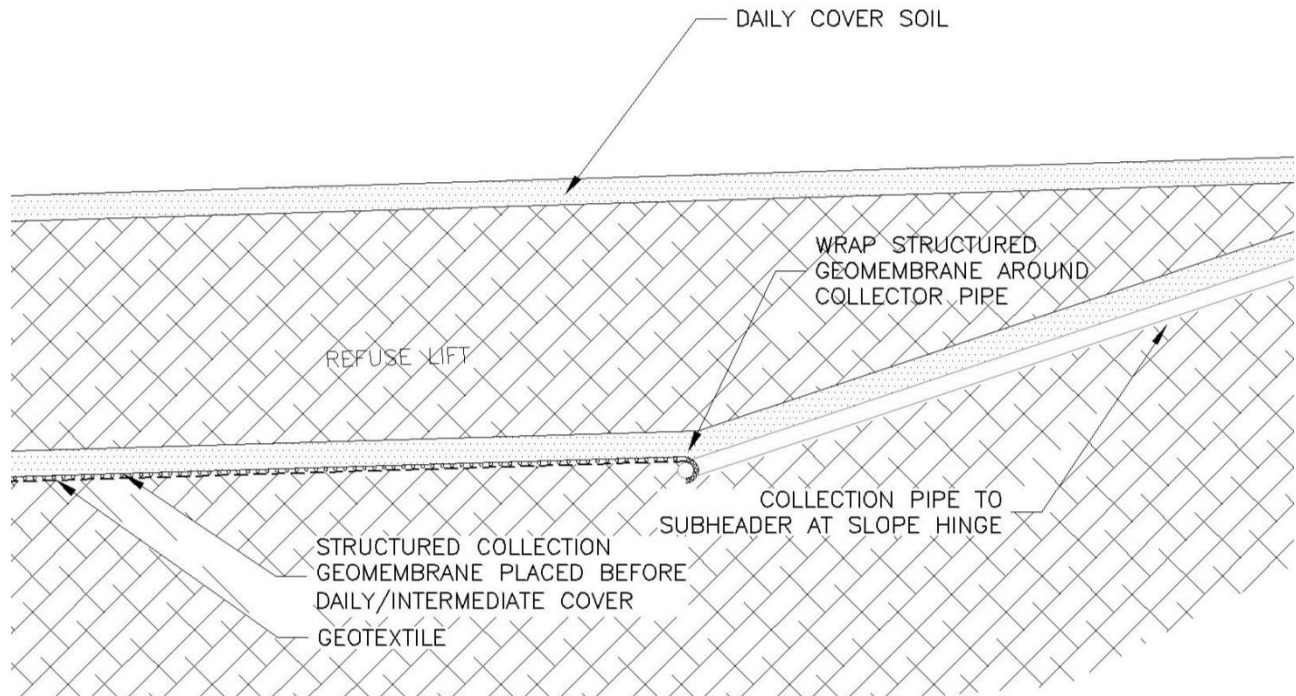

Figure 3. Conceptual Horizontal Geosynthetic Collection Strips

For flow within the refuse mass, Equation 2 is reapplied to create Table 2 for a 1.5-m wide, 90-m long horizontal structured geomembrane LFG collection strip, placed over a refuse lift 9-meters thick (t), approximately 30 meters below grade.

Table 2. Horizontal LFG Collection Strip Pressure and Collector Spacing

Collector Strip Half-Distance L (m)	Ug(x) (Pa)
5	1
10	8
15	26
20	63
25	122
30	212

The calculation in Table 2 assumed a lower intrinsic permeability in the waste mass of 13 darcies due to the much higher overburden stresses. From Equation 3, the corresponding flow in the horizontal strip collector will be 7,650 ml/sec.

3.1 Laminar Flow Conditions within the Horizontal Collector Strip

Using Equation 5 and substituting the values for this application, the flow velocity within the horizontal collector strip is found to be $v = (7,650 \text{ ml/sec}) / (1.5 \text{ m})(.0033 \text{ m}) = 1.5 \text{ m/sec}$.

Using Equation 6, the corresponding Reynolds number is 550 which is higher than the surficial collection strip discussed above. Still, this number suggests spacing between horizontal collector strips can be increased and still satisfy laminar flow requirements within the collector itself. Additionally, the collector strip could be widened to reduce flow velocity within the system, thus reducing losses due to turbulence. This geosynthetic system requires testing in an active landfill to measure actual performance against that predicted in this paper.

3.2 Horizontal Collection Strip Replacement

Horizontal collection strips will be temporary by their very nature. As succeeding lifts of waste are placed over them, additional collector strips are added in those overlying lifts reducing the importance (as well as function) of the initial

collector strip. Fortunately, the strips would be very cost effective in comparison to typical horizontal well construction. Also the topmost strip is what is required for surface emissions control. Deeper strips would have decreasing importance for this function as additional waste lifts are placed.

4. LCRS LFG EXTRACTION

Typical LCRS installations are either gravel collection layers above a primary geomembrane liner or geocomposite drainage layers replacing the gravel. A cross section of a collection trench in the LCRS is depicted in Figure 4.

Figure 4. LCRS Collection Trench

Base liner grades are typically designed using a herringbone pattern with multiple ridges and troughs directing leachate flow to the troughs. The base liner grades are typically 2% towards the trench as depicted in Figure 4. The collection troughs are sloped at a nominal grade between 0.5% and 1% to a LCRS sump where leachate is mechanically removed. The typical design distances from trough to ridge can be approximately 30 to 45 meters.

As leachate begins percolating down through the waste mass, the saturation of the operations soil layer will increase thereby impeding landfill gas migration into the LCRS system. The operations layer will not become fully saturated, however, thereby allowing some buildup of LFG pressure in the LCRS system. This pressure can cause surface emissions near LCRS clean out pipes and extreme venting of LFG when the LCRS pipes are opened for system inspection, exposing maintenance workers to hazardous gases and vapors. Pressure build-up in the LCRS can also increase the risk of LFG migration out of the landfill into the surrounding soil. Migration of LFG through the geomembrane is a much more likely scenario for landfill contaminant release than that risk posed by leachate leakage. Fortunately, LFG risk is also easier to control with active application of LFG system vacuum to the LCRS (Richgels 2000).

To avoid hydraulic blockage in the LCRS sump, LFG collection system vacuum can be applied to LCRS system cleanout pipes that are placed in the collection troughs away from the sump. The flow characteristics allow that system vacuum to quite effectively spread applied vacuum across the entire floor of the base liner. The authors are aware of at least one such application that produced an average LFG flow of $0.25 \text{ m}^3/\text{min}/\text{ha}$ with an average applied vacuum of 6.35 KPa across a 0.3 meter thick gravel LCRS. Back-calculation of Equation 3 indicates gas collection under this scenario may only be from a refuse thickness, t , of 2.7 meters versus the initial assumption of 15 meters. Given the applied vacuum, this confirms the operations soil layer has a significant degree of saturation.

Geosynthetics, being thinner, may not perform as well. Using the flow and refuse thickness variables from the gravel LCRS scenario above, we can estimate the applied vacuum coverage from the LCRS clean-out pipes into the field of a geocomposite LCRS using Equation 2. For a 5-mm geocomposite, typical transmissivity values are reported as $1 \times 10^{-4} \text{ m}^2/\text{sec}$ with a 480 KPa normal load and a gradient of 0.1. These are appropriate conditions for a base liner application. Reducing the geocomposite thickness by a factor of 0.25 to allow for compressive loss in thickness, the resulting hydraulic conductivity of the geocomposite is $2.67 \times 10^{-2} \text{ m}/\text{sec}$. Using Equation 7 again to estimate gas permeability as

2.9×10^{-3} m/sec, and then substituting into Equation 2, distance from the trough to ridge for varying pressure is shown in Table 3.

Table 3. LCRS Trough-Ridge Distance, Applied Pressure, Geocomposite Thickness

Trough-Ridge Distance L (m)	Ug(x), 5-mm Geocomposite (Pa)	Ug(x), 7.5-mm Geocomposite (Pa)
5	7,799	584
10	62,394	4,675
15	210,579	15,780
20	499,149	37,404
25	974,901	73,055
30	1,684,628	126,238
35	2,675,127	200,462

This is too restrictive in some base liner designs with greater trough-ridge distances as noted above. If a 7.5-mm geocomposite is used as the LCRS, the gas permeability increases to 1.72×10^{-2} m/sec. This improves the vacuum “reach” across the LCRS, but is still beyond typical LFG extraction system vacuum (<12,450 Pa) for typical trough-ridge distances. By reducing the refuse thickness across which vacuum is applied (Equation 3), acceptable system vacuum levels can be eventually be found for a geocomposite LCRS. This is generally 10-percent of the vacuum influence distance for a gravel LCRS, or tenths of meters. This implies significant pressure can build within the waste mass above the LCRS. Geocomposite LCRS may be more effective at providing migration control from the landfill base than actual LFG extraction. This concept needs field evaluation from landfills with geocomposite based LCRS.

5. CONCLUSIONS

In general, geosynthetic materials can be used to extract LFG from municipal waste landfills. Geocomposite collection strips placed under the synthetic final cover system have been shown to be an effective LFG extraction system. Use of structured geomembranes collection strips to control LFG movement in active areas of the landfill could provide similar LFG control in active landfill areas as horizontal collection trenches. Placement of structured geomembrane collection strips could be more easily integrated into the landfill operations than installation of excavated trenches. However, this horizontal collector strip design needs to be tested in the field to verify the design assumptions presented in this paper. Horizontal collector strips are subject to a variety of destructive forces within the active landfill. At this time, no credible estimation of a strip service life can be made without application in the field. When compared to gravel based LCRS, a geocomposite LCRS may not be effective as an active LFG extraction system. However, they should be able to provide LFG migration control from the base of the landfill. This should be confirmed with data collection from landfills with existing geocomposite LCRS.

Geosynthetic Clay Liners – Accomplishments and Disappointments - The Do's and Don'ts of GCLs.

B. Herlin. Terrafix Geosynthetic Inc., Toronto, Ontario, Canada. bherlin@terrafixgeo.com

ABSTRACT

Geosynthetic Clay Liners (GCLs) are mainly used in landfill applications, however their use extends to a wide range of applications such as ponds, lakes, canals, dams, roads, railways, waterproofing of buildings, including out of the ordinary situations. When used wisely and effectively, GCLs, have proven to be an effective alternative to other types of liners in applications beyond landfills. This paper will summarize these applications with recent case studies including specific details on when to use them with confidence and when to avoid using them based on site conditions and parameters. Not all GCLs are identical and not all can be used on specific projects. As with all types of liners, when used improperly without any attention, the consequences are enormous to the industry as a whole, however when used properly, can have the complete opposite reaction with repeated success and a complete benefit to all in the Geosynthetic industry.

1. INTRODUCTION

1.1 Landfill Caps & Base Lining with GCLs – An abundance of documented research & case studies.

Since the late 1980s, Geosynthetic Clay Liners (GCLs) have been specified and used mainly in landfill applications such as a landfill caps and/or base seals in combination with and without geomembranes (HDPE) as shown in Figures 1 and 2. The main purpose of a GCL is to reduce/limit the flow of liquid through the GCL or barrier system. The performance of GCLs in landfill applications has been well documented in research papers to outperform Compacted Clay Liners (CCLs) to the point where engineers, government agencies, and landfill owners feel secure to incorporate them in their designs.

The marked increased in Geosynthetic Clay Liners as a whole appears to have been driven by the many advantages they have over traditional construction methods and materials, ie. CCLs. GCLs present numerous advantages over CCLs. They take up less airspace (5-10mm thickness), are resistant to freeze/thaw and wet/dry cycles, can be installed quicker at substantially lower costs, transported to site at a lower carbon footprint than CCLs, they reduce on site QA/QC, improved possibilities of steeper slope applications, and offer equivalent or better hydraulic characteristics depending upon the thickness and quality of the CCL being replaced.

Figure 1. GCL being used in a landfill cap application.

Figure 2. Landfill Base Liner (HDPE over GCL). GCL being used in a composite liner design used in lieu of a CCL component.

1.2 Available GCLs – Numerous GCLs are available – Specific projects require a specific GCL.

There are many types of GCLs available on the market. Not all are identical and everyone is unique to a specific application. Using a particular GCL may work well in one application, however the same GCL may have detrimental results when used in another application, ie. a complete debacle. The many types of GCLs are: stitched, glued, needlepunched, different bentonite content, different geotextile weight, scrim-reinforced, non scrim-reinforced, with thin geomembranes, enhanced polymer, etc. The list is long. Unfortunately over the years and through increased

competition, this area of Geosynthetics Engineering seem to see lower cost GCLs requested for projects. This usually means thinner textiles and/or less bentonite, almost to the point of becoming less a GCL than a double-layered textile. A design engineer should never use tradenames when specifying GCLs. Tradenames change over time and so do the actual properties and values attached to a specific tradename. An engineer should always provide a table of physical properties when requesting a particular GCL which includes basic information as shown in Figure 3.

Geotextile Properties	Test Method	Minimum Test Frequency	Value - SI -
Cap Fabric Mass/Unit Area	ASTM D 5261	1/20,000 sq. m	X g / m ² MARV Usually non-woven
Bottom Fabric Mass/Unit Area	ASTM D 5261	1/20,000 sq. m	X g / m ² MARV Woven or Non-woven or Scrim Non-woven With or without an added coating and/or thin liner.
Bentonite Properties			
Swell Index	ASTM D 5890	50,000 kg	X ml / X g min. Usually 24 ml min & 2 g
Moisture Content	ASTM D 4643	50,000 kg	X % max. Oven dried measurement
Fluid Loss	ASTM D 5891	50,000 kg	X ml max. Usually 18 ml
Finished GCL Properties			
Bentonite Mass Per Unit Area	ASTM D 5993	1/4,000 sq. m	X kg / m ² MARV
Grab Strength	ASTM D 4632	1/4,000 sq. m	X N MARV
Peel Strength	ASTM D 6768	1/4,000 sq. m	X kN/m MARV
	ASTM D 4632		X N min
Permeability	ASTM D 6496	1/10,000 sq. m	X N/m min
	ASTM D 5084		X cm/sec max
Index Flux	ASTM D 5887	1/Week	X m ³ /m ² /sec Max
Internal Shear Strength	ASTM D 6243	Periodic	X kPa Typical

Figure 3. Example of physical properties to list when requesting a GCL, ie. do not use tradenames.

One should never use a top fabric in a GCL to be less than 200 g/sqm, unfortunately as mentioned above, market forces with competition, GCLs with thinner and thinner top fabric weights are specified and used. The bottom fabric of a GCL should always contain a woven (scrim) fabric for numerous reasons (ie. avoid internal erosion, avoid shrinkage of the GCL in a double composite system). The amount of bentonite added to a GCL should not be lower than a certain amount (Maubeuge – Nuremberg 2002) yet from time to time one does see specified requested amount of 0.5 lbs/sqft which seems to be playing with fire. The swell index of a bentonite in a GCL should be above 24ml (min) while the fluid loss test should not exceed 18ml. As far as Peel and Grab Strength values of a GCL, these values can have a wide range depending on what is trying to be achieved in a project, ie. type of application, type of GCL required. Of course, one can never assume what is being requested on a project, is what is being supplied on a project, hence third party testing using samples from the site should be done by a project engineer. Numerous testing labs are available in this regard, however one must use a testing lab with Geosynthetic experience and knowledge of Geosynthetics.

2. GEOSYNTHETIC CLAY LINERS – USED IN PROJECTS BEYOND LANDFILLS

When using a GCL in a landfill application such as a base seal, one doesn't see visually if the liner is working or not. Research papers and data results over the last three decades have told us that GCLs work like a charm in landfill base seals with a High Density Polyethylene (HDPE) membrane, easily outperforming CCLs. However the research data beyond landfill applications is negligible. We do find some GCL related papers beyond landfills, however most of these are case study related papers. Case study papers are beneficial to the industry and most of the background to justify using a GCL in applications beyond landfills are based on findings done on landfill related research of

GCLs. For example, Scrim-Reinforced GCLs vs Non Scrim-Reinforced GCLs. Research done on Scrim-Reinforced GCLs vs Non Scrim-Reinforced GCLs has provided us information on the highest hydraulic head pressure that can be applied over these GCLs based on a certain subgrade below a GCL (Rowe and Orsini, 2002). A Scrim-Reinforced GCL can handle far greater hydraulic head pressures than a GCL which is not Scrim-Reinforced, ie. lacking a woven fabric (Scrim=woven; Scrim-Reinforced NonWoven = woven + nonwoven; Scrim-Reinforcement = needlepunching of a woven and nonwoven geotextile together).

All needlepunched GCLs have a nonwoven top geotextile. The bottom geotextile geotextile is either a required woven on its own and/or a scrim-nonwoven geotextile and/or a non scrim-reinforced geotextile. The thickness of the geotextiles in a GCL depend on the subgrade conditions and the application such as steep slope applications. The Geosynthetic Research Institute (GRI) recommends that the bottom geotextile of a GCL contain a scrim-reinforced nonwoven geotextile. Possible failures that may occur by not using a scrim-reinforced bottom geotextile are internal erosion of the bentonite through the geotextile in hydraulic head conditions as mentioned above, and possible shrinkage of the GCL itself in a composite lining system (GRI White paper, 2005). As per the GRI's White Paper of April 2005, do not use GCLs with needlepunched nowoven geotextiles on both sides of a GCL unless one of the geotextiles is scrim-reinforced. There are numerous possibilities in this regard, but all should have a woven component embedded within, or bonded to, the nonwoven component.

2.1 GCLs in Pond Applications – Storm Water Management Ponds to Golf Course Ponds.

This is an application where you know if it works or doesn't work. With any type of liner, your liner is only as good as the subgrade it's lying on. Pond lining applications require a hard subgrade for the liner to be resting on. If the General Contractor is unable to supply a hard subgrade, walk away until something solid is provided for the liner. Every GCL manufacturer has numerous types of GCL available on the market. Pond applications, as shown in Figures 4 and 5, require an onsite decision to be made once the pond cavity is done, once the subgrade conditions are seen, then the GCL selection is made. Local project engineers who know the subgrade conditions can make a decision well ahead of the project start. Standard regular GCLs such a top fabric nonwoven and bottom woven fabric for pond applications should be avoided unless the subgrade is a silty clay. A subgrade rough in nature such as a gravel base, a scrim-reinforced GCL should be used with the scrim-nonwoven fabric side of the GCL facing down to avoid internal erosion of the bentonite. Should the subgrade contain sand, a coated GCL or GCL containing a thin geomembrane should be used. Geosynthetic Clay Liners are an excellent liner choice for ponds larger than 2,000 sqm. A GCL should not be used for ponds less than 2,000 sqm. Ponds smaller than 2,000 sqm have sharp turns which a GCL is unable to perform. Another factor to avoid lining small ponds with a GCL is that the cover soil thickness of one feet over the GCL is hard to achieve and maintain.

Any General Contractor can install a GCL in a Storm Water Management (SWM) Pond. SWM Ponds are normally larger than 2,000 sqm. GCLs are easy to install and only require minimal start up assistance for the General Contractor. Lining a Golf Course Pond is a different matter entirely. A specialized GCL installer should be used for these types of applications. Golf Course Ponds tend to have awkward shapes like the boot of Italy, they contain pipe penetrations which SWM Ponds normally don't, and they require an aesthetic cover soil thickness over the liner. Using a GCL in pond applications is a lucrative market, however as mentioned, requires more attention up front with the subgrade conditions for the liner, on site assistance, and should allows have supervision during the cover soil placement. Most project engineers like to attend a lining project during the liner deployment, however they should also remain on site during the cover soil placement. Unfortunately, most of them stay in the trailer or are nowhere to be on seen on their own project. Most lining damages are caused during the cover soil placement.

Overlap of the GCL sheets/panels are normally recommended to be one feet (30cm). Over hard subgrade, which should always be provided. However if there's any doubt in the strength of the subgrade, the overlap should be increased to a more respectable value. GCLs are a great liner selection for winter installations. Most cavity holes done for SWM Ponds and/or other ponds have a high water table to deal with. In some cases, project engineers will use a dewatering system around the cavity. In situations where stubborn water (approx. 30cm) remains at the bottom of the cavity, the GCL overlap should be increased to at least three feet (90cm) to compensate for the soft subgrade which may exist below the water level. During winter installation work, stubborn water may exist as ice and the same should be done in these cases; Either remove the ice to an acceptable level or if the ice is at approximately 30cm from the subgrade then the ice can remain in place and the GCL installed with a greater overlap, ie. 90cm.

Figure 4. GCL being deployed for a SWM Pond in winter conditions. Note the ice (30cm thickness), ie. stubborn water (water table). Overlap increased from 30cm to 90cm over the ice.

Figure 5. Placement of the cover soil for any lining projects should always be supervised.

2.2 GCLs in the Mining Industry.

Beyond Municipal Landfills and Ponds, another attractive market for GCLs is the Mining Industry, as shown in Figures 6 and 7. Mostly used in capping applications, GCLs main advantage in this sector is the ease of installation they offer for local general contractors. Most mine sites are located in remote areas far from populated centres and of course specialized trades. Whereas other types of liners require specialized contractors, a GCL can be deployed using local labourers. Other advantages include the rate of deployment and the capability to deploy during winter months. Although the rate of deployment of a GCL can reach high deployment rates, the deployment is restricted by the cover soil placement over the GCL. One can deploy a GCL with specialized deployment techniques, however the need for a specialized machine to deploy a GCL is restricted to the fact that a GCL deployed during a construction day should be covered in that same construction day. Deployment of a GCL can simply be done with a spreader bar by a local contractor. Deployment rates with a simple maintenance free bar are normally between 10,000 sqm to 20,000 sqm in flat conditions during an eight hour work shift. Deployments rates can reach up to 30,000 sqm if the general contractor starts his/her cover soil placement immediately behind the GCL deployment crew.

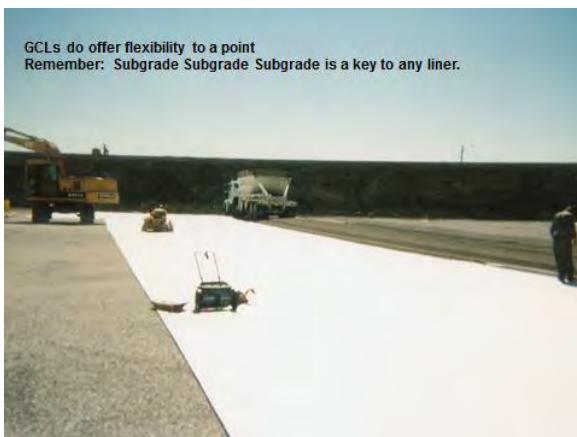

Figure 6. Note Belly dump trucks being used over the GCL for cover soil placement. Dry bentonite manufactured GCL, hard subgrade (no rutting), no sharp turns done by the truck (Mining industry).

Figure 7. GCL being deployed in a dam lining application (Mining industry).

2.3 GCLs in the Waterproofing industry.

GCLs are used extensively in the concrete industry for waterproofing lining applications, as shown in Figures 8 and 9. This type of application requires both the technical expertise at the design level as well as a specialized contractor. Whereas most GCL installation applications do not require any installation experience, this is one application sector that truly needs an experienced contractor. Connection details are paramount to this sector.

Figure 8. GCL used as a component in a waterproofing lining system for a new condominium building.

Figure 9. Concrete being poured over a GCL for a new concrete clarifier (Farming industry).

Figure 10. GCL being deployed inside a new production plant facility – lining underneath new machinery – Liquid Spills from equipment above (machine/equipment not shown).

Figure 11. GCL being used to line underneath a highway – groundwater protection against road salt – GCL containing a polymer.

Figure 12. Can you use a GCL in this application? Every project engineer has his/her needs. GCL being deployed in a SWM Pond containing a high water level. Bizarre situation but required by project engineer who had wanted a liner without dewatering the site.

Figure 13. GCL being used instead of a PVC liner under Storm Chambers due to winter temperatures.

2.4 GCLs in bizarre situations.

Every engineer has his/her projects which requires a solution to a bizarre situation, as shown in Figures 10 thru 13. Can a GCL work in this situation? Sometimes the answer is, I don't know? Can't see why it can't! In these situations, the project engineer or the designer in question has an extensive experience with prior applications with a GCL and/or other types of liners. As shown in Figure 10, the engineer may require a liner below the concrete surface of a new factory to prevent any potential leaks going through the concrete (cracks/expansion joints in the concrete) into the subgrade soil to prevent soil contamination. Figure 12 as you can see requires an excavator operator to wear a cowboy hat in this application. On a serious note, this application was a fast track project where the SWM pond required a liner as requested by local authorities. The SWM pond was required to be in place prior to winter arriving and the official opening date of a regional train service (train station parking lot). For these applications, an experienced lining contractor and an experienced crew is required to perform projects listed as "Can it be done?". Underwater applications with GCLs have been done in the past with success and of course flexibility to the standard guidelines must be altered to accommodate the project at task, ie. greater overlap of the GCL sheets/panels.

3. DON'TS OF GCLS – WHAT ON EARTH WERE THEY THINKING?!

Over the last decade being involved with Geosynthetic Clay Liners (GCLs) not one construction season goes by where I do say to myself "What on Earth were they thinking?!", it's a geotextile (don't leave exposed to the sun), it's clay (loves to crack when dried out), "where's the cover soil?". My favourite is the GCL left exposed without cover soil for weeks and/or months and either the GC or project engineer and/or someone deployed the GCL and called it "project done" without providing a cover soil over the GCL. As mentioned, a GCL is after all a product made of a geotextile and a clay both of which don't like the sun, and one of which needs a confining stress for it to do its function as a liner. Now either the GC and/or project engineer wasn't told to apply a cover soil or not, which hence could be the fault of the manufacturer and/or the distributor for not mentioning this point, but still, it still leaves me in shock to hear "your liner doesn't work". All liners work if done properly, however a GCL liner does need a cover soil, and for one to leave out the final instruction procedure of adding a cover soil is hard to stomach until everyone involved in the project comes to the fact that someone must take the fall for their errors. Alas the damage has been done and hence begins the game that a GCL does not work.

Figure 14. The GCL isn't working. No cover soil ! GCL left exposed for weeks/months. Incredible ! Last item in procedure, "place cover", not done.

Figure 15. GC leaving the site once the GCL has been deployed. No cover soil.

4. SUMMARY AND CONCLUSION

Based on over 20 years of production and application experience with needle-punched Geosynthetic Clay Liners (GCLs), numerous laboratory studies and case histories have shown the excellent performance capable with natural sodium bentonite GCLs. GCLs have shown to work quite effectively in numerous projects with success. The research done on GCLs is fairly extensive: hydraulic conductivity, effect of GCL structure on bulk void ratio, mine waste waters testing, hydrocarbon testing, freeze-thaw, hydration rate, internal erosion, shrinkage, desiccation, peel strength, diffusion, estimated service life, CCL vs GCL. If an engineer has a question, there's no doubt that the research has already been done on a GCL. For all the research done on GCLs, the true advantage of a GCL is the ease of deployment, which does not require any experience. However as mentioned, attention to the cover soil placement over a GCL is far more important than the actual deployment of the GCL itself and of course, your GCL is only as good as the subgrade it's resting on, ie. hard vs soft subgrade. Failure to understand the limitations of a

GCL based on previous research papers can lead to detrimental consequences. When used appropriately, GCLs offer an economical cost advantage to other liners.

ACKNOWLEDGEMENTS

The author would like to acknowledge first and foremost Mr. Kent von Maubeuge who in 2001 provided all the bells and whistles including all the warnings signs on the 5 Ws (What, Where, Why, When, Who) on Geosynthetic Clay Liner including how connections are made in this industry (the Skoda connection).

Geosynthetic Opportunities Associated With Shale Gas Extraction

R. M. Koerner, Ph.D., P.E., NAE., Geosynthetic Institute, USA, robert.koerner@coe.drexel.edu
G. R. Koerner, Ph.D., P.E., CQA, Geosynthetic Institute, USA, gkoerner@dca.net

ABSTRACT

While natural gas contained within shale rock is geologic by its very nature, the practice of its removal by horizontal drilling coupled with hydrofracing is quite recent. Indeed, these dual technologies are making possible the recovery of huge amounts of natural gas. So much so that one can envision natural gas as an energy source rivaling oil, coal and nuclear, while dwarfing all of the renewables combined. The potential in this regard is awesome particularly since it is worldwide in its availability and opportunities.

This white paper briefly describes shale gas drilling and extraction operations, along with its associated environmental concerns. Using this as a background, the paper then describes and illustrates many geosynthetic materials opportunities that exist in order to make the overall operations more efficient, economical, and environmentally acceptable.

1. SHALE GAS PLAYS

Shale is a fine-grained sedimentary rock which is formed by heat and pressure over geologic time. Many formations contain organic materials (they are then called *oil shales*), which upon decay, generates natural gas within the rock itself. The liberation, capture and transmission of this gas is at the heart of the technology. It should be mentioned that natural gas has traditionally accompanied oil drilling operations and has historically been a nuisance to oil drillers.

Shale gas plays are both nationwide and worldwide in their occurrence, e.g., see Figure 1 in which the data is in units of trillions of cubic meters. In the U.S., there is activity in many states as Figure 2 indicates. Of the locations shown, the Barnett formation in the Fort Worth basin is very significant since it was the first large-scale operation using these newer drilling and extraction technologies. By 2004, it had been explored by 15,000 deep wells, over 4000 in 2007 alone, and had produced 1.4 trillion cubic feet; TCF (0.04 trillion cubic meters, TCM) of natural gas in 2008. It appears as though horizontal drilling at great depths coupled with hydraulic fracturing was perfected in the Barnett shale of Texas.

Figure 1. Worldwide conventional and shale gas reserves (The Economist, August 6, 2011).

Figure 2. United States shale gas plays (compl. Wikipedia).

The most recent major gas play is in the Marcellus formation underlying major parts of Pennsylvania, New York, Ohio and West Virginia.

Financial incentives are enormous. For example, Professor Timothy Considine of the University of Wyoming estimates that a *typical Marcellus well* generates \$2.8 M in direct economic benefits, another \$1.5 M from workers and landowners, and \$2.0 M in federal, state and local taxes. This type of financial incentive is, of course, reflected in the present activity associated with shale gas extraction, transportation and eventual usage as an energy source.

2. REGULATIONS AND ENVIRONMENTAL CONCERNS

The U.S. Energy Policy Act of 2005 was, and is, the foremost federal regulatory act governing shale gas plays of the type described in this white paper. Two aspects of this legislation have attracted considerable scrutiny;

- hydrofracking was exempted from the Safe Drinking Water Act, and
- chemical additives to the water used for fracing were exempted from disclosure.

To gain some perspective in this regard a chemical analysis of the flowback fracwater (at a specific site) is of interest, see Table 1. Note should be made of the highlighted alkaline minerals which results in an extremely brackish liquid about five-times the salinity of sea water. Also to be noted is the number of heavy metals, although the quantities are felt to be relatively low.

Table 1. Chemical analysis of flowback water at a site near Williamsport, Pennsylvania (compl. CETCO).

Na, mg/Kg	25,930	Mg, mg/Kg	725	Ag, mg/Kg	12
K, mg/Kg	137	CL, mg/Kg	60,769	Au, mg/Kg	23
Ca, mg/Kg	6,896	HCO ₃ , mg/Kg	275	Ba, mg/Kg	5,145
Fe, mg/Kg	39	Hg, mg/L	<0.001	Cd, mg/Kg	0.12
Cr, mg/Kg	0.28	Pb, mg/Kg	0.80	Se, mg/Kg	1.4
Zn, mg/Kg	33	Cu, mg/Kg	1.6	TSS, mg/L	1.1

It should be noted that pending federal legislation, the so-called Frac Act of 2009, will require disclosure of fracking chemicals and place the entire process under U.S. Environmental Protection Agency regulations.

At the state-level in Pennsylvania, shale gas operations are regulated under various departments, for example;

- drilling via the state Oil & Gas Division,
- fracking water via the state Field & Stream Division, and
- waste disposal via the state Solid Waste Division.

In keeping with an emotionally-charged technology, such as natural gas plays, there are many environmental issues that have been raised by various concerned organizations, such as, federal, state and local regulatory groups, local water authorities, various industry groups, concerned citizens groups, etc. Some (but clearly not all) are mentioned below and have been selected because of the positive potential of using geosynthetic materials to solve, or at least mitigate, the issues listed:

- Containment and storage of large quantities of surface water for drilling and fracturing purposes.
- Storage and reuse of flow-back water from the hydrofracking process.
- Proper disposal of the “cuttings” from drilling operations (ca. 1000 tons per well).
- Drill pad site contamination (each being typically 3-5 acres in size).
- Frac-tank and storage area contamination.
- Access roads, parking and staging areas, and maintenance thereof.
- Minimizing site disturbance and providing level staging and working areas.
- Soil erosion and temporary containment so as to avoid stream and property contamination.

In order to appreciate some of these environmental issues it is helpful to view a composite drilling operation as well as the enormity of the drilling wells themselves, see Figures 3a and 3b.

Furthermore, some knowledge of the actual drilling operations are significant insofar as site development and maintenance. For example, a typical well site usually contains a number of vertical wells (3 to 6) which have horizontal branches going in different directions. Also, each well is generally hydraulically fractured several times. This iterative process depends upon the diminishing gas yield over time. Lastly, it is anticipated that a well pad should have a usable lifetime of approximately 20 to 30 years.

Furthermore, the following generalized goals with these shale gas extraction plays are interesting to keep in mind as we now go into geosynthetic opportunities and solutions;

- the drilling operations are large construction projects with considerable public and regulatory scrutiny,
- once permitted, fast mobilization and deployment is necessary,
- a “low profile” is advantageous particularly with minimization of truck traffic, and
- benefit/cost is always important but maximum benefit often outweighs minimum cost.

Figure 3. Site operations at natural gas plays (compl. Wikipedia).

3. GEOSYNTHETIC OPPORTUNITIES

This section describes some of the many geosynthetic solutions that can be applied to shale gas plays. The section is subdivided according to (i) the drilling operations themselves, (ii) opportunities at permanent locations, and (iii) opportunities at temporary locations.

3.1 Geosynthetics Associated with Drilling Operations

The first, and quite obvious, opportunity is the use of geomembranes for fresh water containment and subsequent use in the well drilling operations. The design stages are well known and consist of the following sequential steps:

- geometry (length, width, depth)
- cross section materials
- geomembrane type
- geomembrane thickness
- subgrade soil stability
- cover soil stability
- runout and anchor trench details

Perhaps the most overlooked design detail is the requirement of providing an underdrain system beneath the geomembrane. Shown in Figure 6 are the all-to-common “whales” lifting up the geomembrane via rising gases within the underlying soil subgrade. Various underdrain solutions that should be considered are the following:

- thick needlepunched nonwoven geotextiles
- drainage geocomposites (complete or strips)
- interconnected perforated pipe system
- geotextiles with small perforated pipes
- sand bedding layer (with pipe network)

The second, and also obvious, opportunity is the containment and re-use of the flow back water which was characterized in Table 1 and is seen to be quite contaminated. Presently, this water is generally being held in mobile holding tanks but geomembrane lined ponds or even underground storage systems offer attractive alternatives. Underground storage systems that are typically used for storm water runoff from industrial and private development sites. Both strategies should be considered in contrast to hundreds of holding tanks interconnected to one another.

A third opportunity for geosynthetics is the containment of cuttings from the drilling operation itself insofar as proper safe and secure disposal is concerned. In this regard, it should be mentioned that each well produces about 1000 tons (\approx 75 truckloads) of contaminated cuttings.

These cuttings can, of course, go to a licensed public or private landfill but alternatively can be placed in geotextile tubes at the site and can even have a decontaminant added such that the treated effluent can be released to the environment. The addition of charcoal, activated carbon, phosphoric rock, or organoclays is necessary and all are within decontamination technology that is associated with geotextile tubes.

3.2 Opportunities at Permanent Locations

Of first priority in this category are the roadways into and out of the drilling site which are necessary for the 20 to 30 years lifetime of the operations. Geotextiles and geogrids have been shown to save from 10 to 50% of the crushed stone thickness of base courses placed on soil subgrades. The functions of separation, stabilization and/or replacement are clearly indicated in the literature since this application has been ongoing for about 30-years. Not only is there a savings in stone base material, the distance from the quarry is significant in the total cost of the application.

A second way of reducing crushed stone thickness there is considerable economy offered by using geocells. They are filled with gravel, sand or locally available soil and their design (which uses a geotextile beneath them) is well established. Thicknesses saved are from 50 to 100% over the use of gravel by itself.

Thirdly, these same geocells in a less-thick format are ideal for parking and staging areas located adjacent to the drill pad.

Fourth, locally available soils (even silts and clays) can be meaningfully strengthened by the addition of discrete fibers or microgrids. Both types lead to major increases in shear strength in the upper 4 to 12 inches (100 to 300 mm) of surface. The technology is well advanced and mature at this point in time.

Fifth, the drill pad site along with adjacent parking and staging areas must be level. To accomplish this in hilly terrain (as is typical in the Marcellus shale area) one needs to create stable soil slopes or even vertical walls. The concept of mechanically stabilized earth (MSE) slopes and walls using geogrid or geotextile reinforcement is ideal in this regard. Not only are these situations the least expensive of all types of retaining structures (GRI Report #20), they are straightforward to construct, have no limitations as to curvature, height, or orientation, and have proven stable insofar as extreme surcharge loads are concerned.

Sixth, the drill pad itself should be lined so as to avoid contamination from spilled fracwater, hydrocarbons or other potential ground contaminants. This calls for a geomembrane, a geosynthetic clay liner, or both, as a composite liner. There are many choices in this regard and a designer should consider the generation of a benefit/cost ratio to select the appropriate liner material.

Seventh, natural gas plays are replete with plastic pipe. Such pipe as shown in Figure 17 is used for many purposes such as;

- fresh water transmission
- frac water transmission
- gas transmission
- surface water drainage

The pipe is generally HDPE or PVC and can be solid wall (for transmission) or corrugated with slots or holes (for drainage). Whatever the case, natural gas plays require the use of plastic pipe in a major way.

3.3 Opportunities at Temporary Locations

First of all, temporary roadways of weeks or months are necessary in connection with setup and eventual demobilization at natural gas plays. The geosynthetics industry has the capability of providing wearing surfaces placed directly on the ground. Shown in Figure 18 are light and heavy roadway systems developed by the Dutch Military for rapid deployment of heavy vehicles and equipment. They are typically 60 ft. long and 10 ft. wide and the weight varies with type. Obviously, they can be redeployed as often as necessary.

Secondly, temporary dams may be used for surface water control or for accidental spills associated with the drilling or containment operations. Figure 19 shows that geomembranes can readily provide such temporary containment and be adaptable to myriad applications.

Third, on sloping surfaces soil erosion is a concern and must be avoided so as to prevent silting of off-site areas and local streams and rivers. Geotextile silt fences have played an economical role in this regard for decades.

Fourth, rather than containing the site's erosion after it occurs it is better to control and stabilize it before it starts. This has been traditionally provided by geosynthetic-erosion control materials of which there are a great variety. The two major categories are slopes and channels/ditches, respectively. Designs are well advanced in both cases.

4. CLOSING COMMENTS

Natural gas plays (including actual drilling, the well pad, staging and parking areas, permanent and temporary roadways and access areas) are extremely large construction projects with enormous natural gas energy potential. They also have attracted considerable public and regulatory scrutiny. That said, once permits are obtained, fast mobilization, deployment and operations are necessary. Within the entire activity a low profile and exposure is always an advantage. All of these aspects can capitalize on geosynthetics in a major way. This White Paper has described many of these opportunities.

Of course, and within acceptable environmental criteria, benefit/cost analyses are always required for alternative and competing systems. We feel that in so doing, geosynthetic materials will invariably be the obvious choice for many of these applications.

Geosynthetics in Drainage Systems

Barry R. Christopher, Ph.D., P.E., Christopher Consultants, barryc325@aol.com

ABSTRACT

This paper provides an overview of the historical uses of geosynthetics in drainage systems, including: trench drains, cutoff drains, retaining wall and building wall drains including toe drains, base drains and chimney drains, and roadway edge drains. The paper includes a brief description of each application of geotextile filters and prefabricated geocomposite drains used as alternates to graded granular materials. Design methods are reviewed for both geosynthetics and conventional drains and these systems are compared on the basis of performance, cost benefit and sustainability based on actual project cost data, case histories and past synthesis national practice.

1. BACKGROUND

In the United States, the use of geotextiles as filters can trace its development back to the late 1950s when Mr. Robert Barrett developed the concept of using geotextiles to replace graded aggregate filters beneath rip-rap along the coast of Florida. The first filtration tests and design criteria were developed around the successful performance of these early applications (Calhoun 1972; and Carroll 1983). The author was fortunate to directly evaluate the performance of several of these early applications (Christopher 1983) and has revisited one of the sites in the late 1980s and again in the 1990s (Christopher and Valero 1999) to confirm the performance of these materials. Because of these early successes as well as their comparable performance, improved economy, consistent properties, and ease of placement, the use of geotextile filters has extended to almost all drainage applications as a replacement for graded granular filters. Geotextiles are used as filters in trench and interceptor drains, blanket drains, pavement edge drains, structure drains, and beneath permeable roadway bases. In addition to geotextile filters, geocomposites consisting of a drainage core surrounded by a geotextile filter are often used as the drain itself in these applications. Geotextiles also continue to be used as filters beneath hard armor erosion control systems.

1.1 Geotextile Filter Applications

The Federal Highway Administration (FHWA) Geosynthetics Design and Construction Guidelines (Holtz et al. 2009) schematically presents the following geotextile filter applications.

Figure 1. Filters around trench drains and edge drains – to prevent soil from migrating into the drainage aggregate or system, while allowing water to exit from the soil

Figure 2. Filters beneath pavement permeable bases, blanket drains and base courses. (Prefabricated geocomposite drains are also used as horizontal drains in pavement systems.)

Figure 3. Geotextile filters and prefabricated geocomposite pavement edge drain applications (NCHRP 1-37A).

Figure 4. Drains for structures such as retaining walls and bridge abutments. (They separate the drainage aggregate or system from the backfill soil, while allowing free drainage of ground and infiltration water. Geocomposite drains are especially useful in this application.)

Figure 5. Interceptor, toe drains, and surface drains -- to aid in the stabilization of slopes by allowing excess pore pressures within the slope to dissipate, and by preventing surface erosion. (Again, geocomposites have been successfully used in this application.)

Figure 6. Chimney and toe drains for earth dams and levees to provide seepage control.

Figure 7. Hydraulic structures such as culverts, drop inlets, and artificial stream channels may require protection from erosion. (In such applications, if vegetation cannot be established or the natural soil is highly erodible, a geotextile can be used beneath armor materials to increase erosion resistance.)

Figure 8. Geotextiles have been successfully used as a filter below: a) riprap for coastal and river bank protection; b) precipitation runoff collection, high-velocity diversion ditches, and slope protection; and, c) scour protection around structures.

1.2 Prefabricated Geocomposite Drains

The in-plane drainage ability of prefabricated geocomposite drains is potentially quite effective in several of the previously noted drainage applications. Virtually all of the drainage applications have a lateral transmission component (i.e., gravel is required to collect and drain infiltration water out of the system). Specific lateral drainage applications include interceptor trench drains on slopes, drains behind abutments and retaining structures, transmission of seepage water below pavement base course layers, pavement edge drains, vertical drains to accelerate consolidation of soft foundation soils, dissipation of pore water pressures in embankments and fills, dissipation of seepage forces in earth and rock slopes, chimney drains in earth dams, leachate collection and gas venting systems for waste containment systems, etc.

Thick nonwoven geotextiles alone can also provide suitable in-plane drainage for some of these applications; however, it should be realized that the flow quantities transmitted by in-plane flow of typical geotextiles (on the order of 2×10^{-5} m³/s/linear meter width of geotextile under a pressure equivalent to 0.6 m of soil) are relatively small when compared to the flow capacity of only 0.15 to 0.3 m of filter sand. Therefore, geotextiles alone should only be used to replace sand or other drainage layers in situations with small seepage quantities. Also the in-plane seepage quantities of geotextiles are highly affected by compressive forces, incomplete saturation, and hydraulic gradients. These considerations have led engineers to use geocomposite drains in most lateral drainage applications.

During the past 20 years or so, a large number of geocomposite drainage products have been developed, which consist of cores of extruded and fluted plastics sheets, three-dimensional meshes and mats, plastic waffles, and nets and channels to convey water, and geotextiles on one or both sides to act as a filter. Geocomposite drains may be fabricated on site although most are manufactured. They generally range in thickness from 5 mm to 25 mm or greater and have transmission capabilities of between 0.0002 and 0.01 m³/sec/linear meter width of drain.

Probably the most common uses for geocomposite drains in highways are pavement edge drains and drains behind retaining walls and abutments. However, the use prefabricated geocomposite edge drains (PGED) in pavements appears to have actually decreased over the past two decades. As noted in a national synthesis of practice on edge drains (Christopher, 2000), this reduction is attributed to a decrease in retrofit edge drain applications and reported problems that have discouraged the continued use of PGEDs by some agencies including "J" bending and crushing of the drain. These reports are somewhat contrary to the PGED research as reported in NCHRP Report 367 (*Koerner et al., 1994*), which found good performance of these materials and reported that most failures were predictable and related to either the absence of design, misapplication, or improper construction techniques. Extensive evaluation of installations in Canada (Raymond et al., 1999) also led to similar conclusions as the NCHRP Report 367. The industry has responded to the bending and crushing issue through the development of ASTM standard test methods (ASTM D6244 - 06(2011) Standard Test Method for Vertical Compression of Geocomposite Pavement Panel Drains) and a detailed guide specification for edge drain installation and specifications requirements (ASTM D6088 - 06(2011) Standard Practice for Installation of Geocomposite Pavement Drains and ASTM D7001 - 06(2011) Standard Specification for Geocomposites for Pavement Edge Drains and Other High-Flow Applications).

There are also issues with any type of edge drain that have discouraged their use, including confirmation of improved pavement performance, rigorous construction quality control to achieve performance (e.g., the use of video inspection), and maintenance requirements, especially at outlets to maintain flow (see Christopher et al., 2010 for a complete discussion of these issues). Another issue discouraging the use of edge drains is a perception by many of the northern agencies that edge drains do not work in cold regions. However, edge drain studies in Maine, Minnesota, Michigan, Ontario, and Wisconsin tend to strongly refute this claim. To the contrary, edge drains may have their greatest benefit in cold regions to rapidly remove water from the pavement during spring thaw. Separate studies of edge drains in Minnesota (*Hagen and Cochran, 1996*) and Maine (*Christopher et al., 1999*) found that more water comes out of the pavement section during the spring thaw than any rain event during the year.

Several states (e.g., Maine, Wisconsin, and Virginia) have also experimented with the use of horizontal geocomposite drains selected to be able to handle the estimated flow and support traffic loads. They are placed either below or above a dense graded base, used as a drainage layer beneath full depth asphalt, or placed between a "crack and seat" concrete surface and a new asphalt layer (e.g., see *Christopher et al., 1999*). In these applications, the drainage path is significantly reduced (i.e., vertically to the horizontal geonet composite versus laterally to the edge of the road), thus allowing the use of a lower drainage quality, lower cost, denser graded aggregate while maintaining very good to excellent drainage.

2. ADVANTAGES OF GEOSYNTHETICS

In most drainage and filtration applications, geosynthetic use can be justified over conventional graded granular filters and drainage aggregate material use because of cost advantages from:

- the use of less-costly drainage aggregate;
- the possible use of smaller-sized drains;
- the possible elimination of collector pipes;
- expedient construction;
- lower risk of contamination and segregation of drainage aggregate during construction;
- reduced excavation.

In addition, geosynthetics often increase drainage system reliability and, considering the value of drainage in geotechnical engineering, a significant cost-benefit can result when the designer is assured of a properly performing drain.

2.1 Cost Considerations

Determining the cost effectiveness of geotextile filters versus graded granular filters in drainage systems is a straightforward process. Simply compare the cost of the geotextile with the cost of a conventional granular filter layer, while keeping in mind the following:

- *Overall material costs including a geotextile versus a conventional system* - For example, the geotextile system will allow the use of poorly graded (less-select) aggregates, which may reduce the need for a collector pipe, provided the amount of fines is small (Q decreases considerably if the percent particles passing the No.200 (0.075 mm) sieve is greater than 5%, even in gravel).
- *Construction requirements* - There is, of course, a cost for placing the geotextile; but in most cases, it is less than the cost of constructing dual-layered, granular filters, for example, which are often necessary with fine-grained soils.
- *Possible dimensional design improvements* - If an open-graded aggregate is used (especially with a collector pipe), a considerable reduction in the physical dimensions of the drain can be made without a decrease in flow capacity. This size reduction also reduces the volume of the excavation, the volume of filter material required, and the construction time necessary per unit length of drain.

Geotextile filters in drainage applications will typically cost in the range of \$.80 to \$1.50 per square meter, depending upon the type specified and quantity ordered. Installation costs will depend upon the project difficulty and contractor's experience; typically, they range from \$0.50 to \$1.50 per square meter of geotextile. 2012 bid prices obtained from the web sites of several state agencies in preparation of this paper strongly support these costs. Higher costs should be anticipated for below-water placement. Labor installation costs for the geotextile are easily repaid because construction can proceed at a faster pace, less care is needed to prevent segregation and contamination of granular filter materials, and multilayered granular filters are typically not necessary. It should be noted that geotextile prices have not risen significantly in the last 20 years, however gravel cost has. The same web pages used for the cost of geotextiles also showed prices of select granular materials ranging from \$3.00 to \$10.00 in place for a 75 mm to 150 mm thick per sq meter layer (i.e., on the order of \$20 to \$30/metric ton) without consideration for special construction and dimensional requirements indicated above. This is typically the volume of gravel that will be replaced with the geosynthetic.

Prefabricated geocomposite drains are used to replace or support conventional drainage systems. According to Hunt (1982), prefabricated drains offer a readily available material with known filtration and hydraulic flow properties; easy installation, and, therefore, construction economies; and protection of any waterproofing applied to an adjacent structure's exterior. Cost of prefabricated drains typically ranges from \$7.50 to \$10.00 per square meter. The high material cost is usually offset by expedient construction and reduction in required quantities of select granular materials. For example, geocomposites used for pavement edge drains typically cost \$3.00 to \$10.00/linear meter installed while a conventional geotextile wrapped gravel drain with a pipe is on the order of \$30.00/linear meter installed.

Geotextile selection should not be based on cost alone. The cost of the geotextile is usually minor in comparison to the other components and the construction costs of a drainage system. Also, do not try to save money by eliminating laboratory soil-geotextile performance testing when such testing is required by the design procedure.

3. DESIGN

Geotextiles, like graded granular filters, require proper engineering design or they may not perform as desired. Unless

flow requirements, piping resistance, clogging resistance and constructability requirements (defined later) are properly specified, the geotextile/soil filtration system may not perform properly. In addition, construction must be monitored to ensure that materials are installed correctly. Thus, the geosynthetic materials must perform the same functions as graded granular filters that they replace:

- allow water to flow through the filter into the drain, and to continue doing this throughout the life of the project; and
- retain the soil particles in place and prevent their migration (*piping*) through the filter (if some soil particles do move, they must be able to pass through the filter without blinding or clogging the downstream media during the life of the project).

Designing with geotextiles for filtration is essentially the same as designing graded granular filters. A geotextile is similar to a soil in that it has voids (pores) and particles (filaments and fibers). However, because of the shape and arrangement of the filaments and the compressibility of the structure with geotextiles, the geometric relationship between filaments and voids is more complex than in soils. In geotextiles, pore size is measured directly, rather than using particle size as an estimate of pore size, as is done with soils. Since pore sizes can be directly measured, at least in theory, relatively simple relationships between the pore sizes and particle sizes of the soil to be retained can be developed. Three simple filtration concepts are used in the design process:

1. If the size of the largest pore in the geotextile filter is smaller than the larger particles of soil, soil particles that tend to move will be retained by the filter. As with graded granular filters, the larger particles of soil will form a *filter bridge* over the hole, which in turn filters smaller particles of soil, which then retain the soil and prevent piping.
2. If the smaller openings in the geotextile are sufficiently large enough to allow smaller particles of soil to pass through the filter, then the geotextile will not *blind* or *clog*.
3. A large number of openings should be present in the geotextile so that water flow can be maintained even if some of the openings later become plugged.

These simple concepts and analogies with soil filter design criteria are used to establish design criteria for geotextiles. Specifically, these criteria are the geotextile must retain the soil particles (*retention* criterion), while allowing water to pass (*permeability* criterion), throughout the life of the structure (*clogging resistance* criterion and *durability requirements*). To perform effectively, the geotextile must also survive the installation process (*survivability* or *constructability* criterion).

Specific criteria to meet these design requirements, design details and construction requirements are provided in the FHWA Design and Construction Guidelines (Holtz et al. 2009) and the text book by Koerner (2012). A National Cooperative Highway Research Program (NCHRP) study by Koerner et al. (1994) of the performance of geotextiles in drainage systems indicated that the FHWA design criteria developed by Christopher and Holtz (1985) were an excellent predictor of filter performance, particularly for granular soils (<50% passing a No.200 (0.075 mm) sieve). The hydraulic design requirements for geotextile filters used in pavement systems can also be evaluated using the FHWA computer program DRIP. The software was developed to evaluate the effectiveness of a drainage system in terms of the quality of drainage. It also provides tools for determining the design requirements for the permeable base, separator layers (i.e., geotextile or subbase), and edge drains, including the geotextile retention and permeability requirements for given natural and imported soil characteristics. The software can be purchased from <http://mctrans.ce.ufl.edu>.

3.1 Design Criteria for Geocomposite Drainage Systems

For the design and selection of geotextiles with in-plane drainage capabilities and geotextile filters for geocomposite drainage systems, there are four basic design considerations:

1. Adequate filtration without clogging or piping.
2. Adequate inflow/outflow capacity under design loads and field boundary conditions to provide maximum anticipated seepage during design life.
3. System performance considerations.
4. The two geotextile filters on the sides of geocomposites should not contact under load for capillary break applications.

Consideration should be given to system performance factors such as distance between drain outlets, hydraulic gradient of the drains, potential for blockage due to vegetation and siltation, small animals, freezing, etc. When using geosynthetics to drain earth retaining structures and abutments, drain location and pressures on the wall or abutment must be properly accounted for. It is important that the drain be located away from the back of the wall and be appropriately inclined so it can intercept seepage before it impinges on the back of the wall. Placement of a thin vertical drain directly against a retaining wall may actually increase seepage forces on the wall due to rainwater infiltration

(Terzaghi et al. 1996; and Cedergren 1989). For further discussion of this point, see Christopher and Holtz (1985).

4. SPECIFICATIONS

Guide specifications for geotextile filters can be found in AASHTO M288 (2006) geotextile material specification and its accompanying construction/installation guidelines; developed for routine drainage and filtration applications. For geocomposite edge drains, as previously mentioned, ASTM D7001 - 06(2011) provides detailed guide specifications. The actual hydraulic and physical properties of the geotextile filter or geocomposite drain must be selected by considering the nature of the project (critical/less critical), hydraulic conditions (severe/less severe), soil conditions at the site, and construction and installation procedures appropriate for the project.

5. CONCLUSIONS

After 50 years of successful practice, the author must conclude that geotextiles can effectively replace graded granular filters in drainage applications and beneath riprap or other hard armor materials in revetments and other erosion control systems. Numerous case histories have shown geotextiles to be very effective compared to graded granular filters in preventing fines. Furthermore, geotextiles and geocomposite drains have proven to be very cost effective in these applications. Indeed geotextile filters have become the standard of practice and geocomposite drainage systems are not too far behind, especially considering the recent increases in the cost of gravel.

ACKNOWLEDGEMENTS

This paper presents the state of the practice in geosynthetics used in drainage applications, a portion of which was extracted from the Federal Highway Administration *Geosynthetics Design and Construction Guidelines Manual* (Holtz et al. 2009). The author wishes to thank his co-authors of the FHWA manual, Dr. Robert Holtz and Ryan Berg for permitting the use of this material and, of course, their efforts in its development.

Geosynthetics: The Solution for Managing Nuclear Power Generation Water Supply in an Arid Environment

C. Eichelberger, American Environmental Group, Ltd. (AEGL), USA, ceichelberger@aegl.net
G. Hersh, American Environmental Group, Ltd. (AEGL), USA, ghersh@aegl.net
S. Pittawala, Arizona Public Service (APS), USA

ABSTRACT

Nuclear power generation requires substantial amounts of water both in the power generating process and the subsequent cooling process. Of the 439 active nuclear facilities in the world, only the Palo Verde Nuclear Generating Station is not located adjacent to a lake, ocean or river. To the contrary, the Palo Verde facility is located in the desert of Arizona, and utilizes treated effluent from Phoenix as the plant's cooling water supply. This is made possible through the construction of more than 780 acres of specialty containment systems which incorporate more than 135 million square feet of various geosynthetic products and results in 4.4 billion gallons of storage capacity. These containment structures utilize state-of-the-art technology such as video monitoring of the leak detection zone, which provides protection of the underlying aquifer. As a result, the Palo Verde Generating Station is able to serve the energy needs of more than 4 million people, generating more electricity than any other facility in the United States.

1.0 INTRODUCTION

The Palo Verde Nuclear Generating Station is located 55 miles west of downtown Phoenix and is the largest power producer of any kind in the United States. Its three units are capable of generating more than 4,000 megawatts of electricity. The facility provides power to New Mexico, California, Texas and Arizona. Palo Verde's design, construction and operation is based upon very robust levels of containment for various materials and processes in compliance with federal and state regulations. On-site containment includes not just radioactive material but more than 4.4 billion gallons of water. This amount of storage is designed to provide sufficient cooling water for longer than one year in the unlikely event of a severe accident.

Given its desert location, Palo Verde is the only nuclear plant in the world that does not sit on a large body of water. Instead, it uses treated effluent from several area municipalities, primarily Phoenix, to meet its cooling water needs. It recycles approximately 20 billion gallons of wastewater annually. The site receives approximately 70-90 million gallons per day (MGD) of wastewater and handles the responsibility of tertiary treatment on site. The use of the wastewater preserves enough ground or surface water for hundreds of thousands of households each year.

2.0 WATER CONTAINMENT FOR TWO PROCESSES

Palo Verde Cooling Water Conveyance System

Figure 1. The Original Cooling Water Conveyance System, Evaporation Ponds 1 and 2, and water usage data are shown above. (Palo Verde Engineering Assessment PowerPoint)

2.1 The Water Reclamation Facility Reservoirs

The design of the massive treatment facility that accepts the 70-90 MGD of wastewater includes two lined reservoirs. The first reservoir was constructed in 1978 and is approximately 85 acres in size, with a second reservoir covering 45 acres being constructed in 2006.

The two storage reservoirs contain approximately a 14 day supply of the water required to operate the facility during normal operations.

2.2 Evaporation Ponds for Storage of Blow-down Water

The second use of geosynthetic lined containment on the site is to store “blow-down” from the cooling systems and to process waste. APS strives to maximize the amount of water that can be recycled through the energy production process. However, a certain percentage of blow-down water must be discharged to control the salinity of the water used in the power plant processes. The cooling water is able to be recirculated through the plant cooling system approximately 25 times, or until its salinity is 20 or more times the salinity of the source water, prior to its diversion to the evaporation ponds.

Regulations specific to the Palo Verde site do not allow discharging of blow-down to the aquifer. Therefore, APS receives 70-90 million gallons of water per day, but operates a “zero discharge” water management plan. To fulfill the requirements, Palo Verde operates three large evaporation ponds, totaling approximately 650 acres of lined area. The 650-acre footprint utilizes multiple layers of geosynthetics, as a means to ensure a BADCAT (Best Available Demonstrated Control Technology) leak-free system. The reservoirs allow the natural environment to evaporate approximately 60 inches / year of water across the 650 acres, which equates to about 1.1 billion gallons per year. Current research is on-going to provide more detail to the amount of water evaporated and the rate of evaporation across different months of the year.

Figure 2. Aerial view of the lined containment reservoirs for municipality wastewater and Evaporation Ponds. The 85-acre and the 45-acre reservoirs are shown above.

Water containment for both purposes on the site is subject to aquifer protection requirements. The following organizations apply oversight to Palo Verde water containment processes: Nuclear Regulatory Commission, Arizona Department of Environmental Quality / Environmental Protection Agency, Arizona Department of Water Resources Dam Safety, and the Maricopa County Flood District.

3.0 INITIAL CONSTRUCTION OF THE RESERVOIRS

The use of a geosynthetic liner material in a reservoir application is a common design/construction option for the storage of various liquids. The relatively impermeable characteristics of a geomembrane provides a cost-effective option, especially in areas with a lack of low permeability soil, and provides superior containment and a decreased construction schedule when compared to a compacted soil liner. Many factors are involved when designing an impoundment with a geomembrane. Key decisions for the Palo Verde facility include:

- Exposure of the geomembrane to the environment (UV rays, wind, etc)
- Expected lifetime of the product and system
- Expected performance of the system (Allowable Leakage Rates)
- Subgrade Preparation and armament of side slopes

3.1 Wastewater Reservoirs

The original design for containment of wastewater at the treatment facility included the construction of an 85-acre reservoir which can store up to 788 million gallons of cooling water. This was the first containment area constructed at the facility and was put into service in 1982. The design consisted of 3:1 side slopes and the chosen lining materials included a rubberized asphalt base liner on the floor and Hypalon on the side slopes.

The impoundment was single-lined and construction utilized state-of-the-art technology for that time. After more than 20 years of operation, the lining began to fail as it reached its operational end-life. The reservoir then was re-designed and reconstructed. Lessons learned from the operation of the first impoundment along with the use of BADCAT provided information that led to a complete redesign for all future impoundments to be constructed at the Palo Verde site.

The newly designed reservoir would need to be taken out of service in order to be relined; however, the plant could not afford to stop service. Therefore, construction of a second wastewater reservoir began in 2005 which allowed the plant to operate while the 85-acre reservoir was under construction. Most importantly, APS not only wanted to be compliant in

its new design, it wanted to set the bar for all future water containment. As with any innovative concept, the design of the next impoundment would incorporate “lessons learned” from the initial construction in order to minimize similar issues going forward. Major revisions included flattening the side slopes to 4:1 in order to reduce the forces of wave action. Additionally, the subgrade on the side slopes was enhanced with soil cement as an additional armament against wave action. This was a very innovative approach at the time and the project was recognized by the soil cement industry. This also would become the site’s first double-lined system with an extensive LCRS (Leak Collection Recovery System); hence, leading to the design of the future evaporation ponds. The redesign and reconstruction of the evaporation ponds is detailed in section 4.0 of the paper.

3.2 Evaporation Reservoirs for Storage of “Blow-down” Water

The initial site design included two large lined reservoirs for evaporation of the blow-down water. The first pond constructed for evaporation purposes was the 250-acre pond termed Evap Pond 1. Initial construction was completed in 1986. The reservoir now is in its third generation, in that the first liner system reached its design life and was replaced in 1991 and the third generation currently is under construction at the time of this paper (August 2012). Evap Pond 1 initially was constructed just after the 85-acre reservoir and utilized a very similar design of 3:1 sideslopes and an asphalt base liner on the floor and Hypalon on the side slopes.

Evap Pond 2 was the next reservoir to be constructed. It utilized high-density polyethylene (HDPE) geomembranes, which were gaining more acceptance within the industry. Construction began in 1988 and was completed in 1989. The surface area is approximately 220 acres and again was constructed with 3:1 side slopes, but utilized a more traditional liner profile, as recognized today. The liner system consisted of a geotextile cushion installed directly over the subgrade and a 60-mil black HDPE geomembrane was placed over the textile. The switch to an HDPE liner produced satisfactory results for the site; however, operational concerns arose regarding the use of 3:1 slopes and the lack of a detection system associated with a single-lined system. The large surface area of the pond allowed desert winds to produce wave action across the pond, thus colliding into the side slopes and eroding subgrade soil from beneath the geomembrane. Evap Pond 2 has since been redesigned and reconstructed with the alternative design addressing these operational issues. The details of the design, construction and operation are discussed in Section 4.0 of the paper.

The initial wastewater treatment (WWTP) reservoirs and evaporation ponds still are in service today, but new materials have been installed using a revised design that incorporates a sophisticated leak detection zone in a double-lined profile. Given the size and depth of the ponds, the minimum standard for leakage between the primary and secondary membrane layers is quite low by industry standards. To monitor this, a state-of-the-art leak detection system was designed which includes remote level sensors and video monitoring of the sumps (See Section 5.0). Additionally, the site includes the 45-acre Wastewater Storage Reservoir and Evap Pond 3 (180 acres) which were both constructed in order to provide operational water storage capacity during reconstruction of the existing ponds.

4.0 PHASE II REDESIGN AND RECONSTRUCTION OF RESERVOIRS AND EVAP PONDS

Construction Timeline - Palo Verde Water Reclamation Facility and Evaporation Ponds

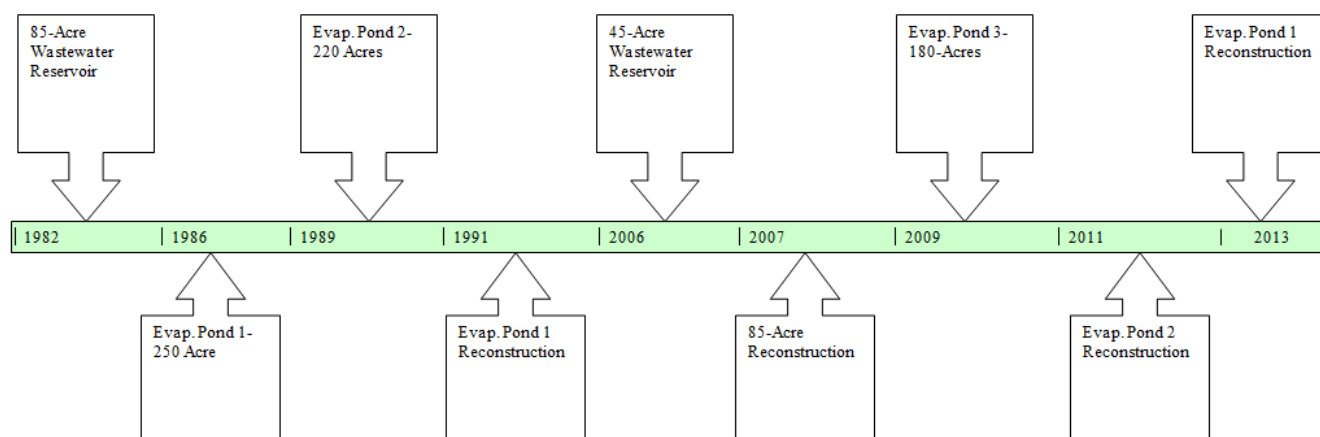

Figure 3 – Timeline of Initial and Reconstruction of Containment Projects.

The first pond that required redesign and reconstruction was Evap Pond 1 and the work was completed in 1991 (Figure 3). This pond consisted of 3:1 side slopes, rubberized-asphalt liner on the floor, and Hypalon on the side slopes. The subgrade beneath the Hypalon material had been eroded in areas due to the wave action across the large 250-acre surface area of the pond. The redesign / reconstruction sought to stabilize the side slopes and a BADCAT evaluation also provided a revised geomembrane material choice for the pond. To stabilize the side slopes, Palo Verde required soil cement armoring on the internal side slopes of the pond. To accomplish this work, the Hypalon material was removed from the slopes and the asphalt floor liner remained. The soil cement layer then was constructed on the side slopes, followed by a geotextile cushion layer and a 60-mil HDPE black geomembrane throughout the entire pond. This was the first project that included soil cement and HDPE geomembrane as the primary components for containment in the Palo Verde site. All additional construction and reconstruction of reservoirs and ponds now include soil cement armament and an HDPE geomembrane product.

The next project implemented by Palo Verde included the addition of a 45-acre reservoir for the water reclamation facility. The existing 85-acre reservoir had been in service since 1982 and was beginning to reach the end of design / service life. Closing the Water Reclamation Facility (WRF) during reconstruction of the 85-acre reservoir and ultimately ending the supply of cooling water to Palo Verde was not an option, so a second reservoir was to be constructed to allow operation of all facilities during construction and to add additional capacity when both reservoirs are operating. The 45-acre reservoir was completed in 2006 and included a cutting-edge design consisting of advanced geosynthetic products and a robust LCRS and monitoring infrastructure. Products included a geosynthetic clay liner (GCL), conductive white-surfaced geomembrane, primary and secondary geomembrane layers and LCRS. Major components of this next generation design for the Palo Verde site have been included in all subsequent projects.

The 45-acre reservoir located at the WRF was the first “new-excavation construction” project since Evap Pond 2, which initially was constructed in 1989. A major component of this new construction included the use of 4:1 side slopes, in contrast to the 3:1 design that had been used on all other projects. The 4:1 slope design, which included the soil cement requirement from Pond 1’s reconstruction, was utilized to combat and limit wave action on the surface of the reservoir (Figure 4).

Figure 4. Side-slope armoring and liner profile used for the 45-acre WRF reservoir and reconstruction of the 85-acre WRF reservoir. (C. Wigginton, M Annala, J Mitchell, R Fongemie and S Pittalwala)

The profile of the liner system from top to bottom now included:

- 60-mil, white-surfaced, conductive, HDPE geomembrane (Primary)
- 200-mil HDPE geonet drainage product
- 60-mil, white-surfaced, conductive, HDPE geomembrane (Secondary)
- Non-woven geotextile cushion layer
- Soil cement subgrade

The addition of a second layer of geomembrane produced a leak detection zone or leak collection and recovery system (LCRS) for the reservoir. The dual-lined or primary and secondary geomembrane layers can be compared with the design and operation of a double-hull ocean vessel, when containment of liquids is discussed. The outer hull or primary geomembrane layer is the initial containment barrier and is subjected to large head pressures, especially in the case of the approximate 30 foot depth of the ponds. The head pressure may expand any imperfections in the primary geomembrane, thus providing a pathway for leakage into the detection zone or space between the two layers.

Detection zone piping then is utilized to pump out the liquid and redistribute it into the evaporation pond. Removing the liquid from the detection zone also removes or eliminates head pressure that could build on the secondary geomembrane. The absence of pressure on the secondary geomembrane greatly increases the overall performance of a liquid impoundment. The incorporation of conductive geomembrane provides for the use of spark testing of the installed geomembrane layers. This test adds an additional layer of quality control to ensure the best possible installation and performance of the system.

Figure 5. Photo of secondary 60-mil conductive white-surfaced HDPE geomembrane with LCRS piping and gravel drain. Geonet drainage layer (black) is installed over the piping.

Palo Verde increased the performance of the detection zone by adding two additional features into the 45-acre reservoir design. The first enhancement required intricate grading of the subgrade elevations. The design used varying elevations that would separate any flow of liquid within the detection zone to separate monitoring areas, or sumps. This now would create subsections in the 45-acre floor plan, thus allowing Operations personnel to determine which area of the primary liner may be leaking in the event that “action level flow values” are exceeded. Additionally, pipe trenches were constructed into the subgrade (above the secondary geomembrane) to quickly collect and transport any leakage to the detection sumps (Figure 5). The detection sumps are equipped with visual operation hatches, flow meters and video monitoring equipment focused on the detection pipe outlets.

With completion and operation of the 45-acre WRF reservoir, reconstruction of the 85-acre reservoir could begin. Reconstruction began in late 2006 and was completed in 2007. All design revisions included in the 45-acre reservoir were implemented into the 85-acre reconstruction project. Although the existing side slopes of the reservoir were 3:1, the reconstruction included removal of the existing Hypalon geomembrane and excavating the slope back to a 4:1, then installing the soil cement armament required on all pond side slopes. With both WRF reservoirs reconstructed and operational, focus was shifted to reconstruction of the evaporation ponds.

A new construction/excavation project now was necessary to address the eventual reconstruction of Evap Ponds 1 and 2. Evap Pond 2 had been in service for more than 20 years by this time and was reaching operational end-life. It was not possible to take Evap Pond 2 out of service and continue to have adequate volume for storage of blow-down, so plans were made to design and build Evap Pond 3, which would be two separate ponds (A and B). Each would create 90 acres of surface area. Evap Ponds 3A and 3B were completed in 2009 and utilized a similar design as the 45-acre WRF reservoir, with two significant exceptions. A GCL product was utilized in place of the geotextile cushion layer that was installed above the soil cement and below the secondary 60-mil HDPE geomembrane. The GCL material layer added a significant amount of increased performance, in terms of overall containment performance of the geosynthetic system. Additionally, Palo Verde installed a video monitoring system within the detection sumps to observe the outlets of the detection system piping. The amount of flow within the detection system is recorded via flow meters. However, the addition of the cameras increased monitoring efforts to a 24-hour “real time” situation (Figure 6). With the completion of Evap Pond 3 in 2009, the site began to focus on the reconstruction of Evap Ponds 1 and 2, as the geosynthetic products in those ponds were reaching their respective design lives.

Figure 6. Leak detection monitoring equipment

After 22 successful years of service life, Evap Pond 2 reconstruction began in 2010 and was completed in 2011. The single-lined containment system of a geotextile cushion layer and one layer of 60-mil HDPE geomembrane was completely removed from the pond (Figure 7). Then, subgrade contours were re-graded to create isolated areas of the LCRS on the floor of the pond (Figure 8). This would allow for more rapid identification of any areas that showed signs of leakage.

Figure 7. Removal of existing geomembrane material in Pond 2

The existing 3:1 sideslopes were reconstructed to 4:1, as has become the standard, and the soil cement armament was installed. Evap Pond 2 utilized the same geosynthetic profile from Evap Pond 3 (GCL, 60-mil conductive white HDPE, geonet drainage, 60-mil conductive white HDPE). One additional design revision was incorporated into Evap Pond 2 construction, however. The berm used to separate Evap Ponds 3A and 3B produced another deterrent to wave action across the full surface area of the pond by splitting the surface area in half from 180 acres to 90 acres for each area. For this reason, two berms were created within the 220 acres of surface area in Evap Pond 2, thus creating Evap Ponds 2A, 2B and 2C.

Figure 8. Regrading of pond floor subgrade in Pond 2. The subgrade elevations isolate identifiable areas and sumps.

Figure 9. Photo of installed primary geomembrane layer and deployment of geonet drainage layer over installed secondary geomembrane.

Reconstruction and the third generation of Evap Pond 1 currently is under construction as of August 2012 (Figure 9). Approximately 50 percent of the geosynthetic materials have been installed in Pond 1B, with plans to move directly into Evap Pond 1C. Evap Pond 1A will be completed during 2013 and with that will complete the redesign and reconstruction of all lined reservoirs and ponds at the Palo Verde site. Evap Pond 1 “third generation” has utilized the same design as the reconstruction of Evap Pond 2.

Accountable installation is required, expected and specified at the APS facility. An installation for a typical APS project will consist of 30 – 40 employees. The labor components of the crew include a production supervisor and additional “non-working” supervisors for each individual component of the work. For example, a “non-working” supervisor is required to oversee the unloading of geosynthetic materials from delivery trucks (Figures 10 and 11). An additional superintendent would be required if GCL was being deployed, while another superintendent would supervise the geomembrane installation over the GCL. A full-time certified safety officer is provided by the installer to oversee and manage all safety requirements at the site. Six to ten operators are required to operate the flatbed trucks, forklifts, bobcats, loaders and water truck.

Another step in providing the greatest level of liquid containment, APS requires that all welding personnel be a Certified Welding Technician as recognized by the International Association of Geosynthetic Installers (IAGI).

Figure 10 – Delivery of geonet drainage material

Figure 11 – Unloading of geonet drainage material using man-lift for attachment of roll straps to excavator.

In total, more than 3,120 acres of geosynthetic materials have been installed and are currently used in operation of the Palo Verde facility. The acreage converts to approximately 136,000,000 square feet of material, or 2,360 United States football fields. For reference, if all of the material was cut into a 12-inch wide strip, that strip would reach around the 24,900 miles of the earth's equator. Innovative state-of-the-art geosynthetic products and accountable highest-quality installation play a major role in the containment of Palo Verde's water resources in this arid environment.

ABSTRACT

The recent FHWA initiative to expand the use of GRS-IBS technology offers a multitude of benefits over more traditional bridge construction, including reduced construction time, 25 to 60 percent cost savings over pile foundations, and the elimination of the “bump at the bridge” problem associated with uneven settlement of the superstructure and the approaching roadway. GRS technology is based on closely spaced, relatively lightweight layers geotextile reinforcement alternated between layers of compacted granular fill, with the bridge superstructure founded directly on the GRS composite. This flexible, simple, and generic technology is a viable option for many single-span bridges, but is often perceived as a “new” technology. This paper presents case studies from 5 bridges built using GRS-IBS technology in the private sector over the last 20 years including a 191-foot span bridge built in Montana, a historic bridge replacement project in one of California’s highest seismic zones, and an abutment constructed on 90 feet of zero blow count soils in Jamaica.

1. INTRODUCTION

1.1 GRS Technology – Ancient Roots

Thousands of years before the concept of “Reinforced Soil” became widely accepted, ancient people had already used soil with vegetative tensile inclusions to build structures. As early as 1000 B.C., early Mesopotamians used layers of reeds and packed clay to build the cores of their ziggurats. Portions of the Great Wall in China were reinforced using the twigs of tamarisks trees between layers of gravel and clay. An engineer named Pan in the Ming dynasty was well known for using willows to stabilize earth dikes in China (Barker, 1994). As recently as the 1960’s, tin miners in Malaysia placed grass stems in their mine tailings piles to prevent slope failures (Hengchaovaich, 1999). Adobe and bricks made from straw and clay have been used for thousands of years (and are still used) from the Southwestern United States to Egypt to Central China.

Modern reinforced soil can trace its roots to French architect Henri Vidal in the mid-1960’s. Vidal’s system, known as *Terre Armee* used a dense array of small steel strips to reduce lateral earth pressure in earthen retaining walls. The first Reinforced Earth wall in the United States was built on California State Highway 39 (Northeast of Los Angeles) in 1972. The technology then spread throughout the country. In the mid-1970’s, these structures began replacing reinforced concrete structures previously developed by the Colorado Department of Transportation (CDOT) along interstate 70 near Vail pass. As I-70 was constructed through Glenwood Canyon, Reinforced Earth walls were also constructed, again using steel as reinforcement (in the form of strips and mesh mats).

Around the same time the U.S. Forest Service in the Pacific Northwest began using geotextiles to enable heavy logging trucks to travel over soft materials (Steward, 1977). In 1974 John Steward of the U.S. Forest Service and Professor Dick Bell of Oregon State University expanded this technology by constructing the first GRS walls in the United States (Holtz, 2004). A 6-ft high wrapped-face wall using lightweight geotextile was constructed in Oregon and an 18-ft high counterpart was constructed in Washington State. Stewart and Bell analyzed the walls using the tieback-wedge analysis, an adaptation of the work of Professor Lee at UCLA in 1973 (Lee, 1973). This theory was based on the geotextiles acting as “tiebacks” and the soil mass acting as it would on a traditional externally reinforced retaining wall. The equivalent lateral earth pressure coefficient (K_A) is determined by assuming a horizontal backslope and no wall friction, given an active zone defined by the Rankine failure plane. The amount of earth pressure at each elevation must be resisted by the geosynthetic “tieback” at that elevation. The “tiebacks” could fail in two modes: pullout and rupture, and the theory analyzed each. The theory was simple and revolutionary, but also over conservative, neglecting any composite behavior of the reinforced soil mass. Although the technology was new, Professor Bell seemed to intuitively understand that close reinforcement spacing would play a key role in wall stability (although Bell was also worried about under compaction, which small spacing helped to prevent).

Once again, CDOT researchers picked up on the revolutionary work with geosynthetics coming out of the northwest. Bob Barrett, Al Ruckman, and J.R. Bell built an 18-ft high wrapped face non-woven geosynthetic demonstration reinforced

soil wall on I-70 in Glenwood Canyon, Colorado with onsite granular backfill and closely spaced (8 to 10-in) reinforcement layers (Bell, 1983). Using the models available at the time, portions of the wall had a calculated safety factor of 0.33, but no failure was observed. Massive earth surcharges were added that lowered the safety factor to 0.11, but again the wall remained unaffected. Even after differential settlement of the wall foundation of up to 2 feet, the wall was unaffected. Fabric was exhumed periodically to determine degradation in soil.

This research project demonstrated that current models were overly conservative and that internally reinforced structures could endure massive surcharges and differential settlement. For the first time, researchers saw that internally supported structures may be more than a low cost replacement for externally reinforced structures, they may actually be superior. What was not understood at the time was that close spacing was the key to this “better than expected” performance.

The capstone to the GRS research efforts (especially for bridge abutment applications) was a CDOT demonstration project carried out in the Havana Maintenance Yard in 1996 that demonstrated the tremendous loads that GRS systems were able to withstand. Shown in figure 1, piers as narrow as 8 feet and over 24 feet tall were subjected to 2,340 kN loads without showing signs of distress during the loading process. Later analysis of the structure demonstrated that these loads were sustained even though the compaction on the piers was sub-optimal (likely due to the difficulty involved in running a plate compactor on an 8 foot wide platform 24 feet above ground) (Abu-Hejleh et. al. 2001).

Figure 1. Havana Yard GRS Pier Demonstration.

Later research also demonstrated that GRS with select granular backfill and closely spaced geotextile was one of the most resilient systems to seismic loading (Wu, 2006).

1.2 Applications

Following these research efforts, the authors and others in the private sector began using closely spaced (12 inches or less), lightweight woven polypropylene geotextile sheets in a well compacted granular backfill matrix in a variety of applications including avalanche and debris-flow barriers, rockfall catchment structures and barriers, retaining walls, and, notably, bridge abutments. All of the case studies presented were completed using design-build contracting on private sector projects. This method of contracting lends itself to the versatile GRS technology. At the time, few bridge engineers were willing to try a “new” technology, so the relatively few design-build firms able to use the technology saw a distinct market advantage over competing firms. Bridges were routinely constructed for less than half what a traditional pile-founded bridge would cost, with construction times often 30% of the traditional option. Today, as more engineers understand the technology most GRS-IBS projects are completed through bid-build contracting, and the technology is much more prevalent in the public sector. Cost and time savings to the ultimate client are similar to design-build contracting once construction commences.

1.3 FHWA Design Methodology

Building on CDOT research efforts and the myriad of GRS abutments constructed starting in the late 1990s, FHWA researchers presented an interim implementation manual for Geosynthetic Reinforced Soil Integrated Bridge Systems (GRS-IBS) in early 2011 (Adams, et al., 2011). The manual identified the GRS-IBS technology as simple to design and construct, easy to modify in the field, and appropriate for construction in various weather conditions. The manual also notes that when compared to traditional bridges systems, GRS-IBS costs less (by 25-60%), can be completed in less time, requires less maintenance (primarily by eliminating the “bump at the bridge” due to differential settlement between the abutment and the superstructure) and is more durable (Adams, 2011).

As the cost savings associated with GRS-IBS would be in the billions if implemented nationwide, the technology was selected for deployment through the FHWA’s Everyday Counts (EDC) initiative. EDC is designed to identify and deploy innovation aimed at shortening project delivery, enhancing roadway safety, and protecting the environment. Selection by the EDC is evidence of how far GRS technology has come from its experimental roots in the 80’s and 90’s, as the program is focused on “taking effective, proven and market-ready technologies and getting them into widespread use” rather than “inventing the next ‘big thing.’”

Currently, the initiative has over 60 public bridges across the U.S at some stage of development and construction, including multiple on the interstate highway system. Ironically, FHWA researchers have had to overcome the incorrect assumption that GRS-IBS is a “new” or “experimental” technology, although, as the case studies below demonstrate, many of these structures are now entering their 15th year of service. Figure 2 shows a typical GRS-IBS abutment cross section.

Figure 2. Typical Cross Section of GRS-IBS Abutment (Adams et al., 2011).

2. CASE STUDIES

2.1 Tied Arch Bridge near Black Hawk, CO (1998)

The abutments were constructed above the city of Black Hawk, Colorado, to support a 118 foot span steel arch bridge. The abutments were constructed with the on-site granular soil and reinforced with layers of a woven geotextile (Amoco brand 2044 fabric) on 12 inch spacing, with native rock as the facing element rather than the more traditional concrete blocks. As with blocks, the reinforcement sheet extended to the front face of the wall to provide a positive frictional connection between the facing and the abutment. Tie rods were drilled through the abutments into bedrock and tensioned to pre-load the abutment prior to bridge installation. Although this method is effective in reducing or eliminating settlement of GRS abutments, later research showed that vertical abutment strain without preloading is well below 0.5% at typical design loads (Adams, 2011). A view of the bridge is shown in figure 3 below.

Figure 3. Black Hawk Bridge, with mortared native stone facing.

2.2 Abutment near Green Island, Jamaica (1999)

A 30 foot tall abutment was constructed near Green Island, Jamaica as part of an island-wide highway upgrade initiative through design-build contracting. Initially, the West abutment of the bridge was to be founded on piling. The design-build contractor from Korea was unable to get the required equipment to the abutment site, which was in a mangrove swamp overlying 90 feet of zero blow count alluvial silt. Layers of geotextile and marl fill provided access to the site and also as the abutment material. Photographs of the construction process and the finished abutment are shown in figures 4 and 5. The abutment was constructed in lifts to allow pore water pressures to dissipate, and settled globally approximately 24 inches. A surcharge was added to simulate the load of the bridge deck. During the process, currency fluctuations and political factors resulted in a change in the international design-build contractor. The new design team was unfamiliar with GRS-IBS technology and opted to abandon the abutment and construct a traditional pile founded bridge at nearly 3 times the cost. This project demonstrated that with proper construction staging and surcharge loading, the GRS-IBS system can be installed on the weakest of soils.

Figure 4. Green Island bridge under construction. The construction was nearly all completed using local unskilled labor and hand tools.

Figure 5. View of abutment after completion of surcharge loading.

2.3 Bridge near Mammoth Lakes, CA

An historic bridge near Mammoth Lakes, CA required replacement due to structural deficiencies of the superstructure. Moreover, the abutments and pillars were of unknown quality but were required to be preserved for aesthetic and historic reasons. After the original superstructure was removed, the area behind the abutment walls was excavated and replaced with GRS composite. A new deck was placed on the GRS composite so that with full loading the deck would not touch the existing pillars (as shown in figure 6). The end result was a modern GRS-IBS bridge that appeared to be resting on historic abutments and piers. This project demonstrated the flexibility of the GRS-IBS system and the cost savings associated with leaving existing abutment walls in place.

Figure 6. Mammoth Lakes bridge. Note that the deck clears the historic piers by approximately 4 inches.

2.4 Private Development Access Bridge near Big Sky, MT (2001)

Access to a private development crossed a protected stream and terminated on an ancient landslide in one of Montana's highest seismic zones. Traditional bridge options required piling and post-tensioned ground anchors. The GRS-IBS approach shown in figure 7 spanned the gorge with a 191 foot single span steel girder bridge founded on GRS abutments, at approximately 25% the cost of the traditional solution. Post construction settlement has been negligible, even after the owners placed a 100,000 pound decorative timber cladding on the bridge in 2004. To the authors' knowledge, this is still the longest GRS-IBS bridge in the world.

Figure 7. Big E-Z bridge. At 191 feet, the longest GRS-IBS structure in the world.

2.5 Private Access Bridge, Sonoma County, CA (2011)

Access to a timber tract in Sonoma County required a single span bridge. The developer had traditionally installed railcar bridges founded on piling, but wanted to reduce the cost of construction. The on-site material was highly granular and met the specifications for GRS-IBS backfill. Figures 8, 9, and 10 show the relatively simple plan set, the site during construction, and the final product. The bridge was completed in approximately two weeks at significant cost savings over the traditional method. Although this case study demonstrates the cost savings associated with using on-site backfill, this would not be feasible in most parts of the United States. Notable exceptions would be mountainous areas in the Rockies, Sierras, and Pacific Northwest, as well as areas with clean sandy soils in the Southeast.

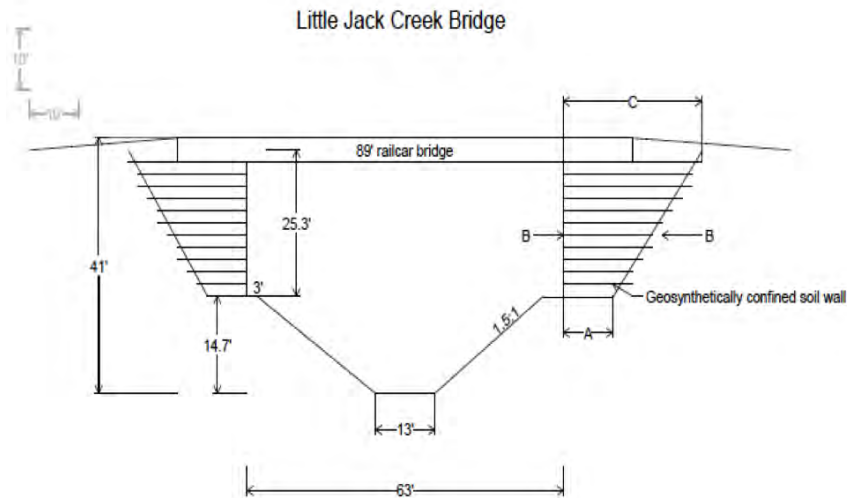

Figure 8. Typical elevation view of access bridge.

Figure 9. Abutments during construction. Using two crews cut construction time in half.

Figure 10. Completed railcar bridge.

3. GRS OBSERVATIONS

Following nearly 30 years of work with GRS, the authors have been continually impressed with the versatility and durability of the technology. However, many misperceptions about how the technology actually “works” remain. The FHWA GRS-IBS interim implementation manual makes great strides in dispelling myths associated with the technology, but a few notable ones continue to pervade the engineering community.

3.1 GRS Is Just a Subset of Mechanically Stabilized Earth (MSE)

Although the components of MSE and GRS are identical (reinforcement, facing, and earth backfill) the similarities end there. The grids used in MSE are designed -- and performs as -- tiebacks. The load in the MSE system is carried by the reinforcement, with only negligible composite behavior. In contrast, GRS using close spacing performs as a unique composite system, where the performance of the structure cannot be accurately quantified by adding the properties of the constituent parts. The function of the reinforcement in GRS is not to carry load, but to confine the granular soil particles so they cannot dilate. If the individual particles are prevented from dilating, they must fail through shear. Shearing of bedrock particles is difficult, and explains why GRS test pillars require nearly 22,000 lbs/sf to fail. For this reason, the authors typically refer to the technology as Geosynthetically Confined Soil (GCS®) to be clear that the confined soil, rather than the confining inclusion, is doing the work in the system.

Unlike MSE, GRS is not reliant on the *quality* of the confining inclusion but the *quantity*. Closely spaced inclusions, 8 to 12 inches, provide significantly better confinement, causing the failure mode to divert to shear through the particles. 8 inch spacing with woven geosynthetics with wide strip tensile capacities of 100 to 400 pounds per foot is a common solution (Wu et al, 2006). Also unlike MSE, where low quality backfill can be used, GRS backfill must be a friction-controlled material (road base or other granular aggregate). On site soils (especially cohesive soils) are generally shunned for lack of consistency and propensity to creep. There are instances where local sands and gravels will meet structural fill requirements and can be used. The operative word here is structural; poor quality backfill will not demonstrate confinement and transition to particle shear failure modes. Compaction is absolutely critical for GRS particle confinement. Uncompacted backfill will not self-compact with loading; rather it will fail, failing the tensile inclusions.

The facing in GRS systems is the weakest part of the system. Unlike MSE, where large proprietary blocks with mechanical connections to the grids have been shown to positively affect global stability, GRS uses lightweight facing with friction connections more as a forming element and permanent erosion control facing. Indeed, if the facing is lost in a GRS system, the only structural issue is subsequent erosion of the actual load-carrying element – the granular backfill.

3.2 GRS Abutments Cannot be Used in Scour-prone Areas

As spread footings, GRS abutments are subject to scour undermining if improperly designed. However, any abutment is subject to scour, regardless of whether the superstructure is founded on deep foundations. The presence of scour should never preclude the use of GRS-IBS, rather, it should necessitate the use of appropriate and site-specific scour protection measures. These include founding the reinforced soil foundation below scour depth, installing riprap aprons, gabion mattresses, articulating concrete blocks, or other proven technologies. The authors have had good success with the use of scour micropiles (shown in figure 11) to protect GRS abutments from undermining. These are typically drilled or launched at a 30-45 degree sub-vertical angle. If the center-to-center spacing of the piles is 3 times the micropile diameter (or less) they will typically behave as a continuous wall.

BRIDGE ABUTMENT / CULVERT SCOUR PROTECTION

Figure 11. Typical Cross Section of scour pile installation.

3.3 GRS Abutments Settle, and Always Require Firm Foundation Soils

As shown in the FHWA Implementation manual, vertical strain in GRS abutments is less than 0.5% under typical design loads (Adams, 2011). Although the internal abutment settlement is negligible, there is always a possibility of settlement of the foundation soils under any bridge abutment. In the authors' experience, settlement of foundation soils for bridge replacements is generally negligible, as the existing abutment served as a long-term surcharge load. For new construction, settlement should be evaluated and taken into account in design, but in itself settlement is not a limiting factor. The abutment in Jamaica settled over 24 inches during construction and surcharge loading. Long-term foundation settlement in GRS-IBS structures is actually superior to that of conventional bridges. In both cases, the abutments settle. In GRS-IBS, this serves to lower the superstructure by a commensurate amount. In a traditional system, the superstructure remains rigid, causing the ubiquitous "bump at the bridge" phenomenon. The only issue with global settlement with GRS-IBS would be differential settlement, which can be mitigated by using a lightweight backfill, pre-loading, or other design measures.

3.4 GRS-IBS Span Length Should be Kept Below 140 Feet

According to the FHWA implementation manual, "[t]he demands of longer spans on GRS-IBS are not fully understood at this time, and it is recommended that engineers limit bridge spans to approximately 140 ft until further research has been completed." While the authors agree with the requirements to quantify loading for all bridges (especially longer spans), our experience with spans as long as 191 feet show that this arbitrary limitation on span length is not necessary and has precluded the use of GRS-IBS in otherwise appropriate sites.

4. CONCLUSIONS

Ancient peoples intuitively understood reinforced soils. In the modern era, this powerful technology was resurrected and quantified by researchers in the public sector. The private sector was the first to adopt the technology due to the significant competitive advantage conferred on early-adopters of the technology. The FHWA effort to bring this powerful technology to the public sector will save the transportation community billions of dollars and should be commended.

ACKNOWLEDGEMENTS

The authors would like to thank Mr. Mike Adams and Dr. J. T. H. Wu for their contributions in providing much of the background information and references for this paper.

Geotextile Constriction Size and Physical and Chemical Clogging Potential

Sangho Lee, Ph.D. and P.E., GESTRA Engineering Inc., slee@gestrainc.com

ABSTRACT

Geotextile constriction size is critical to estimate clogging/blinding potential of base soils planned for drainage or protection from internal erosion. Author updated polyhedra model adapted by Faure (1990) to produce reasonable opening size distribution examinable by bubble point method (ASTM D6767) or apparent opening size (ASTM D4751). Particle size comparison with geotextile constriction enables to analyze potential of either physical or chemical clogging fate. Probabilistic simulation using Markov Chain was conducted to predict the clogging fates of non woven geotextile depending on particle size of filtered soils and geotextile porosity.

1. INTRODUCTION

Geotextile has been used in many civil infrastructures (e.g., retaining wall drainage, road way underdrain and earth dam toe drain) replacing granular filters with advantages of convenient installation process and quality controlled material properties (porosity, constriction size distribution, thickness). However, piping, blinding and internal clogging can occur at geotextile filter as well as granular filters under an unfavorable site soil/hydraulic condition.

Past nationwide field investigation on the drainage systems employing geotextile filters revealed that current deterministic filter design format was incapable of predicting the filter clogging especially associated with non-cohesive fine soils (i.e. well graded silty sands) (Wilson-Fahmy *et al*, 1996). The failures of filter designs were considered from the subtle migration behaviors of the non-cohesive fine particles which is not explicitly explainable with a few deterministic parameters of the current design methods.

Geotextile fabric can be considered as multi layered sieves since seepage flows and soil migration directions are relatively uniform and consistently transverse to the geotextile plane compared to the retained granular layer where fine particle migration shows a more random direction and dispersive pattern. Both granular and geotextile filter regions are characterized with constriction features, but the constituent shapes are spheres for the soil and strings for the geotextile.

Rigo *et al* (1990) found the filter opening size (i.e. $O_f^* = O_{f,90}$ or $O_{f,95}$), the largest opening size of geotextile (GT), has the greatest influence on the filter performance among filter design parameters. This finding implies that fine particle migration in nonwoven GT should be explained with other than a filtration mechanism of granular filters, the retention performance of which is mainly controlled by the minimum constriction size as demonstrated by Giroud (1996). Later, Bhatia and Smith (1996) demonstrated with experimental works that the breadth of opening size distribution (OSD) of nonwoven GT is also related to the nonwoven GT filter performance. OSD presenting the effective pore channels (the smallest constriction sizes) of nonwoven GT can be successfully assessed by the bubble point method (ASTM D 6767) (Bhatia *et al*, 1996). At present, CSD of nonwoven GT is measurable using image analysis (Aydilek *et al*, 2005), or can be inferred from the OSD from the bubble point method (ASTM D 6767) and the filter opening sizes (O_f^*) with a reasonable probabilistic assumption (Giroud *et al*, 1998).

A new filter design is strongly demanded to overcome the limitation of existing deterministic designs which were proven ineffective for well graded and non-compacted soils. Probabilistic model is considered as an effective approach coping with the random features of geotextile CSD and soil GSD, and it enables to envision the behaviors of fine particle migration differentiated by the various filter performances. In this paper, probabilistic models, developed to explain the behaviors of fine particle migration inside geotextile filters, are introduced, and the methodology and basic assumptions of the models are reviewed, compared and modified as for feasibility study to predict physical and/or chemical clogging within geotextile filter.

2. REVIEW OF EXISTING PROBABILISTIC MODEL AND ITS MODIFICATION

2.1 Poissonian Polyhedra Model and Analogy Sieve Model for Geotextile Constriction Size

Probabilistic methods have been developed to predict the filtration behaviors of nonwoven GT associated with various types of soils (Giroud, 1996, Giroud *et al*, 1998, Faure *et al*, 1990 and Elsharief and Lovell, 1996). Faure's *et al* (1990) interpreted the pore structure of geotextile as a layered sieve model consisting of sub elementary sieves, the CSD feature of which can be described with a gamma distribution or Poisson distribution (Figure 1). In the model, fiber specific length, χ plays a critical role to the CSD change of Poissonian polyhedra model (Matheron, 1971).

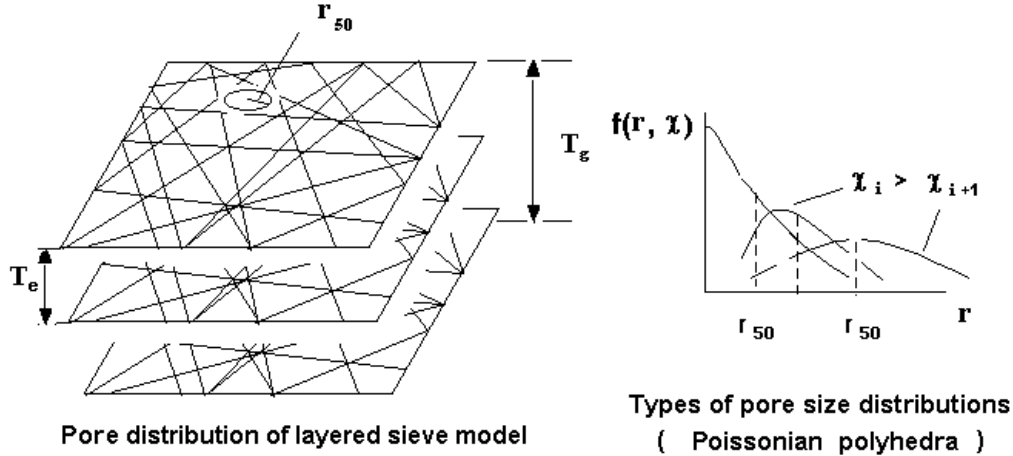

Figure 1 Layered sieve model presenting pore structure of non woven geotextile. (T_e : distance between sub elementary layers, T_g : geotextile thickness, χ : geotextile fiber specific length, r : constriction radius)

The random opening feature of nonwoven GT can be described with a cumulative probability, presented as $F(r, \chi)$, a function of input parameters of specific length, χ (fiber length per unit area) and inscribed constriction radius, r .

$$F(r, \chi) = 1 - [(1 + \chi r)^2 e^{-2\chi r}] \quad \text{from Matheron, 1971 [1]}$$

The probability density function (PDF) can be derived from taking the derivative of $F(r, \chi)$ with respect to constriction radius, r

$$f(r, \chi) = 2\chi^2 r (1 + \chi r) e^{-2\chi r} \quad [2]$$

In Figure 2 the transitions of PDF from Gaussian distribution to Poisson distribution are compared as specific length, χ increases.

The PDF feature of the Poissonian polyhedra model can be confirmed with an analogy model of wired mesh sieve. If $f(x)$ and $f(y)$ present the PDF of the wired mesh spans in x and y axes, respectively, the uniform $f(x)$ and $f(y)$ can represent the CSD of geotextiles with low fiber density and the declined wedge shapes can present the CSD of geotextiles with high fiber density (Figure 3).

Joint probability density function, $f(x,y)$ is calculated from the $f(xy)$ presenting the PDF of the opening area size. However, the $f(x,y)$ itself cannot depict the probabilities of the soil particles confronting the geotextile constrictions with different areas because the soil accessibility shall increase by the constriction area size as well as the constriction frequency. The redefined cumulative probability function, $F^*(z)$ accounting for constriction area where z is defined x times y , can be rewritten as the following formula. This is schematically depicted in Figure 3.

$$F^*(z) = \Pr\{d \leq z\} = \frac{\iint_0^z xyf(x, y) dx dy}{\iint_0^z xy dx dy} = \frac{\int_0^z \alpha f(\alpha) d\alpha}{\int_0^z \alpha d\alpha} \quad [3]$$

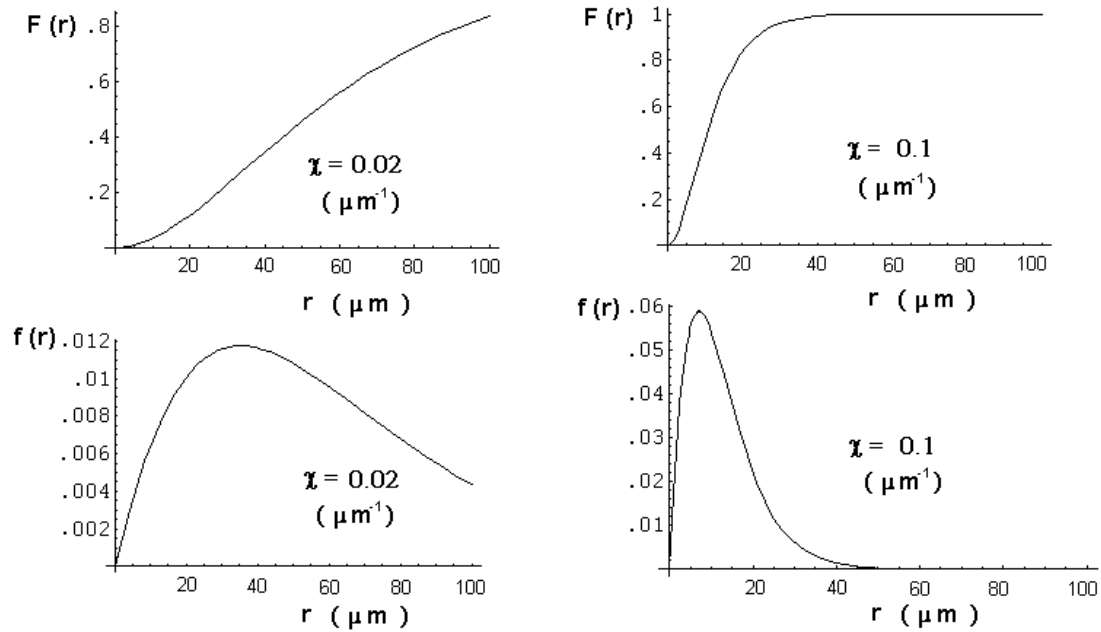

Figure 2 Transitional constriction size distributions of nonwoven geotextile with increase of the fiber specific length (χ) based on Matheron's model (1971). ($F(r)$ is cumulative probability function; $f(r)$ is probability density function where r is constriction radius)

Figure 3 Analogy model of wired mesh openings to explain the constriction size distribution of non woven geotextile. (f is frequency, a is the maximum size of openings, and $z=xy$)

The associated PDF, $f^*(z)$ can be derived from taking the derivative of cumulative $F^*(z)$. Similar to Figure 2, the mesh opening CSD becomes closer to the Poisson distribution as the wire intensity increases (Figure 3).

Fiber diameter (d_f) was considered the sub elementary layer thickness (T_e) in the Faure's model (Faure *et al*, 1990). Thus, calculated $O_{f,95}$ values of the thick nonwoven GT were not compatible with sieve test results due to the excessive sub layer numbers.

Urashima and Vidal (1998 and 2002) investigated experimentally the unit step walk distance with which the geotextile pore structures can be considered consisting of multi sieve layers sharing a common CSD, estimated from a probabilistic model or semi-empirically method such as by image analysis. A greater unit walk distance was measured for geotextile filters from the laboratory experiments compared with the granular filter ones.

2.2 Faure Model Modification for Production of Reasonable Sub Layer Number of Geotextile

If aforementioned findings are acceptable, Faure's model can be modified with a variable T_e , unit sub layer thickness depending on the design parameter, O_f^* (i.e. $O_{f,90}$ or $O_{f,95}$) determined from dry/wet sieving test or OSD from bubble point method, which subsequently influence on the sub layer number defined as $N = T_g/T_e$ where T_g is geotextile thickness.

Passing probability function or complementary cumulative probability function of geotextile constriction inscribed diameter ($d = 2r$) can be calculated with Faure's formula,

$$P(d) = 1 - F(d) = \left(\frac{2 + \chi(d + d_f)}{2 + \chi d_f} \right)^2 \exp[-\chi d] \quad [4]$$

where d_f is nonwoven GT fiber diameter, from Faure *et al*, 1990

Specific length, χ can be determined by the relationship with other geotextile properties. At each sub elementary layer of geotextile, the following equation is satisfied.

$$(1 - n)A \cdot T_e = \frac{\pi}{4} d_f^2 \cdot L \quad [5]$$

where n : porosity of geotextile, A : area of geotextile, L : length of textile fiber within the coverage area of A , T_e : the unit step walk distance between sub elementary layers

Therefore, the specific length, χ ($= L/A$) can be estimated from a determined T_e

$$\chi = \frac{4 T_e (1 - n)}{\pi d_f^2} \quad [6]$$

from Faure *et al*, 1990

The relationship between geotextile CSD and OSD is illustrated in Figure 4. Layer number is a critical parameter in determining the CSD from the OSD which is experimentally estimable by the bubble point method (ASTM D6767). In case OSD information is not available, the CSD can be assessed by the Faure's model with a O_f^* value from dry sieving analysis.

The specific length, χ for an sub elementary layer can be estimated from the value of O_f^* ($=O_{f,95}$ or $O_{f,90}$) measured by sieving tests (e.g. AOS from dry sieving or FOS from wet sieving). The CSD of sub layers is considered more compatible with the AOS value since the AOS is presumably independent of geotextile thickness (T_g) under cyclic dynamic load to facilitate particle penetration.

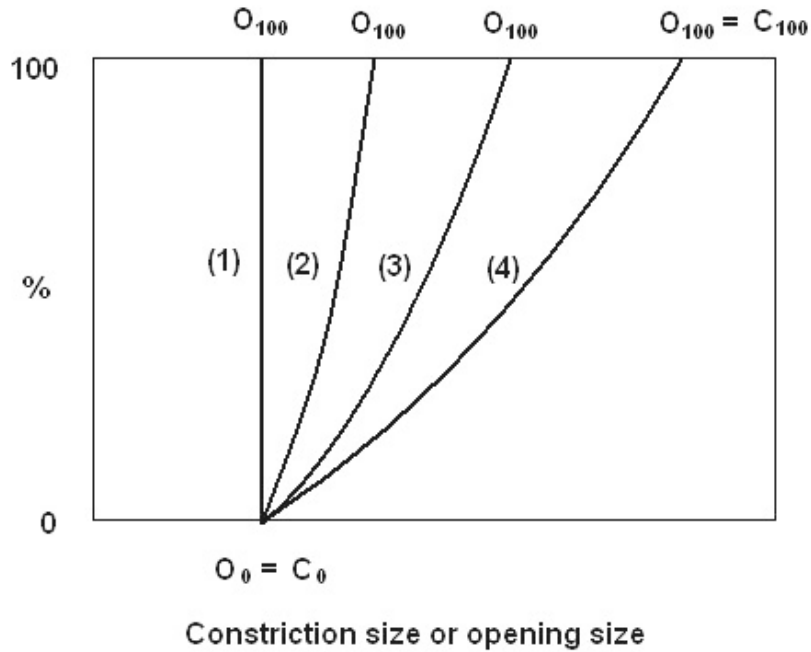

Figure 4 Opening size distribution curves of the four geotextile products from same nonwoven material, but with different thickness: (1) infinitely thick, (2) thick, (3) thin and (4) infinitely thin. (Curve (4) presents the constriction size distribution curves for the geotextiles.) from Giroud et al, 1998

$$P(O_{f,95}) = \left\{ \left(1 + \frac{O_{f,95}\chi}{2 + \chi d_f} \right)^2 \exp[-\chi O_{f,95}] \right\} = 0.05 \quad [7]$$

where O_f^* is based on $O_{f,95}$

The optimum value χ satisfying the experimental output (i.e. O_{95}) can be found by iterative method

$$2\text{Ln}\left(1 + \frac{O_{f,95}\chi}{2 + \chi d_f}\right) - \chi O_{f,95} = \text{Ln}(0.05) \quad [8]$$

Subsequently, the sub layer number, N can be determined from a relationship between T_e and χ (Equation 6). In comparison with original Faure's model (Faure et al, 1990), a CSD with smaller constriction size range was generated from the modified model for the same nonwoven GT porosity ($n=0.89$) and filtration opening size ($O_{f,95} = 0.21$ mm) (Figure 5).

For the nonwoven GT having 1 mm in thickness and 30 μm in fiber diameter, the sub layer number was calculated 6 by Equation 8, far less than 33 estimated by the original model. The modified CSD rendered a more realistic size range since unrealistic constriction sizes (i.e., over 1 mm) of the original CSD (Figure 5) was not produced. The OSD derived from the modified model also concurs with the lab experiment results of Bhatia et al (1996) in which the $O_{f,95}$ values of OSD are consistently smaller than AOS values for the tested geotextiles.

Figure 5 Constriction and opening size distributions of non-woven geotextile from the modified model proposed by author and original Faure's model (1990) where CSD: constriction size distribution; OSD: opening size distribution (detailed GT specifications are described in text contents).

3. PROBABILISTIC MODEL FOR FINE PARTICLE MIGRATION WITHIN GEOTEXTILE

Elsharief and Lovell (1996) developed an internal clogging model of nonwoven GT using the Markov chain theory. Their theory assumed three possible states of geotextile internal clogging exist such as the non-absorbing state when a particle size is smaller than the surrounding constrictions and two absorbing states when a particle size is larger than the constriction size or deposits onto the fiber surface. Even though their model took into account reduction in geotextile porosity under overburden pressure for the first time, Urashima and Vidal (2002) designated ignorance of additional non-absorbed state of small particles released from the fiber as the defect of the model.

In general, the porosity (n) of nonwoven GT influences on soil filtration performances primarily governed by seepage flow rate and capability of fine particle retention. A previous research indicated that the fine particle deposition onto geotextile fiber surface is less probable as the flow rate increases since the specific surface and the critical velocity producing particle deposition are much smaller than granular filter ones (Xiao and Reddi, 2000). However, the fine particle deposition will eventually occur inside nonwoven GT as the flow rate is attenuated by internal clogging process.

The pore sizes of nonwoven GT are more relevant to a physical clogging process, which prevails for non cohesive soils (e.g. fine sand and/or silt) whereas the fiber specific length of geotextile is more relevant to physicochemical process of fine particle deposition on the fiber surface, which prevails for cohesive soils (e.g. clay and/or bituminous soil). Therefore, both the constriction size and fiber specific length should be considered in the probabilistic model to explain the actual clogging behaviors of nonwoven GT influenced by both soil cohesiveness and particle sizes.

Porosity (n) needs to be associated with a retention probability, $1-P(d)$ in function of migrating particle size, d where $P(d)$ is a passing probability or cumulative probability function of constriction size, d since constriction areas are related to GT porosity. Meanwhile, the fiber density ($1-n$) needs to be considered in calculation of the particle deposit probability $q(d)$ (i.e., relative soil affinity to fiber material) in function of particle size, d (Figures 6 (a) and (b)). Hence, Markov chain formula used in the Elsharief and Lovell model (1996) needs to be expanded into including a non-absorb state of particle desorbed from geotextile fiber. Based on the four different cases of particle infiltration within geotextiles (Figure 7), the canonical form of the transition matrix can be reconstructed as following format.

$$\begin{matrix} & A & C & B & D \\
 A & \left[\begin{array}{cc|cc} 1 & 0 & 0 & 0 \\ 0 & 1 & 0 & 0 \\ \hline n(1-p) & (1-n)q & np & (1-n)(1-q) \\ n(1-p) & (1-n)q & np & (1-n)(1-q) \end{array} \right] & \equiv & \left[\begin{array}{c|c} I & O \\ \hline R & Q \end{array} \right] \\
 C & & & & \\
 B & & & & \\
 D & & & &
 \end{matrix} \quad [9]$$

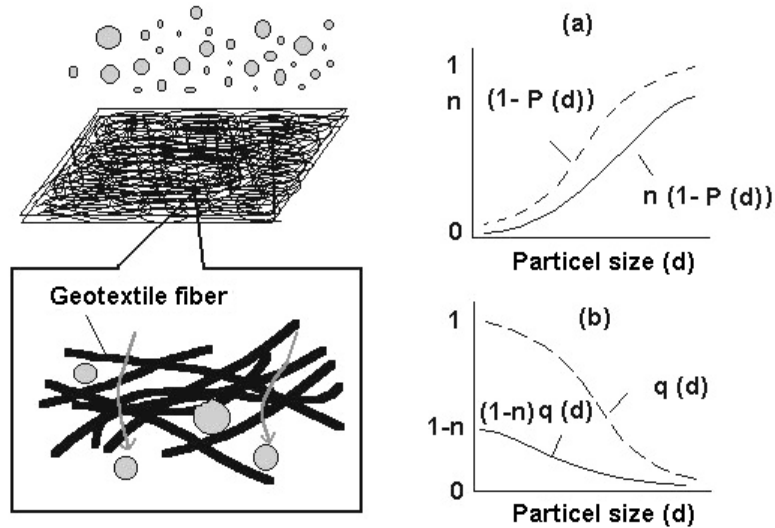

Figure 6 Retention and deposition probabilities of nonwoven GT clogging due to (a) the smaller constriction size and (b) particle affinity to fiber material where $(1-P)$ is cumulative CSD of geotextile ; q is the relative soil affinity strength to fiber material ; n is geotextile porosity

Figure 7 Possible scenarios of soil particle infiltration within nonwoven geotextile where (A) being retained by the smaller constriction; (B) passing across the larger constriction ; (C) being adsorbed to nonwoven GT fiber; (D) being desorbed from nonwoven GT fiber

From operation of the fundamental matrix, $(I-Q)^{-1}$ (Kemeny et al,1966), the probabilities of two ultimate absorbing states where state A is defined with particle retention by smaller constrictions and state C is defined with particle adsorption onto geotextile fiber can be assessed with the properties of geotextiles and soils (geotextile porosity (n), cumulative constriction size distribution $(1-p)$ and relative soil affinity to fiber material (q) where p and q are mutually independent functions of particle diameter, d).

$$\begin{aligned} \Pr\{A\} &= \hat{e}_1^T \cdot (I-Q)^{-1} \cdot R \cdot \hat{e}_1 \\ \Pr\{C\} &= \hat{e}_2^T \cdot (I-Q)^{-1} \cdot R \cdot \hat{e}_2 \end{aligned} \quad [10]$$

where $(I-Q)^{-1}$ and R are the fundamental and residual matrices defined in transition matrix. \hat{e}_1 and \hat{e}_2 are the column basis vectors- $\{1, 0\}$ and $\{0, 1\}$ respectively

The probability values for the ultimate absorbing states - cases A and C can be calculated as the p and q vary from 0 to 1 (Figure 8). Based on the simulation results, the physical pore obstruction by coarse particles will govern internal clogging process if the soil affinity to the fiber material is insignificant (i.e. q approaches to zero), and the particle deposition on the fiber will govern the clogging process especially for small porosity GT if the relative soil affinity is significant (i.e. q approaches to one).

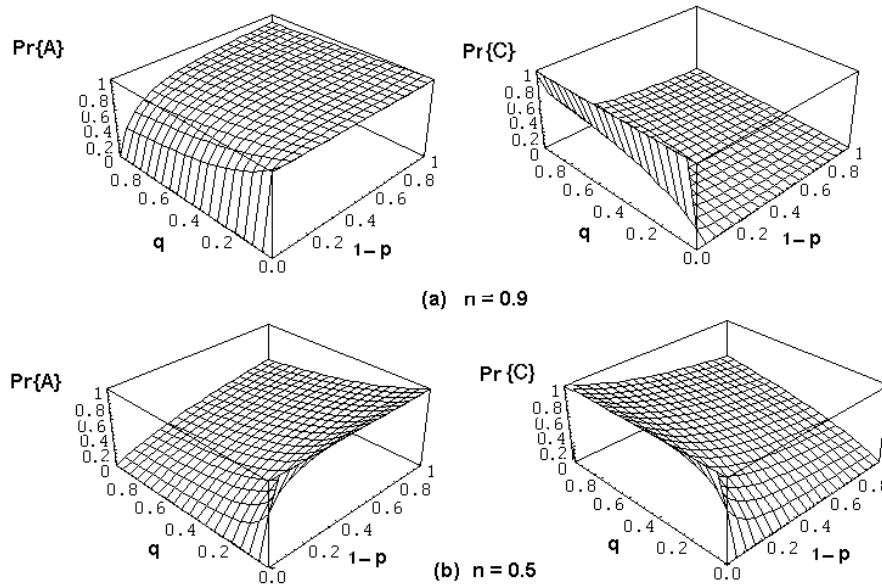

Figure 8 Joint probability distribution in functions of constriction size and soil affinity to filter fabric presenting the ultimate clogging states of non-woven geotextile (cf. $\Pr\{A\} + \Pr\{C\} = 1$) where n : geotextile porosity, $\Pr\{A\}$ and $\Pr\{C\}$: probability functions of cases A and C described in Figure 7

4. SUMMARY

Probabilistic modeling helps envision the subtle behaviors of fine soil particles associated with physical retention or chemical clogging inside geotextile filters. Proposed probabilistic methods showed satisfying results in characterizing of fabric constriction structure and estimating of the different geotextile filter performances subject to the various soil sizes. Due to limitation of existing experimental techniques to assess reliable and accurate pore/constriction size distribution of geotextile filter, these probabilistic approaches will help coping with the uncertainty of test outputs, inherited in the filter designs.

Many probabilistic modeling were conducted based on a best fitting probability function to delineate the features of filter pore/constriction and soil particle size distributions. However, a closer investigation is necessitated to check the feasibility of candidate probabilistic model, if the model has clearly defined the uncertainty of outputs and assumed realistic premise of probabilistic process. A further in-depth study should be followed to investigate whether advanced probabilistic models more relevant to the granular/geotextile filter design are available. The previous researches have already demonstrated that poor output reliability and productivity would be anticipated from the application of probabilistic models especially, if the probabilistic modeling was based on pre-mature assumptions of input parameters (e.g., soil/geotextile GSD and CSD), the authenticity of which could not be demonstrated by available advanced and reliable experimental techniques (image analysis with resin fixation).

5. NOMENCLATURE

AOS : apparent opening size of geotextile (measured by dry sieving)
CSD : geotextile constriction size distribution
 $F(r)$: cumulative probability function of constriction size, the inscribed circle radius, r
 $F^*(z)$: cumulative probability function accounting for the opening area, z ,
FOS : filtration opening size of geotextile (measured by hydrodynamic (wet) sieving)
GSD: soil grain size distributions, volume based
OSD : geotextile opening size distribution
 O_r^* : representative geotextile opening size specified for deterministic designs
 $O_{r,i}$: opening size of geotextile corresponding to i % in cumulative OSD
 $P(d)$, p : complementary cumulative probability function of constriction diameter, d presenting soil or non woven geotextile CSD or passing probability of particle size, d
 $1-p$: retention probability of soil particle due to limited constriction size
PDF : probability density function
 T_e : unit step walk distance between elementary sub layers of nonwoven geotextile
 T_g : geotextile thickness
 d : constriction inscribed diameter of nonwoven geotextile
 d_f : fiber diameter of nonwoven geotextile
 $f(r)$: probability density function of constriction size defined by the inscribed circle radius, r
 $f(xy)$: probability density function of the opening area (xy) associated with wire spans (x and y).
 $f^*(z)$: probability density function of the geotextile opening area (z), compensated for the constriction area ($z = xy$).
 n : porosity
 q : relative affinity of soil particle to geotextile fiber (0 is non- adhesive, 1 is fully adhesive)
 r : the inscribed circle radius of geotextile constriction
 ρ : soil specific density
 χ : fiber specific length in geotextile

ACKNOWLEDGEMENT

This research was performed as addendum part of author's Ph.D. research titled "Filter Performance and Design for Highway Underdrain" published by FHWA/IN/JTRP 2005/1, May, 2006.

Geotextile Tube Failures

Douglas A. Gaffney, P.E., Gahagan and Bryant Associates, dagaffney@gba-inc.com

ABSTRACT

This paper explores the various mechanisms responsible for the failure of geotextile tubes during filling. Geotextile tubes are designed to withstand the rigors of hydraulic filling. While failures are quite rare, they usually happen during filling or immediately after repeated pumpings. When tubes are used for dewatering slurries, they are generally subject to multiple fillings. Each filling subjects the tube to circumferential and axial stresses which cause elongation of the yarns. Repeated cycles can cause fatigue resulting in rupture. Six geotextile tube fabrics were tested using a modified ASTM D 4595 test which increased the tension to 325 pounds per inch in three cycles. During the third cycle, the geotextile was pulled to failure. The five polypropylene fabrics and one polyester fabric were tested in both the machine and cross machine directions. This paper will compare the stress - strain curves and relate the results to actual failures seen in full scale tube projects.

1. INTRODUCTION

1.1 Dewatering with Geotextile Tubes

A geotextile tube is simply a large tube sewn together from sheets of permeable high strength geotextile. Geotextile tubes have been used to dewater a wide variety of liquid wastes and dredged slurries since the early 1990's. While these high moisture content materials vary in viscosity and density, and range from organic to inorganic with widely ranging grain size distributions, they generally behave as a liquid, applying hydrostatic pressure to the geotextile shell. Water is released through the pores of the fabric leaving the solids in the tube. Over time, as the water drains, the percent solids within the tube increases.

Leshchinsky, et al (1996) formulate the shape of a geosynthetic tube filled with pressurized slurry on the equilibrium of an encapsulating flexible shell. The tube is analyzed as it lays on a flat surface and is inflated by the filling pressure. This analysis allows the determination of tensile forces in the axial and circumferential directions during the filling process. Parametric analyses provide two very important observations, namely: 1) circumferential stresses (hoop stresses) are always greater than axial stresses when filled on a flat surface and 2) when the tube circumference is known, the tube height can provide an accurate estimation of stresses in the geotextile and cross sectional area of the tube. Observation 1 is the reason that most geotextiles used in tubes have tensile strengths that are greater in the cross machine direction. Observation 2 allows filling to occur without monitoring the discharge pressure, since height alone has proven sufficient to monitor tensile forces in the tube. This second observation, however, does not account for changes in the geotextile yarns as a result of repeated fillings.

Multiple fillings are commonplace when the purpose is to dewater a high moisture content waste. Figure 1 shows an example of multiple fillings from a fixed volume storage tank into a small circumference tube (from Gaffney et al., 1999). The tube was filled every fourth day, on average. A characteristic curve is evident after each filling where the tube elevation decreases as the percent solids within the tube increases.

Figure 1. Time vs. height for a 15-ft circumference tube with sewage sludge (from Gaffney et al. 1999).

For larger dewatering projects, the usual procedure is to initially fill the tube to its prescribed fill height (note the dashed line in Figure 2), let it dewater, fill it again, and so on until the remaining capacity is too small to allow additional filling. A time history of fillings will resemble Figure 2 (Lawson, 2006). Each time the tube is filled it is pressurized. The pressure results in tensile forces on the yarns comprising the geotextile tube. The tensile forces elongate the yarns.

Figure 2. Filling, dewatering and consolidation stages when using geotextile tubes (from Lawson 2006).

1.2 Types of Failures

The vast majority of tubes are fabricated by sewing. A sewn seam is typically between 50 and 70 percent of the original tensile strength of the geotextile (ASTM D 4595). To account for this loss of strength, most geotextile tube fabrics are generally stronger in the cross machine (XD) direction. Since most tubes are sewn with a longitudinal seam(s) extending along the length of the tube, and since the highest predicted stresses on the tube are circumferential, it would stand to reason that failures would be most common at the longitudinal seam. This is, however, not the experience of the author.

Most tube failures are attributed to contractor error, pumping the tubes higher than the recommended fill height. In rare instances the failure will be along a longitudinal seam. The end seam can also fail for the same reason, although axial stresses are generally less than circumferential. If the tube is installed with the long axis on a slope, however, the low end will be subject to more hydrostatic pressure, and the end seam will experience axial forces greater than predicted. Another rare failure is due to a manufacturing flaw. Once a tube ruptures it can be very difficult to determine the cause

due to the difficulty exhuming the fabric. Sometimes a manufacturing defect can be determined if the failure is limited to one geotextile panel or the direction of failure does not correspond to the major stress direction.

The three most common failures are: 1) stresses induced at the fill ports that are located along the top of the tube, 2) a failure along the top centerline of the tube and 3) failure at the bottom of the tube when it is stacked above a “V” shaped gap between two bottom tubes. Stresses induced at the fill ports can be minimized by proper construction techniques related to the fill nozzle (or discharge pipe). It is good practice to suspend the discharge pipe over the fill port thus minimizing undue stresses on the fill port seam. When this is not practical, the rigid end of the discharge pipe should be minimal, and connected to flexible hose. Care should be taken during filling to adjust the fill line as the tube increases in height to minimize stress on the fill port seam. This paper will concentrate on the remaining two failure modes, namely the top centerline failure and failures when stacking.

2. TOP CENTERLINE FAILURE DUE TO CYCLICAL ELONGATION

2.1 Elongation

The wide width tensile strength test (ASTM D4595) places a load on a geotextile until it breaks. This test results in a stress strain curve similar to Figure 3. As the load is increased, the geotextile experiences elongation until it reaches a maximum elongation at failure. The fabric in figure 3 fails at a mean elongation of 17.34% and a load of 4,418.79 pounds per foot (552.35 pounds per inch).

Figure 3. Stress-Strain curve for Geotextile E, machine direction (MD).

Loading a plastic material such as polypropylene yarns results in elongation. Repeated loading necessarily generates plastic deformations in the yarns. In the case of a tube, filling it once, then allowing the tube to dewater, will induce plastic deformation, that is, the yarns do not completely return to their original length, and presumably loses some tensile strength.

When the tube is allowed to relax during dewatering, the elastic component if the deformation is recovered. The next loading starts at new yarn length due to the plastic deformation generated in the first loading. Repeated loading will increase the plastic (permanent) deformation in the yarns and will eventually break at a certain specific plastic strain. In geosynthetics, if the plastic strain plus the elastic strain induced by the last loading exceeds a certain percentage, breakage will occur. In fact, the material will quickly creep leading to creep strain failure (Leshchinsky, 2012). A modified wide width tensile test was conducted to examine this phenomenon; the test results of which will be discussed in Section 4.

2.2 Example Failures

Actual geotextile tube failures are rather infrequent, and are not generally reported in the literature. Some examples do exist. Taylor, et al (2001) report a failure during “topping off” which started at one of the fill ports and ran the length of

the tube. The description implied repeated fillings, and also that the tube was on a sloped concrete pad. Post-failure testing indicated that there was a loss of tensile strength and this was attributed to UV degradation. Looking back in hindsight, the loss of tensile strength could have resulted from repeated fillings and resultant plastic deformation in the yarns.

In another dewatering project in Michigan, a 45-foot circumference polypropylene tube experienced catastrophic failure when the top of the tube split from one end to the other. Examination of the geotextile revealed telltale elongation of the yarns (see Figure 4).

It was determined that the tube had been filled twice prior to the failure. The fill material was a slurry containing both sand and fine-grained material (silt and clay). When the tube was full, it was allowed to relax during dewatering. During this time, the sand settled in a dense flat "pancake" on the bottom while the fines dewatered. During the second filling, the tube was inflated to normal height. To achieve the characteristic elliptical tube shape, the sides of the tube (now filled with sand) had to be raised off the ground by the tensile strength of the geotextile. The tube was again allowed to dewater and was filled a third time. Again, the sides of the tube had to be raised off the ground to allow the tube to reach its maximum fill height. At this point the stress in the yarns was concentrated in the top center of the tube where the failure occurred.

Figure 4. Elongated yarns at the location of failure.

To test this theory and to prevent future failures, a 10 inch long line was painted on the top of the tube in the circumferential direction. Each time the tube was filled, the line was measured. As expected, the line increased in length, conforming to the elongation. This procedure was so predictable and effective that the contractor used this method to allow filling to the maximum extent prior to planned failures (see Figure 5).

Figure 5. Controlled failure of tube.

3. BOTTOM CENTER FAILURE IN A STACKED CONFIGURATION

As dewatering projects have become larger, with larger circumference tubes and more dredged material to dewater, stacking tubes has become more commonplace. With stacking, a relatively new type of failure is seen at the bottom of the tube. Two examples were reported by Vine and Jury (2005). In both cases, the tubes were being filled on top of a row of previously filled tubes. The configuration is similar to Figure 6.

Figure 6. Schematic of stacked tubes.

In reality, tubes are often not stacked as neatly as Figure 6. Gaps can exist between the underlying tubes resulting in a “V” shaped void. The stresses on the geotextile within this void space can be examined as discussed in Plaut and Klusman (1999). Note the tensile force S_7 in Figure 7. Assuming that the coefficient of friction between the upper and lower geotextile surfaces is 1.0 (in a static condition), the force S_7 can be estimated using the analysis for a container filled with slurry exiting a split barge (see Pilarczyk ,2000). The two bottom tubes are presumed to be solid and the slurry in the top tube behaves as a liquid. The highest stresses are shown to occur when the fill material behaves as a liquid.

Figure 7. Geometry and coordinate systems for three tubes (from Plaut and Klusman, 1999)

The failures reported by Vine and Jury (2005) noted a gap and deep notch under the tube that failed. Figure 8 shows an example of a stacked tube configuration that has suffered this type of failure. In subsequent stacking operations by others, when the gap becomes too large, an attempt is made to fill it. One such method uses a small filler tube. It should be noted that when tubes are circumferentially sewn, there is a longitudinal seam in exactly this region of potential stress.

Figure 8. Example stacked tube configuration.

4. ANALYSIS OF GEOTEXTILE SUBJECT TO CYCLICAL STRESS

A modified ASTM D4595 test was conducted on a variety of geotextiles commonly used in the fabrication of geotextile tubes. In this procedure, the strain is fixed when the load reaches 325 pounds per inch (ppi), and cross head movement is stopped. This load was chosen as it represents a typical stress applied on a tube when filled to 6 feet in height. Then, after 15 minutes the load is completely removed for 15 minutes. This procedure is repeated, then loaded to ultimate. The geotextiles are described in Table 1 below. Geotextiles A, C, D, E and F are woven polypropylene while Geotextile B is woven polyester. Geotextiles A, D, E and F are most similar in terms of yarn type, weave and published MARV tensile strength.

Table 1. Geotextiles used in the modified wide width tensile test

Style	Type	Direction	Ultimate Cyclical Tensile Strength (ppi)	Ultimate Published Elongation (MARV) %	Ultimate Cyclical Elongation %
A	Woven PP	XD	651	9	10.2
A	Woven PP	MD	475	14	12.9
B	Woven PET	XD	1199	17	16.7
B	Woven PET	MD	1233	17	21.5
C	Woven PP	XD	960	18	21.6
C	Woven PP	MD	465	18	20.6
D	Woven PP	XD	639	20	13.4
D	Woven PP	MD	488	20	19.5
E	Woven PP	XD	615	n/a	14.8
E	Woven PP	MD	511	n/a	23.9
F	Woven PP	XD	645	16.5	12.2
F	Woven PP	MD	447	26.5	19.5

Figure 9 is an example of the cyclical stress test results for Geotextile E, machine direction (MD) which can be compared to the results shown earlier in Figure 3. From Figure 3, the average ultimate tensile strength of this geotextile is 552 ppi with the lowest value being 537 ppi. The ultimate tensile strength of the same fabric after the third cycle is less at 511 ppi (see Figure 9). Additionally, the total strain (elongation) is 23.9% in Figure 9, while the average elongation in Figure 3 is 17.34%. Results are similar for the same fabric in the cross machine direction (not shown). Standard stress-strain data was also available for geotextile D. Similar observations were observed, namely that the tensile strength of the fabric was higher when tested in a single pull, and the elongation was lower. To summarize, the act of placing the geotextile under cyclical stress tends to stretch or elongate the yarns making the tube larger in circumference, and slightly weaker over multiple fillings.

Figure 9. Cyclical Stress-Strain curve for Geotextile E, machine direction (MD).

5. SUMMARY AND CONCLUSIONS

In summary, while failures remain infrequent, they can be minimized even further through a better understanding of the physical properties of the geotextiles that make up the tubes. Standard tube geotextiles have been designed for the rigors of most filling applications, and this includes the seams, both longitudinal and circumferential. Actual field conditions, which include foundation slopes, dissimilar fill materials, and gaps under tubes can be accounted for in the design of the fabric and in the recommended fill height, or in the contractor's construction methodology. For example, when designing tubes to be stacked, the specified fill height should account for the possibility of a gap under the tube. In other words, either a factor of safety should be applied, or the additional step of determining that the tensile strength in the scenario of cyclical stress and void space under the tube is adequate.

A very small data set was used in the development of this paper. It is recommended that more testing be accomplished to increase the size of the data set. Based on the above test results which show a loss of tensile strength due to cyclical stress, further analysis should be done to establish a rule of thumb to account for this loss. At a minimum, project owners and engineers should ensure that the design of large dewatering projects, especially stacked tubes on contaminated sites, has addressed the potential for the types of failures identified.

ACKNOWLEDGEMENTS

Granular Columns Reinforced with Geosynthetics: An Overview of Employment Trends

Santos, C.T., Aeronautics Institute of Technology, Brazil, caroline@ita.br
Vidal, D.M., Aeronautics Institute of Technology, Brazil, delma@ita.br
Queiroz, P.I.B., Aeronautics Institute of Technology, Brazil, pi@ita.br

ABSTRACT

Granular columns are vertical structural elements of dense interlocking aggregate or compacted sand, that are intended to increase the foundation overall bearing capacity and provide vertical drainage pathways to expedite the consolidation settlement. They are recognized as highly efficient and cost-effective ground improvement techniques. However the rigidity and load carrying capacity of the columns depend largely upon the amount of lateral restraint or confining stress that can be mobilized in the surrounding soft clay to avoid excessive radial deformation or even to keep the column's integrity. This additional restraint required could be provided by encapsulating the column granular backfilling in a geotextile wrapping, a technique that is referred to as geotextile-encased columns (or just GEC). The GEC represent the most wide-spread technique for improving poor ground using granular columns reinforced with geosynthetics, however other possibilities have been published, which can slightly or strongly differs from the current concept. According to some authors the reinforcement of a granular column can be also achieved by horizontal tensile elements (geosynthetic layers) either in full or partial column length, or by partial encasement of the upper column section that is prone to bulge. Another variation closely related to the conventional GEC technique is to encapsulate columns with geogrids or geocomposites. Hence, the aim of this paper is to present a broad review and a comparative analysis of the techniques proposed to reinforce granular columns with geosynthetics over the last 30 years, discussing the advantages and the feasibility of each method.

1. INTRODUCTION

Ground improvement methods using column-type techniques have been largely employed in construction over poor ground, especially when soft cohesive soils are involved. The current range of column-type techniques includes granular piles (stone columns and sand compaction piles), grout injected stone columns with load transfer mats constructed with geosynthetic reinforcement, combined soil stabilization with vertical columns (CSV-method), geotextile encased sand columns (GEC), cut-mix-injection method (FMI), lime and lime cement columns and friction piles in soft soils. Undoubtedly, granular columns (stone columns and sand compaction piles - or composer piles) represent the most wide-spread column-type technique for improving loose or weak soils (Kempfert 2003).

As the name implies, granular columns consist on the introduction of granular cylinders with intervening native soil which are disposed in a regular grid-pattern according to the soil profile and its mechanical characteristics. Depending to the execution process, the natural soil can be partially replaced by granular material infilled into holes made with the depth vibrator and compacted (vibro-replacement process).

Despite some similarities, granular columns differ from the classical foundation techniques like piles once they act over the terrain improvement and not only on the loads support. Considering that granular elements are stiffer then the local soil, the loads tent to concentrate over them; however, when loaded, the columns deform by bulging into the subsoil strata compressing the native soil. Furthermore, regarding the columns high permeability, the native soil water tends to migrate to them, allowing a faster dissipation of porewater pressures and, consequently, accelerating the consolidation settlements. Hence, the strengthening of the surrounded ground is accomplished and the bearing capacity of the composite ground is increased while its compressibility is reduced. With the development of the process the stress concentration over the columns tends to be relieved and the role of supporting loads is in part transferred to the native soil mass.

The range for granular columns applications includes not only the improvement of in-place soils with an appreciable content of fines. In fact, there are potential benefits in the application of granular columns for the densification of natural deposits or fills made of loose sands and gravels.

The feasibility of using any ground improvement approach in any given case depends on several factors, mainly on soil conditions. The granular columns performance is significantly related with the lateral support provided by the surrounding soil. To maintain the columns integrity, the lateral passive resistance mobilized in the surrounding soil must be at least equal to horizontal stresses exerted by the column, what can be many times impossible in very soft cohesive or organic

soils. It is worth noting that the horizontal support depends also on the vertical pressure over the soft soil, which magnitude can be much smaller than those acting over the columns.

One way to allow the application of granular columns in very soft soils could be made by the employment of some binder, like grout, cement, lime or quicklime, with the aim to confer some cohesion to keep the columns steady. On the other hand, this solution could affect the performance of the columns as drains, and consequently, their contribution on the soft soil improvement.

Another way to enable the employment of granular columns on very soft cohesive or organic soils is reinforcing the granular material with geosynthetics, both by confining the granular backfilling in geotextile, geocomposites or geogrids wrappings or by placing horizontal tensile elements (geosynthetic layers) either in full or partial column length. In the following, the particularities of each one of these solutions are discussed.

2. GEOTEXTILE ENCASED COLUMNS (GEC)

Geotextile-encased columns (GEC) system is a soft soil improvement technique that consists in confinement of granular material by geotextile wrappings. The idea of encasing granular columns with geotextile wrappings is commonly attributed to Van Impe (1986), however the technique devise is still not clear. Gray et al. (1982) were probably the first to recognize that columns could be encased by geosynthetic fabrics, however this work presented a particular concept of reinforcing sand columns internally and externally with geotextiles in a synergistic fashion. This proposal will be discussed in a future item.

Probably the first attempt on GEC employment was an improvement of containment dike foundation to Leitha river in the low Austria, between the cities of Rohrau and Pachfurth in 1991, which was reported by Strauch (2003). In the following Geuder & Bräu (1997) reports the execution of small diameter encased-ballast columns in 1993/1994 used to speed the consolidation of a clay stratum that should to be improved to the construction of railway line embankment. Similar attempt was reported to Kitazume et al. (1993) that presented results of centrifuge model tests of "fabric-packed sand drains" performed to investigate its effect on the improvement of dredged soft sea sediment to be used on the Haneda Airport reclamation in the Tokyo Bay area, which started in 1994. The aim of this study was to assess the effect of fabric encapsulation on sand drains integrity as well as to verify the evolution of the consolidation process and its influence over the effective terrain improvement.

In all of the three first attempts in adding an encasement to granular columns, non-woven geotextiles were employed. Despite columns did not performed as bearing elements in the last two referred projects Kitazume et al. (1993) reports that good results reached in mechanical terms in the Haneda Airport construction, which was confirmed both in laboratory and in the practical application.

It seems that the two following projects just happened 1996 on road embankments projects in Germany, which were reported by Kempfert (1996), Kempfert & Wallis (1997), Raithel & Henne (2000) and deeply analyzed by Raithel (1999). In all of these projects the encasement employed was fabricated using woven and non-woven geotextiles and geocomposites sewn in the radial direction and in the bottom end. However, the significant growth in using GEC system only came with by the development of a woven geotextile encasement manufactured seamlessly in the radial direction, what happened just in the end of nineties. This solution circumvented some problems related to joints in the main load-carrying direction and consequently improving, together with the use of the woven products, the confinement efficiency.

Hence, the GEC ideally suited to cope with extremely soft soils because the confinement and consequently the stiffness that the geotextile encasement adds to the granular columns. The high tensile stiffness and the lower radial strain of the products available to the encasement construction provide the increasing of a single column bearing capacity thus reducing settlements. However, it must be noticed that, despite geotextile encased columns being stiffer than the uncased ones, this solution is still more flexible than conventional piled embankments and its concept remains quite different, once the columns are aimed to improve the proper surrounding soil. Nevertheless, the benefits achieved by the use of the GEC technique are not limited to mechanical advantages that regards to the bearing behaviour. Because of the fine size particles and the low permeability of soft soils, the insertion of the GEC enhances a significant drainage in the foundation. The ability of the geotextile wrap to prevent particle migration while allowing the free passage of water provides the maintenance of the drainage properties of the column. In addition to having suitable filtration properties, the granular column encasement provides a further benefit of separation, i.e., it prevents the intermixing of poor in-situ soil with column backfilling. Lastly, the advantages of the GEC-system in comparison to similar techniques, in special to conventional granular columns, or piled embankments can be summarized as:

- Allow the execution of granular columns into extremely soft soils: in contrast to conventional techniques, geotextile-encased columns can be used as a ground improvement and bearing system in extremely soft soils,

for example peat or sludge with undrained shear strengths $S_u < 2 \text{ kN/m}^2$; uncased granular columns are usually limited to soft soils which possess undrained shear strength superior to 15 kPa.

- Might provide cost savings: studies proceeded by Short et al. (2005) have shown that GEC system was less costly than other methods such as deep mixing or augercast piles with pedestals for the analysed case. Also, in comparison to conventional granular columns, the encasement may allow higher columns spacing, since the bearing capacity of the single units are much higher (Kassem & Imai 2004), and demand smaller volume of filling since the material loose to the soft soil around is reduced due to confinement promoted (Mandal & Kamble 1999).
- Reduce post installation settlement compared to conventional granular columns and prefabricated vertical strip drains (wick drains).
- The encasement provides an uniformly shaped column - The varying diameter of the column over a certain length plays a vital role in load transfer (Muir-Wood, 1990). In addition, whereas geotextile-encased column surface are smoother than piles, they are hardly affected by negative shear stresses that might occur.
- Less time consuming: discard preloading requirement and allow immediate loading after installation avoiding delays with curing, for instance (Short et al. 2005).
- More flexible behaviour: special interesting in situations where secondary settlements will play an important role on the system behaviour, like in organic soils like peat which significant secondary settlements might occur regarding the organic matter decomposition.
- Environment friendly since the amount of backfilling material might be reduced and, when installed by the displacement method, no in-place soil needs to be removed and consequently it is not required off-site disposal, what can be specially interesting on dealing with contaminated soils.

By now, the GEC technique has been applied in almost 30 important projects, most of them in Germany, in which country the technique experimented the major part of its development. Raithel et al. (2005) tabulates all the 20 first projects executed in Germany from 1996 to 2004, Nevertheless GEC projects were also executed in Netherlands, Sweden, Brazil and Spain (Figure 1).

FIGURE 1 – (a) polder construction for EADS Industry enlargement in Germany (Source: Huesker); (b) first GEC Brazilian work – connection between SP-99 Rodovia dos Tamoios and BR-116 Rodovia Presidente Dutra. In details, installed columns.

Regarding installation, two execution procedures were developed to GEC-system: the displacement and the replacement method. The basic difference between them is that in the displacement method no local soil is removed and in the replacement method the soil within the open steel shaft (employed to support the column installation) is taken out by an auger boring. Regarding many advantages, the displacement method is being more employed. The scheme in Figure 2 describes this installation procedure by this method. Details of each of installation process, as well as their advantages, disadvantages and applications interval can be found in Kempfert and Gebreselassie (2006).

In terms of design, the project of GEC-systems has been done essentially on the basis of the design method proposed by Raithel (1999, 2000). Despite this design tool allows the forecast of total settlements with high confidence, but it does not provides a practical approach to the evaluation in terms of prediction and performance, especially regarding consolidation process development. Recently, Santos (2010,2011) a presented a series of analytic solutions which provide a basis for a rational prediction of the system consolidation response. This last method is also capable of addressing the effect of column installation and the stress concentration ratio over the consolidation. Due to the lack of

space, the design procedures are beyond the scope of this paper and we suggest to consult these two last authors to further information about this topic.

FIGURE 2 – Installation by the displacement method using end-closed pipe - from Alexiew et al. (2005).

3. GEOGRID ENCASEMENT

Another variation closely related with the last solution discussed (use of geotextile) is the columns encapsulated with geogrids. Similarly, this technique consist on encapsulating compacted mineral materials by a cylindrical-shaped encasement sleeve formed by a geogrid. The employment of geogrid wrappings are often related to coarse filling (crushes stones, gravel and aggregates) and for that reason the technique is frequently referred as geogrid-encased or geogrid reinforced stone column.

According to Gniel & Bouazza (2009), despite the obvious suitability of geotextile encased columns to certain applications, the technique can be limited by the relatively large settlements that occur as a result of minimal compaction received during installation and geotextile strain during loading. Moreover, according to Schuessler (2002) apud Trunk et al. (2004) sand columns encased by woven-geotextiles require relatively large lateral strains to mobilize the ring-tensile forces, which also can lead fairly large settlements of the overall system. Despite these statements being quite controversial, the idea of employing geogrids as granular columns encasement is to provide a more robust and perhaps stiffer alternative to geotextile and to broaden the appeal of geosynthetics in stone column ground improvement (Gniel & Bouazza, 2010).

According to Lee et al. (2008) another advantage of the geogrid-encased stone column technique in relation to the geotextile encased columns regards to the possibility to employ waste concrete and recycled aggregates as a filling material. Indeed, this range of filling may lend to this solution a series of potential site applications and also may provide economical and environmental benefits.

The use of geogrid encasement has been investigated for many authors like Smoltczyk (1999), Schuessler (2002), Paul & Schwedt (2003), Heerten (2004), Heerten & Ewert (2004), Trunk et al. (2004), Paul & Ponomarjow (2004), Malarvizhi & Ilamparuthi (2004), Gniel & Bouazza (2009), Gniel & Bouazza (2010). Smoltczyk (1999) describes a set of large-scale load tests performed on 5 columns in a field trial and Paul & Ponomarjow (2004) and Trunk et al. (2004) discuss a large-scale unconfined compression laboratorial testing. Malarvizhi & Ilamparuthi (2004) studied the load versus settlement response of geogrid-encased columns by small-scale modeling using three different types of geogrid net.

Regarding geogrid encasement confection, most of references like Heerten (2004) suggest as the construction technique rolling geogrid into a cylinder and mechanically welding a narrow section of overlap (about 30 mm wide) to form the encasement sleeve. According to Gniel & Bouazza (2010) the technique of welding provides an effective method for constructing geogrid encasement sleeves but it is unlikely to be used in practice. The technique requires either the shipment of a large welding frame to site or prefabrication of geogrid encasement sleeves away from site and both methods are unlikely to be cost effective. To overcome this problem Gniel & Bouazza (2010) investigated an alternative method of encasement construction that comprises overlapping the geogrid encasement by a nominal amount and relying on interlock between the stone aggregate and section of overlap. Based on a series of small-scale and medium-scale compression tests using different geogrids types - Figure 3 - Gniel & Bouazza (2010), concluded that the “method of overlap” provides a simple and effective method of encasement construction, providing a level of fixity similar to welding. However, still according to this author, a full circumference of overlap should generally be adopted to achieve adequate fixity. Hence, this solution to the encasement construction also seems to be economically disadvantageous and cost concerns appears as the greater obstacle on the geogrid as encasement adoption.

It must be also pointed out that the “window-mesh” type of the geogrid do not provide the adequate separation of the filling material and the surrounding soft soil as well as this solution fails on the drainage properties maintenance. Indeed, bisection of samples in small-scale laboratorial testing reported by Gniel & Bouazza (2009) showed significant ingress of surrounding clayey material into the prototypes, possibly reducing the columns performance as drains. To overcome problems associated with clogging, some authors suggest the use of a geogrid combined with a mechanically bonded non-woven geotextile (Trunk et al., 2004), creating a solution closer to the use of geocomposites.

With respect to installation, Trunk et al. (2004) also present some field trials regarding the installation using a bottom feed vibrator which, according to these authors, provide the filling with a high degree of density and what can consequently reduce the magnitude of deformations and settlements by loading. In this solution, the geogrid wrapping is positioned around the outside of the vibroflot before driven it down, like the displacement procedure using a depth vibrator to geotextile-encasement columns. On the other hand Gniel & Bouazza (2010) suggest the employment of the excavation method to perform the installation of the geogrid-encased columns - Figure 4.

FIGURE 3 – Medium-scale testing with columns encased by two types of geogrid and one geocomposite performed by Gniel & Bouazza (2010). Extracted from Gniel & Bouazza (2010)

FIGURE 4 – Installation of the geogrid reinforced stone column - Adapted from Gniel & Bouazza (2010)

After all, it seems that the unique attempt on using geogrid-encased columns was reported by Trunk et al. (2004) in the foundation of a training center (Villa Borsig) in Berlin, however the geogrid encasement in this project was employed as a mold to concrete stone columns. More specifically, the geogrid wrapping was used in these project in order to prevent an uncontrolled leakage of the concrete into the soft underground and it had any further function after curing the column. However the effective application of the geogrid-encased stone column method to actual construction was not reported until the present moment, fact which was also outlined by Lee et al. (2008).

4. PARTIAL ENCASED COLUMNS

The lower lateral earth pressure and lower stiffness of near-surface soils may cause greater radial expansion on the upper section of granular columns. This phenomenon known as bulging is one of the most common failure mechanisms for granular piles.

According to some authors like Murugesan & Rajagopal (2006), Gniel & Bouazza (2009), Wu & Hong (2009) the partial encasement of only this zone prone to bulge may adequately reinforce the column. Murugesan & Rajagopal (2006) outlines that this innovative design solution are specially interesting when very long stone columns are involved.

An analytical procedure to determine the optimum column skirting length that prevents the granular column from bulging was presented by Wu & Hong (2009). Theoretical simulations proceeded by these authors indicates that the characteristics of the in situ soil and the stiffness and yield strength of the sleeve govern the optimum skirting length.

Murugesan & Rajagopal (2006) have investigated the performance of partial-encased columns through a parametric study carried out by finite element analysis. Analyses were carried out adopting an encasement stiffness of 2500 kN/m and 0.6 m as the column diameter. Varying the depth of the encasement from the ground level it was observed a settlement reduction over the uncased situation until a depth of encasement that corresponded about two diameters of the stone column (until 1 m) - see Figure 5. Based on these results, Murugesan & Rajagopal (2006) have concluded that this limit determines the optimum skirting length and the stretching of the encasement sleeve up to twice the diameter of the column does not lead to further improvement in performance.

FIGURE 5 – Influence of encasement depth on the settlement response obtained by FEM analysis performed by Murugesan & Rajagopal (2006)

To investigate the impact of partial encasement on vertical and radial column deformation Gniel & Bouazza (2009) developed a laboratory scale model testing program where tests were undertaken on columns with 25 %, 50%, 75% and 100% encasement. In the obtained results for partially encased columns the entire non-encased length was observed to bulge. Still, radial bulging tended to increase in magnitude with increased encased length and the largest lateral deformations occurred directly below the base of the encasement. However, it is expected that by changing the length of encasement, the bulge zone can be transferred to depths able to offer a greater confinement, in a way that columns could be tailored to meet a range of settlement criteria. Hence partially encased columns could be a good alternative for sites with layered stratum, where a soft clay overly a relative firm layer or in profiles where shear strength monotonically increases with depth. Anyway, Gniel & Bouazza (2009) have observed that the fully-encased columns displayed a much stiffer response, contradicting the results obtained by Murugesan & Rajagopal (2006).

However, as many other alternative solutions, it seems that partial encased columns have been not employed in the practice. Still, careful consideration must be given to installation techniques and encasement material selection.

5. IMPROVEMENT BY HORIZONTAL REINFORCEMENT LAYERS

According to some authors the reinforcement of a granular column can be also achieved by placing horizontal tensile elements either in full or partial column length (Wu & Hong, 2009). In fact, it seems that the idea of reinforcing granular columns with geosynthetic layers preceded the encasement concept, as it is inferred by the pioneer Gray et al. (1982) work. In their proposal, Gray et al. (1982) introduced the concept that lateral restraint comes both from encapsulating the sand column with a woven geotextile used conjunctively with intercalated fabric layers (both woven or non-woven) within

the sand - Figure 6. In the following Gray et al. (1989) evaluated the performance of embedded granular structures reinforced independently with internal layered geotextile inclusions and externally encapsulated with a fabric skin.

Figure 6 - Internally/ externally fabric reinforced columns - pioneering proposal of Gray et al (1982). - Adapted from Gray et al.(1982)

It seems that the original concept was to insert reinforcement layers evenly placed in whole column length, however, considering that the most common granular column failure mechanism is governed by bulging near the top portion, this technique is most frequently referred as a resource to prevent the excessive radial displacement in this region. Hence, following the same idea of partial encased columns technique, the idea consists in laying out a certain number of reinforcing sheets (most of times geogrid layers) up to a certain extent of the top region prone to bulge (Sharma 1998, Madhav et al. 1994, Sharma et al. 2004, Wu & Hong 2008). Figure 7 schematize this concept.

FIGURE 7 – Concept of the "laminated reinforced granular column"

In this technique the lateral restraint and the improvement of the column bearing capacity are achieved through the boundary shear stress developed in the granular material - reinforcement interface (Madhav et al. 1994). The inclusion of reinforcement layers results in redistribution of lateral deformation of granular column and, therefore, provides the transfer of lateral stresses from the column to the soft clay (Sharma, 1998).

The improvement provided by this technique depends on the number, spacing and the column length reinforced and also on interactive mechanism at the soil-inclusion interface (angle of shearing resistance of the granular medium and the coefficient of frictional resistance of reinforcement). It seems that all researches agree that the bearing capacity increasing is related to the increasing of the number of reinforcing layers and the spacing decrease among them (Gray et al.1982, Gray et al.1989, Sharma 1998, Madhav et al. 1994, Sharma et al. 2004, Wu & Hong 2008). However, Gray et al. (1982) have observed in a triaxial test programm with sand samples where reinforcements were evenly spaced that although reinforcement with synthetic fabrics increase ultimate strength, they tend to reduce overall stiffness of sand and this tendency is still pronounced as the number or reinforcement layers increase.

According to a parametric study using FEM presented by Sharma (1998) the optimum spacing of geogrid layers was found to be between 0.5 to 1.5 times the diameter of the stone column and the installation of geogrid layers at spacing closer than 0.5 times the diameter of stone column does not result in appreciable increase in column bearing capacity. Moreover, according to laboratorial tests conducted by Sharma et al. (2004) the column load-carrying capacity is further improved when the granular pile was reinforced by geogrids. However in the study presented by Sharma (1998), referred previously, it was concluded that is better to reinforce the stone column using a more flexible reinforcement spaced in smaller intervals than to employ a stiffer reinforcement more spaced apart because the column will evenly deform. Still

according to Sharma (1998) this would result in bulging being distributed over a greater length, thus preventing localized bulging failure and furnishing a better performance.

The stress-deformation response of sand columns reinforced with layers of both woven and non-woven geotextile inclusions was investigated by Gray et al. (1989) that developed a finite element model that was validated against results of triaxial tests. The results of this study showed that the stress-strain response of woven fabrics is best modelled as an elastic, polynomial function of strain, whereas that of non-woven fabric was best represented as a function of confining stress. Also with the aim to investigate the load carrying response of the “laminated reinforced granular column”, Madhav et al. 1994 presented an analytical approach to evaluate the ultimate bearing capacity by modifying the Hughes & Whithers (1974) model proposed to conventional granular columns. In the same line, Wu & Hong (2008) adopted models from Duncan & Chang (1970) and Wong (1990) to formulate the mechanical characteristics of the granular materials and establish analytical procedures to investigate the axial stress-strain response of an encapsulated granular column. The proposed analytical method was verified through laboratory triaxial tests carried out with sand columns reinforced with four layers of horizontal geotextile sheets (Figure 8). The evaluations of these two analytical analysis strongly agree with the studies run by Sharma (1998), Sharma et al. (2004) and, concerning to the triaxial tests proceeded by Wu & Hong (2008) it was observed that the slippage occurs for columns reinforced with stiffer inclusions, what also converge to the results obtained by Sharma (1998).

In addition, this technique does not appear to adequately prevent the clogging of the granular medium and keep the column drainage properties. Moreover, it can not prevents the lateral squeezing of the column backfilling embedded in very soft to extreme soft clays and the limits of the technique in terms of the undrained resistance of the soft soil. Indeed, in the triaxial tests performed by Gray et al. (1982) aforementioned the sand specimens failed by bulging or lateral spreading between reinforcements. In addition, it was observed that below a critical confining stress the reinforcements tended to slip or pullout as apposed to stretching

As the last solution presented (partial encased granular column), no field trial was reported to confirm the technique efficiency in the construction practice.

FIGURE 8 – Laboratory triaxial tests with four-layer reinforced specimen - from Wu & Hong (2008)

6. FINAL REMARKS

There is no doubt that the use of geosynthetics amplified the range of application of the granular columns, furnishing both economic and technical benefits.

Regarding the GEC, that is the most disseminated and employed technique to this aim, an important distinction needs to be drawn between the use of non-woven and woven geotextiles. There are important differences in the stress-deformation response of encased granular columns with relatively low modulus non-woven fabrics to the high modulus woven fabrics. The tensile modulus and allowable elongations in the reinforcement are important considerations and

high modulus reinforcement will greatly inhibit internal soil tensile strains, limit boundary deformations and increase strength. For this reason, when mechanical characteristics of the geotextile are important features in the project as in the cases where very soft soils are involved, woven products appear as the most appropriate choice.

On the other hand great benefits could be reached by the adoption of non-woven encasements when the geotextile reinforcement property is not required (soils in which additional lateral restraint is not necessary) as a separation and filter element in order to keep the good quality and the mechanical properties of the backfill as well as maintain the stability of the columns as drainage elements.

However, many of the techniques here discussed are only theoretical proposals; the feasibility of each technique in practice seems to rely more on the executive procedures and the characteristics of the in situ soil.

The solution of geogrid encapsulation appears to be suitable for relatively rigid clays when high loads are demanded, considering the column's backfilling is more prone to clog. Because of this limitation, the excavation method seems to be the more appropriate installation technique to geogrid reinforced stone column, as it was suggested to Gniel & Bouazza (2010).

To the case "laminated reinforced granular column", regarding the difficulties in constructive operations, the technique seems to be viable just for shallow and large diameter columns. Problems like clogging and the lateral squeezing could be avoided by the conjunctive use of encasement according the Gray et al. (1982) proposal, however the executive constrains remains the same.

High Density Polyethylene (HDPE) Lined Produced/Flow-back Water Evaporation Ponds

Neil C. Nowak, PE, Weaver Boos Consultants, LLC, USA, nnowak@weaverboos.com

ABSTRACT

The problem to be solved is the disposal of millions of gallons of production water (brine water) and flow-back water generated annually from the Rocky Mountain Region oil and gas industry in an environmentally safe, low cost, and efficient manner. A technology that is effective and safe is the evaporation of the water in lined containment ponds after separation and removal of the hydrocarbon component from the water.

Four projects are the case studies for this paper, located near the following cities:

- Cheyenne, Wyoming
- Cisco, Utah
- Dad, Wyoming
- Hobbs, New Mexico

They were designed to evaporate water in a series of geomembrane lined ponds.

1. INTRODUCTION

Some of the aforementioned projects are complete and have been operational for a number of years, while others are currently under construction. The production and flow back water from oil and gas wells in the area local to each site is trucked to the sites for disposal. The water is evaporated in ponds lined with high density polyethylene (HDPE) as the top layer by using a combination of factors that are favorable to the evaporative process, including the following:

- Natural characteristics of the site, including the arid climate, windy conditions, and numerous sunny days,
- The top liner in the ponds is black HDPE, which creates a hot surface,
- HDPE liner was chosen to protect the surface and ground waters of the area and to assist with the evaporation of the water (evaporation is enhanced due to the black color of the liner).

The projects are interesting in that each facility provides oil and gas production companies in the area with a large commercial alternative to production water and flow-back disposal versus numerous small ponds that may service only one well pad, or expensive re-injection wells, or even more expensive water recycle treatment facilities. The regulatory agencies like it for centralization and protection of the state's waters. The facilities protect surface waters in the area due to the large capacity of the ponds, 2 feet (Utah) and 3 feet (Wyoming and New Mexico) of freeboard, and secondary containment in case of catastrophic berm failure (Utah).

1.1 Project Location – Cheyenne, WY

1.1.1 Silo Field, Wyoming

The project is located in a semi-arid region of southeastern Wyoming in Laramie County, which is situated at approximately 5,900 feet above mean sea level (amsl). The site is located approximately 15 miles northeast of the intersection of Interstates I-80 and I-25 in Cheyenne, WY.

1.1.2 Background and Site Conditions

The ground surface is privately owned land primarily used for arid farming and stock grazing. No residences are located within 1 mile of the site. Access to the site is over unpaved roads used primarily for agriculture, oil and gas vehicles.

Topography: The topography at the site slopes gradually from elevation 5,910 ft amsl to 5,890 ft amsl to the east. There are no major watercourses on the site.

Geology and Hydrology: The site is located above the High Plains Formation underlain by Pierre Shale at approximately 5,700 feet thick which is dominant throughout the region. The primary aquifer includes the High Plains Aquifer, consisting of the Ogallala, Arikaree, and White River formations, which total approximately 1,480 feet thick. The Ogallala is the first instance of usable groundwater at approximately 160 to 300 feet below the site.

1.1.3 Climatological Data

According to the U.S. Department of Agriculture (USDA) Natural Resources Conservation Service (NRCS) map, the average annual precipitation is 15.17 inches. The climate survey for Cheyenne, WY (closest weather station to site) according to the Western Regional Climate Center (WRCC) is offered in the following table (re-created from WRCC information).

Table 1. Climate Survey, Cheyenne, WY

Parameter	Jan	Feb	Mar	Apr	May	Jun	Jul	Aug	Sep	Oct	Nov	Dec	Annual
Average Max. Temperature (F)	32.6	36.1	47.6	58.7	68.3	79.3	86.3	83.6	73.9	60.7	43.0	33.8	58.7
Average Min. Temperature (F)	5.2	8.9	20.7	27.9	34.7	41.5	48.1	46.4	37.9	27.6	16.8	7.4	26.9
Average Total Precipitation (in.)	0.44	0.39	0.51	0.87	1.44	0.85	1.16	0.92	1.19	1.35	0.66	0.51	10.29
Average Total Snowfall (in.)	8.4	5.4	5.3	1.9	0.2	0.0	0.0	0.0	0.0	2.0	6.1	8.8	38.2

1.1.4 Design Evaporation Data

The National Weather Service developed an isopleths map of the Free Water Surface Evaporation (shallow lake evaporation) based on 24 years of data. The free water surface evaporation rate is the amount expected to evaporate from the disposal ponds, which is 45 inches per year. Approximately 35 inches of that rate occurs from May to October. The remaining 10 inches would evaporate from November to April. This is based on a water containmentment that is not lined with black HDPE.

1.2 Project Location – Cisco, UT

1.2.1 Danish Flats, Utah

The project is located in an arid region of eastern Utah in the area known as Danish Flat, which is situated at approximately 4,610 feet above mean sea level (amsl). The site is located in Grand County approximately 3.5 miles north of Interstate 70 interchange exit number 214, and approximately 43 miles west of the Utah-Colorado state line.

1.2.2 Background and Site Conditions

The ground surface is privately owned land primarily used for stock grazing and oil and gas transmission piping. No residences are located within 10 miles of the site. Access to the site is over unpaved roads used primarily for oil and gas vehicles.

Topography: The topography at the site slopes gradually from elevation 4,615 ft amsl to 4,600 ft amsl to the southeast. There are no major watercourses on the site.

Geology and Hydrology: The site is located in the Mancos Shale lowland area including the Greater Cisco area. The Mancos Shale Formation is the predominant outcrop in this area. Due to the preponderance of fine-grained sediments and water soluble minerals found in this formation, it does not usually contain any fresh water. Groundwater that comes in contact with the Mancos Shale Formation almost always contains high levels of dissolved solids. Groundwater is usually limited to alluvial deposits along streams and drainages or to sandstone units, some of which are very localized with low recharge rates. Wells in the area are usually drilled with air with little or no water encountered until the Dakota Formation is penetrated (Hunt et al. 1996).

The underlying Mancos shale is a dark grey to black soft shale with sandstone beds at various horizons. The

maximum thickness of the Mancos shale is approximately 900 to 1,000 feet. The Mancos shale is considered a confining unit and is a thick barrier to vertical and lateral groundwater flow. Below the Mancos shale is the lower to upper Cretaceous Dakota Sandstone, which are a yellow-brown and gray friable to quartzitic sandstone and conglomerate sandstone and interbedded gray to black carbonaceous shale with occasional lenticular coal beds (Cashion et al. Map I-736). The Dakota Sandstone is considered to be the first aquifer in the area.

1.2.3 Climatological Data

According to the U.S. Department of Agriculture (USDA) Natural Resources Conservation Service (NRCS) map, the average annual precipitation is six inches. The climate survey for Cisco, UT (closest weather station to site) from 1952 to 1967 according to the Western Regional Climate Center (WRCC) is offered in the following table (re-created from WRCC information).

Table 2. Climate Survey, Cisco, UT

Parameter	Jan	Feb	Mar	Apr	May	Jun	Jul	Aug	Sep	Oct	Nov	Dec	Annual
Avg. Max Temp (F)	37.2	45.7	56.6	68.7	80.3	91.8	98.7	94.3	85.5	72.5	53.4	40.2	68.7

1.2.4 Design Evaporation Data

The National Weather Service developed an isopleths map of the Free Water Surface Evaporation (shallow lake evaporation) based on 24 years of data. The free water surface evaporation rate is the amount expected to evaporate from the disposal ponds, which is 50 inches per year. Approximately 35 inches of that rate occurs from May to October. The remaining 15 inches would evaporate from November to April. This is based on a water containment that is not lined with black HDPE.

1.3 Project Location – Dad, WY

1.3.1 Southern Cross, Wyoming

The project is located in an arid region of southwest Wyoming in the area known as Mexican Flat, which is situated at approximately 6,540 feet above mean sea level (amsl). The site is located in Carbon County approximately 5 miles west of Wyoming State Highway 789, approximately 30 miles south of the intersection of highway 789 and Interstate 80 at Wamsutter, and approximately 22 miles north of Baggs, Wyoming.

1.3.2 Background and Site Conditions

The ground surface is privately owned land primarily used for stock grazing and oil and gas transmission piping. No residences are located within 20 miles of the site. Access to the site is over unpaved roads used primarily for oil and gas vehicles.

Topography: The topography at the site slopes gradually from elevation 6,546 ft amsl to 6,536 ft amsl to the northeast. There are no major watercourses on the site.

Geology and Hydrology: The site is located in the Wasatch/Claron Formation. The Claron Formation also referred to as the "Pink Cliffs," and forms the highest "step" of the Grand Staircase. This formation is also known as the Wasatch Formation. The site is located in the Cathedral Bluffs Tongue of the Wasatch Formation. This outcropping consists of claystone, mudstone and sandstone. The field investigation and laboratory analysis confirmed the published description to the depth of the deepest boring.

The only known groundwater is at a depth of approximately 700 feet based on a recent boring by Devon Energy. This boring is on the north side of the property.

1.3.3 Climatological Data

According to the U.S. Department of Agriculture (USDA) Natural Resources Conservation Service (NRCS) map, the average annual precipitation ranges between ten and twelve inches. The climate survey for Baggs, WY (the closest weather station to site) from 1948 to 2007 according to the Western Regional Climate Center (WRCC) is offered in the following tables (re-created from WRCC information).

Table 3. Climate Survey, Baggs, WY

Parameter	Jan	Feb	Mar	Apr	May	Jun	Jul	Aug	Sep	Oct	Nov	Dec	Annual
Average Max. Temperature (F)	32.6	36.1	47.6	58.7	68.3	79.3	86.3	83.6	73.9	60.7	43.0	33.8	58.7
Average Min. Temperature (F)	5.2	8.9	20.7	27.9	34.7	41.5	48.1	46.4	37.9	27.6	16.8	7.4	26.9
Average Total Precipitation (in.)	0.44	0.39	0.51	0.87	1.44	0.85	1.16	0.92	1.19	1.35	0.66	0.51	10.29
Average Total Snowfall (in.)	8.4	5.4	5.3	1.9	0.2	0.0	0.0	0.0	0.0	2.0	6.1	8.8	38.2

1.3.4 Design Evaporation Data

The National Weather Service developed an isopleths map of the Free Water Surface Evaporation (shallow lake evaporation) based on 24 years of data. The free water surface evaporation rate is the amount expected to evaporate from the disposal ponds, which is 45 inches per year. Approximately 35 inches of that rate occurs from May to October. The remaining 15 inches would evaporate from November to April. This is based on a water containment that is not lined with black HDPE.

1.4 Project Location – Hobbs, NM

1.4.1 CRI, New Mexico

The project is located in an arid region of southeastern New Mexico in Lea County, which is situated at approximately 3,540 feet above mean sea level (amsl). The site is located approximately 25 miles west of Hobbs, NM.

1.4.2 Background and Site Conditions

The ground surface is privately owned land primarily used for oil and gas production. No residences are located within 10 miles of the site. Access to the site is over a paved highway.

Topography: The topography at the site slopes gradually from elevation 3,550 ft amsl to 3,530 ft amsl to the northwest. There are no major watercourses on the site.

Geology and Hydrology: The site is located above the Triassic Redbeds, consisting of Chinle Shale, Santa Rosa sandstone and the Dewey Lake formation. The Triassic Redbeds occur at 40 to 50 feet below the ground surface and are virtually impermeable and therefore prevent vertical seepage beyond the redbed level.

1.4.3 Climatological Data

According to the U.S. Department of Agriculture (USDA) Natural Resources Conservation Service (NRCS) map, the average annual precipitation is 15.6 inches. The climate survey for Duval Potash Mine, NM (closest weather station to site) according to the Western Regional Climate Center (WRCC) is offered in the following table (re-created from WRCC information).

Table 4. Climate Survey, Duval Potash Mine, NM

Parameter	Jan	Feb	Mar	Apr	May	Jun	Jul	Aug	Sep	Oct	Nov	Dec	Annual
Average Max. Temperature (F)	32.6	36.1	47.6	58.7	68.3	79.3	86.3	83.6	73.9	60.7	43.0	33.8	58.7

1.4.4 Design Evaporation Data

The National Weather Service developed an isopleths map of the Free Water Surface Evaporation (shallow lake evaporation) based on 24 years of data. The free water surface evaporation rate is the amount expected to evaporate from the disposal ponds, which is 46 inches per year. Approximately 36 inches of that rate occurs from May to October. The remaining 10 inches would evaporate from November to April. This is based on a water containment that is not lined with black HDPE.

2. PROJECT DETAILS

2.1 Purpose

The main purpose of the projects is to evaporate the production water and flow back water as quickly as possible while maintaining environmental controls and containment. The projects were planned and built in order to service the oil and gas industry for the disposal of production water and flow back water from oil and gas production in the service areas local to each facility location.

Several water disposal options exist, including reinjection wells, frac injection, treatment for surface discharge, and evaporation. The evaporation technology was chosen for these projects due to the ideal site conditions for evaporation, including low precipitation, windy conditions, high ambient temperatures and sun. Other factors that made the project sites ideal include the following; little or no residences within several miles of the site (other than consenting land owners), easy access to/from a major highway, long distance to open water at several miles, deep groundwater, and impermeable formations below the sites.

2.2 Selection of Technology

To enhance the evaporative quality of the projects and to adequately contain the brine water, the top layer of the pond lining needs to be a durable long-lasting product that is cost-effective and helps to enhance evaporation while being acceptable to the regulatory agencies involved. Some of the liner technologies considered include compacted clay, geosynthetic clay liner (GCL), polyvinyl chloride (PVC), polypropylene (PPE), and high density polyethylene (HDPE). While several lining technologies exist and are allowed by the regulatory agencies, the HDPE liner was chosen for the top layer for several reasons, including, durability, resistance to ultraviolet (UV) degradation, chemical resistance, black color, and ease of construction.

HDPE is designed to be the top layer of ponds and be exposed to the elements (sun, freeze/thaw, and physical impact), therefore, the material needs to be resistant to UV degradation and be durable. The addition of the proper amount of high quality carbon black to the geomembrane during manufacturing is universally accepted as being resistant to significant deterioration caused by weathering. In addition to high quality carbon black, highly effective chemical UV stabilizers further extend the life of the liner. These additives absorb incident radiation and/or terminate free radical production, thus protecting the HDPE against thermal degradation and possible chemical reactions with surrounding materials. Other factors that affect the potential UV resistance of a material include average density, density range or dispersion, chemical stabilizer system, catalyst type and amount of residue, copolymer type, combined chemical exposures, and failure criteria (GSE 2003). HDPE was chosen for this application due to these characteristics.

2.3 Implementation

To enhance the evaporative quality of each facility, and to adequately contain the brine water, high density polyethylene (HDPE) was chosen as the top layer. The top or primary liner was designed and constructed with 60-mil thick textured HDPE to help ensure a durable long-lasting containment. The liner was textured to increase the safety factor for personnel using the facility (i.e. the textured surface increases traction and gripping to enable easier egress in case of someone falling into the pond).

The facilities were designed by Weaver Boos Consultants, LLC and have been or are currently being constructed. The facilities consist of the following components (refer to Figures 1 and 2 for details):

- Access road and truck off-loading pad
- Piping and valves
- Acceptance Pits (vaults) or advanced oil/water separation equipment
- Sludge Pond covered with bird control netting or no sludge pond if oil/water separation equipment used
- Evaporation ponds (constructed or planned):
 - Silo Field, WY has 3 ponds out of the permitted 10 ponds in the process of being built at approx. 5.2 acres each and 25 feet deep (double lined HDPE with leak detection in between the liners)
 - Danish Flats, UT has 14 ponds built at approx. 5.2 acres each and are 12 or 22 feet deep (single HDPE liner underlain by compacted clay layer)
 - Southern Cross, WY has 4 ponds built at approx. 5.2 acres each and are 12 feet deep (double lined HDPE with leak detection in between the liners)
 - CRI, NM will have 2 ponds at approx. 4.2 acres each and be 24-28 feet deep (double lined HDPE with leak detection in between the liners)

General: Production water and flow back water is delivered to the sites via tanker trucks from well sites located within the geographic area local to each site, and depends on transportation costs and disposal fees when compared to other alternatives for water disposal in the area. The tanker trucks are off-loaded and the water is sent through a treatment process, including separation vaults, gun-barrel tanks, or state-of-the art equipment.

The Silo Field and CRI facilities will include a truck off-loading area and the water will be treated prior to placement in the evaporation ponds, including the removal of hydrocarbons to a level below 30 parts per million (ppm).

The Danish Flats facility's plan view is shown on the following Figure 2. The operation units include one set of 14,000 gallon three-stage concrete receiving tanks, a sludge pond, and a series of five-acre evaporation ponds. All of the structures are connected via gravity or force-main fed via an underground piping system. The Southern Cross facility process is similar to the Danish Flats layout.

Pond Inlet: Various methods exist for the separation of the oil and water prior to placement in the ponds for evaporation, and the proper removal of the oil from the water will dictate whether or not the ponds should be covered with bird control netting.

The incoming water at the Silo Field and CRI facilities will flow through state-of-the-art oil/water separation equipment capable of removal of the hydrocarbons to a level of 30 ppm or less prior to moving the water to the ponds for evaporation. There will be no sludge ponds used for these facilities. Volatile organic compound (VOC) emissions from the separation equipment and ancillary tankage are controlled to maintain air quality.

The incoming water at the Danish Flats and Southern Cross sites flows through the three-stage concrete settling tank systems and pretreatment tanks (Danish Flats) or one of the three-stage concrete settling tank systems (Southern Cross) and each site uses a the sludge pond before entering the evaporation ponds. The pre-treatment facilities and the evaporation ponds have been designed to follow the topography, allowing for gravity flow throughout the system, and the Danish Flats site is equipped with force-mains to allow pumping of the water from the lower Phase 1 ponds to the upper Phase 2 ponds.

Shut-off valves have been installed on the crossover piping to allow for proper flow management. If necessary, portable gasoline powered pumps will be used to transfer liquid to ponds that are not in the gravity flow line or to empty a pond for maintenance or liner repair.

Slope Design: At Danish Flats and Southern Cross the sludge ponds and evaporation ponds have an interior slope of 3 horizontal to 1 vertical, and a maximum exterior slope of 2 to 1.

At Silo Field and CRI, the pond interior and exterior slopes were designed with 4 to 1 slopes.

The HDPE chosen has a textured surface, which will increase the safety characteristics of the facility by making it easier to walk on, especially on the interior slopes.

Berm Design: Surface water will not be allowed to enter the ponds because the constructed berms are several feet higher than the surrounding ground surface and also diversion and control ditches are used to direct the run-on and run-off for minimizing impact of storm water. The interior berm walls are covered with a protective layer of 60-mil high density polyethylene (HDPE). The HDPE will provide erosion control. The area between the evaporation ponds has been covered with HDPE or compacted clay to prevent erosion, control dust and enhance evaporation. The exterior sides of the berm have been seeded as necessary.

Leak Detection System: As described in the geology/hydrology section of this paper, each site is underlain by impermeable layers of shale or clay, including at Danish Flats approximately 1,200 feet thick of Mancos Shale, and at Southern Cross the Wasatch Formation. The first usable aquifers for human use are below these formations for these sites. The geological investigations did not detect perched groundwater.

At the Silo Field site the first usable aquifer will be protected by the three layers of liner in the pond, as well as natural clay aquitards below the pond bottoms at approximately 30 and 60 feet below the ground surface, which also includes the leak detection under the primary liner. At the CRI location, the geology and hydro geology is favorable including low permeable shale at 50 feet below the ground surface.

In addition to the ideal natural conditions at each site, a 60-mil HDPE liner has been installed as the top layer in all of the ponds. The pond floors slope toward sumps that are fitted with a riser monitoring pipe and leak detection equipment.

The leak detection system is inspected and data recorded as required. A summary of the inspections are reported to the regulatory agencies as needed. Liquid from the sump can be pumped back into the pond, if excessive amounts accumulate then specific protocols for repairing the liner are required if the volume of the leak exceeds certain thresholds.

Livestock/Wildlife Protection Measures: The entire facility area at each site has been fenced and gated to help prevent cattle or other animals from entering. Since the sludge ponds could have oily material on the surface, netting has been used to deter the entry of birds or other wildlife at the Danish Flats and Southern Cross sites.

Capacity: The volume of water able to be stored for evaporation in the ponds is as follows:

- Silo Field – Ponds 1 -3 are 25 feet deep of water holding capacity and nearly 582,000 barrels each for a total water holding capacity of approximately 1,746,000 barrels.
- Danish Flats - Ponds 1 through 8 are 12 feet of water holding depth and nearly 240,000 barrels each (at 42 gallons per barrel) for a total capacity of approximately 2,000,000 barrels. Ponds 9 through 13 are 22 feet of water holding depth at Danish Flats and nearly 632,000 barrels each for a total capacity of 3,160,000 barrels.
- Southern Cross - Ponds 1 through 4 are 12 feet of water holding depth and nearly 240,000 barrels for a total capacity of approximately 960,000 barrels.
- CRI – Ponds 1 and will be 22 feet deep with a total water holding capacity of approximately 650,000 barrels.

Figure 1. Silo Field Pond Liner Details

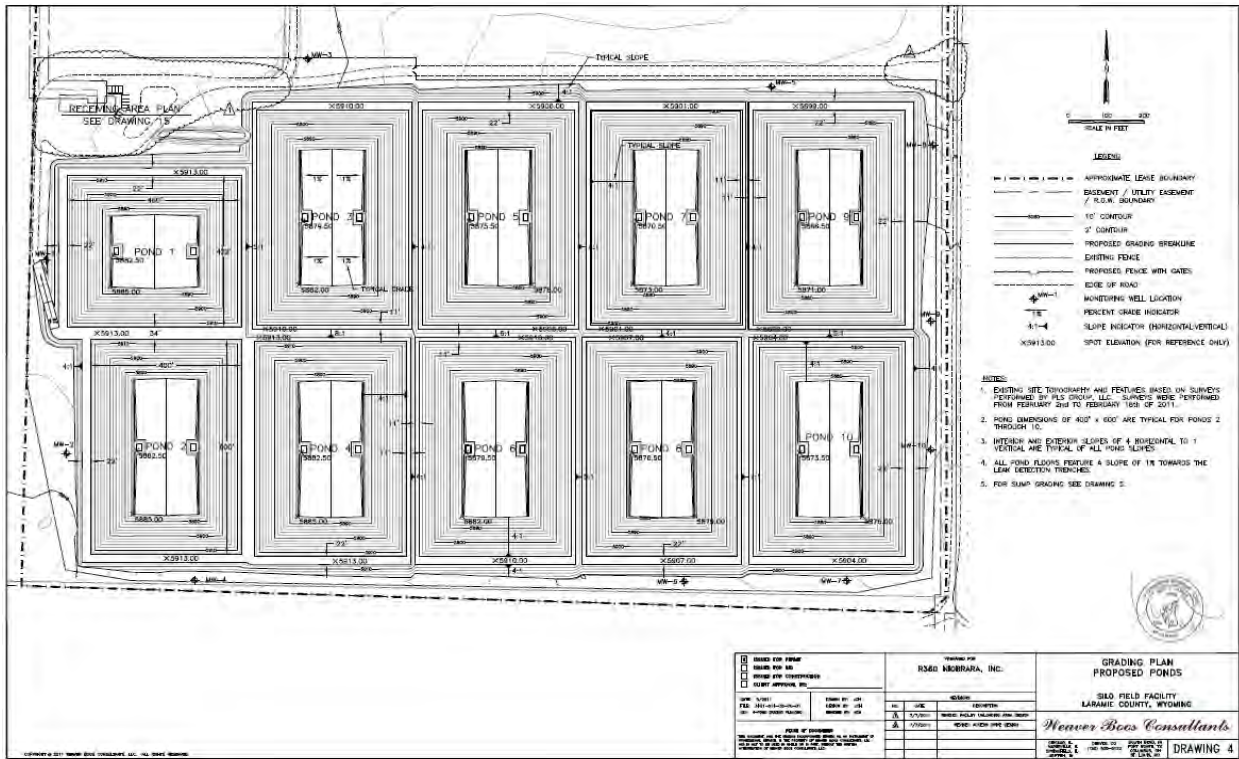

Figure 2. Silo Field - Facility Design Plan View – Permit Approved Layout

Figure 3. Aerial Photo of Completed Project at Danish Flats, UT

The partially completed and partially operational project at Danish Flats was photographed from the air on June 29, 2009 and is shown above. The water was distributed from the sludge pond to the Ponds 1 through 12, which appear as “black”. The Ponds 13 appears to have “brownish” water, which includes some construction water is shown in the background and was not yet approved for water disposal at the time of the photography, but has since been put into operation. Currently, 14 evaporation ponds are operational at Danish Flats.

2.4 Operational Data

At Danish Flats they have experienced various quantities of water deliveries ranging from 10,000 barrels to 35,000 barrels per day. Each barrel is equal to 42 gallons. The water is moved from the off-loading area through the sludge pond and to the evaporation ponds by gravity or via force main for distribution to Phase 2. Each pond at Danish Flats, Utah has a free board requirement of 2 feet, and each pond for the projects in Wyoming at Southern Cross and Silo Field has a free board requirement of 3 feet. The free board at New Mexico is 3 feet.

When an individual evaporation pond was brought on-line, such as Ponds 5 through 8 at Danish Flats, and the water was allowed to flow into the empty pond lined with HDPE, the water was observed as “disappearing” due to the evaporative nature of the HDPE when in combination with the hot sun and arid climate in Utah in July and August.

In Cisco, UT in July and August the ambient air temperatures often exceeds 100 degrees Fahrenheit and the wind normally blows to some extent. The actual evaporation encountered during the months of July and August 2008 at the site was measured to be approximately 15 and 18 inches per day, respectively. The facility operators observed very favorable evaporation of the water and measured the total evaporation for the year 2008 above the estimate of 50 inches for approximately 6 months of operation. In year 2009, the Danish Flats facility was measured to have 60 inches of evaporation, which took place mostly in the months from April 1 to October 31, and again in year 2010 the evaporation total has exceeded 60 inches over the entire water surface of the ponds. The deeper ponds at Danish Flats experienced an approximately 30 percent lower evaporation rate due to the deeper water depth, therefore, the entire depth of water was not able to be achieve warmer temperatures as did the shallower ponds.

Each site is equipped or designed with leak detection systems that are monitored on a monthly basis or continuously, depending on the equipment chosen. Two ponds at Danish Flats were adversely affected by shifting ice at the HDPE pipe boots when the liquid level in the ponds were adjusted, which resulted in leaks at the pipe boots. The liner was easily repaired and there has not been a reoccurrence of any leaks at these ponds.

Figures 4 and 5. Weep system to enhance evaporation

In an effort to increase evaporation with low costs in mind, a “weep” system was added to the allow water to flow and fan out over the surface of the HDPE liner that is above the water line. This system utilizes the exposed HDPE liner to increase evaporation by using the heat generated from the exposed HDPE liner in combination with the increased surface area of the water fanning out over the liner. Please refer to the below photographs of the “weep” system.

This system will be used at Silo Field, CRI, and Danish Flats.

3. CONCLUSIONS

The use of HDPE as the primary liner in the ponds appears to be favorably enhancing the evaporation of the water. At Danish Flats, the estimate of 50 inches of evaporation per year was far exceeded given the 33 inches of evaporation experienced in only July and August 2008, which may have totaled 70 inches for 2008. In years 2009 and 2010, the evaporation rate was over 60 inches. In 2012, the evaporation rate was 42 inches from May through August. The “weep” system was an enhancement to increase evaporation, which was not quantitatively measurable, but may have been a factor in the total evaporation. The deeper ponds at Danish Flats experienced approximately a 30 percent lower evaporation rate due to cooler water at depth. Similarly, the actual evaporation experienced at the Southern Cross project was also more than the pan evaporation estimate based on ponds without the HDPE liner effects, including the increase in evaporation from the estimate of 45 inches per year to nearly 55 inches.

It is anticipated that the evaporation rates at Silo Field and CRI will also be enhanced with the use of the HDPE liner as the top layer and the use of the “weep” system along the exposed liner too.

The durability and resistance to UV degradation due to the proper amount of carbon black in the geomembrane and other factors as discussed above are the major reasons for the use of the HDPE geomembrane liner as the top layer. The increase with the rate of evaporation due to the black color of the HDPE has been a great benefit and in combination with the “weep” system has realized an increase with the total evaporation at each facility.

Some of the liner was installed during the summer months and due to the expansion and contraction of the liner with ambient air temperature gradients, the anchor trenches were only filled during the coolest part of the day to reduce bridging.

The leak detection system is used to capture leaks through the primary liner, which worked as designed at the Danish Flats site when a leak was propagated due to ice on the water and the level in the ponds changing which resulted in the ice grabbing onto the pipe and pulling on the pipe boot. The liner was repaired and the leak did not appear again.

An existing study was conducted on an HDPE liner installed at a site in Colorado after 20 years of service where the liner was not buried and exposed to weathering, UV light and cooling tower blow-down water. The material was tested for various properties and was found to have no significant reduction in the primary physical properties of the HDPE (Ivy 2002).

ACKNOWLEDGEMENTS

Thank you to R360 Environmental Solutions, Danish Flats Environmental Services, and Southern Cross Environmental Services for the use of their projects in this paper. Also, I'd like to recognize Gerald Knudsen, PE of AgriTech who provided his engineering expertise, during the design and permitting of two of these sites, and to John Heap of Colorado Lining, Inc. who provided his installation expertise and also performed the construction of the HDPE liners at the ponds in field, which all are performing exceptionally well and without leaks due to construction.

ABSTRACT

In the geosynthetic reinforced soil integrated bridge system (GRS-IBS), the facing is frictionally connected to the reinforced soil composite. This frictional connection method has performed well for closely-spaced ($\leq 0.3\text{m}$) GRS under both working and failure loads, leading to the removal of the connection criterion as a strength limit within the FHWA's design guidance for the GRS. Conversely, AASHTO LRFD Bridge Design Specifications require a check between the long-term strength, determined through connection testing, and the maximum load on the reinforcement. To investigate the impact this criterion has on the design of the GRS-IBS, connection testing was performed between hollow-core concrete modular blocks and geotextiles and compared to assumed lateral facing pressures. The results of large scale direct shear tests and block pull-out tests conducted at Turner Fairbank Highway Research Center were also compared. This paper describes the testing procedures, results, and implications for design of GRS.

1. INTRODUCTION

1.1 Current Practice

In many segmental reinforced soil walls and abutments, the reinforcement is connected to the facing element through various connection mechanisms. When geosynthetics are utilized as the reinforcement, the connection with the facing elements can be frictional, structural, or a combination of both (i.e. partial friction connection). Fully frictional connections rely solely on the friction between the geosynthetic reinforcement, the facing element, and sometimes the aggregate placed in the core of the unit (Figure 1), while structural connections physically tie the facing and reinforcement together, typically through pins, clips, or shear lips.

Figure 1. Cross-section of fully frictional connection.

Current design methods for mechanically stabilized earth (MSE) allow for any type of connection; however, the strength of the connection must equal the maximum factored tension in any reinforcement layer (AASHTO 2010, Berg et al. 2009). Recent Federal Highway Administration (FHWA) design guidance on geosynthetic reinforced soil (GRS) eliminates the criterion for connection strength, thus, no connection testing is required, provided that the reinforcement is closely spaced, less than 0.3m, and each course of block is frictionally connected to the reinforcement (Adams et al. 2011a). The fully frictional connection method is recommended because of its compatibility with the modular block units, cost, and time effectiveness; it has also been shown to perform well both at the service limit under working loads and at the strength limit under failure loads for GRS with close reinforcement spacing (Adams et al. 2011b). To date, no connection failures have ever been observed on a GRS wall or abutment.

1.2 Connection Testing

In MSE wall design, the connection strength for a particular reinforcement and facing element combination is found either through short- or long-term testing. Long-term testing requires a creep rupture envelope for the geosynthetic (ASTM D5262); this can take over 1 year. Short-term testing is much quicker (on the order of a few days) and is performed in accordance with ASTM D6638. To account for long term design strength, a creep reduction factor is then applied to the short-term ultimate connection strength. Both types of testing are conducted in-isolation (i.e. no soil-confinement effect); the procedures are described in FHWA's Geotechnical Engineering Circular (GEC) No. 11 (Berg et al. 2009).

To investigate the in-service connection strength of a GRS wall, FHWA's Turner-Fairbank Highway Research Center (TFHRC) developed the block pull-out test (Adams et al. 2011b). This test was devised in 1998 to quantify the amount of force required to mobilize or displace a modular block unit from the face of a GRS wall. The test is performed on blocks at different heights along a full-scale GRS test wall to determine the relationship between the normal force on top of the block and the required pull-out force (Figure 2). While the test should provide more realistic results than the standardized short- and long-term connection testing, a full-scale wall is needed to test the strength which is often not practical in design.

Figure 2. Block pull-out test on a GRS wall (Adams et al. 2011a).

1.3 Connection Load

In practice, connection testing provides short- and long-term strength which can then be compared to the estimated loads on the face to ensure adequate strength of the connection in-service. In MSE wall design, the thrust against the face is equal to the internal loads of the reinforced soil system, as calculated according to Equation 1 (AASHTO 2010, Berg et al. 2009). According to Soong and Koerner (1997), this design requirement was first recommended by an industry-wide group; however, it was not based on theoretical calculations.

$$T_{\max} = \sigma_h S_v \quad [1]$$

Where T_{\max} is the maximum tension in each reinforcement layer, σ_h is the average lateral earth pressure within the tributary area of the reinforcement layer under consideration, and S_v is the reinforcement spacing.

For closely spaced GRS, the thrust at the face is not equal to the internal lateral stress, as assumed in MSE wall design. Soong and Koerner (1997) and Wu (2007) conclude that the pressure at the face develops independently between each reinforcement layer and surcharge does not transfer to the face. Wu (2001) proposed that this distribution between closely spaced layers is based on the concept of bin pressure for frictionally connected segmental facing. Ideally, the pressure is zero at the depth of any reinforcement layer within a bin, increases linearly with depth before decreasing to zero at the next reinforcement layer. Because reinforcement may deform slightly at the soil reinforcement interface, the bin pressure diagram shown in Figure 3 was adopted, with the thrust calculated according to Equation 2. Measurements from large-scale test walls have shown the estimated bin pressure magnitudes to be similar to those assumed with bin pressure (Yogarajah and Saad, 1996; Andrawes and Yogarajah, 1994); however, additional research should look at the impact of spacing and thrust against the face to better verify this assumption. Soong and Koerner (1997) theoretically assume a typical active lateral earth pressure distribution between each layer to determine the thrust (Equation 3).

$$F_{bin} = 0.72\gamma S_v^2 K_a \quad [2]$$

$$F_{bin,R} = \frac{1}{2} \gamma S_v^2 K_a \quad [3]$$

Where F_{bin} is the thrust against the face assuming the proposed bin pressure diagram (Figure 3), $F_{bin,R}$ is the thrust against the face assuming a typical lateral earth pressure distribution between each reinforcement layer, γ is the unit weight of the soil, S_v is the reinforcement spacing, and K_a is the active earth pressure coefficient.

Figure 3. Assumed bin pressure diagram for GRS structures (After Wu 2007).

1.4 Objective

The full frictional connection method is not widely used for MSE applications; however, it is recommended for closely spaced GRS applications because of its demonstrated performance and efficiency of construction (Adams et al. 2011a). To date, very few fully frictional connection tests have been published (Bathurst and Simac 1998); testing has also been largely limited to geogrids, whereas geotextiles are widely used in GRS. To investigate the implications of the connection strength criterion on closely spaced GRS walls and abutments, frictional connection tests and large scale direct shear (LSDS) tests were performed at TFHRC and compared to the designed connection loads (i.e. lateral earth pressure acting at the face). The results of the block pull-out tests are also studied to determine the applicability of the connection tests for field applications.

2. CONNECTION STRENGTH TESTING AND RESULTS

2.1 Short-Term Connection Tests

A series of short-term connection tests were performed at Turner-Fairbank Highway Research Center (TFHRC) in accordance with ASTM D6638. The reinforcement tested is a woven polypropylene (PP) geotextile with an ultimate tensile strength (i.e. MARV value) of 70 kN/m; the facing element is a lightweight, approximately 0.2 kN, hollow-core concrete masonry unit (CMU) block with nominal dimensions of 0.2m x 0.2m x 0.4m.

2.1.1 Test Set-Up

A schematic of the test setup is shown in Figure 4. The free length of the geotextile reinforcement was set at 0.2 m for each test with the width of the geotextile specimens equal to two CMU widths, or 0.8m. To isolate the movement of the geotextile relative to the CMU facing, all components except the geotextile were braced to prevent external lateral movement of the test frame and facing elements due to the pull-out force of the geosynthetic connection. A jactuator was used to apply the tensile force to the geotextile; the rate of loading was 6% of the free length of reinforcement per minute, or 12.7 mm per minute. Displacement was measured using two LVDTs set at each end of the geosynthetic clamp. Normal load on the CMU blocks, to simulate additional wall height, was applied using dead weight placed on a 50 mm thick steel plate cushioned with a 6 mm rubber pad to uniformly distribute the load on the hollow-core CMUs.

2.1.2 Testing Schedule

Two sets of connection tests were performed; one with the hollow-core of the CMUs left voided (termed “hollow” throughout the paper) and the other with the hollow-core infilled with stone (termed “infilled” throughout the paper). The former is recommended in the FHWA guidelines for GRS abutments (Adams et al. 2011a), whereas the latter is standard

practice for MSE walls and abutments (Berg et al. 2009). The purpose of testing both methods is to determine the improvement in connection strength due to the additional friction caused by the aggregate infill in the core of the facing.

Figure 4. TFHRC Frictional Connection Test Schematic.

Seven unique tests were conducted for the hollow CMUs at different applied normal pressures: 12 kPa, 35 kPa, 69 kPa, 125 kPa, 147 kPa, 204 kPa, and 237 kPa; this corresponds to the 3rd, 7th, 14th, 25th, 30th, 40th, and 47th course of block from the top of a GRS structure, respectively, to simulate the connection capacity of a 9-m high wall. The test at 125 kPa was repeated 4 additional times and the test at 237 kPa was repeated 1 additional time to determine repeatability of the connection test method at different applied loads, as outlined in ASTM D6638.

In addition, five unique tests were conducted with the hollow cores of the CMUs infilled with AASHTO No. 57 aggregate (Figure 5). The applied pressures in these tests were 14 kPa, 37 kPa, 72 kPa, 128 kPa, and 150 kPa; this corresponds to the 3rd, 8th, 15th, 26th, and 30th course of block from the top of a GRS abutment, respectively, to simulate the connection capacity of a 6-m high wall. The test at 128 kPa was repeated 4 additional times. The slight difference in applied normal pressures between the two sets of tests (i.e. hollow and infilled) is related to the additional weight of the infilled aggregate.

Figure 5. TFHRC Frictional Connection Test with Hollow Core CMUs Infilled with No. 57 Aggregate.

2.1.3 Connection Strength Results

The results of the short-term connection tests conducted between the dry cast CMUs, both hollow and infilled, and the 70kN/m woven, PP geotextile are summarized in Table 1. For each test, the failure mode was pullout of the reinforcement, not rupture. An 11-point moving average was taken to filter the data and reduce noise (Figure 6); the peak ultimate connection force ($T_{ultconn}$) at each applied normal load was determined based on this average.

To determine the interface friction angle, the results presented in Table 1 were plotted and the linear best-fit envelope found (Figure 7). For the hollow and infilled CMUs, the friction angle was measured at approximately 38 degrees and 42 degrees, respectively. The addition of the aggregates in the voids provides increased connection strength; the infilling of the hollow-core CMUs produced a 10% increase in the interface friction angle.

Table 1. Short-Term Connection Strength Results.

Hollow CMUs			Infilled CMUs		
Applied Normal Load (kN/m)	Peak Connection Force (kN/m)	Interface Friction Angle (deg)	Applied Normal Load (kN/m)	Peak Connection Force (kN/m)	Interface Friction Angle (deg)
1.26	1.79	38	1.48	3.25	42
3.50	4.54		3.72	5.54	
6.93	7.51		7.16	9.67	
12.51	11.15		12.73	9.98	
12.51	13.65		12.73	10.65	
12.51	13.35		12.73	13.81	
12.51	11.76		12.73	17.22	
12.51	12.33		12.73	12.24	
14.75	14.98		12.73	11.76	
20.42	17.26		14.97	16.70	
23.72	19.66		-	-	
23.72	19.44		-	-	

Figure 6. Short-Term Frictional Connection Test Results for hollow-core CMUs and 70 kN/m PP geotextile.

Note that Figure 7 does not show every test conducted. The repeated tests at 125 kPa and 237 kPa for the hollow CMUs and at 128 kPa for the infilled CMUs were averaged to arrive at a single value at each applied normal load. For the hollow CMUs, the results of the repeated tests were all within about 10% of the average indicating good repeatability. The results are somewhat more mixed for the infilled CMUs. Out of six tests, three were within 10% of the average; the largest difference was about 36%. The scatter in repeatability is likely attributed to the variability in placement of the aggregate for the infill conditions which can impact the interaction between the infilled aggregate and the geosynthetic.

2.2 Large Scale Direct Shear (LSDS) Tests

As an alternative to the set-up of the short-term connection test, a series of LSDS tests at various applied normal stresses was conducted to determine the interface friction angle between dry cast concrete and geosynthetic reinforcement. The testing was conducted with the LSDS device at TFHRC; the dimensions of the shear box are 0.3m x 0.3m x 0.2m.

To conduct the test, two 0.3m x 0.3m x 0.1 m solid concrete blocks were placed in the device; one in the top box and one in the bottom box of the LSDS device. A woven PP geotextile with a minimum average roll value (MARV) of 70 kN/m was clamped between the concrete blocks at the shear interface of the device. Note that the purpose of this test was to determine the interface friction angle between dry cast concrete and geotextile. The test could also be modified with hollow CMU blocks for conditions with and without gravel placed in the core of the block.

LSDS tests for the interface friction angle were conducted according to a modified ASTM D5321. The shear rate and gap size for the tests were set at 40 mm/min and 0.6mm, respectively. To determine the interface friction angle between the two materials, tests were performed dry at four applied normal pressures: 15 kPa, 25 kPa, 58 kPa, and 103 kPa. Note that the resulting friction angles are for the interface between the reinforcement and CMU blocks; similar tests can also be conducted to determine the interface friction angle at the base of the GRS wall or abutment for direct sliding analysis; however, this is outside the scope of this particular study

Figure 7. Short-Term Frictional Connection Test Results for hollow-core CMUs and 70 kN/m PP geotextile.

2.2.1 LSDS Results

The results of the LSDS tests indicated a measured interface friction angle of 37 degrees (Figure 8). Compared to the results of the short-term connection testing, the results are reasonably close, a 1 degree difference; this is within the variability of direct shear testing (Paikowsky et al. 2010), indicating that for fully frictional connections, the interface friction angle, if necessary for design, can be determined with a LSDS device as opposed to the more complicated short-term connection test set-up.

Figure 8. Large Scale Direct Shear Results between Dry Cast Concrete and 70 kN/m Geotextile.

2.3 In-service Wall Block Pull-Out Tests

The results of the block-pull out tests on a full-scale GRS wall, conducted by TFHRC in 1998, are compared to the results of the short-term connection testing (Figure 9). The interface friction angle for the block pull-out tests is about 37 degrees, the same as for the comparable LSDS tests. Note that for the block-pull out tests, heavier segmental retaining wall (SRW) block, infilled with aggregate, was used in the test wall with 70 kN/m woven, PP geotextile; however, the

resulting interface friction angle is comparable to that of CMUs because the SRW block is also made of dry-cast concrete. This suggests that the short-term connection test is applicable for real-world applications.

Figure 9. Results of Block Pull-Out Tests Compared to Short-Term Connection Tests.

2.4 Summary

Three types of tests were conducted by TFHRC to determine the strength of the frictional connection between a dry-cast modular block unit and geotextile reinforcement: (1) short-term connection testing, (2) large scale direct shear testing, and (3) block-pull out testing. The results are summarized in Table 2. Based on the three tests, the average interface friction angle for dry-cast, hollow CMUs is 37 degrees. Infilling CMUs may lead to an increase in the interface friction angle; however, the use of this friction angle in the design of an MSE wall may not be prudent, as compared to the case with the cores left hollow, because of the inexact nature of infilling aggregate in the facing blocks.

Table 2. Summary of Measured Interface Friction Angles.

Short-Term Connection Test		LSDS Test	SRW Block (Infilled)
Hollow	Infilled		Pull-Out Test
38	42	37	37

3. IMPLICATIONS ON DESIGN

According to current design practice for MSE walls and abutments, the results of connection testing are used to determine the long-term strength and ensure it is greater than the associated lateral loads at the connection (AASHTO 2010, Berg et al. 2009). The long-term connection strength is often computed from the results of short-term connection tests with reduction factors taken to account for durability and creep (Equation 4). The loads at the connection are assumed to equal the product of horizontal stress on the reinforcement due to active earth pressure conditions and the reinforcement spacing (Berg et al. 2009).

$$T_{alc} = \frac{T_{ult} \times \left(\frac{T_{ultconn}}{RF_{cr} T_{lot}} \right)}{RF_D} \quad [4]$$

Where T_{alc} is the nominal long-term connection strength, T_{ult} is the ultimate tensile strength of the geosynthetics reinforcement, defined as the minimum average roll value (MARV), $T_{ultconn}$ is the short-term connection strength, RF_{cr} is the geosynthetics creep reduction factor, T_{lot} is the ultimate wide width tensile strength of the reinforcement material roll/lot used for connection strength testing, and RF_D is the reduction factor to account for chemical and biological degradation.

For the facing, backfill and reinforcement conditions shown in Table 3, and assuming no surcharge or traffic loads, a GRS wall with frictional connections would fail the MSE requirement for connection when the height is more than 1.2 m or 1.6m in height, depending on if the facing is hollow or infilled, respectively (Figure 10). Applying the appropriate load and resistance factors, however, limits the height to less than 1m, effectively making the frictional connection infeasible for real-world application. Note that the connection load was determined according to Equation 1.

Figure 10 also extends the results to an abutment application assuming the same facing, backfill and reinforcement conditions shown in Table 3 and an applied surcharge load of 200 kPa, equivalent to typical bridge design loads. Note that the effect of block-soil friction due to compression of the reinforced soil mass is ignored. The results indicate that fully frictional connections would be prohibited at any height. Furthermore, even assuming no reduction in the short-term connection strength, the full frictional connection is not capable of withstanding the loads at the top of the wall (to about 1.8 m below for hollow CMUs) due to the bridge surcharge (Figure 10). Current MSE design therefore implies that a mechanical connection is required to prevent connection failure for a GRS wall or abutment, regardless of reinforcement spacing.

Table 3. Example Facing, Backfill, and Reinforcement Conditions.

Facing		Backfill		Reinforcement				
Type	Weight (kN)	Unit Weight, γ (kN/m ³)	Friction Angle, Φ (deg)	Spacing (m)	Ultimate Strength, T_{ult} (kN/m)	Lot Strength, T_{lot} (kN/m)	RF_{cr}	RF_D
CMU	0.2	17.3	40	0.2	70	77	4	1.15

Figure 10. Frictional Connection Strength Requirement for MSE walls with geosynthetics.

The requirement of a mechanical connection rather than a simple, full frictional connection is not supported by the numerous examples, both published and unpublished, of closely spaced GRS walls and abutments that have frictionally connected facing elements which have excellent performance (Adams et al. 2011b, Wu 2007, Adams 1997, Adams et al. 2007, Ketchart and Wu 1997, Schiebel, et al., 1996, Barrett, 1997). Earthquake loads, up to 1g acceleration, on a GRS abutment produced no connection failure throughout testing, only some cracked blocks (Helwany et al. 2012). This was supported by a previous NCHRP study on the design of GRS abutments with flexible facings that concluded connection strength is not a design concern for well compacted, closely spaced (less than 0.2 m) systems (Wu et al. 2006). Connection failure is also not evident when GRS walls and abutments are loaded to failure (Adams et al. 2011a, Wu et al. 2006). FHWA design guidance for GRS abutments do not require a design check for connection strength when reinforcement spacing is less than 0.3 m (Adams et al. 2011a). This is because the observed loads at the face for closely spaced GRS are significantly smaller than that assumed in MSE design.

Assuming the more conservative bin pressure (Equation 3) and the conditions in Table 3, the thrust against the face is equal to 0.1 kN/m (Figure 11). By using the reduction factors for creep and durability for long-term strength, as is done in MSE design, the minimum factor of safety is 4 at the top of the wall against connection failure for bin pressure. The

results of this analysis, and the assumed bin pressures, therefore show that connection will not control the design of GRS, therefore supporting the removal of connection as a design calculation for closely spaced GRS, as recommended in FHWA’s design guidance (Adams et al. 2011a)

Figure 11. Comparison of thrust against the face (bin pressure) and assumed long-term connection strength.

4. CONCLUSIONS

The simple frictional connection method has successfully been used on numerous in-service GRS walls and abutments constructed with reinforcement spacing less than 0.3m for more than 20 years. In addition, this connection method has been shown to withstand extreme loading conditions without connection failure. The in-service performance of numerous walls and abutments built with the full frictional method, compared to the long-term connection strength, indicates that the loads at the face for closely spaced GRS are not equal to those assumed internally as in MSE design (AASHTO 2010, Berg et al. 2009). Rather, bin pressure is a more realistic assumption of the thrust against the face for service conditions. Additionally, considering the strength of the frictional connection is significantly greater than the thrust exerted at the face further supports the conclusion that the connection strength criterion does not control the design for closely spaced GRS walls and abutments. The implications of connection strength criterion on larger spaced (greater than 0.3 m) MSE systems, however, still needs to be further investigated.

ACKNOWLEDGEMENTS

The authors would like to acknowledge the support of Tom Stabile, Jan Li, and Moustafa Ibrahim for their assistance in the laboratory testing, and appreciate the review and advice of Dr. Jonathan Wu and Dr. Philip Ooi throughout this study.

Importance of Variability in the Interface Shear Strength between Textured Geomembrane and Geocomposite Drainage Layer in Landfill Covers

Gregory Dellinger, The University of Texas at Austin, USA
Richard Lacey, TRI Environmental, USA
John Allen, TRI Environmental, USA
Robert Gilbert, The University of Texas at Austin, USA

ABSTRACT

A common interface in landfill covers is between a textured geomembrane and an overlying geocomposite drainage layer. The shear strength of this interface is particularly important for stability since it is subjected to water pressures that develop in the drainage layer. The shear strength of this interface can exhibit significant variability at the low effective normal stresses present in a landfill cover. The objective of this paper is to provide insight into how the variability of this interface affects the interpretation of laboratory test results and their use in stability analyses. Laboratory tests are presented and analyzed, leading to the following conclusions:

1. The texturing on blown-film textured geomembranes can be highly variable locally within a sheet as well as between rolls. The height and density of asperities, as well as their shapes, are variable.
2. This variability in texturing can lead to significant variability in the peak interface shear strength, with a coefficient of variation in the peak friction coefficient of about 0.15.
3. These local variations in texturing and interface shear strength are not generally important to the overall stability of a landfill cover slope because the area of the slip surface is typically much larger than the scale of variations. It is the average shear strength from test results and not the minimum tests result that is relevant.
4. In QA/QC, these local variations are important in establishing the number of tests and the criterion for accepting or rejecting material based on the test results. A minimum of five to ten tests are recommended to assess the average peak shear strength for this interface, and the criterion for accepting and rejecting material is best based on the average test result rather than the minimum result.

1. INTRODUCTION

A geocomposite drainage layer overlying a texture geomembrane is a common interface within landfill covers (Figure 1). In many designs, the peak shear strength of this interface will govern the stability of the slope due to the possibility of pore water pressures in the drainage layer. The peak shear strength of this interface can exhibit significant variability in testing due to variations in the roughness of a blown-film textured surface (e.g., Dove and Frost 1996, Stark et al. 1996 and Frost and Lee 2001). This variability could be important for design if relatively large areas of low shear strength are possible. This variability could also be important for Quality Assurance/Quality Control (QA/QC) programs in establishing the number of tests and the criterion for accepting or rejecting material based on the test results.

A recent project involved conducting a large number of shear tests on the interface between a textured geomembrane and a geocomposite drainage layer. The objective of this paper is to use this large data set to quantify the variability in the peak shear strength, to investigate potential sources of this variability, and to develop guidelines for interpreting shear test results for purposes of design and QA/QC.

Figure 1. Typical Landfill Cover Schematic

2. TEST DATA

The shear strength data analyzed in this paper come from a series of testing programs to measure the shear strength of the interface between a textured geomembrane and a geocomposite drainage layer.

2.1 Interface Materials

The textured geomembrane is a 1.0-mm thick, LLDPE, blown-film textured geomembrane. The geocomposite drainage layer is a 6.86-mm thick geonet bonded to 203 g/m² non-woven polypropylene geotextiles on each side. Samples of these materials were obtained from a variety of sources but the same production run of material. First, samples were obtained directly from the manufacturer. Second, samples were removed from a construction project after the textured geomembrane and the geocomposite drainage layer were installed, but before they were covered with cover soil. Third, samples were obtained from a construction project after the installed geomembrane and geocomposite drainage layer were covered with about 0.61 meters of cover soil.

2.2 Shear Tests

A total of 75 shear tests were conducted on this interface between the textured geomembrane and the geocomposite drainage layer at the range of normal stresses typical in a cover system. Two types of test methods were used to measure the shear strength for the interface: 56 large-scale direct shear tests and 19 tilt table tests.

The large-scale direct shear tests were conducted according to ASTM D 5321 using a dead-load large-scale direct shear box. The textured geomembrane specimens were mounted in the bottom of the shear box. The geocomposite drainage layer specimens were mounted in the upper shear box, which reacted against a load cell; the non-burnished side of the geocomposite was in contact with the textured geomembrane. The interface was submerged in a bath of tap water for the duration of the testing. The applied normal stresses ranged from 12 to 24 kPa. The normal stress was applied for a 15 minute seating time before the interface was sheared. A shear rate of 0.5 centimeters per minute was used.

The tilt table consisted of a flat 61-centimeter by 46-centimeter tray on a hinge attached to a steel frame that used a strap with a gear hand crank to raise one side of the tray. A ratchet mechanism attached to the crank was used to hold the table at the desired inclination. A 46-centimeter long by 46-centimeter wide specimen of the textured geomembrane was clamped to the tray. A 20-centimeter long by 10-centimeter wide specimen of the geocomposite drainage layer was then placed on the geomembrane. A loading plate with a roughened surface was placed on top of the geocomposite specimen. Weights were then placed on the loading plate; the center of gravity for the weights was located so that there would be minimal eccentricity when the specimen sheared as the table was tilted. The specimens were placed into a bath of tap water for the duration of the test. A seating time of five minutes was imposed before the table was tilted and shearing stress was applied. The rate of lifting the table was set to give an approximate shear rate of 0.5 centimeters per minute. The applied normal stresses during shear ranged from 4 to 20 kPa.

3. MAGNITUDE OF VARIABILITY IN INTERFACE STRENGTH

The test results are plotted in Figure 2. For slope stability analyses, the quantity of interest is the tangent of the peak friction angle for the interface, $\tan \phi'_{peak}$, which is also sometimes referred to as the peak friction coefficient. A frequency

distribution plot is shown in Figure 3 and sample statistics are summarized in Table 1 for the peak friction coefficient. The frequency distribution is approximately normal. As a check on this approximation, a probability plot is shown in Figure 4. The linear trend in Figure 4, particularly in the vicinity of the smaller values of the peak friction coefficient that are of most concern from a design perspective, indicates that a normal distribution is a reasonable model for the variability.

Figure 2. Peak Shear Strength versus Normal Stress for Shear Test Results

Figure 3. Frequency Distribution for Peak Friction Coefficient

Figure 4. Standard Normal Inverse Plot for Peak Friction Coefficient

The magnitude of variability in peak friction coefficient is noteworthy. The coefficient of variation, the standard deviation divided by the mean, is about 0.15. For comparison, coefficient of variation in the friction coefficient for simple interfaces, such as that between a nonwoven geotextile and a smooth geomembrane or simply the sliding mechanism in the direct shear box, are typically less than 0.05 (e.g., Gilbert et al. 1995 and Allen and Gilbert 2002). Hence, the variability in Figures 2 and 3 is not a reflection of inherent variations in the test procedure itself; instead, it is real variations in the shear strength of the interface. Practical implications of this relatively large coefficient of variation are the following:

- Five percent of measurements will be outside of +/- 30 percent from the mean value;
- Ten percent of measurements will be smaller than 20 percent below the mean value and five percent will be smaller than 25 percent below the mean value; and
- The Minimum Average Roll Value (MARV), which is the 2.5 percentile value, is 30 percent below the mean value.

Therefore, considerable care is warranted in interpreting, comparing and evaluating interface shear results due to this relatively large variability.

4. SOURCES OF VARIABILITY

The following factors were first considered as potential sources of variability in the peak friction coefficient: the shear test method (large-scale direct shear box versus tilt table), the effects of pushing the soil cover over the interface before samples were exhumed for testing, and the effective normal stress during shear. The result of a statistical analysis considering the significance of each of these factors is summarized in Table 1. For conventional significance levels of 1 to 5 percent, none of these factors is a statistically significant source of the measured variability in the peak friction coefficient for this interface (that is, none of the P-values are smaller than 0.01 to 0.05).

Table 1 Summary of Statistical Analysis for Potential Factors affecting Peak Friction Coefficient

Factor	P-value ¹
Direct Shear Box versus Tilt Table	0.84
Before versus After Pushing 2-feet of Cover Soil over Interface during Construction	0.19
Effective Normal Stress	0.44

¹Probability of Obtaining Data Set from Testing if the Peak Friction Coefficient is Not Related (Linearly) to that Factor

The inference from Table 1 is that the variability in the shear strength of this interface is primarily due to variability in the material properties. One possible source of material variability is the effect of construction, such as fibres of the geotextile being strained or asperities on the geomembrane surface being damaged during installation. However, Figure 2 shows that there is no significant difference in the variability and average shear strengths between samples from the

manufacturer and samples obtained after installation. These results suggest that the variability is primarily due to variations in the as-manufactured materials. Previous research on a similar interface (Li and Gilbert 2006) indicates that this variability in interface shear strength is almost entirely due to spatial variability in the texturing of the geomembrane. To investigate this possibility further, the asperity height was measured in accordance with ASTM D 7466 on many of the specimens; the height was measured at nine locations within a 15-centimeter by 16-centimeter grid for each specimen. As with the peak friction coefficient, there is significant variability in the asperity height of the texturing; the coefficient of variation for the asperity height, 0.18, is as large as that for the peak friction coefficient. However, the peak friction coefficient is poorly correlated with the asperity height alone (Figure 5). This result is not surprising as many researchers, such as Dove and Frost (1996), have shown that the roughness of a textured geomembrane surface is a complex, three-dimensional object that cannot be easily represented by the height of the asperities alone. To illustrate this point with this interface, Figure 6 shows a rendering of the coverage of asperities for two different specimens of this geomembrane. These renderings were produced by coating the geomembrane surface with ink, placing the inked surface against a white poster board, and then rolling the poster board with a rigid roller. Both specimens have the same measured asperity height. However, Specimen A had a lower areal density of asperities and a smaller measured peak shear strength compared to Specimen B (Figure 6). Therefore, the variability in the peak interface shear strength is related both to the height and the coverage of the asperities in the test specimen.

Figure 5. Peak Friction Coefficient versus Asperity Height

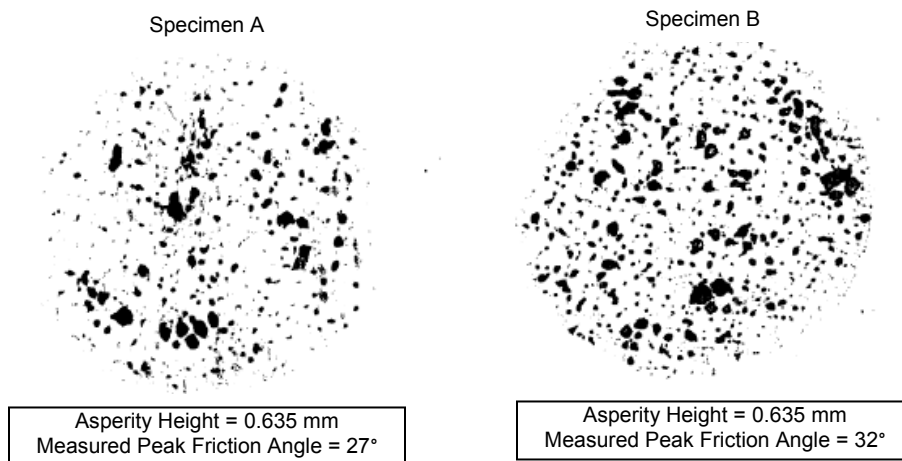

Figure 6. Example of Variations in Asperity Density based on Pressed Ink Images

This spatial variability in texturing exists over a relatively small area, on the order of the size of a 30-centimeter by 30-centimeter test specimen. Figure 7 shows a comparison of measured peak shear strength for specimens that came from within the same roll (and even the same location along the machine direction of the roll) with that for specimens that came from different rolls. If the spatial variations in texturing were over scales larger than the sizes of the specimens,

then there would be a different mean and a smaller standard deviation for the inter-roll specimens than the intra-roll specimens. However, the mean values and the standard deviation values are essentially the same, indicating that the spatial variability in texturing is over a small scale (centimeters).

Figure 7. Comparison of Inter-Roll versus Intra-Roll Variability

5. PRACTICAL IMPLICATIONS OF VARIABILITY

Practical implications of the variability in the peak friction coefficient for this interface between a textured geomembrane and a geocomposite drainage layer include its effects on design and on Quality Assurance/Quality Control (QA/QC).

5.1 Slope Stability Design

The total shear resistance along a slip surface at this interface is proportional to the average peak friction coefficient over the area of the slip surface. The relatively large magnitude of variations in peak shear strength shown in Figures 2 and 3 occur over small areas on the order of 30 centimeters by 30 centimeters, while a typical slip surface would be tens to hundreds of meters in dimension. Therefore, there will be significant averaging of the small-scale variations in the peak friction coefficient over the area of the slip surface, and the uncertainty in the average peak friction coefficient for the slip surface will be markedly smaller than the small-scale variability. As a simple approximation, the coefficient of variation of the average peak shear strength for a slip surface that is L x W in dimension is related to the coefficient of variation measured in large-scale direct shear tests as follows:

$$\delta_{L \text{ by } W \text{ slip surface}} \cong \left[\sqrt{\left(\frac{30 \text{ centimeters}}{100xL} \right) \left(\frac{30 \text{ centimeters}}{100xW} \right)} \right] \delta_{30 \text{ centimeter by } 30 \text{ centimeter test specimen}} \quad [1]$$

where $\delta_{L \text{ by } W \text{ slip surface}}$ is the coefficient of variation in the average peak friction coefficient over the L x W area of the slip surface, $\delta_{30 \text{ centimeter by } 30 \text{ centimeter test specimen}}$ is the coefficient of variation in the small-scale shear test specimens, and L and W are in meters. As an example consider a potential 25-meter by 5-meter slip surface; the coefficient of variation in the average peak shear strength across this slip surface is approximately 3 percent of the coefficient of variation in the measured shear strength, or about 0.003. Therefore, it is the average and not the small-scale variations in peak shear strength that will be of practical concern for slope stability.

5.2 Quality Assurance/Quality Control

For QA/QC purposes, the practical significance of the relatively large variability in the measured shear strength for this interface is that it is difficult to assess the strength of the interface with a small number of shear tests. In addition, it is not useful to measure asperity height as a surrogate for peak shear strength (Figure. 7). Therefore, care is warranted both in deciding how many QA/QC shear tests are to be performed and in establishing reasonable criteria for accepting material based on these test results. One consideration is minimizing the possibility of rejecting material that is actually adequate, and the other consideration is minimizing the possibility of accepting material that is actually inadequate.

Since the average value for the peak friction coefficient is what is relevant for slope stability, it is most useful to evaluate QA/QC test results in terms of the average value. For accepting or rejecting material, a threshold will be specified. If the average peak friction coefficient from the test results is greater than this threshold, then the material will be accepted; otherwise, the material will be rejected. Figure 8 shows how this threshold is related to the number of test specimens and the probability of rejecting material that is actually adequate (Probability of Rejecting Good Material). For a given number of test specimens, the probability of rejecting good material decreases as the required minimum average threshold decreases (Figure 8). Also, for a given probability of rejecting good material, the required minimum average threshold decreases as the number of test specimens decreases.

As an example, consider that the required average value for the peak secant friction angle is 26.6° , a peak friction coefficient of 0.5. In order to achieve smaller than a 1-percent probability of rejecting good material, the specified minimum threshold would be

- 0.80 times the required average (a peak friction coefficient of 0.40 or a peak secant friction angle of 21.8°) for a QA/QC program with 3 test specimens;
- 0.84 times the required average (a peak friction coefficient of 0.42 or a peak secant friction angle of 22.9°) for a QA/QC program with 5 test specimens; and
- 0.89 times the required average (a peak friction coefficient of 0.44 or a peak secant friction angle of 24.0°) for a QA/QC program with 10 test specimens.

Note that even with 10 test specimens, it is not reasonable to specify that the average value from the test results be greater than the required average, 26.6° , without incurring a relatively large probability of rejecting good material.

Figure 8. QA/QC Minimum Average Threshold versus Number of Test Specimens for Different Probabilities of Rejecting Good Material (assumed Coefficient of Variation of 0.15)

Figure 9 shows how the probability of accepting inadequate material is related to the specified average threshold from Figure 8 and the factor of safety between the required average and what is actually needed in the field. For a given number of test specimens, the probability of accepting inadequate material decreases as the design factor of safety increases. Also, for a given factor of safety, the probability of accepting inadequate material decreases as the number of test specimens increases.

Figure 9. Probability of Accepting Material (based on Average Threshold) with an Average Peak Friction Coefficient less than the Required Average Divided by the Factor of Safety QA/QC versus Number of Test Specimens for Different Factors of Safety (assumed Coefficient of Variation of 0.15)

As an example, consider a 3H:1V cover slope (slope angle of 18.4°) with this interface. If the slope is designed with a factor of safety of 1.5 assuming no water pressure acting at the interface, then the required average peak friction coefficient is 0.5 (or a peak secant friction angle of 26.6°). If the probability of rejecting good material is kept below 1 percent, then the probability of accepting inadequate material (that is, an interface with an average peak shear strength corresponding to a friction angle less than the slope angle of 18.4°) is

- about 1 percent for a QA/QC program with 3 test specimens;
- about 0.01 percent for a QA/QC program with 5 test specimens; and
- considerably less than 0.01 percent for a QA/QC program with 10 test specimens.

Since the consequences of a cover slope failure can be substantial, the probability of a slope failure will typically be targeted to be smaller than 0.01 percent. Therefore, a QA/QC program would need to be based on 5 or more specimens in order to achieve this probability of accepting inadequate material.

In some projects, a QA/QC threshold has been established as the minimum value for all of the shear test results. For example, if a peak secant friction angle of 26.6° specified, then the material is accepted only if all shear test results produce a shear strength greater than this minimum. This approach is not recommended for three reasons. First, the average shear strength versus the minimum shear strength is what is of concern for slope stability. Second, it is very likely that adequate material will be rejected based on this approach unless the minimum threshold is set to be considerably smaller than the required average value. Figure 10 shows how this minimum threshold is related to the number of test specimens and the probability of rejecting good material. Unlike for a threshold based on the average value (Figure. 8), the required minimum threshold for a given probability of rejecting good material decreases as the number of test specimens increases because the chance of a smaller test results increases with the number of tests. Third and most importantly, the probability of accepting inadequate material is much higher using this approach (Figure 11).

Figure 10. QA/QC Minimum Threshold versus Number of Test Specimens for Different Probabilities of Rejecting Good Material (Assumed Coefficient of Variation of 0.15)

Figure 11. Probability of Accepting Material (based on Minimum Threshold) with an Average Peak Friction Coefficient less than the Required Average Divided by the Factor of Safety versus Number of Test Specimens for Different Factors of Safety (Assumed Coefficient of Variation of 0.15)

6. SUMMARY

A large number of shear tests on the interface between a blown-film textured geomembrane and a geocomposite drainage layer provided an opportunity to quantify the variability in the peak shear strength, investigate potential sources of this variability, and develop guidelines for interpreting shear test results for purposes of design and QA/QC. At a range of normal stresses typical for a landfill cover, 4.0 to 24 kPa, the variability in the peak friction coefficient, $\tan \phi_{peak}$, for this interface is approximately normally distributed with a coefficient of variation of about 0.15. This variability is due primarily to spatial variations in the texturing and it occurs at small scales, on the order of 1,000-square centimeter areas. This variability is not correlated strongly with asperity height alone; rather it reflects variations in the height, shape and density of asperities across the test specimens.

In cover slope stability design, these variations in the peak shear strength are not important because they are localized and will average out over a relatively large slip surface with an area of tens to hundreds of square meters. Therefore, it is the average value of the peak friction coefficient from multiple tests and not the individual values or the minimum value that is most relevant for design.

However in QA/QC, these variations are important in establishing the number of tests and the criterion for accepting or rejecting material based on the test results. In order to minimize the probability of rejecting adequate material and the probability of accepting inadequate material, a QA/QC test program should include at least five to ten tests taken from any rolls since the variability occurs over a small scale. In addition, the criterion for accepting or rejecting material should be based on the average test result versus the minimum test result. It should be noted that this criterion is specific to the type of materials tested in this study.

Improving the Stability of High Fill Load Structures Built on Low-Strength Geosynthetic Interfaces

Allan J. Breitenbach, P.E., Ausenco, USA, allan.breitenbach@ausenco.com
Chris Athanassopoulos, P.E., CETCO, USA, catha@cetco.com

ABSTRACT

Geosynthetic composite liner systems, consisting of geosynthetic clay liners (GCLs) underlying geomembrane liners, are seeing increased usage in large lined fill structures such as heap leach pads, tailings storage impoundments, and landfills, largely due to improved construction time and enhanced operational liquid containment compared to compacted clay composite liners. The improved hydraulic seepage barrier performance provided by geomembrane/GCL composite lining systems is well documented (Bonaparte et al, 2002). However, there is a concern by engineers and regulatory agencies over the stability of such composite liner systems, due to the low shear strength of hydrated bentonite.

This paper focuses on solving the liner engineer's ultimate long term slope stability challenge (or nightmare): high fill loads on planar composite liner surfaces with low-strength bentonite clays in direct interface contact with a smooth geomembrane liner surface. In particular, the focus will be on the slope stability of heap leach pads as the ultimate lined fill structure challenge due to a combination of several stabilization considerations, including large planar pad surfaces, controlled ore lift stacking to high wet density fill load conditions, downhill sloping gravity drainage surfaces to recover leach solutions in external ponds, and generally without any downhill toe buttress berm fill support. A summary of design and construction stabilization methods is presented to improve the long-term stability of worst-case composite liner strengths on planar surfaces.

1. INTRODUCTION

Textured geomembrane liners in direct contact with the nonwoven geotextile side of GCLs have been functioning successfully for more than 20 years in the mining and landfill industry. However, the primary question for long term closure of lined facilities is the worst-case condition where the GCL loses internal strength due to either rupture, pullout, or degradation of the needle-punched reinforcing fibers, leaving behind only hydrated unreinforced bentonite. Fox and Ross (2011) state that at high normal stress, a textured geomembrane/needle-punched reinforced GCL composite liner system can experience GCL internal failure, as the shear strength between the textured geomembrane and GCL exceeds the strength of the needle-punch reinforcement. The normal stress at which the failure plane transitions from textured geomembrane/GCL interface to GCL internal depends on the specific materials and testing conditions. McCartney et al. (2009) observed no GCL internal failures in a database of 534 geomembrane/GCL interface tests performed at normal stresses as high as 965 kPa (20,150 psf). Fox and Ross observed this transition occurring at normal stresses between 692 and 2,071 kPa (14,450 and 43,240 psf). These types of GCL internal failures appear to be limited to the laboratory however. Koerner (2012) and Fox and Ross (2011) report that there are no known cases of internal shear failure of needle-punched GCLs in the field. Another potentially problematic, but less severe, condition involves the extrusion of hydrated bentonite through the woven geotextile component of the GCL, resulting in a reduction in interface shear strength (Vukelic et al, 2008). This condition can be minimized by specifying GCLs with nonwoven geotextiles, which have a smaller opening size, on both sides of the bentonite clay layer.

If these conditions occur in the field, then large planar composite liner surfaces would approach the residual strength of the bentonite clay at the interface contact with a smooth geomembrane liner surface. Excess pore pressure conditions can be neglected for evaluating long term closure slope stability, assuming operational fill lift loads are placed before post-construction hydration and swell pressures can fully develop over time along large lined fill slope areas.

Traditional methods covered by previous literature and textbooks, such as earthen toe berms and flattened fill slopes (e.g., Abramson et al, 2002) or stabilized underliner toe grades and operational startup lift placement control (Breitenbach, 1997) have been used with success since the 1990's. Slope stability can also be improved through the use of non-planar features to improve liner shear strength. The earliest discussion of this technique is given by Poulter (1995), who presented two case studies. The first involved the addition of a small berm under the toe of a gold heap to stabilize a liner failure in 1990 in South Carolina, USA. The critical slip plane was a smooth HDPE geomembrane against a soft clay soil compacted at wet of optimum moisture content (calculated equivalent friction angle of 11 degrees at failure). The second case study involved the addition of two berms to compensate for low shear strength between a smooth VLDPE geomembrane and a nonwoven geotextile (calculated equivalent friction angle of 8 degrees at failure).

This paper builds on this previous work, and analyzes three basic types of non-planar liner interface stabilizing techniques used primarily in the mining industry on heap leach pads for downhill toe stability. Based on the non-planar slope stability analyses results for an idealized pad liner section and past leach pad experience, these non-planar stabilization techniques can be applied to lined dams and landfill structures as well, subject to low interface strength composite liner conditions during construction, operation or for long term closure scenarios.

2. INTERFACE STRENGTH SELECTION

2.1.1 General

The low interface strength between a composite clayey soil and geomembrane liner or synthetic geotextile to geomembrane liner has been proven by large scale laboratory direct shear testing, theoretical slope stability analyses and construction into operation practice to be the cause of numerous lined fill structure failures (Breitenbach, 1997, Koerner and Soong, 1999). Therefore the selection of the liner interface strength value for stabilized surface grades is the most important factor in designing stable fill structures to function for the life of the facilities to closure.

The general concerns for the GCL in a planar composite liner high load facility are 1) the loss of hydrated bentonite through the geotextile sheets, 2) interface friction strength in direct contact with the overlying geomembrane liner or underlying bedding fill surfaces, 3) loss of internal geotextile needle-punched and/or stitch-bond fabric strength in the reinforced GCL sheets, and 4) long term performance to resist soil creep movement at hydrated low residual strength conditions.

This section discusses GCL materials and a review of past test results for selecting a worst-case interface strength for analyses. The GCL laboratory test strengths provide a guideline for selection by the authors of a typical post-construction hydrated bentonite residual strength value in modeling the stabilization of a GCL composite lined planar leach pad in an idealized study section under high ore heap fill load conditions.

2.1.2 GCL Material

The natural deposits of montmorillonite sodium bentonite clays provide the lowest permeability clayey soil liner materials in the world with few exceptions. The permeability of fully hydrated thin sheets of bentonite clay under 0.6 m (2 ft) of load can achieve permeabilities less than 1×10^{-8} cm/sec (Estornell and Daniel, 1992). Along with the low permeability characteristics of bentonite, the clay material is expansive when wetted from a dry condition (excellent for sealing off local void spaces), however bentonite clay hydration also causes residual low strength conditions.

Geosynthetic clay liners (GCLs) use sodium montmorillonite (bentonite) clays sandwiched between different geotextiles. GCLs can be either unreinforced or reinforced with needle-punching or stitch-bonding. The reinforcement imparts increased shear strength and resistance to hydrated clay swelling. The sodium bentonite clays in Wyoming and Montana USA are formed from weathered or decomposed volcanic ash material deposited long ago in an ancient inland sea marine environment. The bentonite clay in the GCL sheet is essentially "dry" at 15 to 30 percent deployment moisture content for short term exposure before being covered by a geomembrane liner. When wetted from liner leakage or in contact with moist subgrade material, the bentonite clay absorbs water and swells to form a relatively impervious clay barrier. At the same time, the hydrated bentonite clay acts as a low strength planar material, when used in a composite geomembrane and GCL liner system for lined landfills, heap leach pads and tailings impoundments. The hydrated bentonite clay has low internal and interface peak friction strength, in addition to low residual strength after movement occurs. These lined containment facilities are subjected to a range of loading conditions requiring stabilization of the loaded structures for the life of the facility and long term into closure.

2.1.3 GCL Laboratory Test Strengths

Numerous laboratory tests have been conducted on unreinforced and reinforced, needle-punched, needle-punched and thermal bonded, and stitch-bonded GCL in dry to fully hydrated and low to high load conditions. The internal strength of the bentonite itself under hydrated conditions is the controlling factor, since the interface strength interlocking bond with a textured geomembrane liner surface or drain fill materials would be higher. The exception to this rule would be smooth and less flexible geomembrane liner surfaces in contact with hydrated bentonite extruded or squeezed through the GCL geotextile layer under high load conditions.

The numerous variables for the laboratory tests considered delaying loads to reduce pore pressure at failure, rate of shearing to failure, extent of hydration before or during test loading, peak versus large-displacement (residual) strengths, and test apparatus/testing variations. Changes in GCL hydration in conjunction with loading conditions over time were found to have the most influence on interface strengths under the same liner system design conditions. The equivalent

residual friction strength is defined throughout this paper as the straight line slope on the Mohr stress-strain failure envelope drawn through the zero cohesion intercept for ease in comparing the various total and effective stress friction and cohesion strengths to a single equivalent friction strength parameter. This technique is a useful tool for determining a general strength condition for an idealized section, however it has limitations for use in site specific design considerations such as changes in GCL loading and moisture conditions over time.

The GCL strengths are site-specific to the liner design and apply to changing conditions over time from construction to operation to closure of a lined facility. The general conclusion from over 300 laboratory test results on GCL in a single laboratory test environment (McCartney, et al 2002) is the following:

Peak equivalent friction angle:

- Needle-punched GCL = 33.5 degrees
- Needle-punched, thermal bonded = 28.9 degrees
- Stitch-bonded = 12.2 degrees
- Unreinforced = 6.6 degrees

Large-displacement equivalent friction angle (post-peak approach to residual strength):

- Needle-punched GCL = 13.7 degrees
- Needle-punched, thermal bonded = 12.9 degrees
- Stitch-bonded = 6.7 degrees
- Unreinforced = 5.9 degrees

Assuming that the geotextile fabric in GCLs will provide some residual strength reinforcement in the long term decomposition of the liner system, a lower bound worst-case interface strength was selected to be 7 degrees friction for the idealized study section analyses.

3. EVALUATION OF LOW STRENGTH PLANAR SURFACES

3.1 General

The evaluation of these low strength clays for stabilized composite liner design options included several steps: The first step is to select a bentonite clay strength representative of a fully hydrated GCL material with no residual strength excess pore pressures. This would best represent the worst-case long term closure conditions with minimal support from the geosynthetic geotextile materials in the sheet. The second step is to simplify the analyses with an equivalent friction strength only. Cohesive or adhesive strengths of clays in direct contact with geomembrane liners have a tendency to decrease with time, therefore the analyses for this paper considered an equivalent low interface friction strength only and neglected any additional strength from cohesion. The third step included using several techniques that demonstrate increasing the pad liner stability to acceptable factors of safety by breaking up the planar low strength liner interface conditions. These include stability berms, stability trenches and stability benches as discussed in this section and illustrated in Figures 2 to 9.

3.2 Heap Leach Pad Stability Analyses

This paper presents a series of stability calculations for a hypothetical ore heap study section containing a pad composite liner at an assumed very low bentonite clay to geomembrane liner interface friction strength equivalent to 7 degrees friction and no cohesion. An equivalent friction only interface strength was selected for simplification purposes and to represent long term residual strengths at low excess pore pressure conditions.

After preliminary calculations on the baseline planar pad liner surface condition (i.e., no non-planar slope stability improvement measures), a series of calculations were performed to evaluate the benefit of adding non-planar structures to the study section, including the use of stability berms, trenches, and benches.

The hypothetical heap study section used in this analyses was taken from Breitenbach and Thiel (2005). They considered a typical ore heap configuration, built on a planar 2 percent pad grade, with 2H:1V overall ore heap slopes above the pad liner, and no toe berm support, as shown on Figure 1.

Breitenbach and Thiel assumed that the heap leach pad liner system had an interface friction angle of 18 degrees, and that both the ore and subgrade soil had a density of 18.85 kN/m^3 (unit weight of 120 pcf) and a friction angle of 38 degrees. The phreatic surface was assumed to be 0.6 m (2 feet) above the liner throughout the structure. Under these conditions, the modified Janbu method in PCSTABL 5M was used to calculate a critical factor of safety (FS) of 1.44, which would be acceptable to regulatory agencies for a low risk heap leach structure that does not pond water.

The first step in our baseline analysis involved evaluating the same ore heap shown in Figure 1, using the same conditions as Breitenbach and Thiel, as a means of validating our calculation method. The authors employed XSTABL (Sharma, 1996), using the modified Janbu method, and found that, for the same geometry and material properties, the calculated FS was 1.44, the same value and the same critical surface reported by Breitenbach and Thiel.

After this initial baseline step, the liner interface shear strength was reduced from 18 degrees down to a very low strength of 7 degrees friction. This low strength represents an assumed worst-case scenario, where a GCL's internal needle-punch reinforcement has entirely ruptured, leaving behind a weak layer of unreinforced, hydrated sodium bentonite clay. All of the remaining study section parameters were left the same. The XSTABL calculations found that the same heap geometry, built on a layer of unreinforced hydrated bentonite, would be expected to have FS = 0.89, or in other words, be subject to an imminent sliding failure. This scenario now becomes our baseline for applying non-planar stabilization measures for improvements to the ore heap's stability, as discussed in the following section. (Please note that the calculated FS = 0.89 is conservatively based on an assumed friction angle 7 degrees across the entire liner area, regardless of normal stress. If the calculation is repeated to include a more realistic nonlinear Mohr-Coulomb failure envelope, using the large displacement shear strength values measured by Fox and Ross (2011) for a textured geomembrane/GCL interface, the FS increases to 1.16).

Figure 1. Hypothetical Ore Heap Section from Breitenbach and Thiel (2005) used as Baseline Starting Point for this Stability Analyses

3.3 Stability Berms

The first non-planar stability improvement method considered the use of stability berms along the baseline heap study section, as it was the first type of slope strengthening method used in the mining industry. The senior author had considered using what were called “speed bumps” in the analyses for planar leach pad liner surfaces in South Dakota and for a water storage dam upstream section with composite GCL and liner core in Nevada USA in the late 1980’s. Subsequently the speed bump concept was put into practice to remediate a pad liner failure in 1990 in South Carolina USA. The slide occurred along the composite liner interface on a planar 6.5 to 7.7 percent pad downhill toe grade under 15 m (45 ft) of ore lift load. The pad failure extended 60 m (200 ft) inward from the toe, and the non-leached dry ore lift was removed to make the repairs. Several low-level “speed bump” stability berms were suggested to the design engineer for remediation and were constructed in the slide area perpendicular to the direction of slide. Ore lift placement resumed with no further problems, which included multiple placed and leached ore lifts over the following year. The stability berms provide added sliding resistance and cause the critical slip plane to shear through an overall higher non-planar interface surface, thus improving overall stability. A photograph showing a past heap leach project that employed this technique is shown in Figure 2.

In this evaluation, the hypothetical example presented above ($\phi = 7$ degrees, FS = 0.89) was modified by introducing increasing numbers of stability berms along the 2 percent grade, and calculating the improvement to FS. The stability

berms were added in two different orders: (1) starting at the toe of the slope and moving deeper into the pad interior to the failure wedge plane; and (2) starting at the back failure wedge plane and moving towards the pad downhill toe. For the purposes of these analyses, the stability berms were assumed to be 0.5 m (1.5 feet) in height, 3 m (9 feet) wide crest and 1H:1V slopes. The stability berms were spaced 5 m (15 feet) apart to allow for vehicular access. The sensitivity analysis effects of varying stability berm height, width, and spacing are evaluated in a later section of this paper. \

Figure 2. Example stability berm configuration from a heap leach pad liner project (photo courtesy of Comanco)

3.3.1 Addition of Stability Berms (Starting at the Downhill Toe)

Scenarios involving the addition of 1 to 11 stability berms, starting from the toe of the pad inward, were evaluated, as shown in Figure 3. The different critical failure surfaces associated with selected stability berm values is shown in Figure 3. Figure 5 presents a summary of the relationship between FS and number of stability berms. The calculations showed that there was a gradual improvement in FS with the addition of up to four stability berms, with no change in the critical failure surface location. With the addition of the fifth stability berm, there was a corresponding shift in the critical failure surface to deeper within the ore heap. This intuitively makes sense, as the sliding resistance along the toe increases, a greater driving mass of ore would be necessary to overcome the non-planar change in pad interface strength. Nine stability berms were needed to improve the FS to greater than 1.3, and eleven berms were needed to improve the FS to greater than 1.4. The number of required stability berms is reduced as the interface strength is increased, like for a change from smooth to textured liner surfaces.

Figure 3. Critical Failure Surfaces associated with addition of stability berms along liner starting from the toe

3.3.2 Addition of Stability Berms (Starting at the Back of the Failure Wedge)

The evaluation above was then repeated, this time with the stability berms starting from the back of the failure wedge toward the downhill toe, as shown in Figure 4. Figure 5 presents a summary of the relationship between FS and number of stability berms for each of the two scenarios evaluated. Intuitively, one would expect the incremental benefit of each berm added at the back of the wedge would be greater, due to the greater normal stress on the failure plane, and therefore greater shear strength at this location. However, in this scenario, the expected sharp increase in FS was not realized, since the critical failure surface was forced outward, towards the toe of the pad, as shown in Figure 4. (Note that performing the analysis with a fixed failure surface showed that the addition of just one berm at the back of the wedge improved the FS of that fixed surface significantly from 0.89 to 1.14). This movement continued until the addition of eight berms finally forced the critical failure surface deeper into the ore heap. Eight berms were needed to improve the FS to greater than 1.3, and ten berms were needed to improve the FS to greater than 1.4.

Figure 4. Critical Failure Surfaces associated with addition of stability berms along liner starting from the back of wedge

Figure 5. FS versus Number of Stability Berms

3.3.3 Stability Berm Size Sensitivity Analysis

The scenario with eleven stability berms and FS = 1.47 was selected for additional sensitivity analyses of the berm size, looking at variables such as the stability berm height, width, and spacing. As mentioned above, the standard stability berms were assumed to be 0.5 m (1.5 feet) in height, 3 m (9 feet) wide crest with 1H:1V side slopes, and spaced 5 m (15 feet) apart. The subgrade soil was assumed to have an internal friction angle of 38 degrees. With all other parameters kept constant, each of the stability berm variables were changed to evaluate its impact on the overall factor of safety. A constant number of stability berms over a given area was maintained. A summary of the sensitivity analysis is presented in Table 1.

This analysis shows that the stability berm height is not a critical parameter for the model geometry and strengths compared to the stability berm width and spacing. As expected, reducing the subgrade soil's internal friction angle decreased FS. Increasing the stability berm width improved FS, with the greatest improvement seen when combining increased stability berm crest width together with closer spacing. Conversely, reducing the stability berm crest width resulted in the largest observed reduction in FS.

Table 1. Stability Berm Sensitivity Analysis

<i>Parameter</i>	<i>FS</i>
Initial Condition, height = 0.5 m (1.5 feet), width = 3 m (9 feet), spacing = 5 m (15 feet)	1.47
Increase berm height to 1 m (3 feet)	1.55
Decrease subgrade soil friction angle to 25 degrees	1.23
Increase berm width to 5 m (15 feet), with 5 m (15 feet) spacing	1.75
Increase berm width to 5 m (15 feet) and decrease berm spacing to 2.5 m (7.5 feet)	1.73
Decrease berm width to 1 m (3 feet) and increase berm spacing to 7 m (21 feet)	1.17

3.4 Stability Trenches

A similar stability improvement method involves the use of stability trenches, also known as shear keys (Abramson et al., 2002), to provide additional sliding resistance along a planar surface. Stability trenches are sometimes used along with stability berms as a dozed cut to fill non-planar structure, however the trenches are more difficult to design and construct

for gravity drain systems to the downhill pad toe collection ditches and ponds versus leaving openings in key areas of the stability berms to facilitate drainage as shown in Figure 2 (ease in separation of operational solution cell flows). Stability trenches improve the non-planar surface strength depending on the width of the trench cut and steep wall trench cuts are preferred to cause passive wedge resistance to sliding.

Stability trenches were evaluated for the Breitenbach and Thiel baseline scenario. For ease of comparison, the trenches were assumed to be simply the “inverse” of the stability berms discussed previously (11 trenches, each with depth = 0.5 m, base width = 3 m, and spacing = 5 m). XSTABL calculations found that the FS against sliding was 1.45, almost identical to the stability berm case at FS = 1.47. The complex variables for stability trenches should be similar to stability berms with the exception that berms provide more stability in the case where the overlying containment fill strengths become low.

3.5 Stability Benches

Another stability improvement method for ore heaps and earthwork structures in steep terrain involves the use of interior “stair-step” stability benches, or terraces. To evaluate this method, the Breitenbach and Thiel baseline example was modified to include a 3H:1V backwall slope as shown in Figure 6. In this scenario, a base width of 40 m (130 feet) was used, leading up to a 15 m (50 feet) high 3H:1V graded slope, a 5 m (16.5 foot) wide bench, then another 3H:1V slope and bench, repeated until the top is reached. This is a common configuration encountered at sites with existing steep topography. An XSTABL analysis for this steep lined backwall scenario resulted in a very low calculated FS = 0.78 for an assumed 7 degree liner interface friction angle.

To improve the slope stability factor of safety, a series of stability benches was added to the lower portion of the backwall slope (the critical wedge failure area) as shown in Figure 7. Each bench was 5 m (16.4 feet) high and 5 m (16.4 feet) wide, with a 2H:1V slope. Using the geometry, the three benches create an overall 3H:1V slope. A photograph from a past project site where a similar configuration was used is shown in Figure 8. An XSTABL analysis of the scenario shown in Figure 7 resulted in a calculated FS = 1.32, a significant improvement, once again due to the creation of a non-planar feature along a critical planar failure surface.

3.6 Stabilization Combinations

A different approach to improving the slope stability factor of safety is shown in Figure 9. First, the 40-m base initially presented in Figure 6 was extended an additional 45 m (150 feet), resulting in a larger base area able to accommodate several stability berms. A total of eight berms were then added at the back of the wedge, resulting in an improved FS = 1.38. And finally, a series of three 5-m tall, 5-m wide, 2H:1V stability benches was added to the lower portion of the backwall slope. Together, the combination of increased base width, backwall slope benches, and stability berms was able to almost triple the factor of safety (from an undesirable FS = 0.78 to an acceptable FS = 2.01 for low risk fill structures that remain fully drained).

Figure 9. Critical Failure Surfaces associated with increased base width and addition of stability berms along liner starting from the back of wedge

4. CONCLUSIONS

Geosynthetic composite liner systems, consisting of GCLs underlying geomembrane liners, are seeing increased use in large lined fill structures such as heap leach pads, tailings storage impoundments, and landfills, largely due to improved construction time and operational liquid containment. However, there is a concern by engineers and regulatory agencies over the stability of such composite liner systems, due to the low shear strength of hydrated bentonite. Although Koerner (2012) and Fox and Ross (2011) report that there are no known cases of internal shear failure of needle-punched GCLs in the field, laboratory testing has shown that GCLs can experience internal failure at very high normal stresses, corresponding to low residual shear strength. Another consideration that could decrease liner interface strength involves the extrusion of hydrated bentonite through the woven geotextile component of the GCL (Vukelic et al, 2008).

This paper presents a series of stability calculations for a hypothetical ore heap study section containing a pad composite liner with a very low strength (friction angle = 7 degrees) bentonite clay to geomembrane liner interface. After preliminary calculations on the baseline condition (i.e., no non-planar slope stability improvement measures), a series of calculations were performed to evaluate the benefit of adding non-planar structures to the study section, including the use of stability berms, trenches, and benches. The benefit of each individual method alone was evaluated, as well as the combined benefit of multiple methods. For one example study section, employing a combination of methods (increased flat slope base width, backwall slope benches, and stability berms) was able to almost triple the factor of safety (from an undesirable FS = 0.78 to a very favorable FS = 2.01).

These findings have important design implications for lined fill structures with low planar interface strengths. The incorporation of non-planar structures in geosynthetic-lined slopes can improve overall stability and maintain an adequate factor of safety, even in worst-case loss of GCL internal strength due to either rupture, pullout, or degradation of the needle-punched reinforcing fibers, or reduction in geomembrane/GCL interface strength due to extrusion of hydrated bentonite through the woven geotextile component of the GCL. The non-planar liner designs can turn the liner engineer's worst nightmares into his best dreams for liquid containment and stability.

Influence of Textile Structure in Relationship to Filtrate Quality in Dewatering Applications Using Geotextile Containers

Christopher Timpson, TenCate Water & Environment, USA

ABSTRACT

Geotextile containers offer a cost effective alternative to mechanical dewatering processes. Geotextile containers are constructed of a specially engineered textile which allows a high flow rate of effluent while restricting solid particles from passing through the textile. This technology reduces disposal costs by consolidating higher solids with very little maintenance when compared to mechanical dewatering processes. Chemical conditioners and polymers are used to promote flocculation and improve solids retention.

The dewatering performance is influenced by the type of sludge, pumping rate, chemical conditioning, and filtration properties of the specially engineered textile. All of these factors determine the quality of filtrate which filters through the engineered textile. The common assumption is that the filter cake building up inside of the geotextile container determines the filtrate quality, however this paper summarizes a study of how the textile structure can influence filtrate quality.

The GDT (Geotextile Dewatering Test) is a very efficient and effective test method for predicting dewatering performance and results. This test is conducted in an enclosed system which best simulates an actual geotextile container versus other bench test methods. The current GDT test method can be modified by applying a specific amount of discharge pressure during filling to better simulate actual project conditions. This improvement in the GDT test is known as the P-GDT (Pressurized Gravity Dewatering Test). With the P-GDT test set-up, several types of textile constructions can be evaluated for dewatering performance in a controlled environment using the same sludge, polymer dosage, and pressure.

This paper will address the development of a dewatering testing protocol, dewatering experiment, fabric weave construction analysis, and resultant filtrate quality in relation to textile structure of various weave constructions. The dewatering experiment was performed with contaminated river sediments and water treatment sludge.

1. INTRODUCTION

Geotextile containers have been used since the 1960's as shoreline protection in marine and river structures such as breakwaters, dikes, artificial islands, and jetties. Over the years, this technology has transferred into the dewatering of wastewater with the aid of chemical conditioning. Geotextile containers for dewatering applications have proven both reliable and efficient. There are three basic stages to dewatering with geotextile containers which are confinement, dewatering, and consolidation (See Figure 1). The specially engineered textile which the geotextile containers are fabricated allows confinement of the fine solids inside the container but allows water to filter for dewatering. As the water drains, the solids continue to densify inside the geotextile container and the volume inside the container continues to consolidate over time.

Figure 1. Three basic stages of geotextile container dewatering.

As their use becomes more prevalent, the overall knowledge of the technology advances along with the methods of testing to predict their suitability and efficiency for specific applications. Over the years there has been some evolution in the bench testing of sludge. The GDT is a very efficient and effective test method for predicting dewatering performance and results. This test is conducted in an enclosed system which best simulates an actual geotextile container versus other bench test methods like the cone test and hanging bag test.

With GDT testing, a large amount of sludge can be evaluated versus the smaller quantity used in cone test. Typically 20 to 40 gallons of sludge can be used in GDT testing. The hanging bag test can be conducted using a larger quantity of sludge, but the action of pouring the conditioned sludge in the hanging bag assembly may break down the floc formation of the suspended solids as shown in Figure 2.

Figure 2. Hanging Bag Testing

The current GDT test method can be modified to apply a specific amount of discharge pressure during filling to better simulate actual project conditions. This improvement in the GDT test is known as the P-GDT (Pressurized Geotextile Dewatering Test). The concept for this testing was developed by Jim Meagher of Mineral Processing Services, LLC. In this controlled environment the sludge, polymer dosing, and pressure during filling can all remain constant to allow for evaluation of dewatering performance. A three-phase filling cycle is conducted to simulate the filling, dewatering, and re-filling as seen in real world pumping of geotextile containers.

2. TEXTILE WEAVE CONSTRUCTIONS

The broken twill weave is the dominate textile construction used in the fabrication of geotextile dewatering containers, see Figure 3. A twill weave is produced by passing the weft yarns over or under two or more warp yarns which produces diagonal type pattern and appearance. This weave provides for the optimum performance to allow open area within the construction for free water to flow through the textile and interlacings to provide a filter media to restrict solid particles from passing.

Figure 3. Typical Broken Twill

Although the broken twill weave construction is a major factor in determining the dewatering characteristics of the textile, the yarn constructions which build the weave influence the dewatering performance. Several variations of the broken twill weave construction were evaluated in this experiment, see Table 1. A double layer construction will be evaluated to understand any differences in filtration properties compared to a broken twill construction.

A tape yarn typically has a flat and wide cross-section. A fibrillated tape is a tape yarn which has been serrated, the slits in the cross-section allow the yarn to be flexible to fold and twist. A monofilament yarn typically has a rounded, cylindrical cross-section.

Table 1. Textile Weave Constructions Evaluated

Weft Yarn	Warp Yarn	Weave Construction
Fibrillated Tape	Monofilament	2x2 Broken Twill
Tape	Tape	2x2 Broken Twill
Fibrillated Tape	Fibrillated Tape	3x3 Broken Twill
Fibrillated Tape/Continuous Filament	Monofilament	Double Layer

The combination of these various yarn types in a broken twill weave construction can influence the permeability, percent open area of a textile, and porosity. The water flow results in Table 2 show the potential flow characteristics of each construction without any regard for potential filtration properties. Water flow was tested according to ASTM D4491. The P-GDT test will be used to evaluate the filtration characteristics of each weave operating under similar conditions with the same sludge, polymer dosing, and filling pressure.

Table 2. Water Flow Results of Weave Constructions

3. TEST PREPARATION

This testing protocol was developed to provide best practices for fabrication of GDT bags, seam preparation, polymer conditioning, set-up of P-GDT test equipment, and sampling. This procedure was established based on the experiments conducted during this study with contaminated river sediments and water treatment sludge (alum).

All fabrics must be cut from a standard template to produce a 21-inch x 21-inch GDT bag. A 2-inch PVC flange port must be installed for filling. The sewn edges of the GDT must be sealed with a clear PVC cement to prevent leakage. Leakage at the seams during P-GDT testing will permit solid particles to pass through the seam which can influence test results.

Figure 4. GDT Test Bag Preparation

Bench scale testing must be conducted prior to P-GDT testing to determine the appropriate polymer and dosage required for the slurry or sludge to be tested. Before proceeding with P-GDT testing, conduct floc tests to guarantee equivalent polymer performance with the slurry or sludge which will be tested.

The amount of unconditioned slurry or sludge required is dependent on the number of products which will be tested. It is recommended to acquire a large quantity of unconditioned material in a sizeable tote. The tote must be continuously agitated to keep all particles in suspension and prevent settling at the bottom of the tote. This will provide consistency of unconditioned slurry across all GDT products tested.

Each GDT test requires a 30-gallon sample of unconditioned material. The unconditioned material will be chemically conditioned with polymer in individual batches of the same dosage and mixing rpm. Figure 5 illustrates the set-up of the P-GDT testing equipment. The discharge pressure required to fill the GDT bag is dependent on the circumference of a full size tube. The discharge pressure is calculated based on the dimension of the full size geotextile container which is simulated.

Figure 5. P-GDT Test Machine Set-up

To simulate the repetitive filling, dewatering, and consolidation phases, this testing using a three phase filling cycle for each GDT Test. This allows the GDT bags to simulate the filling and dewatering of full scale geotextile dewatering containers.

First Phase Fill

1. Weight empty GDT to determine initial weight.
2. Obtain sample of unconditioned slurry from 40-gallon container.
3. Add appropriate amount of polymer and mixing energy required for flocculation.
4. Fill GDT until discharge pressure is obtained.
5. Maintain discharge pressure for 60 secs, then stop pumping.
6. Allow GDT to drain for 20 mins. Collect filtrate sample underneath drainage tray while draining.
7. Record gallons of slurry pumped and volume of filtrate collected.

Second Phase Fill

1. Fill GDT until discharge pressure is obtained.
2. Maintain discharge pressure for 60 secs, then stop pumping.
3. Allow GDT to drain for 20 mins. Collect filtrate sample underneath drainage tray while draining.
4. Record gallons of slurry pumped and volume of filtrate collected.

Third Phase Fill

1. Fill GDT until discharge pressure is obtained.
2. Maintain discharge pressure for 60 secs, then stop pumping.
3. Allow GDT to drain for 20 mins. Collect filtrate sample underneath drainage tray while draining.
4. Record gallons of slurry pumped and volume of filtrate collected.
5. Weigh GDT to determine final weight.
6. Clean off test equipment prior to next sample.

For each GDT test, a sample of unconditioned slurry, first phase filtrate, second phase filtrate, and third phase filtrate must be collected. The dewatering performance of each textile construction will be evaluated on filtrate quality based on turbidity and total suspended solids (TSS). The turbidity is an indication of how clear and transparent the filtrate passing through the textile appears. The total suspended solids include all particles suspended in water and the greater the total suspended solids, the murkier the filtrate will appear. The percent dry solids of unconditioned slurry, turbidity, and TSS of filtrate for each phase will be measured. The percent dry weight solids must be calculated at 1-day, 3-day, and 7-day intervals.

In this study the filtrate samples, percent dry weight solids of unconditioned slurry, and percent dry weight solids of dewatered cake sample inside the GDT were measured according to U.S. EPA Methods 160.2 and 160.3. Turbidity was measured with a portable meter and TSS was measured with a HACH DR 2800.

4. WASTEWATER COMPOSITION

Two P-GDT tests were conducted to understand the dewatering performance of various textile constructions. The first test was conducted on-site at an active dewatering project and evaluated the dewatering performance of contaminated river sediments. A tote was filled with 250 gallons of unconditioned slurry and diluted to approximately 3% solids. A two-part chemistry was used for chemical conditioning. The P-GDT testing was performed with a discharge pressure of 3.5 psi. This testing was conducted outdoors at the project site.

The second test was conducted in a laboratory and evaluated the dewatering performance of water treatment sludge (alum). A tote was filled with 250 gallons of unconditioned water treatment sludge and continuously mixed. A cationic polymer was used for chemical conditioning. For the second test, the discharge pressure was reduced to 3.0 psi

5. CONCLUSIONS

The dewatering performance of fabrics is determined by of the rate of dewatering, filtration under stress, and filtrate quality. The rate of dewatering is the fabric's ability to allow flow through the fabric and this flow rate is most critical when the fabric is stressed. As the fabric is stressed, the pores of the fabric are closed off and pressure will build up inside of a geotextile container. As the pressure increases inside the tube and flow is restricted, the potential for rupture

is magnified. The dewatering performance was based on the clarity and quality of the filtrate exiting the textile structure. Tables 3 is an illustration of the filtrate quality of the P-GDT testing of sediments. Table 4 is an illustration of the filtrate quality of the P-GDT testing of alum sludge. In both tables, the data shows better performance in filtrate quality with monofilament and fibrillated tape constructions. The high clarity of the filtrate was visible versus the other weave constructions.

Table 3. P-GDT Results of Sediments

Table 4. P-GDT Results of Alum

Weave constructions using only tape yarns have a lower rate of dewatering which leads to a shorter time to blind off since the weave construction closes up under stress. Weaves which are only composed of fibrillated yarns allow for a high rate of dewatering but produce poor filtrate quality given that the more open structure allows for too many solid particles to flow through the fabric.

A double layer construction acts a good filter media but restricts the rate of dewatering. Although this construction has a lower rate of dewatering, it has a high rate of filtration under stress unlike the tape/tape and fibrillated yarn constructions. As the construction closes up while under stress, the double layer construction allows for depth filtration and yields a high retention of solid particles.

In these experiments, the monofilament and fibrillated tape construction produced the optimum dewatering performance. The monofilament warp yarn and fibrillated tape fill yarn create a structure which maintains a consistent rate of dewatering when the fabric is stressed and has a high retention of solid particles.

The three-phase filling cycle of the P-GDT demonstrates there are two distinct dewatering stages. The initial fill has the highest percentage of solid particles passing through the fabric which indicates initial filtration is based on the fabric construction. After a short time, a filter cake builds up and both the fabric and filter cake determine the dewatering performance. In the later filling stages, the filter cake is mostly responsible for dewatering and the rate of dewatering is greatly affected by the tendency of the fabric to blind off.

The turbidity and TSS data demonstrate this phenomenon as the filtrate quality consistently improves with subsequent filling stages with all weave constructions tested. This experiment shows that the monofilament and fibrillated tape construction produces a better quality filtrate versus other variations of the broken twill constructions. The ability of the textile construction to allow filtrate to flow yet retain solid particles will produce the optimum construction for dewatering.

Influence of the Protection Used for Installation Damage in Long Term Durability of Soil Reinforcement Elements

R. Lozano. Senior Geotechnical Engineer – Corporate Geosynthetics Specialist. The Reinforced Earth Company. USA

J. Sankey. Vice President of Engineering. The Reinforced Earth Company. USA

L. Naït-Ali. Materials Engineer Terre Armée Internationale. France

ABSTRACT:

Currently in Mechanically Stabilized Earth (MSE) technologies, there are two main families of reinforcing elements; metallic and polymeric. Depending on the material, the protection of such elements against the potential for damage during installation is critical to the long term performance of the structure. Reduction of available strength during the process of installation is well known to be one of the factors that affect soil reinforcement elements. Depending on the type of reinforcement selected, this factor could account for a large reduction of the available strength for MSE design. Inadequate means for protection against installation damage will have synergistic effects on the durability and long term performance of the reinforcement; these effects being hard to predict but in some cases could potentially accelerate degradation rates causing early failures. This paper explores 40 years of evidence for in service performance of reinforcement materials used in MSE structures and provides a corresponding guide for designers for the correct material selection and specification of reinforcing elements material selection and specification of reinforcement elements.

1. INTRODUCTION

The proper selection of a specific type of reinforcing element by owners and/or design engineers to is critical to the performance and stability of Mechanically Stabilized Earth (MSE) structures during the assigned design life. The current state of the practice for MSE structures is limited to two types of reinforcing materials; metallic and polymeric. Each of these reinforcing materials possess unique performance and behaviors in both short and long term. Indeed metallic and polymeric reinforcement are typically separated in terms of inextensible and extensible design methodologies (AASHTO LRFD 2010)

Common to both types of reinforcement are some level of protection, either active or passive, to mitigate and/or reduce the initial damage and stress caused by installation. The effectiveness of the protection is highly dependable on the type of material selected and the effective interaction of these barriers with the reinforcing element substrate.

Installation damage only affects the strength of the material immediate to the installation and will act synergistically to reduce or facilitate other ageing factors to further reduce the strength of the material during the service of the reinforcement. While installation damage does not depend directly on the material used as reinforcing element, the resistance to withstand and survive the installation depends directly on the protection provided to the reinforcement and the installation practices observed.

2. MECHANICS OF INSTALLATION DAMAGE.

MSE structures consist of reinforcement elements placed in intimate contact with compacted soil; in all cases the reinforcement will be subjected to the process of installation and construction induced stresses until the structure reaches completion. The basic construction consists of placing the reinforcement in to position followed by installing fill in compacted, discrete layers. The fill is normally spread by mechanized equipment, which requires vehicular traffic to pass over the working area underlain by reinforcement in areas of active installation. The construction process may physically damage the reinforcement by way of the physical characteristics of the fill, the construction practices employed and/or equipment used. These processes are used to form the basis to quantify the damage inflicted on the reinforcement.

Figure 1 Reinforcing elements on a MSE structure

Aggressive means of install backfill directly related to the type of materials used in the MSE structure. The fill itself will be controlled by the physical properties of gradation, coefficient of uniformity, origin of the material and relative hardness, which serve as potential sources of damage inflicted upon the reinforcement members. It is well accepted that crushed, angular hard gravel from blasting quarries is more aggressive than rounded natural sand or silty sand materials, since coarse and hard aggregates rapidly transmit the mechanical efforts of compaction directly to the reinforcement causing damage.

The installation processes effectively reduce the strength of polymeric reinforcement by abrasion when the spreading of the backfill is moved against the reinforcement. Abrasion is highly dependent on the type of backfill, construction practices used to spread the aggregate and type of reinforcement were elements with wide exposed area and stiffer in nature are prone to higher damage.

Dynamic impact damage is caused by the compaction process when backfill particles are push against the reinforcement members; which are in turn placed over firm compacted substrates that score, cut or mar the available cross section and reduces the carrying loads in the reinforcement. Dynamic impact is more pronounced in coarse materials such as gravel and crushed aggregates, and attacks all the reinforcements (metallic and polymeric) in similar fashion.

Bending of the reinforcement is caused by unevenness of the substrate or incorrect compaction under the substrate receiving the reinforcing element, and if pronounced, can produce additional localized damage when the reinforcement moves and deforms to accept a forced contour. This type of damage is characteristic of soft soils, poorly compacted backfills but is more evident in connection points with blocks and other types of fascia.

The equipment selection ultimately provides the source of energy to produce the damage. While sheepsfoot rollers are considered one of the most damaging and aggressive type of equipment it is typically used in construction practice with finer grain silty sands which causes less damage potential (the use of sheepsfoot rollers are unusual in metallic MSE construction but less uncommon in polymeric MSE) practices .and soils that are low in injurious effects. Heavy smooth vibratory rolls are the most common equipment used with coarse materials; the transferred of energy from the equipment through the soil is almost direct and has a potentially harmful effect on the reinforcement unless construction practices are correctly selected to reduce damage. Hand held light weight equipment in almost all cases does not have deleterious effects on any type of reinforcement due to the low impact/energy applied.

2.1 Polymeric Reinforcements and Installation Damage.

All polymeric reinforcements are susceptible to lose a percentage of the ultimate tensile strength by the construction stresses imposed on the material. Installation damage as a reduction factor is the only immediate term that affects the nominal long term reinforcement design strength, since damages caused by installation reduce the effective available strength of the material when the material is installed.

$$T_{al} = \frac{T_{ult}}{RF_{ID} * RF_{CR} * RF_D} \quad [1]$$

Where

T_{al} = Nominal Long Term Reinforcement Design Strength
 T_{ult} = Minimum Average Roll Value of Ultimate Tensile Strength
 RF_{ID} = Reduction Factor for Installation Damage
 RF_{CR} = Reduction Factor for Creep
 RF_D = Reduction Factor for Durability

Equation 1 Nominal Long Term Reinforcement Design Strength equation (AASHTO LFRD 2010)

The assessment of this reduction was considered critical since early developments in polymeric reinforcement. A controlled trial for evaluation was proposed by Watts and Brady (1990) as methodology for assessing the installation damage to reinforcement under field conditions. This method was rapidly accepted as the best practice to obtain the reduction factor for installation damage to be used in design of MSE structures with polymeric reinforcement. Currently this method of exposing polymeric reinforcement is complemented with the ASTM D5818, "Standard Practice for Exposure and Retrieval of Samples to Evaluate Installation Damage of Geosynthetics" and the guidelines presented in FHWA-NHI-10-024/025, FHWA-NHI-090-87 and the protocols used in the National Transportation Product Evaluation Program (NTPEP) for polymeric reinforcement evaluation. The installation damage reduction RF_{ID} factor then is determined as the ratio of the initial Ultimate Tensile Strength (T_{ult}) of the reinforcement, to the Retained Tensile Strength ($T_{Exposed}$) after damage:

$$RF_{ID} = \frac{T_{ult}}{T_{Exposed}} \quad [2]$$

Equation 2 Ratio for obtaining the Reduction factor for installation damage

In AASHTO LFRD 2010, 11.10.6.4.2b-1 established the minimum criteria for acceptance of polymeric reinforcement for use in assigned default reduction factor for installation damage is required to have a mass per unit area of 270 grams per square meter. However, Section 11.10.6.4.3b also assigns a minimum value of this reduction factor as 1.10, even with site specific test available. The use of both of these values is highly conservative and does not reflect the current state of manufacturing geosynthetics using highly durable materials with high survivability against installation damage. It is noted in NTPEP reports that several manufacturers have products evaluation results reporting installation damage factors well below 1.10.

The ISO Installation damage approach is radically different. The objective of the test is to use a bench scale test focused on quality control to provide an index of the production. ISO 10722 has proven difficult to perform due to the lack of availability of the designated aggregate and low test reliability due to the of the high cyclic load use. This test is so aggressive that results obtained using ISO 10722 have reported losses over 90% of the ultimate tensile strength while the same material using full size installation damage trials with aggressive compaction, angular coarse aggregate have reported losses of 30 to 40 percent.

2.1.1 Extrusion Coated Polymeric Bars and Strips

The technology of extrusion coating of filaments and yarns with an extruded sheath was developed in the UK during the late 1960s. The process pulls yarns made from filaments through an extrusion die while a polymer with a lower melting point is extruded completely encapsulating the yarn. This process provides an integral barrier that, depending on the rate of extrusion of the selected polymer for the sheath and the resulting thickness, provides variable resistance to installation damage. This material was initially used as a reinforcement element in mid 70s showing exceptional survivability to installation at that time due to the particularly thick sheathing. Currently manufactured polymeric strips benefit from the use of compatible polymers and the latest technology on extrusion and resin developments, with reported values in

NTPEP and other publications showing the polymeric strips rarely exceed reduction factors higher than 1.10, even in conditions where coarse, angular and aggressive compaction is used.

2.1.2 Punch Drawn Grids

As reported by NTPEP, punch drawn geogrids in mid to mildly aggressive soils such as sandy gravel and sandy silt the installation damage values of this type of grids ranges from 1.12 to 1.02. While these value have been well documented in other sources and published papers, installation damage factors in coarser more aggressive fills were reported as high as 1.25 (Certificate No. RF 2/07 CEED Hong Kong 2007) for coarse gravels in aggressive conditions.

While loosely related to punch drawn grids, geogrids manufactured from extruded profiles that are then welded have being proved as excellent survivors for installation damage. As reported in some independent sources the reduction factors to this grids ranging from 1.15 to as low as 1.05.

2.1.3 Woven or Knitted Coated Grids

Most of the textile grids reviewed in this paper were polyester either woven PVC coated or knitted grids with PVC or acrylic polymeric coating. Early textile grids had low survivability on installation damage. Historically reported during the late 80's and later starting in the 90s by the Geosynthetics specifier's guide (formerly known as Geosynthetics Fabrics Report GFR) early PVC coated grids manufactured were prone to suffer higher damage than their modern versions. Reduction factors have consistently dropped from the upper 1.50 to mid 1.20 ranges on average. Current advancements in weaving and coating technology allows manufacturers to greatly improved the survivability of textile grids with reduction factors in the range between 1.30 to 1.05, depending on specifics such as strength of the grid and type of soil used during the installation damage trials. In the case of geogrids, the coating is an essential element for the stability of the material during handling. A great deal has being learned in the last years with regards to the effectiveness of PVC coatings being linked directly to viscosity, percentage of solids and dueling time for drying. Viscosity of the coating in liquid form is critical since it has a direct impact on the penetration of the fibers in the yarn bundles and interstitial spaces, effectively linking all the structure protecting the filaments from probable damaged caused by fine abrasive particulate and direct abrasion and impact during compaction. One of the largest consequences of the use of PVC in textile grids is the direct impact on the mass per unit area of the finished product versus the greige textile, the increase of mass per unit area ranges from 1/3 to 1/2 of the total mass per unit area of the finish geogrid, this also provide an indication how much the coating influence the survivability of the finished grid during installation damage.

The latest innovation in protection against installation damage of grids is the use of new polymeric coating that show great improvement in the protection of the yarns, some relative new materials use acrylic heat set polymers with high penetration and high abrasion resistance. The introduction of this new coating during the mid 2000s showed a great reduction of installation damage particularly in grids with less than 270 grams per square meter, where the coating accounted for less than 1/3 of the total weight.

2.1.4 Woven and Knitted Geotextiles

Geotextiles either from polyester or polypropylene have proven to be susceptible to damage during installation and only rely on mass of yarns to protect the fabrics. Other than modifying some of the traditionally patterns used for weaving the yarns non coated textiles, reduction factors are currently in the range of 1.5 and higher, with some examples of light weight woven polypropylene and some of the weft insertion polyester fabrics reporting factors in excess of 1.8.

2.2 Metallic Reinforcements and Installation Damage.

Metallic (typically carbon steel) reinforcements do not typically have deleterious effects due to installation damage. Metallic strips, bars and grids have a higher relative strength and hardness than the backfill used, hence the possibility of damage immediately reducing the strength of the members is relatively nonexistent. However while the effect of installation damage on metallic reinforcement is not directly related to losses of strength in the member, the effects of installation may still influence the durability depending on what is used to protect the metallic reinforcement against long term metal losses. The main objective of galvanic protection of metallic reinforcement is to increase the durability of the element by modifying the metal losses rates but this is ultimately dictated by the electrochemical environment present in the surrounding soils.

Hot dip galvanization is the common practice used as protection of metallic elements and has proved effective in extending the duration of the life of steel in soil reinforcement applications. It is important to note that the term galvanization term is sometimes incorrectly used to describe steel layered with zinc-rich paint, electro plated or mechanically applied zinc since all of these methods of applying zinc to steel for corrosion protection are different from

hot dip galvanizing and are inappropriate for reinforcement soil applications. Hot dip galvanization changes the external layers of the steel making an alloy with different electrolytic behavior of the base steel or the zinc alone.

The galvanic metallurgical process is more than a simple barrier to prevent metal losses; the barrier created by this process provides a layer integrally bonded to the surface of the steel element that is fully impermeable and uniform with variable hardness depending on the exact position on the thickness of the galvanic layer. The first 3 layers (Gamma, Delta and Zeta) are harder than steel providing excellent resistance to abrasion and hardness against impact. The last Eta layer is ductile providing one more layer of impact resistance by some dissipation of the impact.

Figure 2 Representation of the alloy layers in hot dip galvanized carbon steel

Additionally, the intrinsic electrolytic behavior that zinc provides is extra protection in case of damage to the alloy protection. The dielectric exchanging electric current between the zinc rich outside layer to the bare steel will make zinc migrate to areas with less rich zinc, effectively protecting any exposed area. This self-healing ion exchange process takes place in the reinforcing member as long as the zinc is present.

Another alloy available for protection of metallic reinforcement elements is Galfan[®] (registered trade name by the International Lead Zinc Research Organization) Galfan is an alloy consisting of 95% zinc and 5% aluminum, ductile in nature and applied to steel using a hot dip bath. Galfan was originally engineered as protective coating against corrosion on cars and industrial equipment but its use has migrated as alternative for protection of soil reinforcement metallic elements. Any advantages of using the proprietary alloy versus pure zinc have not been demonstrated, particularly because the conditions of metallic reinforcement elements in prolonged soil burial are completely different than what Galfan was initially intended.

Other attempts of using paint, epoxy coatings or sheathing have been documented in the literature. While paint and fusion epoxy coatings are intended as barrier for corrosion, those offer no significant resistance against installation damage, negating any benefit gained as barriers. Polyolefin sheathing and PVC focus is commonly used as justification for thinner or no galvanic protection in wires with claims that this treatment will increase the durability and life span of the materials when used as soil reinforcement elements, these claims still are unsubstantiated with testing.

According to Berg et al (2009) in order for polymeric coating and sheathing to be effective, the coatings must be impermeable to gasses, moisture and free of microscopically thin gaps, but it is also critical to have a compatible hard bond to the base metal. Since current techniques in polymeric treatments use a softer-than-metal treatment, and there is no affinity with the metallic base intended to be protected, the sheathing has a higher probability to be breached by impact or abrasion. The lack of intimate contact between the sheathing and the metallic substrate also leaves a microscopic gap that will allow capillary flow of water creating an ideal environment to promote corrosion. In both cases the mechanism relative to the resistance of metallic reinforcement against installation damage changes. The potentially deleterious effect of the coating should be taken into consideration by site specific, long term testing under the same conditions of installation. Unless the use of metallic elements protected with co-extruded polymers is limited to non-aggressive installation practices with non-aggressive soils, the sheathing will have a high probability of being breached and negate any benefit of increasing durability on the reinforcing elements.

New developments in fusion epoxy bond coatings may have a promising future, particularly when combined with galvanization. Since new epoxy bond coatings are applied in controlled environments, outstanding adhesion to the metal substrate is achieved, compounding the survivability of the reinforcing elements against installation damage opening the possibility to achieve higher durability for the associated MSE structure. The composite use of hot dip galvanization with new fusion epoxy bonding is promising but long term testing is still unavailable.

3. SELECTION GUIDE OF REINFORCEMENT BY INSTALLATION DAMAGE RESISTANCE

While the selection of the specific type of reinforcement not only depends on the condition of installation but on the overall structure use, type of materials available, performance needed and design life; the intention of this paper is to present a general guide for designers of how have an informed decision on the effects of installation damage on the selected reinforcement. Table 1 provides a general guide for criteria on the selection of reinforcement members based on their performance in installation damage.

Table 1. Characteristics of reinforcement elements currently in use.

Type of reinforcement	Protection used	Effect	Recommendation
Metallic bars and wires	Galvanization ⁽¹⁾	No effect	Use with all soil gradations and compaction equipment
	Galfan	Unknown	Use with site specific testing. May affect durability. Test needs to be provided.
	Paint	No recommended	Not able to survive installation. Does not provide any survivability protection to base material. Deleterious effect on durability of the reinforcement
	Epoxy coating and polymeric sheathing	Deleterious	Only recommended with non-aggressive backfills and non-aggressive compaction equipment.
Polymeric bars and strips	Co-extrusion	Minimal	Use with all soil gradations and compaction equipment. Apply correct reduction factors depending on site conditions and gradation specific installation damage trials.
Punch drawn grids	Integral	Minimal to moderate	Use with all soil gradations and compaction equipment. Apply correct reduction factors depending on site conditions and gradation specific installation damage trials. Coarse gradation may be problematic
Woven textile coated grids	PVC or heat set acrylic	Minimal to moderate	Use with all soil gradations and compaction equipment. Apply correct reduction factors depending on site conditions and gradation specific installation damage trials. Coarse gradation may be too aggressive
Woven and knitted geotextiles	None	Moderate to Aggressive	Use with non-aggressive soil gradations and compaction equipment. Apply correct reduction factors depending on site conditions and gradation specific installation damage trials. Coarse gradation may be too aggressive to withstand installation

NOTES:

(1) Hot dip galvanization is not provided as protection for installation damage but for protection against metal losses

4. CONCLUSIONS

Polymeric reinforcement is susceptible to damage during installation. Correct assessment and application of the reduction factor for installation damage based on actual full scale tests and applied in the design is critical for the performance of the structure.

During the last 20 years the evolution of polymeric reinforcement manufacturing have reduce the sensitivity of the reinforcement to be damaged during installation, however current US codes of practices still uses conservative default values not updated to reflect this changes.

Installation damage depends greatly on the type of reinforcing element selected. While metallic reinforcements are generally immune to installation damage some process such painting and polymeric coatings are deleterious to the long term performance.

There is direct correlation between the compatibility of materials used for protection of metallic reinforcement and the substrate, incorrect selection of the protection on metallic reinforcement instead of increasing the long term durability of the metallic member by accelerating the rates of degradation.

Regardless of the type of reinforcement used in MSE structures, the use of reputable manufacturers with serious commitment to quality assurance, supporting reports from actual testing of materials intended to be provided are necessity for owners and designers.

ABSTRACT

A field investigation was undertaken to determine deformations and associated strains in bottom liners in municipal solid waste landfills. Data were obtained at landfills in New Mexico and Alaska. Geomembranes were instrumented with linear sensor arrays extending from the perimeter to the center of a cell with multiple monitoring points. Displacement measurements were taken using linear potentiometers installed at the perimeter of the cell. Temperatures were monitored along the strain measurement setups both below and above the liner systems. Data have been collected for 7 and 4 years for Alaska and New Mexico, respectively. Maximum tensile strains (approximately 2.6% and 0.4 for Alaska and New Mexico, respectively) were measured near the toe of the slopes at both sites. Compressive strains up to 1.3% were present along the slope and on the floor of the cells. Liner displacements reached stable levels relatively soon after overlying waste placement.

1. INTRODUCTION

Geomembranes are used extensively in waste containment facilities for providing barrier function to isolate wastes from the surrounding environment. While geomembranes have been demonstrated to be effective in reducing leakage and emissions from landfills, concerns remain related to the long-term performance of these materials (NRC 2007).

Stress-strain characteristics of geomembranes have been established in the laboratory, however data commonly are not available for field investigations for mechanical performance. Measurement of localized strain in geomembranes is complicated due to difficulties of attaching sensors to the polymeric materials, as adhesives typically are not available for bonding sensors to geomembranes particularly for polyolefin materials. In the case of thermal bonding, the properties of the geomembranes are potentially altered by the heat applied to the material. Similarly, adhesive and mechanical attachments also can affect the properties of the membrane. In addition, access to sensors and ability to conduct measurements is complicated by normal landfill operations and by presence of overlying wastes.

Numerical analyses have been reported to predict stress/strain characteristics or displacements of geomembranes used in bottom liners of landfill systems. The numerical analyses indicated:

- In a veneer analysis of cover soils, a buttressing effect at the toe of the slope was quantified and the response of the geomembrane liner to heavy equipment loads was determined to be a function of the travel characteristics of the heavy equipment (e.g., upslope or downslope backfilling) (Koerner and Soong 1998).
- Load-displacement analysis demonstrated that maximum geomembrane tension increases as the slope angle increases (Kodikara 2000).
- Local stability of liner systems due to waste settlement (and associated downdrag on the liner system) was documented as a valid concern (Jones and Dixon 2005), even though such analyses are not often employed in engineering practice (NRC 2007).
- Finite element analysis of liner systems conducted by Reddy et al. (1996) indicated that: displacements of smooth geomembranes were significantly greater than textured geomembranes, displacements increased with increasing waste placement height, minimum displacements occurred near the toe of the slope (i.e., connection point between base liner and side liner), displacements increased with increasing slope angle, and waste filling strategies could be used to minimize liner displacements.
- A number of the investigations demonstrated that limit equilibrium approach was not sufficient for describing displacement/strain behavior of liner system response to loading conditions (e.g., Reddy 1996, Kodikara 2000).
- Waves and wrinkles were analyzed numerically for localized effects and tensile stresses resulting from wrinkling strains are limited to approximately 5 to 8% (Soong and Koerner 1999, Gudina and Brachman 2011).

This investigation was conducted to directly determine field response of geomembranes in bottom liner systems. A novel measurement approach was developed to measure displacements and strains occurring in the geomembranes. Displacements were measured over a duration extending from initial waste placement onward for extended periods.

2. EXPERIMENTAL PROGRAM

2.1 Test Sites

The field investigation was conducted at two landfill sites, in Anchorage, Alaska and Las Cruces, New Mexico. The sites are Subtitle D municipal solid waste landfills. Basic statistics about the sites are presented in Table 1.

Table 1. Characteristics of Test Sites

Parameter	Alaska	New Mexico
Design volume (m ³)	32,360,000	11,754,000
Permitted area (m ²)	67 ha	79 ha
Waste intake rate (tonnes/year)	275,000	140,000
Slope ratio (Horizontal:Vertical)	3:1	5:1
Bottom liner components (from bottom to top)	Native subgrade (gravelly sand with clay), 150-300 mm compacted sand protection layer, GCL, 1.5-mm thick HDPE geomembrane (smooth on floor, textured on slopes), nonwoven geotextile, granular leachate collection and removal layer consisting of washed gravel, woven geotextile separator, 600-mm thick operations layer consisting of sandy gravel. On slopes, additional layers of nonwoven geotextile, geogrid, nonwoven geotextile reside between the GCL and geomembrane.	Native subgrade, 100-mm thick compacted caliche clay base, GCL (nonwoven geotextile, bentonite, woven geotextile), 1.5-mm thick HDPE geomembrane (smooth on floor, textured on slopes), 600 mm of sand.

2.2 Measurement System

Strain measurements were made using a custom fabricated system using displacement monitoring coupons attached to the HDPE geomembrane liners. The displacements were measured using linear potentiometers (i.e., stringpots), UniMeasure Model P420-50 (1250 mm range) that were connected to the coupons with extension wires. The linear potentiometers were placed at the crest of the slope, just outside the anchor trench. The displacement monitoring coupons were installed along a linear path extending over the length of the slope and out onto the floor of the landfill cell. Thermocouple arrays were installed along the same alignment to measure temperatures, both below and above the liner system. Details of the temperature array configurations were described in Hanson et al. (2010). The displacement monitoring coupons were placed at 10, 30, 50, 65, 75, and 100 m from the crest of the slope in Alaska (where the toe of the slope was 69.2 m from crest of slope) and at 5, 15, 25, 35, 45, and 55 m in New Mexico (where the toe of the slope was 38.9 m from the crest of the slope). Most coupons were placed on the slope and the two farthest coupons were placed on the floor of the landfill cells (Figure 1). Using this configuration, strains were calculated between consecutive coupons in the arrays. This method of measurement provides global geomembrane displacements and associated strains and therefore avoids the complications associated with localized measurements described above.

Figure 1. Schematic of displacement monitoring array.

A schematic of a displacement monitoring coupon is presented in Figure 2 and hardware details associated with anchorage mechanism is presented in Figure 3. Extension wires (stainless steel) were attached to the displacement monitoring coupon. The extension wire was placed inside a hard and smooth polyethylene tube that progressed up the slope from the monitoring coupon to a monitoring station, which was located at the perimeter of the cell (at the crest of the slope, directly outside the anchor trench). As the membrane slides up or down the slope due to loading of the heavy equipment or application of waste mass or alternatively due to thermal expansion/contraction, the wire responds to indicate the magnitude of the displacement of the coupon. Electrical current readings of the linear potentiometers were used to determine the distance traveled by the monitoring coupon. Corrections were applied to account for thermal expansion and contraction of the stainless steel extension wires. The coupons were installed in summer 2005 in Alaska and summer 2008 in New Mexico and have been monitored since. Some periods of limited measurements were present due to problems with the measuring equipment.

3. RESULTS AND DISCUSSION

Results of the investigation are presented as plots of displacement versus elapsed time (Figures 5 and 6). Downslope displacements (i.e., moving downhill or towards the center of the floor of the cell) are positive. Temperatures of the liner system near the perimeter of the cell and near the center of the cell (i.e., at the end of the measurement array) and waste height above the floor of the cell also are presented in Figures 5 and 6.

Figure 5. Geomembrane displacements at Alaska site.

(Only partial temperature results are presented due to sensor malfunction)

Figure 6. Geomembrane displacements at New Mexico site.

Strains were calculated for sections of geomembrane between the individual measurement coupons. The average stable strains are presented in Table 2. Variations of strains with time are presented in Figure 7 for both sites. Tensile strains are positive and compressive (i.e., wrinkling) strains are negative. Strains reached stable values after approximately 500 days in Alaska and after 200 days in New Mexico. The long-term strains in the geomembranes are presented graphically in Figure 8. Overall, the strains were greater at the Alaska site than at the New Mexico site. This was attributed to the steeper slope and greater waste height at the Alaska site. Overall, the measured displacements and strains were relatively low and do not represent levels of immediate concern for the two test sites. The long-term response of the liners (beyond approximately 1000 days at both sites) indicated onset of small and continued displacements, which may be resulting in wrinkling strains in the long term. Whereas the geomembranes are undergoing seasonal thermal fluctuations near the perimeters of the cells, a seasonal response of displacements or strains was not observed.

Table 2. Measured Long-Term Strains

Zone Number	Alaska Coupon Locations	Alaska Strain ¹	New Mexico Coupon Locations	New Mexico Strain ²
1	0-30 m	-0.16 %	0-5 m	-1.32%
2	30-45 m	-0.05%	5-15 m	+0.36%
3	45-50 m	-1.10%	15-25 m	-0.03%
4	50-65 m	-1.17%	25-35 m	-0.38%
5	65-75 m	+2.62%	35-45 m	+0.18%
6	75-100 m	-0.71%	45-55 m	+0.41%

¹tension is positive, calculated as average strain from day 500 to day 1500

²tension is positive, calculated as average strain from day 200 to day 1200

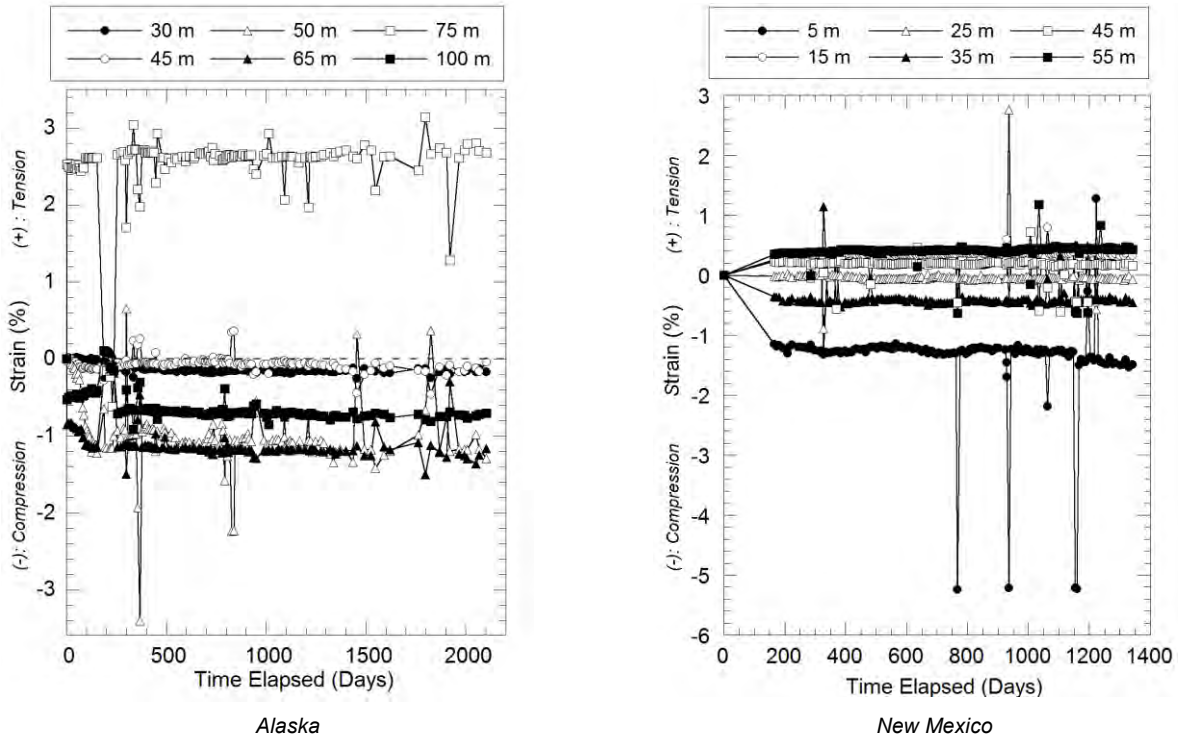

Figure 7. Geomembrane strains at the sites.

Figure 8. Graphical representation of measured strains.

The majority of the displacement monitoring coupons moved upslope. Upslope displacements were attributed to the following mechanisms: a) buttress effect of waste mass, b) thermal contraction of anchored geomembrane upon cooling relative to exposed conditions during installation of liner system and displacement monitoring coupons, c) translational movement, primarily in the machine direction, of the geomembrane in response to shrinkage strains of the underlying GCL (Hanson et al. 2012). The upslope movement of geomembranes with time and the associated compressive strains have not been widely reported through analytical or numerical investigations. Predictions of liner performance have generally indicated tensile displacements based on numerical analysis. The relatively large displacements observed in the field support the use of residual interface shear strength values for stability analyses.

4. SUMMARY AND CONCLUSIONS

Displacement monitoring systems were installed to measure response of geomembrane liners in municipal solid waste landfills in Alaska and New Mexico, USA. Displacements were monitored for extended durations from initial waste filling to several years after waste placement. Based on the investigation, the following conclusions were drawn:

- Displacements of geomembranes were observed in the field after construction, and prior to and during waste placement.
- The maximum displacements were on the order of 125 mm downslope and 300 mm upslope corresponding to strains on the order of between approximately -1.3% (compressive) to +2.6% (tensile) as calculated from sequential displacement monitoring coupons, supporting the use of residual interface shear strengths for stability analyses.
- Maximum tensile strains occurred near the toe of the slopes.
- The magnitudes of strains at the Alaska site were larger than at the New Mexico site, which was attributed to the steeper slope and greater waste height at Alaska.
- Maximum displacements occurred within 0.5 to 2 years after construction with limited further displacements occurring in the long-term.
- The long-term response of the liners (beyond approximately 1000 days at both sites) indicated onset of small and continued displacements, which may be resulting in wrinkling strains in the long term.
- Upslope displacements were common at the test sites and were attributed to buttress effect, thermal contraction, and translational movement between underlying GCLs and the geomembranes. In general, tension in geomembranes had been predicted in previous studies based on numerical analysis.

ACKNOWLEDGEMENTS

The cooperation and sponsorship of Anchorage Regional Landfill (Anchorage, Alaska) and the South Central Solid Waste Authority (Las Cruces, New Mexico) are acknowledged. Specifically, Mr. Mark Madden, Mr. Keith Howard, and Mr. Steve Cooper (Alaska), and Mr. Patrick Peck (New Mexico) facilitated the instrumentation installations and field monitoring. The Global Waste Research Institute provided additional support for the project. Mr. Raymond Ziegler and Mr. Wilson Wong assisted with the field installations. Mr. Nicolas Oettle assisted with analysis.

ABSTRACT

The Los Angeles Department of Water and Power is planning to build two side-by-side reinforced concrete reservoir structures in the southeastern San Fernando Valley of Los Angeles. An important part of the operations of the reservoirs will be a detection system below the bottom of the reservoirs to determine if there are leaks or discharges of water. It is planned to use a bituminous geomembrane (BGM) beneath the reservoirs to collect any leakage and convey the water to a monitoring location outside of the reservoirs. Because of regulatory requirements, the design earthquake ground motions are quite high and there was concern that a plane of weakness would be present at the interface with either the predominantly granular soils beneath the BGM or the Class 2 permeable material above the BGM. Direct shear testing (ASTM D5321) was performed to determine the soil friction for these two interfaces.

1. INTRODUCTION

The Headworks Reservoir project will consist of two underground reservoirs. The east reservoir will have a capacity of 54 million gallons and the west reservoir will have a capacity of 56 million gallons. The reservoirs will be about 30 feet apart, about 40 feet high and will contain about 30 feet of water. The reservoirs will be covered with a 3-foot thick soil layer on the roof. The reservoirs are planned to be supported on mat foundations. At this time, the rough grading work for the east reservoir is complete and the construction of the east reservoir foundations will commence in the near future (at the time of this writing); the west reservoir will be constructed at a later date.

The upper on-site soils beneath the east reservoir were only medium dense and were subject to liquefaction settlement on the order of a few inches. To remediate the liquefaction settlement, the on-site soils were remediated in-place by removal and recompaction to a depth of about 20 feet below the mat foundation. Although the reservoir is designed not to leak, due to its critical function, a leak detection system is planned beneath the bottom of the reservoir structure. Above the compacted fill, it is planned to place a 3-foot thick drainage layer consisting of a series of perforated pipes in a parallel pattern surrounded by permeable material. The drainage layer will be placed above the compacted fill and the below reservoir mat foundation. The pipes are intended to collect any water leaked from the reservoir structure and transmit it to individual collection systems designed for each reservoir quadrant. The purpose of the leak detection system is to also trace the location(s) of the potential leaks at least to a quadrant-level to qualitatively assess the severity of the cracking in the reservoir foundation and plan for remedial work, if needed. In the unlikely event of an excessive leakage, the leak detection system would provide early warning to take timely actions for emptying the reservoir especially after a large magnitude earthquake. As part of this leak detection system, a relatively impermeable membrane is planned immediately beneath the drainage layer. The impermeable membrane layer is needed due to high permeability of the underlying sandy soil foundation materials and to allow increased spacing of the perforated pipes.

To meet the objectives of the leak detection system, a membrane underlying the drainage material was required to have a relatively low permeability. A bituminous geomembrane (BGM) was considered because of its relatively low permeability on the order of 10^{-10} to 10^{-13} centimeters per second (Koerner 1990) and long history of success in canal, reservoir and pond lining as well as in containment of industrial and nuclear wastes. The BGM is planned to be placed beneath the entire reservoir footprint.

2. BITUMINOUS GEOMEMBRANE

Bituminous geomembrane (BGM) is an asphalt-impregnated non-woven polyester geotextile. A typical cross-section of the BGM is shown on Figure 1. A BGM manufactured by Coletanche Limited is being considered for the project. Two types of products are available, namely the NTP and ES products. The NTP and ES products are manufactured in four different thicknesses varying from 140 to 240 mils (NTP 1 through NTP 4 and ES1 through ES-4). The weight of geotextile (which affects the thickness and its mechanical properties) varies for the different products from 200 to 400 grams per square meter. The NTP product contains blown (oxidized) bitumen and has lower resistance to ultraviolet (UV) exposure that could make the bitumen brittle and cause alligator cracking over time. The ES products are polymer-

based and contain elastomeric bitumen which is considered more stable to UV exposure and subject to less cracking (Coletanche, 2008). The non-woven polyester geotextile in both products provide the mechanical resistance and the bituminous binder provides waterproofing, chemical resistance and good aging behavior. The BGM is sanded and roughened on one side and has a shiny smoother texture on the other side (see Figure 2).

Figure 1. Typical cross-section of geomembrane.

Figure 2. Smooth and sanded sides of BGM.

Five properties of the BGM were evaluated: physical properties (thickness), mechanical properties (tensile and puncture resistance), waterproofing (permeability) and interface frictional resistance achieved with the materials in contact. An ES-3 product with a thickness of 192 mil (4.8 millimeters) was selected for the project based on the prior experience with this product for similar applications.

3. BGM/FILL AND BGM/CLASS 2 PERMEABLE INTERFACES

The two materials that will be in contact with the BGM are (1) the overlying 3-foot thick drainage material consisting of permeable material and (2) the underlying subgrade consisting of compacted fill. The sanded/roughened surface of the BGM will be in contact with the compacted fill and the smoother surface with the drainage material. The drainage material consists of Class 2 permeable material as specified by California Department of Transportation (2006). The compacted fill material is the on-site soil that was overexcavated and recompacted to 95% of the maximum dry density obtainable using ASTM Designation D1557 test method. The particle size distributions of the Class 2 permeable material and the on-site fill are presented in Figure 3. According to Unified Soil Classification System, the compacted fill and Class 2 permeable materials classify as silty sand (SM) and poorly-graded gravel with sand (GP), respectively. The compacted fill is primarily a sandy material with about 10 percent fine gravel. The Class 2 permeable material contains about 65 percent fine to coarse gravel. The largest gravel size in the compacted fill is 12.7 millimeter (1/2 inch) whereas the Class 2 permeable material contains coarse gravel up to 19.1 millimeter (3/4 inch in size).

Figure 3. Particle size distribution of compacted fill and Class 2 permeable material.

The foundation improvements and grading work for the east reservoir site was completed in late 2011. Based on over 50 gradation tests performed during grading work, the compacted fill predominately consisted of silty sand with about 10 to 30 percent fines (passing No. 200 sieve). The compacted fill and Class 2 permeable materials beneath the mat foundation were specified to be compacted to at least 95% relative compaction. The maximum dry density for the compacted fill and Class 2 permeable materials were 21.2 kN/m^3 and 21.5 kN/m^3 , respectively; the optimum moisture content for both materials was about 8 percent. These maximum dry density and the optimum moisture content values were based on the compaction tests performed on the fill and Class 2 permeable samples used for interface friction testing.

For the seismic analysis of the reservoir, it is important to evaluate if a plane of sliding occurs at either the BGM/Fill interface or the BGM/Class 2 interface. Therefore, direct shear testing was planned to evaluate the frictional resistance for these two interfaces. A three-interface testing of Fill/BGM/Class 2 Permeable would simulate the field conditions better; however, for the dynamic soil-structure interaction (SSI) studies of the reservoir, strength parameters (cohesion and friction angle) for the two interfaces were required as separate input parameters. Therefore, separate tests were planned for the two-interface types. The direct shear test equipment used for the interface friction testing and the test procedure are presented in the following sections.

4. DIRECT SHEAR TEST EQUIPMENT

The interface friction between a soil and geomembrane or geotextile can be evaluated using an adapted version of direct shear test equipment typically used in geotechnical engineering (Koerner 1990). Other methods such as pull-out tests either in laboratory or field can be performed, if economically feasible, however, the elongation of the geomembrane could affect the usefulness of the test results. Therefore, conventional direct shear tests in the laboratory but with a larger shear box was used to evaluate interface friction.

The test equipment used for interface friction testing was a Brainard-Kilman LG-112 model with an effective test area (plan dimensions) of 305 millimeters by 305 millimeters (12 inches by 12 inches) and a depth of 51 millimeters (2 inches). The shear box consists of an upper rigid box and a lower moveable box as shown on Figure 4a. The upper box has plan dimensions of 305 millimeters by 305 millimeters whereas the lower box is slightly larger with plan dimensions of 305 millimeters by 406 millimeters (12 inches by 16 inches).

Figure 4. Direct shear test equipment.

A large-sized shear box was used considering the size of the material being tested, particularly the coarser gravel in the Class 2 permeable material. Per ASTM D 5321, the minimum dimension of the shear box should be at least 15 times the D_{85} (the size corresponding to which 85% of the sample is finer) of the coarser material and the depth of the box should be a minimum of 50 millimeters or six times of the maximum particle size of the coarser soil tested whichever is greater. The gravel in Class 2 material was coarser than that in compacted fill material. The estimated 15 times D_{85} for the Class 2 material is about 286 millimeters which is smaller than a 305-millimeter shear box used for the interface friction testing.

The BGM sheets received from the supplier were carefully inspected for surface defects prior to trimming them to 356 millimeters by 483 millimeters sample size for an effective test area of 305 millimeters by 305 millimeters. The thickness of the sample was also verified to be 4.8 millimeters for the ES-3 product specified for the project. If significant variation of BGM thickness was observed from the specification, the supplier was notified to resend the specified BGM material.

The BGM was secured to the lower box using flat bar clamping with seven pairs of bolts and nuts spaced at about 25.4 millimeters (1 inch) on centers on one end of the lower shear box as shown on Figure 4b. The surface of the lower box (substrate) has a roughened texture which assists in gripping the BGM in-place and avoids slippage of the BGM during testing. The material being tested against the BGM (compacted fill or Class 2 permeable) was compacted in the upper box to the specified density and moisture content. The on-site soil and Class 2 material was moisture conditioned to the optimum moisture content and with the known volume of the upper shear box, the soil was placed in relatively thin lifts and tamped to achieve the specified density. The upper shear box was weighed before and after placing the tested material to ensure that the material was compacted to the specifications.

5. INTERFACE FRICTION TEST PROCEDURE AND TEST CONDITIONS

The interface friction testing was performed by Precision Geosynthetic Laboratories (PGL) of Anaheim, California using the procedures stated in ASTM D 5321 (Determining the Coefficient of Soil and Geosynthetic or Geosynthetic and Geosynthetic Friction by Direct Shear Method).

Two test conditions were evaluated in the direct shear testing: (1) non-saturated condition—wherein the materials were compacted to 95% of the maximum dry density and at optimum moisture content, and (2) saturated condition—wherein the material was compacted at 95% of the maximum dry density at optimum moisture content and was inundated with water in the shear box for about 24 hours under a given normal load for consolidation and maintained inundated during shearing. Although the materials being tested were primarily granular (either SM or GP), it was desired to have the sample consolidate for about 24 hours and allow enough time to attain uniform moisture content throughout the sample. The BGM material itself has a low permeability on the order of 10^{-10} to 10^{-13} millimeters per second and was therefore not anticipated to absorb significant moisture content and undergo some reduction in strength. For the non-saturated condition, the normal load was sustained for about 15 minutes prior to applying the shear load. To evaluate the effects of sustained load, tests were also performed for the non-saturated condition but with normal load maintained for 24 hours before shearing.

The tests were performed at a constant rate of displacement of about 2.5 millimeter per minute (0.10 inch per minute) to ensure that pore pressures were not developed during testing. Although ASTM D 5321 suggests a shearing rate of 1 millimeter per minute (0.04 inch per minute), a higher rate was used considering the materials tested were primarily granular and would not develop excess pore pressures. For a maximum displacement of 76.2 millimeters (3 inches), a single test was completed in about one-half hour.

The normal load was applied on the shear box either using dead weights for lower test loads (less than 50 kN/m²) or hydraulically using a bladder for the higher test loads (50 to 250 kN/m²). The shear load was applied to the lower box with a pulling mechanism. The shearing process was carefully monitored to ensure that the shear load was applied in the horizontal direction with little or no tilting of the equipment to avoid applying torque which could cause non-uniform pressures on the interface. The displacement rate was monitored during testing through a digital readout unit. The normal pressure remained the same during testing due the constant shearing area. The cumulative horizontal shear displacement was also monitored; however vertical displacements were not monitored during the test. The test was continued until a maximum displacement of about 76 ± 0.5 millimeters (3 ± 0.2 inches) was reached. After the tests, the BGM specimen was usually inspected to determine if there were any shear strains (evidence of stretching) in the BGM or at the clamps. Tests were repeated if either excessive stretching (greater than 13 millimeters or 0.5 inches) of the BGM or slipping of the BGM over the substrate occurred.

The BGM has different surface textures on its two sides: (1) smooth side – which acts as a waterproofing membrane and is in contact with the Class 2 permeable material, and (2) rough/sanded side – which is in contact with the compacted fill. Direct shear tests were performed for both BGM surfaces depending on which material (compacted fill or Class 2 permeable) was being tested against. The BGM properties are reportedly uniform in both longitudinal and transverse directions on the same side. As stated by the manufacturer, the direction of testing did not have a significant impact on the test results. The tests were conducted using three normal pressures of about 50, 120, and 240 kN/m². The test loads were selected based on the range of pressures anticipated in the field for empty reservoir and full reservoir cases. All tests were conducted at the laboratory test conditions at a temperature of 71.6 ± 3.6 degrees Fahrenheit and 60 ± 10 percent relative humidity.

6. INTERPRETATION OF TEST RESULTS

The interface friction tests can be classified into four subgroups as listed below for the purpose of evaluating the results.

- BGM/Fill (non-saturated)
- BGM/Fill (saturated)
- BGM/Class 2 Permeable (non-saturated)
- BGM/Class 2 Permeable (saturated)

For each test, the peak shearing resistance of the stress-strain curve was used in the interface shear stress vs. normal load plots presented in this section. The designation “24-hour” on the plots means the sample was consolidated for 24 hours prior to shearing; the designation “15-minutes” means the sample was consolidated for 15 minutes prior to shearing.

To evaluate the interface resistance to sliding for the two interfaces, it was important to first evaluate the test results as presented in Figure 5 for the BGM/Fill and BGM/Class 2 Permeable interfaces for non-saturated condition. As evident from Figure 5, the BGM/Class 2 interface has higher shear resistance at low confining pressures, whereas the BGM/fill interface has higher shear strength at medium to high confining pressures. In addition, the cohesion and frictional components of the two interfaces are significantly different. The interface friction angle for BGM/fill interface is at least 15 degrees higher and the cohesion for the BGM/Class 2 interface is about five times higher than that for BGM/Fill interface.

The test results for the BGM/Class 2 interface for the non-saturated condition under 15-minute and 24-hour sustained load cases are presented in Figure 6. As clearly observed from the figure, the 24-hour sustained load conditions yields a significantly higher friction angle (10 degrees higher) compared to the 15-minute sustained load test. It is believed that the coarser gravel particles of the Class 2 permeable material are pushed into the outer layer of the bitumen at higher confining pressures thereby engaging the tensile strength of the BGM to result in a higher cohesion and frictional resistances. In contrast, a similar comparison of the test results for the BGM/Fill interface presented in Figure 7 indicates that the frictional angles are nearly the same. The 24-hour sustained load case does not seem to improve the frictional resistance for the BGM/Fill interface as the particle size of the fill is much smaller than the Class 2 permeable material resulting in less penetration of particles into the bitumen. It is also noted that the friction angle of the BGM/Fill interface ranges from 36 to 37.5 degrees, which is much higher than that obtained for the BGM/Class 2 interface. It appears that the shear failure for the BGM/Fill interface occurred within the fill material as noted from a thick soil film retained on the BGM after testing (see Figure 8).

Figure 5. Test summary for BGM/fill and BGM/class 2 interface (non-saturated condition).

Figure 6. Test Summary for BGM/Class 2 interface (24-hr versus 15-min) for non-saturated condition.

Figure 7. Test summary for BGM/Fill interface (24-hr versus 15-min).

Figure 8. Thick soil film retained on BGM/Fill Interface after testing (non-saturated condition).

To evaluate the effect of moisture content on the interface friction, tests were performed on the BGM/Class 2 interface but with 24-hour sustained load for both saturated and non-saturated conditions; the results are presented in Figure 9. The effect on saturation on the interface friction appears to be relatively small. In addition, the friction angles are the

same indicating that the effect of 24-hour sustained load is significantly higher than the increase in moisture content upon saturation for the granular material.

Figure 9. Test Summary for BGM/Class 2 (non-saturated condition versus saturated condition).

7. DESIGN FRICTION VALUES

The results of all tests performed for the BGM/Class 2 interface and BGM/Fill interface are shown on Figure 10. A lower-bound cohesion and friction angle were chosen as the design values for the two interfaces. The lower-bound of the 24-hour saturated versus 15-minute non-saturated condition test was used for the BGM/Class 2 interface and the lower bound of the BGM/Fill saturated condition versus non-saturated condition was used. The 15-minute versus 24-hour sustained load condition did not appear to improve the shear strength for the BGM/Fill due to shear failure within the fill material (i.e., the interface friction of BGM/fill was possibly higher than the frictional resistance of the fill material).

The design interface shear strength parameters (cohesion and friction angle) for the BGM/fill and BGM/Class 2 interfaces as well as anticipated governing sliding interface are shown in Figure 10. The design parameters estimated from the direct shear tests for these two interfaces were used in the SSI studies.

Figure 10. Test Summary for BGM/Class 2 and BGM/Fill interface and estimated design shear strength.

8. DETERMINATION OF CRITICAL SLIDING INTERFACE

As shown in Figure 10, the BGM/Fill interface has lower shear strength than the BGM/Class 2 interface at lower confining pressures (less than about 70 kN/m²), beyond which BGM/Class 2 interface has lower shear strength. In other words, the BGM/Fill interface is expected to be the weaker sliding plane for low confining pressures and the BGM/Class 2 interface would be the weaker sliding plane for medium to high confining pressures.

For the operating conditions of the reservoir, the BGM/Fill interface would govern the behavior for an empty reservoir condition (where confining pressures are low), whereas the BGM/Class 2 interface would govern the behavior of the full reservoir structure. It is noted again that at higher confining pressures, the tensile resistance of the BGM becomes engaged in resisting the shear load when in contact with Class 2 permeable material resulting in a higher cohesion with a lower contribution of the interface friction angle. If direct shear tests were to be performed on Class 2 material itself, a friction angle of at least 40 to 45 degrees would be expected. Therefore, for the full reservoir case, a greater shear displacement is expected to occur within the BGM material itself than in the overlying Class 2 permeable material or the underlying compacted fill. For the empty reservoir case, the greater shear displacement is expected to occur within the compacted fill or at the BGM/Fill interface.

The SSI studies of the east reservoir that were performed using design peak ground acceleration (PGA) of 1.0g indicated that sliding (i.e., permanent displacement after earthquake) was not expected at either interfaces. Since the reservoir is covered with 30-foot high compacted fill embankments on all four sides, the additional lateral resistance derived from these embankments likely assisted in resisting the sliding forces due to earthquake load. A discussion of the SSI studies and the modeling details of the BGM/Fill and BGM/Class 2 interfaces below the reservoir are provided in Hudson et al. (2012).

9. CONCLUSIONS

The test results indicate that the critical sliding plane is the BGM/Fill interface for low confining pressures (less than about 70 kN/m²) such as for empty reservoir case and the BGM/Class 2 interface for medium to high confining pressures (70 to 250 kN/m²) such as for full reservoir case. As expected, the Class 2 permeable material has sufficient frictional resistance within itself to be not the weakest sliding plane. The sustained loading condition (24-hour) as expected in the field would in-fact yield higher interface frictional strength than the design values. The tensile resistance of the BGM would be engaged for higher confining pressures such as when the reservoir is full. The maximum shearing resistance (load) on the BGM surface is expected to be about 192 kN/m² (4,000 pounds per square foot) for the full reservoir condition. In the event of excessive leakage through the reservoir or rise in groundwater level that could saturate the compacted fill, the interface friction tests indicate that the reduction in frictional strength upon saturation is relatively minor for both BGM/Fill and BGM/Class 2 interfaces.

ACKNOWLEDGEMENTS

We would like to thank Dr. Tarik Hadj-Hamou of Strategic Engineering and Science, Inc. for providing information regarding bituminous geomembrane and for providing geomembrane samples for testing. We also thank Ms. Cora Queja and Mr. Carmelo Zantua of Precision Geosynthetic Laboratories International for diligently performing the interface friction testing. We also acknowledge Mr. Alek Harounian and Dr. Marty Hudson of AMEC Environment and Infrastructure, Inc. for their help in reviewing the test results and Ms. Kelly Dudek of AMEC Environment and Infrastructure, Inc. for assisting with the figures.

ABSTRACT

During the final stages of construction of a composite landfill final cover cap, a gas bubble occurred at the toe of the final cover slope before the surface water diversion berms were constructed and the final cover was stabilized with vegetation. As the gas pressure in this area was relieved, several large wrinkles were noted in the geomembrane that extended over a lateral distance of approximately 73 meters. This paper presents the investigation of the gas bubble and the geomembrane wrinkles through the visual evidence found at the landfill, the geomembrane sample tests, and calculations modeling the actual construction sequence. The investigation indicated that two different situations may have contributed to the gas bubble and the wrinkles: first, placement of the soil cover from top to bottom with 40-ton haul trucks backing down the slope to dump soil on the slope; second, the combination of some stretching of the geomembrane in the area where the gas bubble developed and the accumulation of the stretched geomembrane and possibly some excess geomembrane being walked down the slope.

1. INTRODUCTION

The landfill is located in the Southeastern United States. In the latter months of 2006 and into early 2007, the final cover system was installed on approximately 2.4 hectares of the landfill.

Before the surface water diversion berms were constructed and the final cover stabilized with vegetation, high gas pressures caused the geomembrane cap to expand under the vegetative cover soils in the lower portions of the cover slope. At the toe of the slope (Figure 1a), the gas pressure was sufficiently high that the vegetative cover soils were pushed off the geosynthetics, resulting in a gas bubble approximately 3 meters high, 1.8 meters wide and 4.6 meters long.

a A Gas Bubble

b Geomembrane Wrinkles

Figure 1

The pressure was relieved by cutting through the geomembrane and directing the gas through a flexible pipe to the landfill gas collection system. As the gas pressure in this area was relieved, several large wrinkles were noted in the geomembrane (Figure 1b). Landfill personnel exposed the geomembrane to define the extent of the wrinkles, and found that they extended over a lateral distance of approximately 73 meters. Further investigation in the upper portion of the slope above the area where the gas bubble had occurred, indicated that the geomembrane had been stretched resulting in the thickness of the geomembrane being reduced to 60 to 90 percent of its original thickness.

This paper presents the investigation of the gas bubble and the geomembrane wrinkles through the visual evidence found at the landfill, the geomembrane sample tests, and calculations modeling the actual construction sequence. Based on the field investigation results and calculations, the paper discusses the mechanisms that contributed to the elongation of the geomembrane.

2. BACKGROUND

2.1 Final Cover Cross Section

The cross-section of the permitted final cover is as follows (from the bottom up):

- A 457-mm thick soil foundation layer;
- A geomembrane and drain layer combination of,
 - a 1.00 mm (40 mil) textured LLDPE with geocomposite above, or
 - a 1.50 mm (60 mil) textured HDPE with geocomposite above, or
 - a 1.25 mm (50 mil) Supergripnet™ drain liner with a 271 g/m² (8 oz./yd²) geotextile above;
- A 457-mm thick vegetative cover.

The partial closure included a 1.25 mm Supergripnet™ Drain Liner installed over the compacted soil foundation layer, topped by a 271 g/m² non-woven geotextile and the 0.45 meters thick vegetative soil cover. The final cover has a general slope of 3.0 horizontal to 1.0 vertical (3H:1V), with diversion berms located every 9.1 meters to control storm water and soil erosion.

During the design phase, the stability of the final cover against sliding along the interfaces of the different materials was evaluated. The stability analyses were conducted for the following conditions:

- Long-term static conditions, with no construction loading, and up to 0.15 meters of water within the cover drainage layer; and
- Short-term conditions to evaluate the slope during construction, specifically during placement of the vegetative cover layer.

The design of the slope was based on Factors of Safety (FOS) against sliding as follows (Koerner, et al. 1998):

- FOS = 1.6 for static conditions with no equipment loading;
- FOS = 1.2 for static conditions with seepage forces; and
- FOS = 1.3 for low ground pressure equipment loading during placement of the vegetative cover soil. Note that this analysis assumed that the vegetative cover soil would be placed upward from the bottom of the slope.

2.2 Conditions of Gas Collection and Control System in the Area of Interest

There were four extraction wells upslope from the area where the gas bubble developed designated as G1 through G4. The liquid level measurements in these wells taken in early January of 2007 showed that in all but one of these wells the liquid level was above the top of the well screen. Furthermore, well G1 had only about 25 percent of the screen above the liquid level. High liquid levels in the gas wells are generally indicative of perched zones of leachate or high condensate generation rates causing the well screen to become flooded with leachate. Historically, replacement wells have been installed within 9.1 meters of a well that was flooded without encountering saturated waste. However, it is possible that saturated conditions could have been present in the waste underlying the cover area.

Throughout the final cover construction period, the four extraction wells were monitored approximately every two weeks for gas quality, temperature, and pressure. These wells exhibited elevated oxygen concentrations and, in some cases, high positive pressures. This is a common occurrence with gas wells where the liquid level is high because the limited screen space available for the gas to enter the well increases the potential for the atmospheric intrusion (oxygen) through the fittings in the wellhead or sample ports when vacuum pressures are applied to extract the gas.

On October 19, 2006, when problems were noted with operation of the flare and/or gas header, a positive pressure of 1.2 meters of water was measured in one of the wells. Smaller positive pressures (less than 0.13 meters of water) were measured in the other wells in the investigation area during this same monitoring event.

The pressures measured in the flooded wells (wells with no screen available) were unlikely to represent the overall gas pressure within the landfill. When the wells are flooded with leachate, gas pressure typically increases in the headspace

of the well as gas "bubbles up" through the leachate. When the well is closed, positive pressures will continue to increase until they are allowed to vent. To measure the gas pressure in the landfill, it would be necessary to have a well with the screen properly exposed to the waste and that has been shut-off (i.e., not allowed to vent) for a period of time that would allow the gas pressure within the well to stabilize.

2.3 General Sequence of Construction and Discovery of Landfill Gas Bubble

The following summarizes the geomembrane and vegetative layers construction timeline:

- The geomembrane was installed over a period of 5 days. CQA conformance tests were conducted during the installation. The average geomembrane thickness at time of placement based on seven conformance tests was 1.4 mm with a standard deviation of 0.056 mm and the lowest interface friction angle was measured to be 25.6 degrees between the geomembrane and the underlying soil foundation layer. This is from laboratory testing of the interfaces between the geotextile and geomembrane and geomembrane and soil foundation layer using four different types of direct shear tests.
- Placement of vegetative cover began on December 12, 2006 according to the Contractor's records. Significant activity for vegetative cover placement began on December 18, 2006, with over 150 loads placed per day until December 21, 2006. Forty-ton trucks were used to haul and dump the vegetative cover material down the slope from the top.
- The vegetative cover material was placed over all of the final cover area and was compacted and smoothed with a smooth drum compactor prior to the beginning of a shut-down period from December 22, 2006 to January 2, 2007. The erosion control diversion berms along the slope were not installed prior to the shut-down.
- Approximately 63.5 mm of rainfall fell during the shut-down period with one event producing 37.3 mm of rainfall.

A bubble near the toe of slope was noticed by the landfill personnel on when they came back on site, but the exact date of when the bubble began to form is unknown. A gas extraction well located approximately 45.7 meters up the slope from the bubble was investigated due to an apparent vacuum leak. During the walk up the slope, several small (less than 25.4-mm wide) tension cracks were observed at irregular intervals up the slope. Several erosion rills running up and down the slope had formed.

In addition to the largest bubble near the toe of slope, several smaller bubbles were noticed in the area; including one immediately north of the largest bubble and another located approximately 23 meters further up the slope. The Contractor also observed a bubble near the tie-in with the adjacent closed area after returning from the shut-down period. The following lists information related to the bubbles.

- In preparation for the holiday shut down, the Contractor left the longitudinal anchor trench adjacent to the existing capped area open on December 21 to facilitate venting of the gas. On returning, Contractor noted that the anchor trench had been silted in and they uncovered the anchor trench. At this same time, the Site Superintendent also observed a gas bubble near this tie in. Upon cleaning the silt from the anchor trench, this bubble dissipated without having to lance the bubble.
- The largest bubble (Figure 1) was noted the same day and was lanced.
- Inspection of the bubble on January 2 revealed no obvious signs of a slope failure at the time.
- The largest bubble was estimated about 4.6 meters long, 1.5 to 1.8 meters tall, and 3 meters wide.
- The bubble located immediately north of the largest bubble appeared to have deflated when lancing the largest bubble. The smaller bubble located approximately 23 meters up the slope was covered and the soil was reworked.
- While attempting to repair the area surrounding the largest bubble, the geomembrane at the toe area near the bubble was exposed. Numerous wrinkles were noticed and the liner continued to be exposed over an area approximately 6 meters wide and 73 meters long to determine the extent of the wrinkles.

3. FIELD INVESTIGATION

3.1 General

After the gas "bubble" occurred, the author visited the site on several occasions and sampled the geomembrane to observe the soil under the geomembrane and for laboratory testing. The locations of the samples are shown on Figure 2. Note that the sample locations are described relative to the surface water benches designed on the slope, These benches were not installed before the bubble appeared and they did not have an impact on the wrinkling or the stretching of the liner. The design location of the storm water diversion benches are shown only as location markers. The samples were taken as follows:

- Twenty-nine geomembrane samples were taken at toe of slope in the area of the wrinkles one month after the contractor resumed work on the cover. These samples are marked with an “x” on Figure 2 and denoted as “S-1” to “S-29.” Among these samples, S-19 was taken next to the punched hole that was used to release the bubble.
- A few days after the initial sampling, four (4) geomembrane samples were taken higher up the slope. These were denoted as “Bench Sample 1” to “Bench Sample 4.”
- Eight (8) geomembrane samples were taken higher up the slope ten (10) days later and denoted as “# 1” to “# 8.”

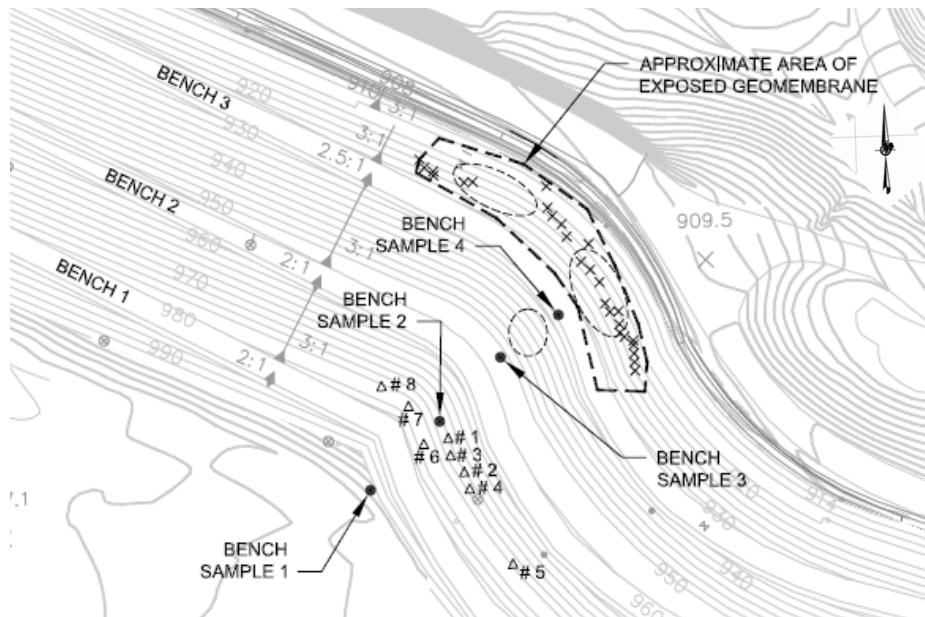

Figure 2 Geomembrane Sampling Locations

3.2 Field Observations

3.2.1 Observations in the Bubble Area at the Toe of the Slope

After the gas bubble was pierced and deflated, the geomembrane that had been uncovered was noticeably wrinkled. The width and length of the affected area was measured to be about 6 meters wide by 73 meters long. The increase in length of the geomembrane creating the wrinkles was measured along the wavy surface from top to the bottom of the exposed geomembrane at six different locations. The length of geomembrane ranged from approximately 6.9 meters to over 11 meters, averaging about 1.6 meters (141% of the original length) longer than should have theoretically been present at the exposed location. Several samples were cut from the geomembrane. The surface of the foundation soil under the geomembrane samples was relatively dry, but several areas were marked with downhill progressive penetrations (not continuous drag marks) caused by spikes in geomembrane as shown in Figure 3a.

3.2.2 Observations on the Slope

To further investigate the cause of the wrinkles, test pits were excavated on the slope from the top down (Bench Samples 1 through 4) and on the upper portion of the slope (samples #1 through #8) and samples were taken from the exposed geomembrane. Several geomembrane samples obtained in the upper portion of the slope were notably (visually) thinner than indicated by the conformance testing. Also, the geomembrane was under tension and separated easily when the samples were cut. The surface of foundation soils under several samples from the top of the slope showed clear “dragging” marks, as shown in Figure 3b.

Furthermore, the spikes on the bottom of the geomembrane sample taken between Benches 2 and 3 were bent, indicating that the geomembrane had been dragged down the slope, as shown in Figure 3c.

The soil beneath the sample taken between Benches 2 and 3 did not exhibit the same drag markings, as shown in Figure 3d.

3.3 Laboratory Testing

3.3.1 Thickness Measurement

Table 1 Geomembrane Thickness Results from Conformance Tests

Sample ID	Sample Date	Average Sample Thickness (mm)	Minimum Thickness Reading (mm)
146101-06		1.55	1.33
146317-06		1.45	1.31
146433-06		1.43	1.25
146548-06	11/2006	1.46	1.31
146764-06		1.39	1.23
147104-06		1.38	1.24
147220-06		1.40	1.26
Average		1.44	

The thicknesses of the 41 samples obtained from the geomembrane were measured at multiple locations along the perimeter of each sample. The thickness test results are summarized in Tables 2, and 3. The thicknesses of samples taken for conformance testing during the installation are also included in Table 1 for reference. The thicknesses measured in the conformance tests ranged from 1.38 mm to 1.55 mm, with an average of 1.44 mm and a standard

deviation of 0.056 mm. The thicknesses of samples taken between Benches 1 and 2 ranged from 0.85 mm to 1.54 mm (Table 2). The thicknesses of samples taken from the toe of the slope in the area of the wrinkles ranged from 1.24 mm to 1.53 mm, averaging 1.38 mm (Table 3).

Table 2 Geomembrane Thickness Test Results on Slope Samples after Gas “Bubble” Occurred

Sample ID	Sample Date	Average Thickness (mm)	Sample Thickness Reading (mm)	Minimum Thickness Reading (mm)	Percent Deformation	Meet Specifications?	
						Min. Average (=1.25 mm)	Min. Value (=1.14 mm)
Bench Sample 1		1.54		1.46	0.0%	Yes	Yes
Bench Sample 2	2/7/07	1.03		0.76	28.0%	No	No
Bench Sample 3		1.47		1.39	0.0%	Yes	Yes
Bench Sample 4		1.29		1.22	9.9%	Yes	Yes
# 1		1.33		0.90	7.4%	Yes	No
# 2		0.87		0.66	39.3%	No	No
# 3		0.85		0.34	41.1%	No	No
# 4	2/18/07	1.09		0.86	24.1%	No	No
# 5		1.29		1.23	10.3%	Yes	Yes
# 6		1.24		0.91	13.8%	No	No
# 7		1.53		1.38	0.0%	Yes	Yes
# 8		1.18		0.95	18.1%	No	No

Note:

1. Percent deformation was calculated in comparison to the average sample thickness from conformance tests (=1.44 mm).

Table 3 Geomembrane Thickness Test Results on Samples from Toe of Slope

Sample ID	Average Sample Thickness (mm)	Minimum Thickness Reading (mm)	Percent Deformation	Meet Spec?		Sample ID	Average Sample Thickness (mm)	Minimum Thickness Reading (mm)	Percent Deformation	Meet Spec?

S-9	1.27	1.26	11.3%	Yes	Yes	S-24	1.41	1.28	1.8%	Yes	Yes
S-10	1.34	1.28	6.9%	Yes	Yes	S-25	1.31	1.25	8.5%	Yes	Yes
S-11	1.50	1.33	0.0%	Yes	Yes	S-26	1.34	1.24	6.5%	Yes	Yes
S-12	1.35	1.28	6.2%	Yes	Yes	S-27	1.31	1.23	8.8%	Yes	Yes
S-13	1.47	1.33	0.0%	Yes	Yes	S-28	1.34	1.30	6.5%	Yes	Yes
S-14	1.42	1.35	0.7%	Yes	Yes	S-29	1.24	1.18	13.3%	No	Yes
S-15	1.51	1.43	0.0%	Yes	Yes						

The thickness measurements of the samples indicate the following:

- The liner in the toe area appears to be slightly stretched.
- Sample S-19 was taken adjacent to the hole punched to release the gas. Samples S-20, S-21, and S-22 were taken adjacent to S-19, but away from the hole. S-19 was likely at the bottom or side of the bubble where elongation would be expected to be lower than along the upper part of the bubble. Since the thicknesses of samples S-20, S-21 and S-22 are less than that of S-19, it is inferred that the liner at the top of the bubble was likely stretched even more.
- The liner between the first bench and the second bench (top down) was stretched. The thicknesses of five of the eight samples, i.e. Bench Sample 2, and samples #1 to #8, were generally less than 1.27 mm (see Table 2).

- The liner immediately uphill from the liner exposed in the toe area may have been under slight tension, since the thickness of Bench Sample 4 was approximately 10% less than the conformance tests average.

3.3.2 Stress-strain Behavior of the Geomembrane

Wide Width Tensile Strength tests were also conducted on three 203-mm by 203-mm specimens cut from the samples # 1, # 2, and S-23, respectively. The tests were performed based on ASTM 4885, except that, instead of 12 specimens per sample, only one specimen was tested.

The Wide Width Tensile Strength tests indicated that samples # 1 and S-23 were not stretched or stretched very slightly, but sample # 2 was stretched significantly. Based on the results of the Wide Width tests, the geomembrane would behave elastically when the tensile stress is less than 15.8 newtons per millimeter (N/mm). Over 15.8 N/mm, the geomembrane will display plastic (permanent) deformation. The results of the Wide Width tests are shown on Figure 4 below:

Figure 4

4. STABILITY ANALYSES

4.1 Cases Analyzed

For a landfill cover system, veneer stability is developed through the interface shear strength between the layers and the internal shear or tensile strength of the material in each layer. Veneer stability is typically evaluated using a two dimensional force balancing model (Koerner, et al. 1998; Qian, et al. 2002).

Calculations were performed to assess the difference in FOS between placing the vegetative cover layer on the geomembrane from the toe of the slope up (as designed and specified), and placing the vegetative cover layer from the top of the slope down (as constructed). Cases 1 and 2 are indicative of design conditions, as described above in Section 2.1, while Cases 3 and 4 represent the construction conditions. For Cases 3 and 4, Case 3 assumes that the geomembrane does not take any tension and Case 4 estimates the tension experienced by the geomembrane during construction. These calculations do not include the effect of gas pressure beneath the geomembrane.

A separate calculation (Case 5) was performed to estimate the magnitude of the gas pressure that would be required to counter the weight of the vegetative cover (after construction) such that the contact between the geomembrane and the underlying soil was broken (i.e., zero interface friction). Under these conditions, the down-slope component of the weight of soil above the geomembrane is essentially carried by tension in the geomembrane. This loading condition also estimates the length of soil along the slope that, when lifted by gas pressures, would cause sufficient tension to elongate the geomembrane past the yield point (transition point from elastic to plastic behavior), which is approximately 15.8 to 17.5 N/mm (see Figure 4b).

4.2 Veneer Stability Analyses Results

The results of the stability analyses for the conditions described in the previous section are summarized in the following table.

Table 4 Veneer Stability Analyses Results without Gas Pressures

Case	Construction Direction	Equipment On Slope	Tension on Geomembrane (ppi)	FOS	Comments
1	NA	No	0	1.6	As designed
2	Upslope	LGP Dozer	0	1.5	As designed
3	Downslope	LGP Dozer and Truck	0	0.9	As Built – assumes the equipment is on 9.1 m of the slope with no tension on the geomembrane.
4	Downslope	LGP Dozer and Truck	154	1	As Built – assumes the equipment is on 9.1 m of the slope and allows tension in the geomembrane.

Table 5 Veneer Stability Analyses Results with Gas Pressures

Case	Tension (N/mm)	Gas Pressure Under Membrane (H ₂ O mm) Needed to Overcome Weight of Soil	Comments
5	16.8	No	Assumes there is no contact between the geomembrane and the foundation soil layer along 1/3 of the slope, and no construction loads

The results of these analyses results are discussed in the following section.

5. DISCUSSIONS

5.1 General

The focus of the investigation was to assess what mechanisms would result in the elongation of the geomembrane along the upper and lower portion of the slope, and whether these elongations were related to each other and to the large gas bubble that occurred at the top of the slope.

The wrinkling of the geomembrane when uncovered at the toe of the slope raised the question of whether the geomembrane had been stretched along the entire slope and why this had occurred. The geomembrane is manufactured with low-density polyethylene which is an elastoplastic material, meaning that it exhibits both elastic and plastic behavior. Under lower tensile loading, the geomembrane deforms elastically and rebounds when the load is removed. Under higher loads, beyond the elastic (or yield) limit, the geomembrane deforms plastically; it will not fully rebound when the load is removed and if the load is maintained, the geomembrane will continue to deform without an increase in load (creep). Since it was known that the geomembrane had stretched and thus been under tension, the long-term creep (increase in deformation under constant load) resistance of the geomembrane on the slope was of concern. While the main focus was to assess what caused the problems identified and identifying potential ways to prevent future occurrence, one part of the investigation was geared towards assessing whether the geomembrane would continue to creep under the static load imposed by the vegetative cover soil layer and the diversion berms.

5.2 Potential Geomembrane Elongation Mechanisms

5.2.1 General

The results of the stability analysis summarized in Section 4 (Table 4 and 5) confirm that, as indicated by the physical state of the geomembrane samples taken from the investigation area, the geomembrane had been stretched, and therefore tensioned, during construction and by gas pressures that built up under the geomembrane. The following sections discuss, based on the stability analyses and field observations, how these mechanisms are likely to have occurred.

5.2.2 Discussion of Elongation During Construction

The effect of equipment loading was analyzed by performing the veneer stability analyses to compare design to construction conditions as described in Section 4.0. The design analyses of the slope (Cases 1 and 2 with no gas

pressure) result in factor of safety (FOS) greater than 1.0, indicating that the geomembrane on the slope would not be in tension during and/or after construction if the slope was properly drained, both externally and internally.

Case 3 uses construction loading conditions (soil placed from the top of the slope to the bottom) and assumes that there is no tension in the geomembrane; the resulting FOS of 0.9. This FOS is indicative of a condition where the cover materials would have slid along the geomembrane/soil interface had it not been for the increase in tensile strain (and stress relief) of the geomembrane. Case 4 was analyzed to quantify the tension (stress relief) that would have developed in the geomembrane to keep the cover materials on the slope.

Case 4 is representative of the cover conditions as evidenced from the geomembrane samples and the soil surface beneath the samples. There was no visually apparent indicator of mass sliding failure, such as a large tension crack in the soil surface or obvious visual evidence of significant elongation of the geomembrane below the soil placement area reported by the CQA personnel. However, the geomembrane was stretched in the area that the loaded haul trucks traversed and dumped the soil as indicated by the reduction in the thickness and tensile strength of the samples taken in the upper 1/3 of the slope (between Benches 1 and 2). This is the area where the forces from the construction loads would have been the greatest. Also, sliding of the geomembrane in this area is visually apparent from the striations observed in the soil surface exposed beneath the geomembrane when the samples were cut (see Figure 3b), as well as the direction of bending of the spikes observed in geomembrane (see Figure 3c).

Once the geomembrane had been tensioned, and despite the fact that the equipment was no longer on the slope, the friction resistance of the geomembrane/soil interface was reduced to a value less than the peak friction resistance and approaching the residual friction resistance of the interface. Consequently, the FOS against sliding for that portion of the slope that has been stretched was somewhat less than the original design FOS = 1.6, although it cannot be accurately estimated.

5.2.3 Discussion of Elongation Potentially Caused by Gas Pressures

The existence of the gas bubble at the toe of the slope is of significance because it brought to light the existence of wrinkles within the geomembrane in this location. As indicated on Table 5, the intent of the Case 5 veneer stability analyses was to quantify first, the gas pressure needed to counter the weight of the soil and thus “break” the contact between the soil and the geomembrane, and second, to estimate the tension in the geomembrane once there was no contact between these two components. Based on this analysis, the gas pressure necessary to lift the geomembrane when there is no equipment on the slope is about 762 mm of water (about 6.9 kPa). Given that the geomembrane bubble pushed the soil away and was exposed, this level of gas pressure is known to have occurred. As described in Section 4, if the soil on about 1/3 of slope length is lifted by gas pressure, the geomembrane would be in tension at approximately its yield point, which could cause some permanent elongation.

The samples indicate that there was elongation of the geomembrane in the vicinity of the largest gas “bubble,” but the elongation was not as severe as the elongation of the samples in the upper portion of the slope. The elongation of samples taken from what is inferred to be the top portions of the gas bubble has been estimated from the reduction in thicknesses of these samples that varies from 1.24 to 1.32 mm (i.e., an 8% to 13% reduction assuming an original average thickness of 1.44 mm). Given the reduction in thickness of the geomembrane, there would be a similar percentage elongation of the geomembrane within the exposed area as indicated by the graph included in Figure 4. Samples obtained from an area just upslope of the bubble would also be slightly elongated.

In addition to the slight elongation at the gas bubble area, it was noticed that the soil under the geomembrane samples had been marked by the geomembrane spikes in a pattern that indicated that the geomembrane had “jumped” downhill, rather than dragged downhill, as was observed in the upper portions of the slope. This can be seen in Figure 3a where the spike pattern clearly shows a series of individual spike holes without drag marks, indicating that the geomembrane was lifted off the soil and then re-set. The pattern of the spike marks also indicates that the movement was down the slope. These observations, together with the results of the stability analysis that includes gas pressure, leads to the explanation that it is likely that as the gas pressure built up in the lower portion of the slope the cover system components were lifted, breaking the contact between the soil and the membrane, and the down-slope component of the weight of the soil was transferred to the geomembrane, which carried the load in tension. As the bubble expanded, the gas pressure under the geomembrane temporarily decreased, allowing the cover to drop back down onto the foundation soil, but since the geomembrane was slightly stretched, the new contact location was slightly downhill from the original location. As the gas pressure built up again, the process repeated itself, several times as indicated by the pattern of the spike marks.

6. CONCLUSION

The evidence observed at this site, the geomembrane sample tests results, and the results of the calculations indicate that two different conditions, possibly unrelated, caused the final cover geomembrane to stretch. First, the stretching of the geomembrane between benches 1 and 2, in the upper part of the slope, occurred during construction and it is ascribed to placement of the soil cover from top to bottom of the slope with the 40-ton haul trucks backing down the slope to dump soil on the slope. Second, the wrinkles in the geomembrane noticed after the gas bubble had been deflated were likely a combination of some stretching of the geomembrane in the area where the gas bubble developed along with the accumulation of the geomembrane and the excess geomembrane being “walked” down the slope as landfill gas built up and dissipated over a short period of time. There is some excess geomembrane from small waves that occur during normal geomembrane deployment and with top-to-bottom construction, some of this excess would have also been walked down the slope. The excess geomembrane in the wrinkles near the toe of slope is not thought to be a result of the stretching upslope, since this amount of material would have been noticed during construction, which was not so recorded in the construction quality assurance records. Also, the excess geomembrane at the bottom of the slope was not the result of a mass slide of the cover down the slope pushing geomembrane to the bottom since there was no evidence of such sliding either in the soil cover or at the soil/geomembrane interface on the slope below midslope.

Investigation of Temperature Variation in Soil Backfill and its Consequence to Tensile Strength of Geogrid

ABSTRACT

Use of geogrid reinforcement in Mechanically Stabilized Earth (MSE) walls can provide a feasible and economical alternative to using inextensible steel reinforcement. The latter can undergo elevated levels of corrosion, over time, such as was discovered in two well-documented field cases in Southern Nevada. Nevada DOT has used inextensible steel reinforcement for all of their MSE walls thus far. Therefore, use of geogrid reinforcement may become necessary since it also comes with relatively easier installation during construction. However, long term performance of geogrid reinforcement under elevated temperatures, such as those encountered in Southern Nevada, remains uncertain especially since polymeric materials exhibit temperature-sensitive behavior. Current design manuals (AASHTO 2002a and AASHTO-LRFD 2007) limit the design air temperature at the wall site to 30°C in long-term static design. This study showed that this threshold is exceeded in select cities in Southern Nevada, which presents a dilemma relative to undertaking geogrid reinforced soil wall designs in such locations. By evaluating laboratory and field data, an attempt has been made to develop a design framework to address the effect of elevated temperatures on long term performance of geogrid reinforcement. Arrhenius modeling to model strength degradation due to long term exposure to elevated temperatures, and thermal modeling to model soil backfill temperatures, are presented here as integral parts of the proposed design framework. Strength of geogrid was evaluated through the ultimate tensile strength test in accordance with ASTM D6637 under temperatures ranging from 20°C to 40°C.

1. PROBLEM STATEMENT

1.1 Introduction

Mechanically Stabilized Earth (MSE) wall is one of the least expensive earth retaining structures and it is used extensively in Nevada. Nevada DOT has used inextensible steel reinforcements for all of their MSE walls thus far. However, one major concern that has become apparent recently is the elevated corrosion of steel reinforcement. This is because within the last ten years, two well-documented field cases of substantially elevated corrosion have come to light in Southern Nevada. Across the United States there is a growing trend towards favoring use of geosynthetic reinforced soil (GRS) walls because of their improved performance capabilities and relative installation ease during construction.

Use of geosynthetic reinforcement can avoid the corrosive aspects of the degradation of reinforcing material. However, geosynthetic materials may have other potential degradation issues that are specific to the conditions in Nevada. Such issues include uncertainty of field performance at elevated temperatures along with wide swings that can substantially accelerate the degradation of strength and stiffness with aging (e.g., creep). Design manuals limit the design air temperature at the wall site to 30°C in long-term static design (AASHTO 2002a and AASHTO-LRFD 2007). The temperatures in many locations in Southern Nevada exceed this limit thereby presenting a dilemma relative to undertaking geosynthetic wall designs in such locations.

This paper presents a design framework, based on laboratory and field data to account for the effect of elevated temperatures on performance of geosynthetics in future MSE wall designs in Nevada. The ultimate tensile capacity, which is a critical design input to GRS wall design, was the focus of the laboratory investigation.

1.2 Design Temperature at Selected Sites in Southern Nevada

The effective design temperature is defined as the temperature which is halfway between the average yearly air temperature and the normal daily air temperature for the warmest month at the wall site and should not exceed 30°C for permanent applications (AASHTO LRFD, 2007). The cities of Las Vegas, Laughlin and Henderson were selected as being representative sites in Southern Nevada to first establish a historical temperature profile at each of these sites.

These data were then used to arrive at the effective design temperature. Use was made of the Mechanistic Empirical Pavement Design Guide (MEPDG; AASHTO 2002b) software in this effort. The MEPDG is a widely used and most recent AASHTO design procedure to undertake pavement design. One of the initial steps in this design procedure is to establish the pavement temperature based on air temperature at a given site. The MEPDG temperature analysis is undertaken with a climatic database containing hourly data from 800 weather stations across the United States. The data source embedded in MEPDG is from the National Climatic Data Center (NCDC). Given location e.g. latitude and longitude, the software computes and outputs interpolated air temperature distribution data, by month, from nearby weather stations. It interpolates across two or more weather stations that are closest to the user-defined location. Table 1 shows the stations used for the three cities identified above.

Table 1. Weather Stations used to determine design temperature in select Southern Nevada cities

City	Station	Latitude, Longitude	Distance from Selected Site, km	Complete Data Available, Months
Las Vegas ¹	McCarran Int. Airport, NV	36.05, -115.10	11.9	116
	North Las Vegas Airport, NV	36.13, -115.12	11.9	65
Laughlin ²	McCarran Int. Airport, NV	36.05, -115.10	95.6	116
	Needles Airport, CA	34.46, -114.37	62.4	62
Henderson ³	McCarran Int. Airport, NV	36.05, -115.10	15.4	116
	North Las Vegas Airport, NV	36.13, -115.12	27.4	65

¹Las Vegas latitude and longitude are 36.08, -115.17, respectively

²Laughlin latitude and longitude are 35.14, -114.62, respectively

³Henderson latitude and longitude are 36.03, -114.98, respectively

The Design Guide uses a base unit of one month (30 days), as the analysis period, in establishing the temperature history at a given site. In situations where freeze-thaw cycles are present, the analysis period is reduced to 15 days to account for rapid changes in the pavement material properties during the freeze-thaw period (AASHTO, 2002b). Due to lack of swing in temperature, a 30-day analysis period was considered to be appropriate for Southern Nevada. The software generates a table for average monthly quintile air temperatures at the pavement surface in accordance with the following steps. Quintile temperatures are simply temperatures that represent 20% of the temperature data in the analysis period.

- The analysis starts out with 720 hourly air temperature data points for each month (24 hrs x 30 days);
- The data points are rearranged in ascending order;
- Data is then split into 5 segments of 144 data points each i.e. quintiles;
- The average temperature in each quintile is then computed;
- Repeats the above steps for each corresponding month in every year for which data is available;
- Computes averages of each of the corresponding quintiles for the specific month;
- Finally computes mean of the quintiles in each month to obtain their corresponding mean surface temperatures.

The MEPDG uses these surface temperatures, among other data, to produce the temperature profile in the pavement. These data are then used in pavement performance models to predict pavement distresses. As a representative historical temperature data, only the computed average monthly quintile air temperature data for Las Vegas is reported in Table 2. The air temperature data used span from July 01, 1996 to February 28, 2006. In determining the effective design temperature, the average yearly air temperature was computed as the arithmetic mean of the monthly mean temperatures in Table 2. The normal daily air temperature for the warmest month was read off as the highest mean temperature. July was observed to be the warmest month at each of the three locations considered. The effective design temperature at the wall site was finally computed as the arithmetic mean of the average yearly air temperature and the normal daily air temperature for the warmest month. Table 3 summarizes the design temperature calculations for the three cities evaluated. The results in Table 3 show that the AASHTO threshold of 30°C is exceeded for all three cities. The approach discussed above is preferred to one that uses only maximum and minimum air temperature data because the latter skews the analysis and is bound to produce lower effective design temperatures. This approach therefore, ensures safer MSE wall designs in locations where temperature may be an issue.

1.3 Review of a Case Study

The Tanque-Verde GRS wall project located in Tucson, AZ is a well-instrumented wall site located in the Sonora desert whose conditions closely approximate those in Southern Nevada. The environmental conditions at the site provide an ideal case study to address many of the geosynthetic wall behavior concerns in Southern Nevada (Crouse et al. 2003).

Table 2. Quintile Air Temperatures-Las Vegas

Month	1 st Quintile, °C	2 nd Quintile, °F	3 rd Quintile, °C	4 th Quintile, °C	5 th Quintile, °C	Mean Temp., °C	Std. Dev., °C
January	3.6	7.4	10.6	14.4	20.6	11.3	-11.7

Table 3. Effective Design Temperatures in select cities in Southern Nevada

City in Southern Nevada	Average Yearly Air Temperature, °C	Normal Daily Air Temp. (Warmest Month), °C	Effective Design Temperature, °C
Las Vegas	24.2	38.1	31.2
Laughlin	27.2	41.4	34.3
Henderson	23.2	37.6	30.4

The project was completed with full-height precast concrete wall facing in October 1985 and serves as a grade separation for a highway project (Fishman et al. 1991). The geosynthetic reinforcement used on this project featured the uniaxially oriented SR2 geogrid made of extruded high density polyethylene (HDPE) from Tensar International Corporation. This geogrid had a maximum tensile strength of 79 kN/m (Fishman et al. 1991).

The wall was instrumented with the goal to study the response of the wall system and compare it with design assumptions and calculations that were made. Instrumentation included resistance thermometers to determine the distribution of temperature within the reinforced soil backfill. Figure 1 shows temperature readings within the wall section taken in March 1986 at 11:00 am, June 1986 at 3:00 pm, and June 1996 at 8:30 am (FHWA 1989 and Wayne et al. 1998). The soil backfill temperatures observed in Figure 1 clearly reflect the influence of air temperature measurements shown on the wall face. The highest backfill temperature was 39°C recorded at 8:30 am in June 1996. At that time the average wall face temperature was 44°C. This represents a 5°C reduction in backfill temperature relative to wall face temperature. It should be noted that wall surface temperatures are directly influenced by air temperature fluctuations and presence of cloud.

Despite the high soil backfill temperature, the overall performance of the Tanque-Verde wall has been reported to be satisfactory over the last 25 years with no major issues (Berg et al. 2009). The applicability of this one observation to other geosynthetics, soils and environmental conditions would however be questionable. In addition, a large safety factor of 10 was used on this project (FHWA 1989). According to NOAA weather data presented for major US cities by Bonaparte (1987), the maximum and average air temperatures in Tucson, AZ were lower than those in Las Vegas, NV. The maximum and average air temperatures were reported as 37°C and 30°C, respectively, for Tucson, AZ whereas Las Vegas temperatures were reported as 40°C and 32°F, respectively. This observation, coupled with the soil backfill temperature trends in Figure 1 and the fact that design temperatures in Southern Nevada exceed the AASHTO threshold (Table 3), justify the GRS wall design concerns for Southern Nevada. Moreover the temperature immediately behind the facing could be higher than the air temperature for walls which face the sun (AASHTO 2002a, AASHTO-LRFD 2007).

Figure 1. Temperature readings within wall section (Wayne et al. 1998).

1.4 Design Approach

According to AASHTO-LRFD (2007) wall design procedures, the allowable long-term reinforcement tensile strength (T_{all}) required to prevent rupture calculated on a load per unit of reinforcement width basis is defined as:

$$T_{all} = \frac{T_{ult_lot}}{RF} \quad [1]$$

where,

$$RF = RF_{ID} \times RF_{CR} \times RF_D \quad [2]$$

T_{ult_lot} is the average lot-specific ultimate tensile strength for the unaged (fresh) lot of material (ASTM D6637) and RF is a combined reduction factor to account for potential long-term degradation due to installation damage (ID), creep (CR) and rupture of reinforcement due to strength degradation (D). Representative values of RF_{ID} , RF_{CR} and RF_D have been suggested by Elias et al. 2009 and AASHTO 2002a, AASHTO-LRFD 2007, among others. Notably, elevated temperatures directly affect RF_{CR} and RF_D factors. The ultimate tensile capacity, which was the focus of the foregoing study, is reflected in the RF_D factor as shown in Equation 3 below;

$$RF_D = \frac{T_{ult_lot}}{T_D} \geq 1.1 \quad [3]$$

where, T_{ult_lot} is as defined before; and T_D is the extrapolated lot-specific tensile strength after degradation based on laboratory aging tests. Elias et al. (2009) propose that a Product-Specific Durability Study be undertaken to arrive at the appropriate design RF_D value. In such an undertaking, laboratory aging tests along with the use of Arrhenius modeling are recommended. Arrhenius modeling allows for time-temperature superposition and is widely used to forecast strength degradation in polymer science. Details on this are presented subsequently.

2. LABORATORY TESTING

This effort was geared towards evaluating the effect of elevated temperatures on the strength of geogrid. The ultimate tensile strength and failure strain of geogrid were measured in accordance with ASTM D6637.

2.1 Geosynthetic Material Evaluated

The uniaxial (UX1600MSE) HDPE geogrid from Tensar International Corporation was evaluated. A roll of the material, size 1.33 m x 61 m, was obtained and out of it, single rib samples were cut and used in the tensile testing. Industrial Fabrics Association International (2011) provides an ultimate tensile strength of UX1600MSE geogrid of 144 kN/m. This value is consistent with that reported on Tensar International Corporation's website. The recommended minimum RF_{ID} , RF_{CR} and RF_D values by Tensar International Corporation for the UX1600MSE geogrid are 1.05, 2.60 and 1.0, respectively.

2.2 Laboratory Test Temperatures

The temperature data in Table 2 was used to estimate representative test temperature ranges for use in laboratory testing. The following temperature ranges were selected arbitrarily: <27°C, 27 - 32°C, 32 - 38°C, 38 - 43°C, 43 - 49°C and >49°C. The average percentage of time, in days, for which a temperature range is exceeded in a year, was then computed and the results plotted in Figure 2(a). According to Figure 2(a), on average, the hourly air temperature in Las Vegas exceeds 30°C for 33% of the time in a year. This amount of exposure to elevated temperatures may not be trivial to GRS wall performance.

Further, using the results in Figure 2(a) the annual exposure time to the selected range of temperatures was computed and the results graphed are shown in Figure 2(b). A year was considered to have 360 days, consistent with 30-day month analysis periods in the MEPDG procedure. From the results in Figures 2(a) and 2(b) it was decided that the elevated temperatures for laboratory testing would be 20°C, 30°C and 40°C. 20°C was included as being on the lower end of the 30°C threshold and also because it is the standard test temperature as per ASTM D6637.

2.3 Laboratory Test Setup and Testing

The ASTM D6637 procedures were used with the higher test temperatures mentioned in the previous section. In other words, all other requirements of the test standard were adhered to except the test temperature. An environmental chamber to facilitate elevated and controlled temperature testing was constructed around the Universal Testing Machine (Figures 3(a) and 3(b)).

Preliminary testing included both unconditioned (fresh) and conditioned geogrid samples. The fresh samples represent strength properties at the early stages of service (i.e. immediately after construction) whereas conditioned geogrid represents the aged material in the field. Conditioning constituted hanging geogrid samples in a forced air draft oven (Figure 3(c)) at 91°C for durations of 1, 5, 10 and 30 days i.e. heat-aging. The conditioning temperature was selected as the high end of the range recommended for HDPE polymers by Elias et al. (2009) while the choice of conditioning durations was limited by project duration and budget. Different conditioning durations provide a simple means of evaluating tensile strength property changes with age in the field.

Testing was conducted on a single longitudinal rib cut from a grid sample. The effective length of rib under tension was 0.44 m. The test was conducted at a constant rate of extension of 10% per minute at 20°C, 30°C and 40°C. A total of 5 replicates were tested for each sample category.

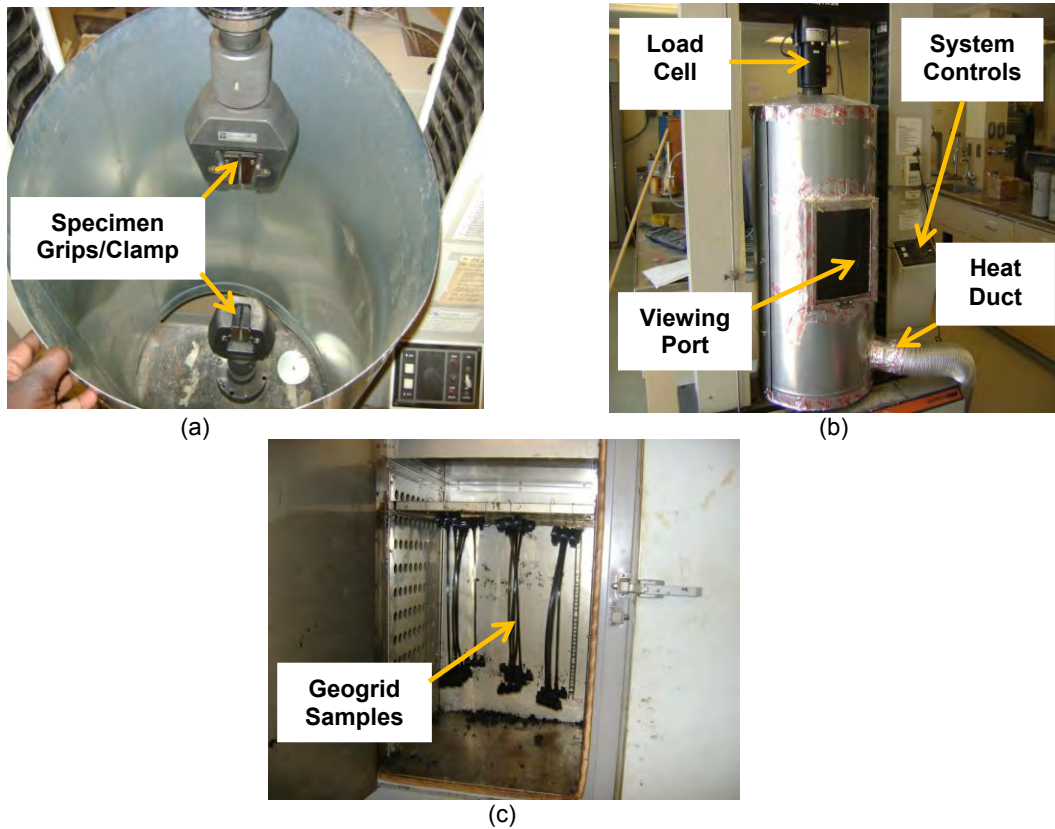

Figure 3. (a) Plan view inside chamber; (b) Chamber in front elevation view; (c) Oven conditioning of Geogrid samples

2.4 Results and Discussion

Table 4 shows a summary of the test results. Tensile strength ratios were calculated by normalizing the conditioned value at the test temperature with the unconditioned value at the same temperature. Failure strain ratios were calculated in a similar manner. When ratios are greater than 100%, the property is higher at the elevated test temperature.

The data obtained on fresh samples showed a decrease of 8% in ultimate tensile strength at 30°C and a further 15% decrease at 40°C. This is based on tensile strength ratios calculated by normalizing the value at elevated temperature

with that at 20°C. In a similar manner, the data showed a 12% increase in strain required to develop the peak tensile strength at 30°C and a further 13% increase when the temperature increased to 40°C. The latter is believed to be due to the geogrid becoming slightly more ductile as test temperature increased. This would most likely result in more distress in the form of higher MSE wall deformations before failure. Further investigation is necessary to address this issue. The data obtained on the heat-aged geogrid samples showed that overall, sample conditioning increased both the ultimate tensile strength and the failure strain of the geogrid at the elevated temperatures. However as expected, for a given conditioned sample (i.e. same conditioning duration) the ultimate tensile strength decreased as the test temperature increased. Additionally, for a given test temperature, both the ultimate tensile strength and failure strain generally increased with conditioning duration.

It is worth noting that results of tensile tests conducted in air are conservative compared to observed in-soil behavior. In-soil behavior is such that under load, both soil and geogrid deform and stresses develop within the geogrid. Upon load withdrawal, McGown et al (1995) report that the geogrid attempts to recover its original shape but this is resisted by the soil particles within the geogrid apertures. This results in locked-in stresses in the geogrid which are transmitted to the trapped soil as compressive stresses. It is the presence of residual tensile strains in the geogrid, as shown by McGown et al (1995) that indicates presence of these locked-in stresses. However, the in-air tensile test results discussed above are invaluable to defining overall trends in the material behavior under elevated temperatures.

3. PROPOSED DESIGN FRAMEWORK

In order to account for the effect of elevated temperatures on long term performance of geogrid reinforcement, a design framework was proposed as shown in Figure 4. The design framework is such that results from both Arrhenius and thermal modeling are required to modify the design. These are explained in the following sections.

Table 4. Results of tensile strength testing on both conditioned and unconditioned samples

Conditioning Time, days	Ultimate Tensile Strength, kN/m	Tensile Strength Ratio, %	Tensile Strain at Failure, %	Failure Strain Ratio, %
Testing Temperature = 20°C				
0	141.7	100	11.3	100
1	149.6	106	13.8	122
5	150.7	106	14.2	126
10	154.5	109	15.1	134
30	151.9	107	16.3	144
Testing Temperature = 30°C				
0	130.0	100	12.7	100
1	127.1	98	14.9	117
5	131.9	101	16.8	132
10	129.7	99	15.8	124
30	130.9	106	15.9	125
Testing Temperature = 40°C				
0	109.2	100	14.1	100
1	105.4	97	15.0	106
5	113.6	104	16.4	116
10	114.5	105	17.1	121
30	108.9	99	17.0	121

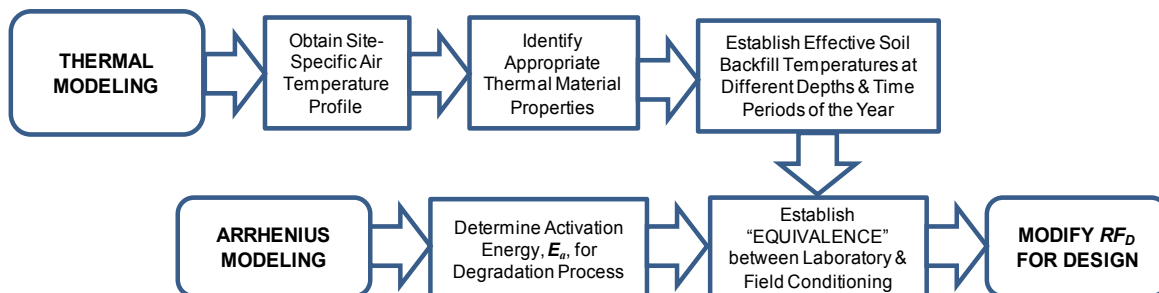

Figure 4. Elements of the proposed design framework to account for effect of elevated temperatures

3.1 Arrhenius Modeling

Arrhenius modeling, which is based on time-temperature superposition, is the predictive technique most widely used by industry for polymer degradation (Elias et al. 2009). It uses material behavior under predefined testing conditions (time and temperature) to predict similar behavior under field conditions and/or vice versa. The process involves conditioning the polymeric material at high temperatures, followed by laboratory testing to define physical or chemical properties so as to extrapolate the experimental behavior to a site-specific and lower temperature (Koerner et al. 1992). In the foregoing study, the ultimate tensile strength of geogrid was the physical property of interest. Arrhenius modeling is ideally suited to account for the effect of elevated temperatures on selection of design long-term tensile capacity of geogrid reinforcement.

The rate of polymer degradation is temperature-sensitive and can be modeled using the Arrhenius rate equation shown below in Equation 4.

$$K = Ae^{\frac{-E_a}{RT}} \quad [4]$$

Where: K is the rate constant at temperature, T, in Kelvin; A is the pre-exponential factor; E_a is the activation energy, or minimum energy required for intermolecular movement to occur, in Jmol^{-1} ; and R is the universal gas constant ($8.3136 \text{ Jmol}^{-1}\text{K}^{-1}$). Based on a melting point range of 120 – 130°C typical of medium and high density polyethylene, 116°C was selected as the highest conditioning temperature so as to ensure significant changes in the ultimate tensile strength of the geogrid. Subsequently, 93°C and 104°C were also selected since additional conditioning temperatures are required to complete the Arrhenius modeling scheme. The geogrid was conditioned at these temperatures in a forced draft oven for various exposure times.

Geogrid samples were retrieved from ovens after various exposure times and were immediately tested for ultimate tensile strength at 20°C in accordance with ASTM D6637. Table 5 shows the results of this effort. The percent reduction in strength is calculated with reference to the unconditioned value i.e. strength at zero days.

Table 5. Results of tensile strength testing on retrieved samples for Arrhenius modeling

Aging Time, days	T = 93°C		T = 104°C		T = 116°C	
	T _{ult} , kN/m	% Strength Reduction	T _{ult} , kN/m	% Strength Reduction	T _{ult} , kN/m	% Strength Reduction
0	141.7	0.0	141.7	0.0	141.7	0.0
1	141.0	0.5	139.2	1.8	135.4	4.5
10	-	-	136.0	4.1	-	-
15	-	-	-	-	92.9	34.5
20	-	-	-	-	89.5	36.8
30	138.1	2.6	128.4	9.4	82.1	42.1
50	-	-	118.6	16.3	-	-
60	136.4	3.8	-	-	-	-
72	134.6	5.1	-	-	-	-

Based on these results, linear regression analysis of percent strength reduction versus exposure time was used to compute the strength degradation rate constant, K for each of the conditioning temperatures. In such linear regression, K is simply the slope of the straight line as seen in Figure 5(a). Rearranging Equation 4 reveals that when the natural logarithm of K is plotted against the inverse of temperature, T, a straight line with slope, $-E_a/R$, is obtained (Figure 5(b)). This enabled determination of activation energy, E_a , as $16696.5 \text{ Jmol}^{-1}$, for the tensile strength degradation process evaluated. From Figure 5(b), Equation 6 provides the relationship that can be used to estimate the reduction rate in ultimate tensile strength at various temperatures.

$$\ln K = -20051 \left(\frac{1}{T} \right) + 51.97 \quad [6]$$

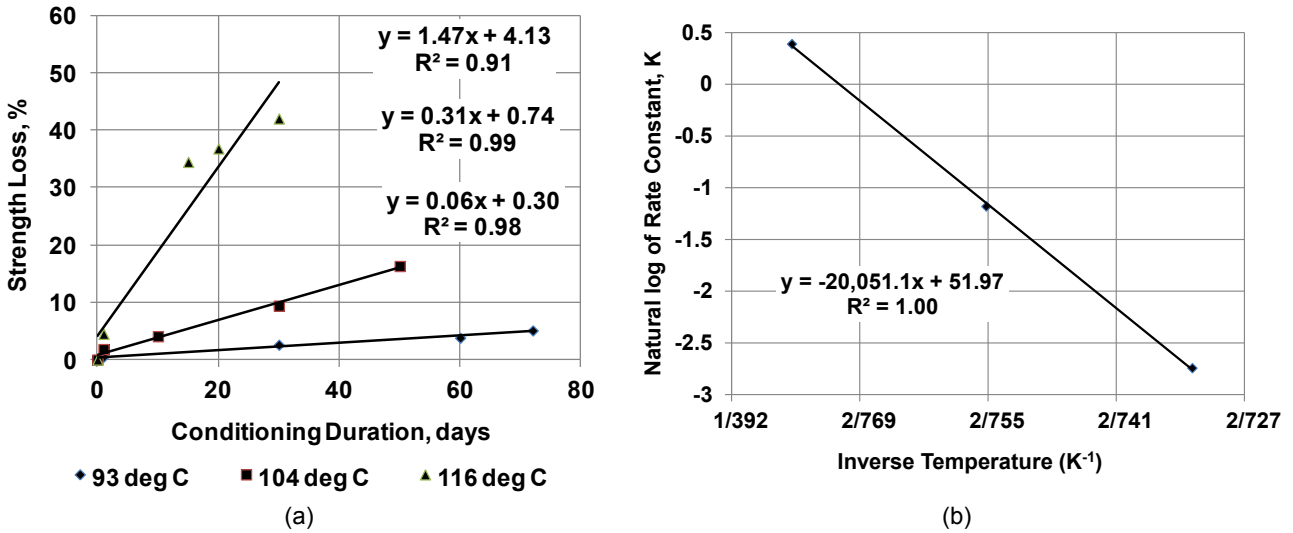

Figure 5. (a) Linear regression analysis of test data to determine strength degradation rate, K; (b) Determination of Arrhenius equation parameters

3.2 Thermal Modeling

3.2.1 ANSYS Modeling

In order to estimate soil backfill temperatures, a one-dimensional (1D) transient heat flow analysis was conducted using the finite element-based solver/software, ANSYS Fluent 12.1. The mid-section of the Tanque-Verde wall shown in Figure 1 was selected for modeling purposes. The trends of the concrete face panel and soil backfill temperature data in Figure 1 suggest that the soil backfill temperatures in the top section are influenced by the concrete pavement at the top while those in the bottom section are influenced by the absorptive nature of the in-situ soil acting as a heat sink along with presence of a hot mix asphalt layer to the bottom left of the wall. Focus was therefore given to the mid-section where 1D modeling may be appropriate. The model consists of a concrete face panel section and an adjacent soil backfill section, which is the primary area of interest. Figure 6 shows a schematic of the model with the appropriate dimensions. To make the problem 1D, the upper and lower boundaries of the mid-section were made insulated, as shown in Figure 6. An insulated boundary condition was also applied at the far end of the soil since temperature there remains relatively unchanged. It is believed that numerical modeling is an ideal tool for estimating soil backfill temperatures where no field data are available.

Figure 6. Schematic diagram of the 1D transient heat flow analysis model

The domain was uniformly meshed with square elements of size 0.005 m. A time increment of 450 s was selected as the time step size for the transient solution and a total of 20 iterations for every time step was used.

3.2.2 Thermal Material Properties

The thermal material properties of interest in heat flow analyses include thermal conductivity (K), density (ρ) and specific heat (C_p). These were carefully selected based on the collation presented in Table 6 which provides a summary from different sources. Medium weight concrete was used for the concrete face panel since it is typically non-structural. As such, its thermal conductivity was selected as 1.194 W/m $^{\circ}$ C which corresponds to a density of 1920 kg/m 3 (Neville 2009). Its specific heat was selected as 840 J/kg $^{\circ}$ C, resulting in a thermal diffusivity of concrete face panel of 7.4×10^{-7}

m²/s which is within the range (Neville 2009). Thermal diffusivity (ψ) is the ratio of thermal conductivity to the product of density and specific heat.

Table 6. Summary of relevant thermal material properties from different sources

Thermal Property	Concrete Face Panel	Soil Backfill (Sandy)	Source
Thermal Conductivity (K), W m ⁻¹ °C ⁻¹	0.1 – 0.7	0.15 - 2	Engineering Toolbox, 2012
	-	4.5 – 7.1	Geo Studio, 2010
	0.360 – 1.488	-	Neville, 2009
	-	0.25 – 2.5	Mitchell et al. 2005
Density (ρ), kg m ⁻³	-	0.23 – 2.8	Jumikis, 1966
	1120 - 2080	-	Neville, 2009
Specific Heat (C_p), J kg ⁻¹ °C ⁻¹	-	1900 - 2000	Jumikis, 1966
	895	830	Engineering Toolbox, 2012
	840 - 1170	710	Geo Studio, 2010
	-	-	Neville, 2009
	-	2.4 + 427 ω /100 g *	Mitchell et al. 2005
Thermal Diffusivity, (ψ), m ² s ⁻¹	653	837	Jumikis, 1966
	5.6 x 10 ⁻⁷ – 2.0 x 10 ⁻⁶	-	Neville, 2009

* ω is water content based on mass and g is acceleration due to gravity

Assuming 4% water content for the soil backfill and selecting a density of 1900 kg/m³ (Jumikis, 1966) as reasonable, the thermal conductivity of the soil backfill was selected as 1.5 W/m/°C and specific heat as 878 J/kg/°C (Mitchell et al. 2005). This gives a thermal diffusivity of soil backfill of 9.0 x 10⁻⁷ m²/s and this was used in the modeling.

3.2.3 Boundary and Initial Conditions

Equation 7 (Jumikis, 1966) is the governing equation for the 1D transient heat flow analysis with x as the horizontal distance from the exposed surface of the concrete face panel to the interior of the soil backfill.

$$\frac{\partial T}{\partial t} = \psi \frac{\partial^2 T}{\partial x^2} \quad [7]$$

Equations 8 – 11 show the boundary and initial conditions that were used in the modeling.

$$T(x = 0, t = 0) = T_{s,avg} \quad [8]$$

$$T(x > 0, t = 0) = T_{s,avg} \quad [9]$$

$$T(x = 0, t > 0) = T_s \quad [10]$$

$$\frac{dT(x = 1.2, t > 0)}{dx} = 0 \quad \text{(Boundary condition at right hand side or far-end of domain)} \quad [11]$$

where; $T_{s,avg}$ is the average surface temperature also assumed to be the initial temperature, and T_s , the concrete face panel surface temperature assumed to follow a sinusoidal function with time, t, as shown in Equation 12 and Figure 7. A similar sinusoidal temperature variation was also suggested by Bonaparte (1987).

$$T_s = T_{s,avg} + \Delta T_s \sin(\omega t - \phi) \quad [12]$$

where: $\Delta T_s = T_{s,max} - T_{s,avg} = T_{s,avg} - T_{s,min}$; $\omega = \frac{2\pi}{T}$, T = period = 24 hours; and ϕ is the phase shift.

Figure 7. Sinusoidal temperature variation at the concrete face panel surface

Based on Figure 1, 45°C was used as the maximum surface temperature in the analysis, and $T_{s,avg}$ was taken as 29.4°C, which is the measured soil backfill temperature at the far end. In case surface temperature is unknown, it can be determined from air temperature (T_{air}) using Equation 13 in which ΔT is the increase due to solar radiation as suggested by Bonaparte (1987).

$$T_s = T_{air} + \Delta T \quad [13]$$

Obtaining site-specific data such as that shown in Table 2 would be helpful in obtaining T_{air} .

Figure 8. Transient temperature profiles at different soil backfill locations

Figure 9. Comparison between Tucson, AZ field-measured data and computed data from ANSYS modeling

3.2.4 Thermal Modeling Results

In order to establish the time it takes for a steady state condition to occur, temperature-time histories were evaluated using ANSYS at different soil backfill locations as shown in Figure 8. According to Figure 8, steady state is reached after about 60 days. However the field measured temperature at $x = 0.35$ m, in the soil backfill, occurs between the first and third day. This is explained by the fact that the field data were taken in June, which is early summer, with yet more heating to occur in the latter parts of the summer. In addition, the initial temperature (29.4°C) was set high enough to match computed data with field data at an early stage of simulation. It is also worth noting that locations closer to the concrete face panel (i.e. $x = 0.2$ m and $x = 0.35$ m) exhibit significant temperature fluctuations compared to those that are deeper in the interior of the soil backfill. This is because the former are more influenced by air temperature fluctuations due to their proximity to the exposed surface. Figure 8 also shows that the temperature gaps between points reduce as the system approaches quasi steady state condition.

Based on the results from Figure 8, the spatial temperature distribution was plotted for different times of simulation as shown in Figure 9. In all cases since the backfill temperatures were measured at 3:00 pm on June 16, 1986, the computed temperature values also correspond to those at 3:00 pm. This time of day corresponds to the highest temperature value in the daily variation shown in Figure 7. It is clear from Figure 9 that the computed data matched well with the field data after about 36 hours of simulation, which falls on the second day.

3.3 Integration of Elements of Design Framework

As noted above in Figure 4, there are many elements that need to be integrated to account for the role of elevated soil backfill temperatures. The following steps outline the proposed design framework.

- a. Establish site-specific air temperature profile data, such as those shown in Table 2, for the selected site of interest (section 1.2);
- b. Undertake thermal modeling to establish the temperature profile within the soil backfill (section 3.2);
- c. Using Arrhenius modeling, determine the percent strength loss (or reduction) per day versus inverse of temperature relationship to evaluate the strength loss (section 3.1, Figure 5(b));
- d. Integrate the steps a and b above to evaluate the total strength loss, progressively as a function of time, over the entire life time of the geosynthetic reinforcement;
- e. Evaluate a conservative estimate for RF_D that can be used in design so that the role of elevated temperature is accounted for in future designs of GRS walls

The proposed design steps are consistent with the Product-Specific Durability Study proposed by Elias et al. (2009).

The ANSYS modeling conducted to establish the backfill temperature utilized a simple 1D model. Though this may be appropriate for the mid-section of the GRS walls, a more appropriate 2D model that allows for the role of the concrete pavement and other boundary conditions (e.g. in-situ or foundation soil conditions) may be required. In addition, this

study focused on tensile strength degradation only. Another design concern is creep and this also can be of importance, since geosynthetics undergo noticeable creep under elevated temperatures.

4. CONCLUSIONS

This study showed that limitation of long term static design air temperature to 30°C imposed by current design manuals (AASHTO 2002a and AASHTO-LRFD 2007) presents a dilemma relative to undertaking geogrid reinforced soil wall designs in Southern Nevada. Using laboratory and field data, a design framework to address this issue has been proposed. Both Arrhenius and thermal modeling are presented as integral parts of the proposed design framework. Following are the conclusions that were made from this study.

- a. Geogrid reinforcement exhibits temperature-sensitive behavior as evidenced by the ultimate tensile strength results conducted in accordance with ASTM D6637 under temperatures ranging from 20°C to 40°C on both fresh and conditioned samples. Conditioning, which was conducted under elevated temperatures ranging from 91°C to 116°C, constituted heat aging in an oven at various exposure times.
- b. Using Arrhenius modeling principles, the activation energy, E_a , of the evaluated geogrid material was established as 134522 Jmol^{-1} . This activation energy relates degradation of tensile strength with time and temperature.
- c. A one-dimensional heat flow analysis was undertaken using ANSYS Fluent 12.1 software to model soil backfill temperatures. By comparing computed data with field-measured data from the Tanque-Verde geogrid-reinforced soil wall in Tucson, AZ, it was shown that thermal modeling is capable of predicting soil backfill temperatures based on air temperatures. This is particularly useful where no field data are available.
- d. A major phase in the proposed design framework is the integration of laboratory-measured degradation of tensile strength and the elevated backfill temperature. This is helpful in predicting long term geogrid performance in the soil backfill. A step by step procedure to accomplish this undertaking is outlined in the paper.
- e. The paper addressed only the tensile strength degradation brought on by elevated temperatures and thermal modeling was limited to a 1D model using ANSYS. The investigation of the role of creep and 2D temperature modeling may be important.

ABSTRACT

The objective of this study was to evaluate the performance of geosynthetic-reinforced aggregate bases for unpaved roads over soft subgrade using laboratory plate load test. The model tests were conducted in a 1.5 m long, 0.91 m wide, and 0.91 m deep steel test box. The load was applied through a 190.5-mm diameter steel plate. The parameters evaluated in this study included the thickness of aggregate base surfacing, the location and tensile modulus of geosynthetics, and the number of geosynthetic reinforcement layers. Test results indicated that the geosynthetic reinforcement resulted in appreciable reduction of surface deformation and increase of bearing capacity for unpaved aggregate base over soft subgrade. The test results also showed obvious effects of the geogrid arrangement/location on the unpaved test section's performance, with the double reinforcement location consistently yielding the largest improvement. Higher tensile modulus geosynthetics performed better than others. Greater improvement due to geosynthetic reinforcement was seen for test sections with thinner aggregate base surfacing.

1 INTRODUCTION

Weak subgrades are a common problem in road construction. Whether it is a temporary access road or a permanent road built over a weak subgrade, a large deformation of the subgrade can lead to deterioration of the paved or unpaved surface. The use of geosynthetic material in unpaved roads built over a weak subgrade is known to provide a reinforcing benefit to the roadway sections. Geogrids and geotextiles help distribute the loads more efficiently, increase the effective bearing capacity of the subgrade, and hence provide a better alternative to costly, conventional, stabilization methods. Geosynthetic materials have been widely used as reinforcement in structures with unbound materials, such as pavements, slopes, retaining walls, and embankments. Geosynthetic stabilization and reinforcement is a mechanical process. Geosynthetics placed either on top of the subgrade or within the base course layer, works with the soil and granular material to create a reinforced section through separation, confinement, and/or reinforcement functions. Several studies have shown that in a pavement system, the inclusion of geosynthetic materials at the interface between the pavement base course and subgrade can significantly improve the performance of the pavement structure on a weak subgrade, based on both laboratory tests and full-scale field experiments (Barksdale et al. 1989, Al-Qadi et al. 1994, 2007, Perkins 1999, Hufenus et al. 2006). Due to the soft nature of Louisiana soils, it is a common practice to stabilize the subgrade layer to create a working platform for pavement construction. For pavements built over weak subgrade, distresses are first identified along the wheel path, followed by top-down cracks (Tarefder et al., 2008). Advanced pavement distresses are inclusive of widening longitudinal cracks, side-by-side cracking, rutting, shoving, and potholes. Weak subgrade may be stabilized, using geosynthetic materials as an alternative to lime or cement stabilization, to create a working platform and to resist the surface vehicular load. Geosynthetic material (mainly geogrids) may also be used to reinforce the base layer within the pavement section.

2 OBJECTIVES AND SCOPE

The main objective of this research is to evaluate the performance of geosynthetics (geogrids and geotextiles) to stabilize subgrade and/or to reinforce base course layers in unpaved test sections. For this purpose, extensive small-scale in-box static plate load tests (PLTs) were conducted on several unreinforced and geosynthetic reinforced unpaved test sections. The parameters investigated in this study included the location of geosynthetic material, geosynthetic tensile modulus, number of geosynthetic layers, and base course layer thickness.

3 MATERIAL PROPERTIES AND TEST PROGRAM

3.1 Material Properties

Two different types of geomaterials (silty clay and Kentucky crushed limestone soils) were used in this research study. The silty clay soil used in this study is a marginal embankment soil with low to medium plasticity that is often encountered in embankments in southern Louisiana. The soil has a maximum dry density of 1,670 kg/m³ and an optimum moisture content of 18.75% as determined by the Standard Proctor test. From the Atterberg Limits test, the silty clay is classified as CL according to the Unified Soil Classification System (USCS), and A-6 according to the American Association of State Highway and Transportation Officials (AASHTO) classification systems. The crushed limestone has a maximum dry density of 2,418 kg/m³ and an optimum moisture content of 6.6%, as determined by a modified Proctor test. It is classified as GW and A-1-a according to the USCS and AASHTO classification system, respectively.

The small-scale laboratory PLTs were conducted inside a test box at the Geotechnical Engineering Research Laboratory (GERL) of the Louisiana Transportation Research Center (LTRC). The model tests were conducted inside a steel test box with dimensions of 1.5 m (length) × 0.91 m (width) × 0.91 m (height). The method of performing PLTs on subgrade soils and pavements are described by ASTM D1196-93. Nonrepetitive static plate load tests were performed on soils, as well as unbound base and subbase materials, in order to determine the modulus of subgrade reaction or to measure the shear strength of pavement components. A loading device, a hydraulic jack, bearing plates of 7.5-in. (190 mm) dia, dial gages (two or more), a reaction frame, and a deflection beam were used in the static plate load test.

Several types of geogrids and geotextiles were used in this research study. Biaxial geogrids BX1100, BX1200, BX1500, BXG10, BXG11, BXG12 with rectangular aperture shape, triaxial geogrids TX5, TX6, TX7 with triangular aperture shape, and geotextile RS580i and RS380i were used to stabilize the subgrade and/or reinforce the base material in unpaved test sections. The physical and mechanical properties of these reinforcements as provided by the manufacturers are listed in Table 1.

3.2 Section Preparation and Compaction Control

The subgrade soil was first placed and the required amount of water was added to achieve the desired moisture content. The soil was compacted inside the box, using a 203 mm × 203 mm plate, adapted to a vibratory jack hammer to a predetermined height to achieve the required density. The jackhammer delivers compaction energy of 58.3 m.N and blows at a rate of 1,400 per minute. The preparation of crushed limestone base layer followed the same procedure as the subgrade layer.

The crushed limestone was placed on top of the subgrade layer inside the test box with the required depth; then water was added. The compaction-quality control processes to achieve the required soil densities were accomplished by conducting three passes of vibrating compaction: the compaction effort was applied through the plate for approximately ten seconds in the first pass, five seconds in the second pass, and two seconds in the third pass at each location.

The dry densities measured by the nuclear density gauge varied from 1,570 to 1,630 kg/m³ for a subgrade, silty clay layer and the moisture contents varied from 21.5 to 22.5%, to achieve a weak subgrade of CBR≈1. The corresponding resilient modulus from geogauge stiffness moduli (EGG) ranged from 9.5 to 11.8 MPa, and from the light falling weight deflectometer stiffness moduli (ELFWD) ranged from 8.6 to 9.8 MPa.

The measured-in-place dry density and water content of the crushed limestone base course layer were 2,290 to 2,340 kg/m³ and 4.0 to 5.5%, respectively. The corresponding geogauge stiffness moduli (EGG) were in the range of 160 to 220 MPa. A Dynamic Cone Penetrometer test was also used in the crushed limestone base course layer, and the measured penetrometer values in mm/blow were in the range of 4 to 9 mm/blow. The corresponding resilient moduli from geogauge stiffness moduli (EGG) were in the range of 81 to 86 MPa. The corresponding resilient modulus from light falling weight deflectometer stiffness moduli (ELFWD) were in the range of 38 to 40 MPa for 305 mm, 46 to 47 MPa for 457 mm, and 35 to 38 MPa for 203 mm thick base course layer. The corresponding resilient moduli from DCPI were in the range of 34 to 41 MPa.

3.3 Experimental Testing Program

The in-box static plate load tests were conducted to evaluate the performance and benefits of geosynthetic stabilized subgrade and geosynthetic base reinforcement in unpaved test sections. A total of 47 tests were performed on unreinforced and geosynthetic stabilized/reinforced unpaved test sections. Three different thicknesses in base course layers were used in this research. The parameters investigated in this study included the number of geosynthetic reinforcement layers, the location and tensile modulus of the geosynthetics, and the thickness of aggregate surfacing layer. The test results showed that the inclusion of geosynthetic materials can significantly improve the performance of unpaved sections over weak subgrades [California Boring Ratio (CBR) ≤ 1%]. Table 2 summarizes the testing program and test variables.

4 TEST RESULTS AND ANALYSIS

The results of the in-box static plate load tests for unpaved test sections are summarized in Table 2. In this table, the BCR values were determined at 25 mm (1-in.) and 51 mm (2-in.). Table 2 presents the results for the 305 mm (12 in.) thick base course layer; Table 3 presents the results for the 203 mm (8 in.) thick base course layer; and Table 4 presents the results for the 457 mm (18 in.) thick base course layer.

4.1 Effect of Reinforcement Location

The location of geosynthetic reinforcement within the base course layer is one important factor on the performance of unpaved sections. For the 457 mm thick base course layer section, the use of reinforcement at interface is not so effective. From Table 4, one can see that for geosynthetic reinforcement at the interface location in 457 mm thick base course layer, the BCR values are not significant. Whereas, geosynthetic reinforcement located at mid depth or the upper one-third position shows better improvement than at the interface location. For example, at 51 mm settlement, the BCR increased from 1.06 to 1.11, with a layer of TX7 reinforcement placed at interface and at the upper one-third position of the base course layer, respectively. Also at 25 mm settlement, the BCR increased from 1.06 to 1.11, with a layer of TX7 reinforcement placed at interface and at the upper one-third position of the base course layer, respectively. Similar performance was observed for a layer of BXG11 reinforcement. Therefore, based on the laboratory test results of the unpaved test section, the optimum location of reinforcement is located at the upper one-third position of thick base course layer.

However, for a thin base course layer like 203 mm of thick crushed limestone base, placing geosynthetic reinforcement at the interface location is very effective (Table 3). The BCR values were also improved significantly in a 203 mm thick base course layer (up to 1.42) through the use of different types of reinforcements. For the 305 mm thick base course layer, the BCR value showed an increase from 1.21 to 1.25 by moving the TX7 reinforcement from the interface to the upper one-third position of base course layer. From Figure 1, one can see that when geogrid reinforcement is placed at the upper one-third position of a base course layer, rather than at an interface location, BCR values will increase.

Figure 1 BCR values for unpaved test sections with geosynthetic reinforcements placed at different locations

4.2 Effect of Number of Reinforcement Layers

A series of in-box static plate load tests were conducted on unpaved test sections, where two layers of geosynthetic material were used. One geosynthetic layer (geogrid or geotextile) was placed at the base-subgrade interface and the other geosynthetic layer (geogrid only) was placed at the upper one-third of the base course layer. As expected, the BCR increased as the number of reinforcement layers increased. For example, at a 51 mm settlement for the 305 mm thickness base course layer, the BCR increased from 1.11 to 1.43 for the BX1200 geogrid; 1.09 to 1.39 for the TX5 geogrid; and 1.21 to 1.46 for the TX7 geogrid. The combination of RS580i and BXG11 gave the best performance in the 305 mm base course layer. By using the RS580i and BXG11, the BCR increased from 1.28 (only RS580i) to 1.53 (RS580i+BXG11). For the 457 mm thickness base course layer at a 51 mm settlement, the BCR

increased from 1.03 to 1.28 for the BX1200; 1.03 to 1.22 for the TX5; and 1.06 to 1.31 for the TX7. Again, the RS580i and BXG11 combination demonstrated the best performance in the 457 mm base course thick layer, where the BCR increased from 1.11 (only RS580i) to 1.33 (RS580i+BXG11). Figure 2 depicts the BCR values of 305 mm and 457 mm thick base course layer reinforcements. Using RS580i and BXG11 combination in these base course layers allowed a performance better than any other combination of reinforcement. Among the two-layer geogrids, the triangular TX7 geogrid performed better than BX1200 and TX5 geogrids. From this research, we obtained BCR values of 1.53 and 1.36 in 305 mm and 457 mm thickness base course layer sections respectively, by placing RS580i geotextile at interface and BXG11 at the upper one-third of the section.

Figure 2 BCR values for unpaved test sections with double reinforcement layers

4.3 Effect of Tensile Modulus of Reinforcement

Eleven different types of geosynthetic reinforcements with different strength/modulus were used in the in-box, unpaved, static plate load tests. These include biaxial geogrids: BX1100, BX1200, BX1500; and BasXgrid10, BasXgrid11, BasXgrid12 geogrids; triaxial geogrids: TX5, TX6, TX7; and RS580i, RS380i geotextiles. The properties of these reinforcements were presented earlier in Table 1. The comparisons between the different types of geosynthetic reinforcement, in terms of bearing capacity ratio versus strength/modulus are described in Figure 3a and Figure 3b, for the 305 mm, and 203 mm thick base course layer sections with geosynthetic reinforcement placed at the base-subgrade interface. From the figures, one can see that the bearing capacity generally increases with the increase of the tensile modulus of the reinforcement. The tensile modulus-related increase in the BCR is more appreciable at low tensile modulus, and the effect gradually decreases as the tensile modulus increases. For the unpaved test section studied herein, the BCR increased almost linearly when the geosynthetic tensile modulus increased from 267.5 to 550 kN/m. After that, the BCR increased at a much lower rate and appeared to approach a limiting value at a tensile modulus of 750 - 800 kN/m.

Figure 3 BCR versus tensile modulus for single layer reinforcement placed at the interface.

4.4 Effect of Different Thickness Base Course Layer in BCR

Figure 4 presents a comparison between the 203 mm, 305 mm, and 457 mm thick crushed limestone base course layer sections with different types of geosynthetic reinforcement placed at the base-subgrade interface. From the figure, one can see that for the 203 mm base course layer section, the improvement in bearing capacity values is the highest, when compared with the 305 mm and the 457 mm thick base course layer sections. The BCR values decreased as the thickness of base layer increased for all types of geosynthetic reinforcement. However, the BCR values were not the same for each base course thickness as discussed earlier, since the BCR also depends on location, geometry, and tensile modulus of geosynthetics.

Figure 4 BCR values for 203 mm, 305 mm, and 457 mm thick base course layer sections with geosynthetic reinforcements placed at base-subgrade interface.

5 CONCLUSIONS

Based on the results of the present study, the following conclusions can be drawn:

1. The bearing capacity ratio (BCR) generally increases with the increase in tensile modulus of geosynthetic reinforcement (up to 1.53) and approaches a limit value as the tensile modulus of geosynthetic reinforcement exceeds 550 kN/m.
2. Placing the geosynthetic material in the double location yielded the largest improvement. For the single layer of reinforcement, the upper one third locations yielded highest improvements.

3. The geogrid benefits were more appreciable in sections with thin base course layer compared to those in sections with thick base course layer.

Lake Tahoe California Lake Shore Bluff Stabilization and Restoration

J.P. Chinchio, Landslide Solutions, Inc., United States of America

ABSTRACT

Restoring the natural look of an area following a landslide or severe erosion repair can often rank just as high a project priority as the actual stabilization. This paper presents a non-traditional biotechnical stabilization and restoration approach using ballistic soil nails, galvanized steel mesh and native plant impregnated coconut fiber geocells in an area prone to rotational slope failures along the western shore of Lake Tahoe, California. Working within stringent Tahoe Regional Planning Agency (TRPA) guidelines, the project produced a restored shoreline face with a walking path through a newly stabilized high bank waterfront property. In addition to preventing further rotational failures, the approach mitigated widespread surface erosion and sloughing of the shoreline face. Traditional methods of mechanical slope stabilization such as benching, shotcreting, or anchoring would have been effective at stabilizing the shoreline movement and accommodating a new walking path. However, those approaches would have substantially altered the appearance of the shoreline and would have been unacceptable to TRPA and the property owners. In this case study, the benefits of biotechnical stabilization were crucial to the acceptance of the project. A combination of ballistic soil nails and custom vegetated mats both stabilized the existing rotational failure and provided anchorage points for the vegetated mats. That concept allowed cuts up to six vertical feet in the unstable sandy silt shoreline material. Working close to a protected lake and establishing plantings in the semi-arid Lake Tahoe environment presented real challenges, but a biotechnical stabilization system using mechanical elements and appropriate high mountain desert native vegetation met both the structural and aesthetic demands of the project.

1. THE SITUATION

Bluff erosion and stability is an ever present problem along the shoreline of pristine Lake Tahoe and one such area presented itself during the planning phase of an estate reconstruction project along the west shore of Lake Tahoe. The inherent problem of an eroding unstable bluff is quite obvious. In this situation the problem was intensified by the desire to build a high end housing structure just feet from the top edge of the bluff while planning to restore the bluff face and construct a walking path to the beach below. In addition, because of tough environmental regulations, most of the work would need to take place from the top of the bluff thus requiring specialized equipment and construction techniques.

Stringent Tahoe Regional Planning Agency (TRPA) and local county permit requirements then made design and construction factors even more difficult and limited time for construction from May 1st to October 15th. The ultimate goal of the project was to protect, strengthen, support, preserve and provide global stability to the existing bluff surface all without noticeably changing the appearance of bluff.

If bluff surface erosion was not corrected at this site the bluff would have continued to erode back thus reducing usable property at the top of the bluff. If overall global stability of the slope was not corrected the housing structure would have had to be placed on a piling system sufficient enough to support the house should the bluff continue to fail.

Picture Sample of the Bluff before Construction

2. THE SOLUTION

Several stakeholders, agencies and industry professionals worked in harmony to develop the final bluff erosion and stability issue. Those entities included the owner, project architect, project civil engineer, permit specialist, geologist, landscape design / build contractor and specialty slope stabilization design / build contractor.

After considerable thought and consultation with erosion control vendors and consultants, it was decided that a hybrid biotechnical solution would be required - a smorgasboard of stabilization recipes. Ultimately, a combination of ballistic soil nails, steel wire mesh and a specialty custom vegetated coconut coir cellular confinement was chosen.

The ballistic nails were primarily chosen because of the ability to install them with minimal impact to the bluff, faster production rates relative to traditional nails and the ability to install the nails from the top of the bluff (no need for equipment on the beach). Cost was also an important factor with regards to the final decision to utilize ballistic soil nails.

Ballistic soil nails are long steel or fiberglass rods installed to reinforce or strengthen the existing ground. Ballistic soil nails are inserted using high-pressure air approaching 2500 psi (17.2 MPa) by a launcher that can be mounted on a hydraulic excavator (Figure 1). As the soil nail passes into the soil, the ground around the nail is displaced by compression at the nail tip. This forms an annulus of compression which reduces the soil drag on the nail. As the nail comes to rest, the soil rebounds onto and bonds with the nail. The soil nails reinforce the locally unstable soil mass by transferring the nail's tensile and shear resistance through the failure plane of the sliding soil. The nails maintain the resisting force because they are anchored beyond the slip plane.

In order to determine the length and spacing of the ballistic soil nails both a slope survey and a soils report were used. These documents were provided by the project geologist and information gleaned from them was imported into a commercially available slope stability software tool. The tool then calculated probable slide planes under varying circumstances and at a defined Factor of Safety (FoS). An appropriate FoS at this site was determined to be 1.5, effectively meaning that the repair is capable of handling 50% more than the maximum expected load. Without any stabilization measures the stability of the slope was approximated at a FoS 1.0. With the installation of ballistic nails on 5-ft x 5-ft spacing it was determined the slope could be augmented to reach the targeted FoS 1.5 (Figure 2).

Figure 1 - Installation of Ballistic Soil Nails

Figure 2 – Slope W Output File

Galvanized wire mesh was then attached to the tips of the nails with the purpose of providing cohesiveness to the ballistic soil nail system, a medium to attach the coir cellular confinement and a last defense for erosion in the event of localized coir failure (Figure 3, 4 and 5). The mesh was carefully tensioned across the entire slope face. At the bottom of the slope native rocks were hand selected and placed to provide slope buttressing and to protect against high water wave action (Figure 6). The wire mesh was installed prior to the placement of the rocks thus the rocks provided another source of tension as they were set in place.

The success of the entire stabilization system depended in large part on the erosion control and beautification provided by the vegetated surface treatment. The installation of custom vegetated cellular confinement surface treatment was installed immediately after the placement of the steel mesh and native rock. Vegetation selected for planting within the cellular confinement area included; large deeply rooted woody shrubs, forbs, sub-shrubs, ground-cover and grasses that were chosen based on esthetic appeal and ability to retain soil. In order to support these species amended soil was imported and placed within six inch deep honeycomb-configured coir cellular confinement. This biodegradable six inch deep blanket was securely anchored to the steel mesh and stretched in six foot stripes from top to bottom of the slope forming a continuous three dimensional form covering the slope.

Soil sources were tested and a biologically active green-waste composted soil formula was selected. The soil needed to hold and distribute moisture, rapidly germinate seed, grow healthy plants, texture and color to blend with native soil and adhesiveness. Soil was conveyed and packed into the coir layer.

A diverse mix of native plants was specified, ranging in size from 4" native grass plugs to 44" ball and burlap native trees. Larger tree species, Incense Cedar and Jeffery Pine were placed lower on slope to avoid being blown over by the wind. Smaller scale, slower growing native trees such as Mountain hemlock (*Tsuga mertensiana*) and Subalpine fir (*Abies larsiocarpa*) and other native shrubs were placed higher on the steepest exposed areas of bluff. The native shrubs provide shade, bird habitat and forage for fowl and small mammals. Boulder groupings pinned periodically in the slope with Launched Soil Nails™ also provided an opportunity for small mammal colonization and complimented the boulders throughout the rest of the property. Native ground covers and forbs like Squaw Carpet (*Ceanothus prostratus*) and Mountain Pride Penstemon (*Penstemon newberryi*) added color, attracting beneficial insects. Additionally, small burnet (*Sanguisorbia minor*) provided nitrogen fixing.

Five gallon and larger plants were installed in small openings cut through the cellular confinement and steel mesh. Inserting the root mass of these larger plants into the subsurface soil allowed space for root growth and trunk flare. A final mulch layer formulated with a matrix of long, medium and fine natural fibers was distributed throughout the entire area. The mulch layer was composted with a small amount of formulated soil for one week to activate microbial activity, and then firmly felted on the surface. After mulching, a seed mix of shrubs, forbs and native grass was broadcasted evenly over the mulch. A three foot wide path was constructed and surfaced with recycled rubber composite pavers. The construction process was completed by September 15, 2010. By October seed had begun to germinate and plant materials already exhibited growth. The entire planted area is now irrigated and controlled by a sophisticated irrigation controller that automatically turns the entire irrigation system off if any irrigation line breach is detected. The system controls an in-line drip irrigation system providing low volume, low impact supplemental irrigation for the first three growing seasons.

Late October 2010 brought an unusually strong rain event (4-inches within 24 hours). The stabilized area weathered the storm without an issue. Project monitoring and maintenance will continue through October 2015.

3. CONCLUSION

From conception to completion this project took more than three years. Construction took two and one half months with more than two years in planning and permitting negotiations. The project has met the expectation of all entities involved and provides an attractive natural looking footpath to the beach, stabilized slope suitable for a building above and a restored view from land and water (Figure 6).

ABSTRACT

Flexible pavement with geosynthetic reinforcement in the base course layer is typically designed using empirical techniques. The empiricism is developed from the construction of pavement test sections similar in cross section and materials to the expected design and observation of the improvement in pavement performance due to the reinforcement. Modified structural layer coefficients for the reinforced base course layer, expressed within the context of the AASHTO 1993 Pavement Design Guide, are sometimes used to express the improvements observed from these tests. However, design approaches based on these test results are often extended beyond the range of empirical evidence and often do not account for the influence of subgrade strength and overall thickness of the pavement cross section on structural improvement. Several mechanistic-empirical models for analysis and design of reinforced flexible pavements have recently been reported, which allow a thorough evaluation and confirmation of these postulated improved design values. One of these methods is used to analytically generate benefit values for a range of pavement design conditions. In this paper, the steps involved in this approach are presented. The results show the importance of the strength of the subgrade and the thickness of the proposed pavement cross section on the layer coefficient ratio.

1. INTRODUCTION

The design of flexible pavements with geosynthetic reinforcement in the base course layer is typically accomplished via empirical techniques involving the construction of pavement test sections similar in cross section and materials to the expected design and observation of the improvement in pavement performance (AASHTO, 2011). The results of these tests are often expressed in terms of an improvement in the structural layer coefficient of the base course layer, which is done within the context of the AASHTO '93 Pavement Design Guide (AASHTO, 1993) or a Traffic Benefit Ratio, *TBR*, which can then be related to an improvement in the base layer coefficient. *TBR* is defined as the ratio of traffic passes for a certain level of pavement rutting for a reinforced pavement compared to an otherwise identical unreinforced pavement. This approach requires an extensive research and testing program to establish benefit values for the range of variables known to be of influence. These variables include the subgrade strength, the thickness of the asphalt concrete, base aggregate and subbase, if present, the structural quality of these materials, the geosynthetic type and the placement position of the geosynthetic within the base layer (Berg et al., 2000).

Several mechanistic-empirical models for analysis and design of reinforced flexible pavements have recently been reported (Perkins et al. 2009, Perkins and Edens, 2003). These models have been calibrated against the type of pavement test sections suggested by AASHTO (2011). In this paper, the method by Perkins and Edens (2003) is used to analytically generate benefit values for a range of pavement design conditions involving differences in subgrade strength and overall pavement thickness. In a previous paper, Perkins et al. (2012) showed comparable results obtained by the two methods of Perkins et al. (2009) and Perkins and Edens (2003).

2. REVIEW OF DESIGN METHODS

Three empirical design methods for reinforced pavements, referred to as Manufacturer Method 1, 2 and 3, were identified that use improved structural base layer coefficients within the context of the AASHTO '93 Pavement Design Guide. References for these methods are Tenax (2001), TenCate (2010) and Tensar (2010), respectively. These methods are briefly reviewed and discussed in this section.

2.1 Manufacturer Method 1 (MM1)

MM1 was developed based on the AASHTO '93 pavement design equation and uses a Layer Coefficient Ratio (*LCR*) to modify the structural contribution of the base when reinforcement is added. *LCR* has a value greater than or equal to one and is used in Equation 1 to modify the structural number (*SN*) for use in the AASHTO '93 pavement design equation. Equation 1 can be used to calculate the required thickness of the asphalt layer (D_1) or the base layer (D_2).

$$SN = D_1 a_1 + D_2 a_2 m_2 LCR + D_3 a_3 m_3 \quad [1]$$

In Equation 1, a_1 , a_2 and a_3 are the layer coefficients for the asphalt concrete, base aggregate and subbase layers, respectively, D_3 is the subbase thickness, if present, and m_1 and m_2 are the drainage coefficients for the base aggregate and subbase layers. All layer thickness are in units of inches.

LCR was determined from test sections for a particular multilayer polypropylene extruded biaxial geogrid. Test sections were constructed in a pavement test box where a cyclic load was applied to a stationary plate (Cancelli et al. 1996). In these test sections, a fine sand subgrade was used. A subgrade with a CBR ranging from 1 to 18 was produced for different test sections by placing the sand at different dry densities. Placement of loose sand to produce low values of subgrade CBR results primarily in volumetric compaction when subject to traffic loads, which is considerably different from an undrained shear distortion pattern of deformation typical of weak soft subgrades.

From the results of the study a design chart was produced where LCR varied from 1.81 to 1.41 and was a function of subgrade CBR . The results indicated an LCR of over 1.4 for subgrade CBR values greater than 8, which corresponded to a TBR of 4.5.

Subsequent test sections were constructed in an outdoor test track and subjected to truck traffic (Cancelli and Montanelli, 1999). A clay subgrade was used in the outdoor test track and placed at a CBR ranging from 1 to 8. Results from this study were analyzed by Berg et al. (2000) and for the subgrade at a CBR of 8 a TBR of 1.6 was obtained. This produces an LCR considerably below 1.4 and is in conflict with the data presented in the design curve.

2.2 Manufacturer Method 2 (MM2)

MM2 was originally developed for reinforced pavements within the context of the 1972 AASHTO pavement design equation (Pearce, 1981). The approach is similar to that used in MM1 in that the AASHTO equation for structural number is modified by adding a term (M) to the structural contribution of the base course aggregate containing a geosynthetic (Equation 2). The design method was advanced for two woven polypropylene geotextiles. Values of M were given as a function of the CBR value of the subgrade and the design traffic for the roadway. Values of M ranged between 1.08 and 1.22. While reference was made to the use of theoretical behavior models for structural analysis (Thompson and Radd, 1979) and consideration for geosynthetics used for both separation benefits and confining effects, the basis for the M values used in the design method was not provided.

$$SN = D_1 a_1 + D_2 a_2 M \quad [2]$$

The method was recently updated and expressed within the context of the AASHTO '93 design equation for structural number. The parameter M was replaced by a Geosynthetic Structural Coefficient (GSC). Values of base course reduction (BCR) factors were provided for four polypropylene woven geotextiles and two coated polyester woven biaxial geogrids as a function of the CBR of the subgrade. Values of BCR ranged from 3.7 to 60.9 % for CBR values ranging from 20 to 0.5 with varying BCR values for each geosynthetic within that CBR range. The basis for these values was not provided. It can be shown that a relationship between BCR and LCR , which is the same as between BCR and GSC is given by Equation 3. For the BCR values listed above, GSC values ranging from 1.04 to 2.56 are obtained.

$$GSC = LCR = \frac{1}{1 - BCR} \quad [3]$$

2.3 Manufacturer Method 3 (MM3)

The MM3 design method for reinforcement of paved roads was originally developed for extruded polypropylene biaxial geogrids (Tensar, 1996). That method relied upon the use of Traffic Benefit Ratio (TBR), which is formally defined in Equation 4 as the ratio of the traffic passes carried by a reinforced and unreinforced pavement having otherwise identical pavement materials and layer thickness.

$$TBR = \frac{W_{18-R}}{W_{18-U}} \quad [4]$$

Results from tests sections by Collin et al. (1996) were used to express TBR as a function of the thickness of the base course and the allowable rut for the roadway. Results from other studies (Haas, 1985, Barksdale et al., 1989 and Webster, 1992) were used as support for the TBR values used from Collin et al. (1996). Design curves were provided for two extruded polypropylene biaxial geogrids. TBR values as a function of subgrade strength were not provided.

TBR was used to extend the performance period of the pavement by direct use of Equation 4 or to reduce the base thickness for an equivalent performance period as the unreinforced pavement. The latter was accomplished within the context of the AASHTO '93 pavement design equations by solving for the structural benefit of the base giving a particular *TBR* and using this benefit to reduce the base thickness to yield the same traffic level as the unreinforced pavement.

This approach has been updated for use with a new extruded polypropylene triangularly configured geogrid. MM3 describes how the structural layer coefficient, as used in the AASHTO '93 pavement design equation, for an aggregate base is modified for the geogrid and how it is dependent on the thickness of the asphalt concrete layer and the subgrade strength. The improvement factors for a given set of pavement design conditions are calculated from regression equations supported by various experimental studies involving the evaluation of laboratory-scale and full-scale test sections. The improvement factors are calculated within a licensed program (Tensar, 2012). The design method can be used for pavements with an asphalt thickness as great as 250 mm, however the method warns that empirical evidence for reinforcement benefit is available only up to asphalt thickness of 200 mm.

The improvement in the structural layer coefficient for various pavement design conditions was calibrated from several experimental studies, however only one study was documented and referenced. Jersey and Tingle (2010) showed results for a geogrid for a pavement with 50 mm of asphalt concrete and 200 mm of aggregate base on a subgrade with a *CBR* of 3. Other supporting studies are reported to be documented in internal reports.

The Tensar licensed program was used to evaluate *LCR* values for an unreinforced pavement cross section consisting of 75 mm of asphalt concrete and 300 mm of aggregate base and for a subgrade having a *CBR* ranging from 0.5 to 20. The program was used to evaluate *BCR* by decreasing the reinforced base thickness until a number of traffic passes equivalent to the unreinforced section was obtained. Equation 3 was then used to calculate *LCR*. Values of *LCR* ranging from 1.76 to 1.04 were obtained

2.4 Discussion of Design Methods

The three design methods reviewed predict an increase of benefit as the subgrade *CBR* decreases. The three methods predict different levels of benefit, which is partly due to each method being for a particular geosynthetic and partly due to each method being calibrated from different experimental studies. MM3 appears to limit the reinforcement benefit below a subgrade *CBR* of 3 whereas the other two methods show this benefit to continue to increase.

There are three principal limitations associated with these methods. The first involves the level of documentation associated with establishing the basis for the benefit values used in the methods. As discussed previously in this section, MM2 and MM3 do not provide adequate public documentation to allow the designer to judge the basis for the benefit values reported. MM1 provides sufficient documentation, however the use of an unrealistic subgrade and the lack of consistency with field test sections raises questions concerning the appropriateness of the benefit values reported.

A second limitation of MM1 and MM2 is the suggestion that a single benefit curve for a given geosynthetic product that is a function of the subgrade strength or modulus but is not dependent on other pavement variables. As discussed previously, reinforcement benefit is known to depend on the thickness of the pavement layers, the structural quality of these materials and the placement position of the geosynthetic within the base layer (Berg et al., 2000). MM3 accounts for layer thickness, however the basis for this accounting could not be established.

The third limitation with these methods concerns the relatively high values of benefit predicted for subgrade strengths approaching and exceeding a *CBR* of 8. Berg et al. (2000) reviewed available studies and showed conflicting results regarding expected reinforcement benefit for pavements on a subgrade with a *CBR* approaching 8. In general, the majority of studies tended to show diminishing benefit for subgrade strength approaching a *CBR* of 8. To the knowledge of the authors, no experimental test sections exist for clay or silt type subgrades with a *CBR* exceeding 8. At the time of the Berg et al. (2000) report, this led to a recommendation of a subgrade with a *CBR* of 8 being the typical limit for expected reinforcement benefit.

Since the Berg et al. (2000) report, a study by Henry et al. (2009) was conducted, which tends to support the above. In this study, eight test sections were constructed and loaded by a moving wheel load. The sections were constructed on a subgrade having a post construction resilient modulus ranging from 109 to 138 MPa (*CBR* = 10-13). Prior to trafficking, the subgrade was soaked with water. Subgrade resilient modulus was backcalculated from falling weight deflectometer tests and shown to range from approximately 55 to 75 MPa (*CBR* = 5-7). The test sections were constructed with an asphalt thickness of 100 and 150 mm and with a base thickness of 300 and 600 mm. *TBR* values for reinforced test sections were no greater than 1.5, however the results were difficult to interpret due to variable subgrade conditions. These results tend to support the conclusions in Berg et al. (2000) that low values of reinforcement benefit should be expected for higher values of subgrade strength and for thick pavement layers. The relatively high values of benefit for

subgrade *CBR* equal to and greater than 8 should be viewed with caution until they can be verified by a combination of analytical modeling validated by results from experimental test sections. In this paper, a process of analytical modeling is illustrated to provide an example for how this can be accomplished.

3. MECHANISTIC-EMPIRICAL MODEL

A mechanistic-empirical model for reinforced flexible pavements was used in this study to illustrate how analytical models can be used to generate benefit values for reinforced pavements. The model was previously calibrated against pavement test sections of the type recommended by AASHTO (2011). This calibration process was performed for several types of geosynthetics. This provides confidence in use of the model for other types of reinforcement products. This section provides background information on components contained in the model and how the model was formulated. The input parameters for the model used in this study are given in Section 4 along with model results.

The mechanistic-empirical model by Perkins and Edens (2003) is based on a project reported by Perkins (2001a,b). The mechanistic model consists of a three-dimensional (3-D) finite element model matching the nominal conditions for the pavement test facility described in Perkins (1999). This facility consisted of a 2 m by 2 m by 1.5 m deep reinforced concrete box in which the roadway cross section was constructed and loaded by 40 kN applied cyclically at a period of 1.5 seconds to a 304 mm diameter steel plate resting on a waffled rubber pad in turn resting on the asphalt concrete surface. A 3-D model was used to account for the potential influence of the box's square corners and for the geosynthetic inclusion that has direction dependent material properties. Symmetry of the box was recognized such that a model of one-quarter of the box was created. Figure 1 illustrates the geometry of the model. Layer thickness was varied for the parametric study performed.

The model used elasto-plastic constitutive models for the majority of the pavement layers. The bounding surface plasticity model described by Dafalias and Hermann (1986) was used to account for the positive effect of aggregate confinement on the increase in stiffness and strength of the base course aggregate. An orthotropic linear-elastic model was used for the geosynthetic. Anisotropy was included to account for differences in elastic modulus between machine and cross-machine directions and allowed for specification of the in-plane shear modulus and in-plane Poisson's ratio. The principal response parameters extracted from the finite element model include vertical strain in the top of the subgrade and bulk stress in the unbound base aggregate layer. These response parameters were used in empirical damage models for the prediction of long-term pavement performance and the definition of reinforcement benefit. Reinforcement benefit is defined in terms of an extension of service life of the pavement, a reduction in aggregate thickness for equivalent service life, or a combination of the two. The damage models were calibrated from reinforced and unreinforced pavement test sections. The model was shown to provide general descriptions of reinforcement mechanisms that are consistent with those previously observed in instrumented pavement test sections. Additional details are provided in Perkins and Edens (2002).

Figure 1. Finite element model for the Perkins and Edens (2002) model.

The mechanistic-empirical model was used in a parametric study to generate regression equations describing reinforcement benefit in terms of variables relating to pavement geometry, subgrade strength and geosynthetic properties. These parameters included asphalt concrete and unbound aggregate thickness, quality of these materials, subgrade strength and geosynthetic elastic properties. A total of 465 pavement design cases were analyzed. The model therefore consists of a series of regression equations used to predict reinforcement benefit for a given set of pavement design conditions.

4. PROJECT MODEL AND RESULTS

The Perkins and Edens (2003) model requires the input properties shown in Table 1 with the values listed as those used in this study. Quality of the asphalt concrete and base aggregate materials is defined in terms of layer coefficients defined in the AASHTO '93 method. The tensile stiffness of the geosynthetic is defined by a modulus at 2 % axial strain. Differences in modulus between the two principal directions of the geosynthetic are accounted for by the modulus ratio. The parametric study performed to originally develop the model was conducted by including geosynthetics having different classes of interaction properties and in-plane mechanical behavior as defined by an in-plane Poisson's ratio and an in-plane shear modulus.

Table 1. Input for Perkins and Edens (2003) model.

Property	Value
Asphalt concrete thickness, D_1 (mm)	75
Asphalt concrete layer coefficient, a_1	0.40
Base thickness, D_2 (mm)	Variable (150 – 1000)
Base layer coefficient, a_2	0.14
Base layer drainage coefficient, m_2	1.0
Subgrade CBR	Variable (0.5 – 8.0)
Geosynthetic modulus, $G_{SM-2\%}$ (kN/m)	1140
Geosynthetic modulus ratio, G_{MR}	0.995
Reduction factor for interface shear	1.0
Reduction for Poisson's ratio	Checked
Reduction for shear modulus	Unchecked

A range of pavement cross sections and subgrade strengths were used in the model, as noted in Table 1. The model produces a value of BCR , which is used in Equation 3 to determine LCR . For a pavement with a subgrade CBR of 2.0, the base course thickness was varied between 150 to 1000 mm to produce a range of values of structural number (SN) according to Equation 2. For each pavement cross section, the model was used to predict BCR , with corresponding LCR values shown against SN in Figure 2. The results show LCR to decrease with increasing base layer thickness and structural number. Reinforcement benefit becomes insignificant beyond a SN of approximately 5.

Figure 2. Effect of pavement structural number on LCR .

For a pavement with a base course thickness of 300 mm, the pavement subgrade *CBR* strength was varied between 0.5 and 8. The model was used to evaluate the *BCR* for each case with the resulting *LCR* shown against subgrade *CBR* in Figure 3. The results show that *LCR* decreases with increasing subgrade *CBR*. The results in Figures 2 and 3 show the ability of this model to account for two key components known to influence the benefit derived from geosynthetic reinforcement.

Figure 3. Effect of pavement subgrade *CBR* on *LCR*.

5. CONCLUSIONS

Three currently available proprietary methods for the design of geosynthetic reinforced pavements that rely upon the use of improved layer coefficients for the base course layer were reviewed and shown to have several limitations. The three methods are empirically based and rely upon the demonstration of benefit from reinforced test sections. Limitations of these methods involved: 1) the lack of documentation of benefit values derived from test sections; 2) the inability of some methods to account for the effect of pavement thickness on reinforcement benefit; and, 3) the tendency for all methods to produce relatively high values of benefit for subgrades with a *CBR* of 8 and greater, which is not supported by recent independent full scale test sections. These limitations should be considered when using these methods for the products that they support.

This paper outlined an approach for determining reinforcement benefit using analytically based models that have been previously calibrated against reinforced test sections. The benefit values for the model used produce reasonable results when compared to studies involving the construction of reinforced pavement test sections. This approach is considered favorable due to its ability to account for the variables that are known to influence reinforcement benefit values in a consistent manner that relies upon engineering materials testing and analytical modeling principles. This was illustrated by using the model to examine the influence of the pavement's structural thickness and the strength of the subgrade on layer coefficient ratio. Validation of this approach is needed for those conditions for which benefit values have not been clearly established. Those conditions include stronger subgrades and medium to thick pavement cross sections.

ABSTRACT

A new geomembrane product, Leak Location Liner, developed by GSE specifically for electrical liner integrity surveys (ELIS), enables leak detection surveys for otherwise unfeasible applications and improves leak detection sensitivity for common applications. The capability of this new geomembrane to enable leak detection surveys on the primary liner of a double-lined installation, sites with complete subgrade desiccation, holes at the peak of a wrinkle, under a seam flap, and in an area of poor contact with the subgrade were all tested and verified. In order to compare the leak detection sensitivity of a survey performed on Leak Location Liner to a survey performed on traditional geomembrane, comparative bench-scale testing on both was conducted. The ratio of a leak signal obtained on the Leak Location Liner setup relative to a leak signal obtained on the traditional geomembrane setup was calculated and is here-on referred to as the improvement factor for ease in interpreting the comparative data. This improvement factor was quantified for a spectrum of subgrade soil resistivity values by varying the moisture content of the subgrade soil. The results of comparison trials with the subgrade soil condition varying from near zero moisture content to saturation show the improvement in leak detection sensitivity as a function of subgrade resistivity when Leak Location Liner is used. The results of the testing include expected improvement factors for single-lined applications as a function of subgrade soil type and moisture content, as well as in a multitude of hole conditions.

1. INTRODUCTION

1.1 Background

The electrical liner integrity survey (ELIS) is currently the most effective and practical means of locating leaks in installed geomembranes, particularly after cover soil installation. This type of survey includes ASTM methods D7002, D7007 and D7703. However, a few boundary conditions are critical to its success. The technology functions along the principal that polyethylene geomembranes are electrically isolative and by applying an electrical potential across a geomembrane, an electrical current will flow only if a hole is present in the geomembrane. The various survey methods track the flow of electricity in order to pinpoint a leak. This is only possible if there is an electrically conductive medium both above and below the geomembrane. For geomembranes covered with soil, the soil provides the conductive medium above the geomembrane. Traditionally, subgrade soil acts as the conductive medium below the geomembrane when the application allows it. For single-lined applications using traditional liner there is typically no problem performing an ELIS, as long as the subgrade soil maintains natural moisture content. In applications featuring encapsulated geosynthetic clay liners (GCL) desiccation issues have been reported to preclude surveys on primary geomembranes (Peggs, 2007). Although hydrating encapsulated GCL has been suggested (Beck et. al., 2008), this idea has not been embraced by the industry and GCL desiccation is still an unresolved issue when performing an ELIS on traditional liner. Subgrade soil electrodes are sometimes placed in the subgrade before deployment of the geomembrane, in order to shorten the electrical path during an ELIS and thus increase survey sensitivity for soils with low conductivity. However, when using Leak Location Liner, the conductive layer in the geomembrane serves as the lower conductive medium and the aforementioned are no longer concerns. One solution to these issues has been conductive geotextile, which is quite expensive and requires the installation of an additional layer of material under the geomembrane to be tested and therefore has not been widely used.

Another issue that frequently arises during an ELIS is poor hole contact. An example of a hole with poor contact would be a hole that is located at the peak of a wrinkle. A hole on the peak of a wrinkle is unlikely to be detected by an ELIS on traditional liner because the electrical path is broken by the lack of intimate contact between the hole and the subgrade soil. Holes located under seam flaps are also difficult to locate due to the lack of intimate contact with the cover soil.

The recently improved Leak Location Liner features a conductive backing designed to carry sufficient current for a ELIS, acting as the conductive medium below the geomembrane. Successful pilot projects of the product have shown that the conductive backing sufficiently carries the required range of survey current and specialized wedge welders prevent false positives at the seams (Ramsey, 2012, Gallagher, 2012). Designed for enabling a survey where it was previously unfeasible or ineffectual, the product has also enhanced the overall quality of an ELIS on any application. A series of

tests were performed on a bench scale in order to quantify the increase in survey quality when Leak Location Liner is used in comparison with traditional geomembrane for single-lined applications, including situations with poor hole contact.

1.2 ELIS Quality

The essence of ELIS quality lies in the size and number of leaks that can be located in the geomembrane during a survey for subsequent repair. A higher quality survey will naturally locate more leaks in the geomembrane than a lower quality survey. The authors chose to employ ASTM method D7007 as the means to quantify survey quality. The measure of survey quality is taken to be the signal to noise ratio as calculated during the sensitivity test portion of ASTM method D7007.

The signal to noise ratio is expressed as:

$$R = (S+N)/N \quad [1]$$

Where R is the signal to noise ratio, (S+N) is the magnitude of the difference between the highest and lowest voltage potential readings when travelling across a hole location per the ASTM D7007 dipole spacing requirements and N is that magnitude when the hole is not there, otherwise known as the background noise of the survey area.

A higher signal to noise ratio means that smaller leaks can be located compared with a lower signal to noise ratio, based on the authors' field experience. Below a signal to noise ratio of 3:1, the leak is not considered to be locatable per ASTM D7007. As the sensitivity (i.e. signal to noise ratio) increases, smaller leaks become detectable, and therefore smaller leaks that would otherwise go undetected become detectable and more leaks are located during the survey.

2. TEST METHOD

The survey quality when using either traditional liner or Leak Location Liner was quantified in parallel, identical bench-scale test set ups. The signal to noise ratio, referred to henceforth as the leak signal, was measured for a given hole in both traditional geomembrane and Leak Location Liner.

2.1 Bench-scale Setup

A small-scale geomembrane-lined survey area was created for a bench-scale dipole testing apparatus. The dimensions of the bench-scale set up measured 61 cm (24") wide by 91 cm (36") long by 8.9 cm (3.5") tall. The dipole instrument used to take voltage potential readings employed a spacing of 7.6 cm (3"). The subgrade portion of the apparatus measured 6.3 cm (2.5") thick and the cover soil portion measured 2.5 cm (1") thick.

The subgrade consisted of a box of moisture-conditioned soil confined by a wooden frame. The soil type used in these tests was sandy clay. The wooden frame ensured the same depth of subgrade material for each trial. The subgrade soil box was covered by the geomembrane being tested. Holes in the geomembrane were carefully drilled out and a clay plug the thickness of the geomembrane was inserted into each hole to provide the same hole contact for each test run. Hole diameters of 1.6 mm (1/16"), 3.2 mm (1/8") and 6.4 mm (1/4") were used. For background noise measurements, electrical tape was placed over the holes. The cover soil was kept at a constant moisture content of approximately 18% for all tests and was the same material as the subgrade soil. This higher moisture content was chosen so that the effects of subgrade moisture content could be clearly measured, since drier cover soils were more susceptible to contact quality errors, both between the probes and soil and the hole and soil. The cover soil was placed with a wooden frame to ensure uniform compaction and depth throughout the testing, as shown in Figure 1. A voltage of 50V was applied to the cover soil in one corner of the box. The power source ground was placed in the opposite corner of the box in the subgrade soil for the traditional geomembrane trials and it was clamped directly to the conductive backing of the Leak Location Liner at approximately the same location for the Leak Location Liner trials.

Figure 1. Bench-scale dipole test apparatus as cover soil is placed.

For each trial, two measurements of voltage potential were taken; one as the dipole approached the hole location and the second as the dipole was just past the hole location, with the position of the dipole relative to the hole placement as prescribed by ASTM D7007. A template was created to ensure the same dipole placements for each trial. The system current for each trial was recorded in tandem with the dipole voltage potential measurements for quality control.

2.2 Bench-scale Test Method Descriptions

Four series of tests were performed, referred to as Tests A through D. The test setups, results and discussion are reported in alphabetical order throughout this text.

Test A was designed to calculate the improvement factor when Leak Location Liner is used instead of traditional geomembrane in applications where historically traditional geomembrane would have been used. Hole diameters of 3.2 mm (1/8") and 6.4 mm (1/4") were used. A total of 34 trials were performed on each of the traditional and Leak Location Liner geomembranes. For each set up, at least two measurements were taken for each hole size, digging up the cover soil and recompacting it between trials to account for any variation in hole to cover soil contact. The moisture content of the subgrade material was measured after each test was performed using ASTM D2216. The soil resistivity value was measured while the subgrade soil was in place using the soil resistivity method developed by Erik Kramer, PhD (Beck et. al., 2008). The moisture content of the soil was varied from a desiccated condition (~0.5%) until saturation (~25%). Leak signals were measured for both the Leak Location Liner and traditional geomembrane and then the improvement factor was calculated by dividing the leak signal obtained from the Leak Location Liner setup by the leak signal obtained from the traditional liner setup.

Poor hole contact situations were simulated for Test B. Three different scenarios were tested; a hole at the peak of a wrinkle, a hole located above a slight depression in the subgrade, and a hole located underneath a seam flap. All holes for this test measured 3.2 mm (1/8") in diameter. The simulated wrinkle consisted of an 13 mm (1/2") diameter wrinkle molded into the geomembranes, as shown in Figure 2. The slight depression in the subgrade was made with an index finger and checked after the test to verify that there was no direct subgrade to hole contact, as shown in Figure 3. The hole drilled under the seam flap was similarly checked after the test to have maintained separation with the cover soil, as shown in Figure 4.

Figure 2. Hole at Peak of Simulated Wrinkle.

Figure 3. Hole Over Depression in Subgrade.

Figure 4. Hole Under Seam Flap.

The leak signal as a function of distance from the hole was investigated for Test C. The subgrade moisture content was 2% and the hole size was 1.6 mm (1/16") diameter. The first dipole readings were taken at the initial location as specified by ASTM D7007 and the subsequent readings were taken increasingly further away in 51 mm (2") increments. One trial was done on each geomembrane type for each distance point.

Test D was designed to evaluate the impact of the placement of the power source ground electrode on the leak signal. The electrical contact of the power source electrodes are very important for the current path of a ELIS. The series of improvement factor trials in Test A had been grounded to the subgrade soil for the traditional liner trials and clamped directly to the conductive backing of the Leak Location Liner for the Leak Location Liner trials. The ground placement trials were performed on Leak Location Liner at a subgrade moisture content of 25%. Leak signals were recorded on the same bench-scale set up for three different grounding positions; subgrade ground only, ground clamped to conductive backing, and grounded to both the subgrade and conductive backing. Each set up was tested twice, digging up and recompacting the hole locations between trials. It was a direct comparison test, which measured the leak signal as a function of ground placement.

3. RESULTS

3.1 Test A: Improvement Factors for Currently Used Applications

The most significant result of this test was that the traditional geomembrane setup did not produce a leak signal for the lowest moisture content tested. The improvement factor is exponential, with drastic increases in improvement at lower values of subgrade moisture content.

The observed improvement factors as a function of subgrade moisture content from 2% to 15% are presented in Figure 5. The reported moisture content is only valid for the type of soil used in the bench-scale test. Improvement factors for other soil types are reported in the discussion section of this paper. The data points represent an average of two or more trials. There is more data scatter at the lower moisture contents, likely because the electrical contacts become more difficult to control at lower moisture contents.

Figure 5. Observed Improvement Factors in Single-Lined Applications.

3.2 Test B: Poor Contact Situations

Leak signals were measured twice for each poor contact scenario on each geomembrane type. The average leak signals obtained are reported in Table 1. Leak signals are dimensionless and the following data is used as a comparison between leak signals in various conditions using each liner type.

Table 1. Leak Signals for Poor Contact Situations.

Geomembrane Type	Void Under Geomembrane	Hole Under Seam Flap	Hole on Wrinkle
Traditional	12	2	0.4
Leak Location Liner	86	21	91

3.3 Test C: Distance from Hole Testing

The measured leak signals are shown as a function of lateral distance from the hole location for both geomembrane types in Figure 6.

Figure 6. Leak Signals as a Function of Distance from Hole Location.

3.4 Test D: Ground Placement Investigation

The results of the ground placement investigation are reported as average values for the two trials measured for each condition.

Table 2. Average Leak Signals for Various Ground Placements.

Subgrade Ground Only	Sheet Ground Only	Multiple Grounds – Subgrade and Sheet
163	271	327

4. DISCUSSION OF RESULTS

The results of Test A showed that Leak Location Liner can provide a more sensitive survey than traditional liner, especially if the subgrade soil is placed at a lower moisture content or desiccates in the field before placement of the geomembrane. As the moisture content of the subgrade increases, the sensitivity of a survey on traditional liner also increases, which decreases the improvement in sensitivity that Leak Location Liner can provide.

The improvement factors calculated from the raw test data in Test A are shown as a function of moisture content of the specific soil used as the subgrade material for the bench-scale testing. Soil resistivity values were also measured at the various moisture contents of the soils in order to obtain results that could be applied to different soil types. Subgrade soils are generally placed at near optimum moisture content, which is a function of soil type. The resistivity value of the soil is a function of both soil type and moisture content, among other factors. A literature survey of resistivity values ranges for soil types and moisture contents was performed. Figure 7 shows values of resistivity for various soil types as a function of a range of values for moisture content. Potential improvement factors for a range of resistivity values are presented in Figure 8. These improvement factors apply if the Leak Location Liner is grounded to the power source by only the conductive backing. Greater improvement is expected when multiple grounds are used.

Figure 7. Subgrade Resistivity Values as a Function of Soil Type and Moisture Content.

Figure 8. Improvement Factor as a Function of Subgrade Resistivity.

The values of the leak signals reported for Test B represent a bench-scale set up where the hole size and thickness of cover soil are not proportional to a field-scale set up. The leak signals reported cannot be compared directly to the ASTM D7007 requirement for a 3:1 signal to noise ratio as a limit for hole detection. The average leak signal value for the traditional geomembrane bench scale test was approximately 300, roughly five times a signal that would be considered excellent in field conditions. Therefore, the reported values should be scaled down by a factor of five to approximate a similar field condition, based on the author's field experience. The scaling down of the leak signal results in the approximations of signal strength and the likelihood of locating the hole in a field situation shown in Table 3.

Table 3. Approximated Field Signals and Hole Detection Evaluation in Poor Contact Situations.

Geomembrane Type	Void Under Geomembrane	Hole Under Seam Flap	Hole on Wrinkle
Traditional	Very weak signal; not likely to be detectable	Not detectable	Not detectable
Leak Location Liner	Very good signal; detectable	Weak signal; detectable	Very good signal; detectable

Holes that are difficult or impossible to detect on traditional geomembrane can be detected when Leak Location Liner is used. The reason why the Leak Location Liner enables the leak signal in the poor contact situations is because the conductive backing carries the current even in the absence or poor conductivity of the subgrade material. In the case of the hole located under the seam flap, the flap of the seam also has the conductive backing, which completes the circuit between the cover soil and the hole.

Test C directly illustrates how a stronger leak signal results in greater survey sensitivity. Due to the increase in signal strength relative to the background noise, the leak can be detected at a further distance from the hole. In terms of survey grid spacing for the bench-scale setup, the hole could be seen during multiple passes of the dipole equipment as it got closer and closer to the hole. The signal being seen on multiple passes decreases the likelihood of a dipole operator passing over a hole location.

As the moisture content of the subgrade soil increased beyond 15% in the Test A trials, it is theorized that the combination of the subgrade geometry and the lower resistivity value resulting from an increase in moisture content caused the subgrade to be a more preferential path for current flow than the conductive backing of the sheet. In addition, the grounding electrode contact in the subgrade improved as the moisture content increased. By grounding to both the sheet and the subgrade, the current is not only allowed to travel the path of least resistance, whichever it may be, but also travel the two paths at once. This is similar to the case when there are two resistors in parallel in a circuit. The overall resistance is diminished when a resistor is added in parallel, and the overall resistance is always less than just one of the resistors wired in series. Although Test A was not repeated with multiple grounds, the Test D results show that a substantial further increase in leak signal can be achieved by utilizing the multiple grounds in tandem with Leak Location Liner when the application allows it. This set up should cause the Leak Location Liner to show continued improvement over traditional liner at any subgrade moisture content and in any application.

4.1 Applicability to Large-scale Installations

A mathematical model was created and compared to the bench-scale test in order to extrapolate the performance of Leak Location Liner on a large-scale installation. The model used a single charge point to model the hole and appropriate image charges to model the boundaries. The model can calculate simulated improvement factors for the Leak Location Liner versus traditional geomembrane. As well, it can calculate simulated voltage signals of a given grid spacing and correct for input impedance.

Figure 9 shows that the model's calculated improvement factors compare well to the measured data for a 3.175 mm (1/8") hole from Test A, confirming the accuracy of the model in small scale. The theory curve was generated by the model's formula for improvement factor with geometric inputs matching those specified for Test A, cover soil conductivity matching measurements, and manufacturer data on liner conductivity and thickness.

Figure 9. Observed Data and Theoretical Curve for 3.2 mm (1/8") hole.

Additionally, curves comparing the theoretical voltage signals and real data as measurements are taken over a hole from large installations showed that the theoretical signals matched field data in general form. This result means that the theoretical model still holds true when scaled up to real world site conditions and can be used to show expected improvement factors when Leak Location Liner is used in a full-scale application.

In applying this model, various common field geometries and site conditions were entered into the model to observe the performance of the Leak Location Liner. In each of the cases the model output showed that the improvements seen in small scale testing of the Leak Location Liner over traditional geomembrane were mirrored in large-scale field applications.

5. CONCLUSION

In addition to enabling an ELIS on the desiccated subgrade soil where the traditional liner could not be used, the results of the testing showed that the Leak Location Liner could also increase ELIS sensitivity on single-lined applications for a wide range of soil types and moisture contents. Leak Location Liner also makes it possible to locate holes in poor hole contact situations such as at the peak of a wrinkle, over a depression in the subgrade and under a seam flap. By increasing the signal strength, holes can be detected at further distances from the hole location, increasing the survey quality. The follow-up testing utilizing multiple grounds showed promise for an even greater improvement factor when Leak Location Liner is used. This should result in survey quality improvement no matter what the soil subgrade resistivity value.

For double-lined geomembrane applications, Leak Location Liner enables an ELIS where it would have previously been impossible. For sites with encapsulated GCL or large installations where subgrade conductivity might be an issue, Leak Location Liner can ensure the success of a ELIS where otherwise the results might range from marginal survey quality to a complete failure to perform the test.

ABSTRACT

High-density polyethylene (HDPE) geomembrane (GMB) is commonly specified as the preferred lining for shrimp aquaculture industry in South East Asia. Shrimp farms generally consist of extensive water canals surrounding grow-out, culture and treatment ponds. The water canals and ponds are relatively shallow in depth and commonly designed and constructed to 1.5m to 2.5m deep. Both the water canals and ponds are generally lined with thin gauge ($\leq 0.75\text{mm}$) HDPE GMBs mainly to maintain water level and control of water quality amongst other lining benefits. Due to the shallow depths, a significant section of the GMB lined canals and shrimp aquaculture ponds are therefore exposed to direct sunlight between the water freeboard level to the crest of bund and hence susceptible to UV degradation. The durability and lifetime prediction of HDPE GMBs particularly for the landfill industry where the common thicknesses range between 1.0mm to 2.5mm depending on the design and regulation of respective countries around the world have received much attention from engineers and researchers alike. However, there is a lack of information from the industry on the lifetime prediction of thin HDPE GMBs installed in the exposed environment particularly common to the shrimp aquaculture industry in South East Asia. Furthermore the properties of thin ($\leq 0.75\text{mm}$) HDPE GMBs are not covered by the industry standard of "GRI Test Method GM13" and needs to be extrapolated. This paper seeks to collate available information on the durability and lifetime prediction of GRI GM13 standard HDPE GMBs both in the exposed and buried environment and proposes a cautious extrapolation method in order to arrive at a reasonable lifetime prediction for the thinner gauge GMBs for the shrimp aquaculture industry.

1. INTRODUCTION

Aquaculture output has increased rapidly in Southeast Asia over the past 15 years resulting in six of its member countries namely Indonesia, Malaysia, Myanmar, Philippines, Thailand and Vietnam being ranked among the top 25 countries in the world in terms of aquaculture volume. Shrimp aquaculture is the largest farmed fish by species in Southeast Asia in terms of output as well as value where shrimp consists of 22% of the total 5.03 million tons of the regions' fish aquaculture output in 2005. Although the output by weight is only 1/5 of the total regional output, the value of shrimp aquaculture is US\$4.36 billion (46% of total farmed fish value) in 2005 (Hishamunda et al. 2009).

Youngblood and Ng (2008) states that HDPE GMB appears to be the liner of choice for shrimp farms due to its beneficial characteristics such as high chemical resistance, low permeability rate and superior UV resistance among other properties. Profitability of shrimp farmers are known to increase when HDPE GMB liners are used to line the ponds as it lowers the mortality rate of shrimps, promote growth and preferential color, reduce possible spreading of disease, ease of water quality control and faster harvest to culture turnover.

Commonly required HDPE GMB thicknesses for the shrimp aquaculture industry are 0.5mm, 0.65mm and 0.75mm. HDPE GMB thickness specified by the client are generally based on extensive observational experience of the site ground condition pertaining to installation and operational survivability rate of the liners and not subject to mechanics based engineering computation nor governed by regulatory requirements. The typical properties of thin gauge HDPE GMBs for shrimp aquaculture are ordinarily obtained by extrapolation from the internationally widely accepted Geosynthetic Research Institute's (GRI) specification no. 13 as illustrated in Table 1. The mechanical properties of HDPE GMBs as presented in Table 1 have been observed to meet the installation and operational requirements for the shrimp aquaculture industry.

However, the theory that thinner gauge GMBs have lower lifetimes when compared to thicker GMBs (Kay et al. 2004 and Koerner et al. 2012) compounded with the widely accepted fact that UV exposed GMBs have lower lifetimes compared with buried environments poses a significant issue of HDPE GMB durability for the aquaculture industry where a significant portion of the liners are exposed to UV from the water freeboard level to the crest of bund.

Islam and Rowe (2007), Rowe et al. (2010), Ewais and Rowe (2012) have carried out studies on the durability effect of HDPE GMB thickness in the buried environment exposed to synthetic landfill leachate. Tarnowski and Baldauf presented a case study on a sludge deposit pond in Galing, Germany where it was observed that the top layer of a 2.5mm HDPE GMB has lesser remaining OIT when compared to its middle layer and hence concluded that thickness has a major influence on antioxidant depletion which leads to lower liner durability. Apart from these, the authors find that there is at present a paucity of industry information with regards to thickness effect on the lifetime prediction of HDPE GMB and this pertinent issue remains a research needs especially for UV exposed thin gauge HDPE GMBs (Koerner et al. 2012).

Table 1. Typical thin gauge HDPE GMB properties extrapolated from GRI GM 13 for shrimp aquaculture.

Properties	ASTM Test Method	Units	0.5mm (20mil)	0.65mm (25mil)	0.75mm (30mil)

2. DEGRADATION MECHANISM OF HDPE GMBS AS POND LINERS IN SHRIMP AQUACULTURE

2.1 Buried Section

Degradation mechanism of HDPE GMB below water level could possibly come from chemical degradation and / or thermal degradation. The presence of oxygen below water level is also very low and hence yields an environment for lower oxidation.

Table 2 presents the optimum water quality conditions for cultured shrimp ponds recommended by ASEAN (2005). HDPE GMBs are found to be chemically resistant to these conditions.

Table 2. Optimum water quality conditions for cultured shrimp pond (ASEAN 2005).

Parameter	Value	Units
Dissolved Oxygen (DO)	> 4	mg/L
pH	7.5 – 8.5	-
Ammonia	< 0.1	mg/L
Transparency	30 – 45	cm

With regards to thermal degradation, the water temperature of the shrimp pond is generally only slightly higher than ambient due to conduction from sunlight as water is a low heat conductor. As such, the water temperature in shrimp aquaculture ponds does not pose a concern to thermal degradation effect on HDPE GMBs.

For HDPE GMBs buried in the anchor trench, the degradation mechanism is dependent on the soil type and moisture content as both sides of the liner are in direct contact with the soil.

Given the above, liner durability at sections below water level does not pose serious concerns for HDPE GMBs when compared to the UV exposed section.

2.2 Exposed Section

It has been widely published and generally accepted that GMBs constructed in the exposed environment has a lower durability compared to the buried environment due to detrimental degradation mechanisms such as lush presence of oxygen, photo-oxidation from UV degradation and thermo-oxidation due to increase in liner temperature (Rowe and Sangam 2002 and Koerner et al. 2012) as HDPE GMB is a good heat conductor. Moreover, the presence of oxygen for the exposed section has oxygen concentrations 8 times the section covered by water (Hsuan and Koerner 1995). As such, the section of GMB liner above the water level up to the crest of bund is exposed to severe degradation mechanism.

However, a point to note is that the UV radiation intensity as well as heat exposure is largely dependent on the geographical location of the shrimp aquaculture farm. Several world solar maps have been published such as Annual Irradiation Energy Isocurves in “kLy” after Van Wilk and Stoezer (1986) (Koerner et al. 2012), Average Annual Solar Radiation in “kWh/m².year” (Keller et al. 2009) and Local Noon Erythermal UV Irradiance in “mW/m²” after USA National Aeronautics and Space Administration (NASA) (Tencate 2010) and may be referred to for correlation purposes. Furthermore, the intensity of solar radiation is also dependent on the GMB liner facing direction in relation to the site geographical location (Martin 2005).

Given the above, liner durability at sections above water level is the critical section for liner durability and lifetime prediction of HDPE GMBs for shrimp aquaculture and is the main focus of this paper.

2.3 Summary of Various Liner Exposure Sections in Shrimp Aquaculture Ponds

Figure 1 schematically illustrates the various sections of HDPE GMBs exposed to different possible degradation mechanisms as discussed in Section 2.1 and 2.2 above. Table 3 summarizes the different possible degradation mechanisms for the various sections in a shrimp aquaculture pond as illustrated in Figure 1 and discussed in Section 2.1 and 2.2 above.

It is noted that for some applications where aggressive solutions are being contained, location D may be the most critical section in terms of durability of the GMB due to antioxidants leaching out by water when exposed to high temperature. This however is unlikely for the shrimp aquaculture application where the general water quality is as given in Table 2 above. As such, it is hypothesize that HDPE GMBs at location A, E and F are envisaged to have higher durability compared to location B, and C whereas location D is likely to have estimated durability in between the fully buried and fully exposed sections.

Note: A – Anchor trench; B – Horizontal runoff; C – Above high water level; D – Intermittent level; E – Below low water level; F – Pond bottom

3. CASE STUDY: 0.65MM HDPE GMB EXHUMED FROM A SHRIMP AQUACULTURE FARM IN MALAYSIA

3.1 Background

0.65mm HDPE GMB was selected as the pond liner for a shrimp aquaculture farm in Malaysia. Malaysia receives an average of about 7 hours of sunshine per day with maximum temperature of 34°C and minimum temperature of 23°C. The annual irradiance energy for Malaysia obtained after Van Wilk and Stoezer (1986) from Koerner et al. (2012) is 140 kLy.

Table 3. Summary of various exposure levels in respective liner sections.

GMB Liner Section (Ref. Fig. 1)	Exposure Level				
	Oxygen	UV Radiation (Photo-oxidation)	Heat (Thermal-oxidation)	Water (Chemical degradation)	Sludge/Waste (Chemical degradation)
A	Subjective ¹	No	No	No	No
B	High	High ²	High ²	No	No
C	High	High ²	High ²	No	No
D	Moderate	Moderate	Moderate	Moderate	No
E	Low	Low	Low	High	Low
F	Low	No	Low	High	High

¹Quantity of oxygen in saturated soil is dependent on the type of soil and moisture content (Hsuan and Koerner 1995);

²Intensity of UV radiation as well as heat exposure from sunlight is dependent on the geographical location of the shrimp farm as well as the facing direction of the liner.

Apart from water canals and water treatment ponds, the shrimp aquaculture farm has grow out ponds with an approximate area of 0.9ha and the slope gradient is 1V:1.5H with run-out length of 0.5m and nominal anchor trench depth.

The slopes and berms of the ponds were lined in year 2010. In year 2012, a 0.5m wide x 3.8m long GMB liner strip was exhumed from the run-out length to the toe of berm. The GMB liner strip was taken from a pond berm facing south-west. Figure 2 presents pictorial records of the GMB samples exhumed from site.

Figure 2. Photograph of field exhumed samples

3.2 Properties of 0.65mm HDPE GMB After 2 Years of Field Exposure

Four testing locations demarcated with reference to Figure 1 were identified on the exhumed GMB. Table 4 summarizes the results of index, mechanical and durability properties' tests carried out on the four locations of the exhumed GMB in

comparison with values extrapolated from GRI GM 13 as well as the original roll values. It was unfortunate that the exact roll number could not be identified at site and hence average values were tabulated for reference.

3.3 Discussion of Results

In general, with the exception of elongation at break on sample E (-3%), all other index and mechanical test properties from the aged GMB complied with or exceeded the specification of GRI GM 13 extrapolated values. The minor shortfall of -3% elongation at break (i.e. 0.4% short of specification value) for sample E is deemed to be within the normal testing variance and uncertainty of GAI-LAP geosynthetic tests (Koerner et al. 2006).

Table 4. Summary of 0.65mm HDPE GMB properties exhumed from site.

Aged Sample ID	D5199		D792	D6693 Type IV				D1004	D4833	D5397	D4218	D3895	D5885

GRI GM 13 ²	0.65	0.585	0.94	9.0	12.0	18.0	700	80	210	300	2 – 3	100	400

¹Average original values from all HDPE GMB rolls ; ²GRI GM 13 extrapolated values; ³All samples did not break but test was ceased after reaching 550 hours; ⁴SCR was not carried out due to unavailability of equipment at time of testing; ⁵Actual test was not carried out as Std OIT was opted to be measured at time of production. Average HP OIT values were estimated from database.

Comparison of results and comments are listed as follows:

- Measured density values are similar for all locations;
- Tensile strength at yield is consistent for all locations and the values exceeds GRI GM 13 and average original values;
- Elongation at yield appears to be consistent, exceeds GRI GM 13 but is slightly lower than average original values for all locations;
- Tensile strength at yield is fairly consistent for all locations, exceeds GRI GM 13 but is slightly lower than average original values except for sample C. The variation from original is -3.7% to 2.8% which is deemed within testing variability;
- Tear and puncture resistances comfortably exceeds both GRI GM 13 as well as average original values for all locations;
- Measured carbon black content values are similar for all locations;
- With the exception of location B, the OIT depletion following ASTM D 3895 follows envisaged results where location C has undergone the greatest degradation due to UV exposed condition followed by location D where it is only intermittently exposed and location E in buried condition. The retained OIT value for location B is the highest when compared to the other three locations. This is counter intuitive as location B is supposed to have undergone greater degradation due to full UV exposure. It is hypothesized that location B may have been protected by collection of dust on the flat portion of the GMB whereas rain would have constantly washed the dust off the sloped areas. Further investigation is necessary to understand this condition;
- Results of OIT depletion following HP OIT test method is generally similar to the findings of standard OIT test where location B presents highest retained OIT values followed by sample E. The HP OIT values for sample C and D is similar likely due to inherent testing variability.

4. LIFETIME PREDICTION

4.1 General

The service life of a HDPE GMB is characterized by the duration before it reaches its 'half – life'. The notion of 'half-life' is ascertained by the 50% reduction of a specific design property of concern (Hsuan and Koerner 1995).

Lifetime prediction of HDPE GMBs have been expounded by Hsuan and Koerner (1995) and Sangam and Rowe (2002). In summary, the lifetime of HDPE GMBs undergoes three distinct stages namely A, B and C. Stage A is where the HDPE GMB is protected through the presence of antioxidants. Stage B also known as induction time to onset of polymer degradation starts when the HDPE resin is unstabilize through antioxidant depletion until the value of 0.5 minutes for standard-OIT and 20 minutes for HP-OIT (Hsuan and Koerner 1998). Stage C starts when the HDPE GMB begins to lose its properties until it reaches 50% of the specific design property of concern.

Stage A antioxidant depletion rate can be estimated through the following equation:

$$\ln(\text{OIT}) = \ln(P) - (S)(t) \quad [1]$$

where P = Initial value of OIT in the GMB (min.); S = antioxidant depletion rate (month⁻¹ or year⁻¹); t = ageing time (months or years); OIT = OIT at time t (min.)

Equation [1] can also be used to estimate the antioxidant depletion time once the antioxidant depletion rate is determined by rearrangement as follows:

$$t = [\ln(P) - \ln(\text{OIT})] / S \quad [2]$$

It should be noted that the above equations and findings were derived from simplifications and reductions after Hsuan and Koerner (1998) where black HDPE GMBs conforming but not exceeding GRI GM 13 specifications were used in the research. The proposed model by Hsuan and Koerner (1995) is adequate for the purpose of comparing GMBs but may not reflect actual long term degradation rate of the particular GMB due to the many variations such as different resins, antioxidants and exposure conditions.

Literature review on lifetime prediction and thickness sensitivities to antioxidant depletion of HDPE GMBs through laboratory studies and field performances of HDPE GMBs in the exposed environment have been carried out by Denis et al. (2012) and will not be repeated in this paper. Only published references where relevant data is required for comparison and careful extrapolation in this paper shall be summarized in the following sections.

4.2 Stage A Analysis

Conditions of a UV exposed 14 year old 1.5mm HDPE GMB used to line a lagoon storing nonhazardous leachate from industrial, municipal and commercial landfill in Ontario, Canada were studied by Rowe et al. (2003). Ivy (2002) reported on the performance of a 20 year 2.5mm HDPE GMB exposed to UV in a surface impoundment of a power plant in Colorado, USA. Tarnowski and Baldauf provided data on a 2.0mm HDPE GMB that was installed in a water reservoir in Levante, Spain where samples were tested after 11 years of outdoor weathering. Swihart and Haynes (2002) from the US Bureau of Reclamation reported the performance of an exposed 2.0mm HDPE GMB as part of its long term study to investigate the most suitable canal lining system. Hsuan et al. (1991) published data on the effects of a 1.5mm HDPE GMB 7 year outdoor exposure in a disused domestic solid waste leachate storage facility. OIT test results from these published references are summarized with the results obtained from the case study in Table 5 for sample location C and D as identified in Figure 1 only so that reasonable correlation may be carried out. Figure 3 illustrates the correlation of antioxidant depletion rate in the form of normalized OIT in natural logarithmic scale versus time.

Koerner et al. (2012) carried out extensive long term studies for lifetime prediction of laboratory UV exposed GMB. A correlation of 1200 light hours exposure at 70°C in ASTM D7238 device as equivalent to 1 year service life in a hot climate similar to West Texas and Southern California was established. Stage A period of 19 years was inferred from the graph of Strength retained (%) versus light hours for a 1.5mm HDPE GMB and included in Figure 3 a) for correlation with the other results.

Table 5. Summary of OIT depletion rates from published data for correlation with case study.

(References) HDPE GM thickness	Sample Location	t (years)	P (min.)	OIT ³ (min.)	S (year ⁻¹)
(Ivy 2002) 2.5mm (100mil)	C	20	50 ²	32	0.022
(Rowe et al. 2003) 1.5mm (60mil)	D	14		36	0.016
(Hsuan et al. 1991) 1.5mm (60mil)	C	7		1.8	0.237
Tarnowski and Baldauf ¹ 2.0mm (80mil)	D	11	145	3.3	0.194
Swihart and Haynes 2.0mm (80mil)	C	10	73	11	0.216
Shrimp Aquaculture 0.65mm (25mil)	C	2	122	25	0.099
	D			61	0.079
				108	0.027
				47	0.044
				17	0.985
				23	0.834

¹Values of OIT are based on DIN EN 728, 190°C; ²Value of P is estimated based on typical values for HDPE GMBs manufactured during period respective period of construction in North America (Ivy 2002; Rowe et al. 2003); ³Average values obtained from respective references.

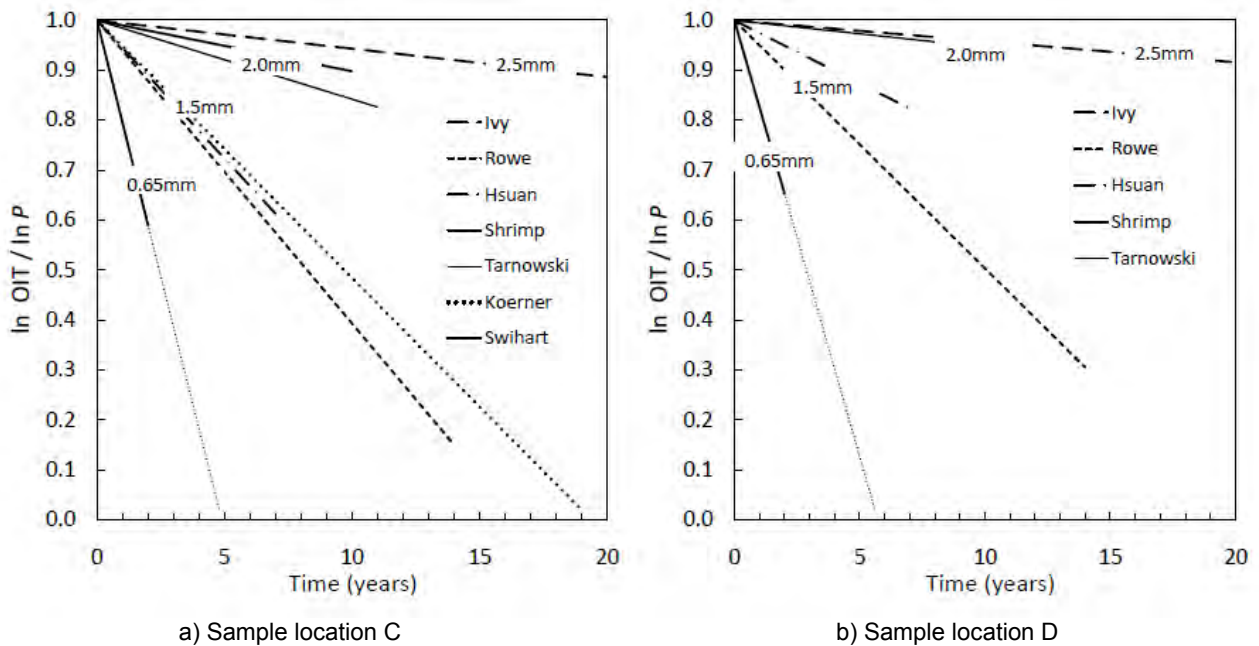

Figure 3. Normalized natural logarithm of standard OIT over natural logarithm of P against time for GMB thickness 2.5mm (100mil), 2.0mm (80mil), 1.5mm (60mil) and 0.65mm (25mil)

Good agreement was observed in Figure 3 a) for antioxidant depletion rate of 1.5mm HDPE GMB derived from data after Ivy (2002), Hsuan et al. (1991) and Koerner et al. (2012). Figure 3 a) also presents antioxidant depletion rate in the same order of magnitude for 2.0mm HDPE GMB. The slightly varying values between the two data would also be affected by the different test conditions employed between ASTM and DIN EN. Antioxidant depletion rate for sample location C was further analyzed for thickness sensitivity and the result is presented in Figure 4.

Antioxidant depletion rate for sample location D yielded similar trends as location C where the depletion rate for thicker HDPE GMB is lower compared to thinner gauge GMBs. However, no strong correlation was observed for HDPE GMB of similar thickness such as the 1.5mm HDPE GMB as published by Rowe et al. (2003) and Hsuan et al. (1991). Unlike sample location C where the degradation mechanisms are limited to exposed environment, sample location D is partly exposed to the pond liquid and hence antioxidant depletion could be affected by chemical degradation mechanism of the varying liquid at respective sites. As such, some degree of differences in the degradation mechanism is likely to occur from one application to the other.

4.3 HDPE GMB Thickness Sensitivity to Antioxidant Depletion Rate

Figure 4 plots the antioxidant depletion rate versus HDPE GMB thickness from data obtained in Table 5. From Figure 4, it was observed that antioxidant depletion rate for UV exposed HDPE GMBs increases exponentially with the decrease of GMB thickness. Data for sample location D (partially exposed) also shows similar trend to fully exposed sample denoted as location C.

Figure 4 a) extrapolates the data from commonly used HDPE GMB thickness to thinner gauge HDPE GMB. The coefficient of determination (R^2) for Figure 4 a) is 0.9482 and is statistically deemed a very good fit. Figure 4 b) includes the data obtained from the case study of 0.65mm HDPE GMB exhumed from a shrimp aquaculture site in Malaysia. The R^2 for Figure 4 b) is 0.9691 which is better than Figure 4 a). Figure 4 b) thus serves to validate that the extrapolation process done in Figure 4 a) is reasonable.

The trendline exponential equation given in Figure 4 a) and b) cannot be used for exact extrapolation / interpolation of antioxidant depletion rates of HDPE GMB but is presented for the sole purpose of illustrating that durability of HDPE GMB is sensitive to its thickness following the exponential trend and not linear.

Figure 4. OIT depletion rate, S against HDPE GMB thickness.

5. DISCUSSION AND CONCLUSION

Correlation of antioxidant depletion rate versus thickness carried out in Section 4 took the following liberty:

- Initial OIT value, P were estimated at 50 minutes for data from Rowe et al. (2003), Ivy (2002) and Hsuan et al. (1991) following comments from Ivy (2002) and Rowe et al. (2003) in order to arrive at the estimated antioxidant depletion rate;
- Only 2 points were available or estimated for each set of data to compute the antioxidant depletion rate for all thicknesses;
- The likely variability of UV irradiation and differences in temperature for each respective sites were not taken into account in the correlation process;
- Data for 1.5mm HDPE GMB from Koerner et al. (2012) was inferred from published graph and not from OIT test results;
- OIT values for data from Tarnowski and Baldauf were obtained following DIN EN 728 instead of ASTM D 3895;
- Initial OIT value, P for the case study of 0.65mm HDPE GMB was estimated based on average values as the original roll could not be traced;

With regards to the above, the authors wish to express that at this juncture, there is limited information to fully validate the findings of antioxidant depletion rate and its correlation to HDPE GMB thickness in the exposed environment.

Furthermore, use of different HDPE GMB formulation, resin and antioxidants would result in varying behavior. As such, the data presented in this paper is an estimate at best and should be carefully interpolated or extrapolated with engineering judgment in order to predict the lifetime of UV exposed HDPE GMBs especially for thinner gauge liners.

However, the information obtained from this study clearly showed that antioxidant depletion rate does not increase linearly but exponentially with decreasing HDPE GMB thickness. It is therefore wise for stakeholders to be cautious in the lifetime estimates of thinner gauge HDPE GMBs in the exposed environment.

Tarnowski and Baldauf also reported that for thicker UV exposed HDPE GMB such as 2.5mm, remaining OIT at the top 0.9mm portion of the GMB is significantly lesser than the middle 0.9mm portion. As such, it can be hypothesized that thinner gauge HDPE GMB is fully exposed to UV radiation throughout its entire core whereas the middle portion of the thicker HDPE GMB is significantly protected from UV radiation.

Correlation for lifetime prediction for Stage B and C for thin UV exposed HDPE GMBs was not carried out at this moment as there are no available published data apart from the 1.5mm HDPE GMB from Koerner et al. (2012).

Lastly, the authors would also like to note that lifetime of HDPE GMBs in the field is also largely dependent on the quality of installation works. Better field workmanship is required as the GMBs get thinner especially for thicknesses of < 1.0mm.

ACKNOWLEDGEMENTS

The authors are grateful to their colleagues Simon Gilbert St-Pierre and Teoh Pei Ching who provided valuable critique of the paper and carried out the laboratory tests for samples obtained from the shrimp aquaculture farm in Malaysia.

Lining Systems for Shale Gas Drilling Activities

Theresa Andrejack Loux, Ph.D., InterGEO Services, USA, theresa@intergeoservices.com
Archie Filshill, Ph.D., InterGEO Services, USA, archie@intergeoservices.com

ABSTRACT

In the past several years, there has been an influx of oil and gas companies breaking ground in the Eastern United States and Canada for the purpose of natural gas extraction from the Marcellus and Utica formations. Geosynthetic lining systems have been utilized at many shale gas drilling sites as a solution to control environmental contamination and to contain large quantities of surface water; these applications include protection at drill pads and frack-tank storage locations, freshwater impoundments for drilling and fracking purposes, and stormwater control basins. The robustness of the geosynthetic lining systems that have been used at shale gas drilling sites varies widely by owner and location. There is also the potential for the use of geosynthetics in frack water surface impoundments and the proper management and disposal of drill cuttings.

This paper presents an overview of the geosynthetic lining systems that are, or could be, used for applications relating to shale gas drilling, a summary of the current regulations that exist for these applications, the concerns that face the engineers designing the lining systems, and finally, the challenges that are confronted by the geosynthetic contractors during installation.

1. INTRODUCTION

Natural gas has long been used to heat buildings, and more recently, it has been used to fuel internal combustion engines and power plants. With natural gas providing an alternative to oil, gasoline, and coal in these applications, it promises a marked decrease in the dependence of the U.S. on foreign oil. It is often seen as a “cleaner” fossil fuel and has been easier to harvest with the advancement of drilling techniques including horizontal drilling and hydraulic fracturing (also known as “fracking”). In 2008, studies were published citing the recoverable gas potential of the Marcellus Shale to be around 363 trillion cubic feet as a low estimate. It is not surprising this information set off a large prospecting rush throughout the Northeast (Wilber 2012). Gas has been extracted from shale basins worldwide; Figure 1 shows identified shale gas plays within the continental United States. The Marcellus Shale extends from Virginia to New York, with the distribution of Marcellus Shale Play as presented in Table 1.

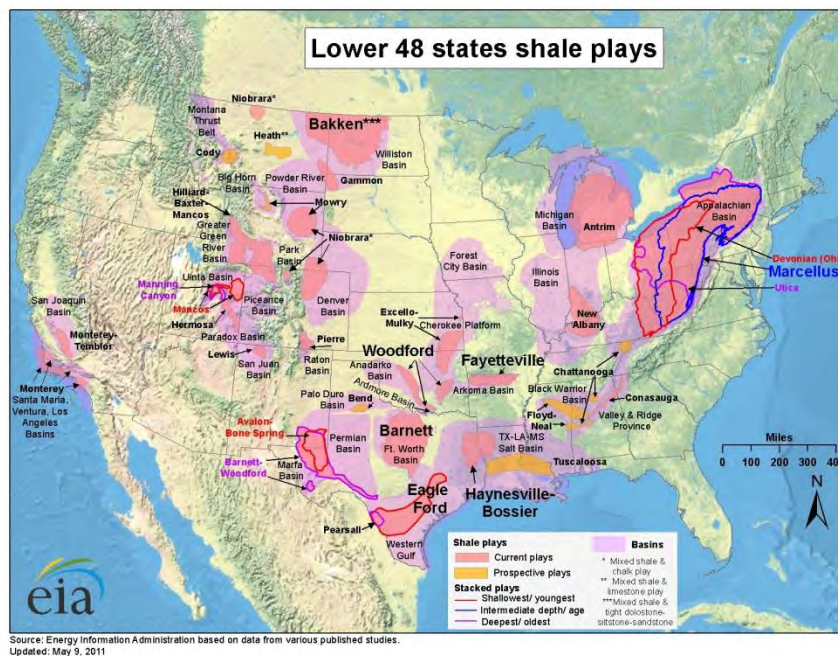

Figure 1. Shale Gas Plays in the Continental United States [U.S. Energy Information Administration (2011)].

Table 1. State Distribution of the Marcellus Shale Play [U.S. Energy Information Administration (2011)].

State	Area % of Marcellus
Pennsylvania	35.4
West Virginia	21.3
New York	20.1
Ohio	18.2
Virginia	3.9
Maryland	1.1

Fresh on the heels of the Marcellus Shale speculation is new information hypothesizing that the Utica Shale formation, covering a more extensive footprint in the Appalachian Basin and several thousand feet deeper, will rival the resource potential of the Marcellus play (Wilber 2012).

A large source of potential contamination during shale gas drilling activities is from the mixture of water, sand, and chemicals used during fracking operations. This mixture is forced under high pressure through the vertical and horizontal bore in order to split the rock and free the trapped gas (Wilber 2012). Without these additional pathways for gas to flow out, the shale rock would not be permeable enough to extract large quantities of gas. The chemicals that are added during fracking serve roles such as reducing friction or killing bacteria (Galbraith 2012). Additionally, the recovered water from fracking, also known as flowback or produced water, will contain these added chemicals as well as naturally occurring contaminants that exist within the subsurface profile. Thus, the contaminant profile of the flowback water is very site-specific. Commonly found contaminants in flowback water include mineral salts, heavy metals, and organic compounds, and naturally-occurring radioactive elements (U.S. Environmental Protection Agency 2000).

A complication to environmental protection during shale gas drilling is that only some U.S. states have disclosure laws requiring oil and gas companies to provide information on the chemical makeup of the fracking fluid additives that they are using. Even in states where disclosure laws exist, there is often a “trade secrets” clause that enables companies to prevent this information from ever entering the public sphere (Galbraith 2012).

2. APPLICATIONS OF LINING SYSTEMS IN SHALE GAS DRILLING

Geosynthetic lining systems have been vetted by the solid waste industry for the past 50 years to ensure the adequate protection of our groundwater sources and the surrounding environment from potential contamination. Other industries are quick to adopt these systems, including similar material types, configurations, and quality control techniques during construction, when confronted with the same goal. Similarly, the materials used to waterproof ponds for freshwater storage or stormwater control have been in existence for many years, and these lining systems are ubiquitous in modern E&S control plans.

2.1 Drill Pads and Frack Tank Storage

Typically, there exists three (3) to six (6) vertical well heads at a single well site. Large drill rigs are brought in to complete the vertical and horizontal drilling of each well. These wells are usually concentrated in an area onsite known as the drill pad. While the well heads are usually clustered together at a site, it should be noted that because of the existence of horizontal drilling, the “reach” of a single well site can extend radially outward for several miles from the drill pad. The pumps and pipe lines required for fracking are connected at these access points on the drill pad.

Frack tanks are often located in close proximity to the well heads, in many cases utilizing the same underlying lining system to protect against any spills or leaks from the tanks, piping network, or pump system.

2.2 Freshwater Impoundments and Stormwater Control Basins

During fracking operations, large quantities of fresh water are consumed. Thus, a reliable method of storing the required water is necessary and is often a geosynthetic-lined impoundment. The inclusion of lined stormwater control basins at shale gas drilling sites may be necessary depending on the BMPs that govern an individual site.

2.3 Frack Water Surface Impoundments and Drill Cutting Disposal

There are sites where frack water is stored in impoundments rather than onsite, above-ground tanks. These flow back pits may also serve as temporary storage facilities for drill cuttings that reside onsite during drilling operations. Eventually, these cuttings are normally sent to a nearby solid waste disposal facility for permanent removal.

3. GEOSYNTHETIC LINING SYSTEMS OVERVIEW

All geosynthetic lining systems acting as barriers are designed to be “impermeable”; that is, they are intended to prevent or restrict the transport of liquid or gas through them. Geosynthetic materials that function as barriers include geomembranes and geosynthetic clay liners. There are many types of geomembranes that vary with resin type (LLDPE, HDPE, PVC, etc.) and additives, texture, and thickness. The resin type and additives will be most critical when determining compatibility of the contaminants with the geomembrane. Geosynthetic clay liners are more expensive than most geomembranes and should be analyzed for compatibility issues if utilized to contain flow back water.

The design for a liner system includes specified items including: geometry of the liner, cross section including underlying and overlying materials, geosynthetic type and thickness, and runout and anchor trench details (Koerner 2005).

The design lifetime for the lining systems at shale gas drilling sites can vary greatly. Some of the freshwater impoundments are only required for the initial vertical and horizontal drilling at these sites which may take around one year to complete. Other applications, such as the liner system under the well pad itself will be in use for the lifetime of the wells (as long as 40 years). The applications detailed above can be divided into two categories: the first must prevent the migration of generally fresh water while the second must prevent the migration of contaminants.

3.1 Containment of Freshwater

Additionally, it is imperative to include an underdrain system in these freshwater impoundments to prevent gas “whales.” These whales are pockets of gas that get trapped beneath a geomembrane liner and have no pathway to escape. Common underdrain systems include: sand bedding layers, thick needle-punched nonwoven geotextiles, drainage geocomposites, and geotextiles outfitted with small perforated pipes within its cross section. A typical cross section and installation photograph is shown in Figures 2 and 3.

Figure 2. Typical liner system cross section.

Figure 3. Photograph of the installation of an exposed, 1.5 mm (60 mil) HDPE liner underlain by a draitube geocomposite.

While the freshwater impoundments described above are generally designed to balance cut-to-fill earthwork quantities, certain circumstances such as a high water table or permitting issues, lead to mobile impoundment construction. These mobile impoundments consist of fabricated steel trusses with a geomembrane liner overlying them (Figure 4). While generally more expensive than the in-ground impoundments, the only site requirement for these systems is a flat, competent subgrade. These systems also have the benefit of being able to be deconstructed and reused, giving them an economic advantage in cases where the impoundment will be in service for a relatively short period of time.

Figure 4. Photographs of an above-ground impoundment for water storage.

3.2 Containment of Contaminated Water and Waste

A more robust lining system would include both a primary and a secondary liner, with a collection system in between the two liners and a detection system beyond the secondary liner. While this type of system is common in landfills where leachate will be generated over hundreds of years, the containment of flow back water will only be necessary for the design life of the well pad (likely 20- to 30-years).

The author has seen a gamut of well pad designs. The minimum requirement is generally a single geomembrane or geosynthetic clay liner. Other designs combine the two materials to form a composite liner. Yet other systems that have been proposed include a geomembrane liner overlaid by a cushion geotextile and then topped with geocells or other specialty mat or cushioning product (Figure 5).

Figure 5. Photographs of a potential well pad system that consists of, from the bottom upwards: a 1.5 mm (60 mil) HDPE textured geomembrane, a 340 g/m² (10 oz./yd²) cushion geotextile, a 50 mm (2 in.) recycled foam product, and a durable, reusable specialty mat product.

4. REGULATIONS REGARDING LINING SYSTEMS IN SHALE GAS DRILLING

To attempt to summarize all of the regulations regarding shale gas drilling in the U.S. would be an onerous task as there is a fair amount of variation state-to-state.

Koerner and Koerner (2012) compiled survey results of 35 U.S. state environmental departments to determine how many departments were involved with the shale gas drilling permitting process. Alarming, 18 states responded to the survey indicating that two to four departments were involved in the permitting process. Many of these states are those that are relatively new to shale gas drilling activities. It should also be noted that currently, New Jersey has a ban on all fracking within the state and New York has had a moratorium on shale gas drilling for the past four years while the environmental impacts of hydraulic fracturing are evaluated.

As an example, a review of the Pennsylvania regulation (PA § 78.56) for pits and tanks required for the temporary containment of polluttional substances and wastes during and produced from drilling, the following requirements are set forth:

- Two (2) feet of freeboard should be maintained at all times.
- The synthetic liner should have a coefficient of permeability of less than 1×10^{-7} cm/s.
- The synthetic liner thickness should be greater than 0.75 mm (30 mils).
- The protective subbase should be greater than 150 mm (6 inches) thick.
- The bottom of the pit should be at least 20 inches higher than the seasonal high groundwater table.
- The pit or tank should be protected from third parties at all times.

Many companies with drilling operations in Pennsylvania have chosen to exceed the requirements listed above, most notably with an increase in the thickness of the synthetic liner. Also in Pennsylvania, there exist recommendations to provide a secondary containment system with a leak detection layer in between the secondary and primary liner system for flow back pits and drill pits.

5. CONCERNS

5.1 Engineering Perspective

In many cases, the state in which a given site is in will dictate the minimum lining system requirements in a freshwater or containment liner system. While the culture of the oil and gas company often contributes to the assent of increasing the robustness of the system that is designed and installed, many engineering firms should also be commended for their expert guidance that they have provided.

Those local engineering firms that are active in the solid waste sector and already experienced with all aspects of designing long-term containment solutions likely had an easier transition to providing oil and gas companies with lining system design and oversight services. Additionally, these companies would be familiar with the geology in the areas where drilling operations commenced. In some states, it might be an advantage to be familiar with the solid waste

regulators if shale gas drilling impoundments also fall under their jurisdiction. In other states, Pennsylvania included, many engineering firms deal with an entirely different department for shale gas impoundments and liner systems than they do for solid waste.

Best management practices (BMPs) influencing liner system design and selection include but aren't limited to: material strength (its resistance to tear and puncture), liner material compatibility with the contained medium, installation methods, quality control and inspection, and maintenance and repair procedures. The underlying geotextile or geocomposite should be designed to serve two primary roles: to provide drainage to prevent the formation of whales under the liner system and to provide puncture protection to the geomembrane liner from the subbase material. In any liner system design, the subgrade soil stability and cover soil stability should always be evaluated, and may affect the selection of the liner. Common geomembrane liner materials are 40- or 60-mil textured LLDPE or HDPE geomembranes.

Also, with regards to the regulatory hurdles, certainly those states with a single department that acts as the point of contact for all shale gas permitting has a more transparent and easier to navigate permitting process than those which do not.

5.2 Contractor Perspective

Some of the biggest challenges for geosynthetic and earthwork contractors working at Marcellus Shale sites are the locations themselves. The sites are generally rural, mountainous, and out of cell phone reception (Figure 6). Combined with the capricious weather in the Northeast U.S., contractors must be organized and prepared for adverse conditions, as well as somewhat flexible in their installation schedules. The pace of construction has slowed somewhat in the past year as natural gas prices reached all-time lows, but there are still many wells being permitted and drilled at this point in time.

Quality control is of utmost importance during the installation of the liner system itself. A fusion weld or extrusion weld is utilized to seam LLDPE or HDPE geomembranes. The more conscientious owners and engineers will insist that the field crew completing these welds should have sufficient training, experience, and qualifications. The geosynthetic contractor may be required to complete nondestructive field testing of every seam and weld in the liner system and document these and the panel locations in field as-built drawings. Additionally, destructive tests are completed at given intervals to ensure proper seam strength. There is usually a third-party CQA consultant present at all times during liner installation to ensure proper installation conditions and procedures. Once the liner system installation is complete, a leak-detection survey may be done before the pit is put into service.

Figure 6. Aerial photograph of a remote drilling site in Central Pennsylvania.

6. CONCLUSIONS

The regulations and governing agencies that influence lining system design at shale gas drilling sites varies by state within the U.S. Within a single U.S. state, the lining system requirements may differ for pits or tanks that will contain potentially polluted sediments or liquid compared to those that are constructed to hold freshwater reserves or stormwater

runoff. Geosynthetics offer versatile and cost-effective solutions in lining systems to minimize the impact of shale gas drilling activities on the surrounding environment.

Market Impacts for Geosynthetics from the Regulation of the Storage of Coal Combustion Residuals

Authors: B. Ramsey, GSE Environmental LLC., Houston, Texas, USA, bramsey@gseworld.com
A. Aho, Director, Technical Markets, Industrial Fabrics Association International, Roseville Minnesota USA

ABSTRACT:

The Geosynthetic Materials Association (GMA) is a United States based industry and trade organization with the goal of expanding the marketplace for geosynthetics. GMA provides a forum for consistent and accurate information to increase acceptance and promote the correct use of geosynthetics. Activities center on five areas: engineering support, business development, education, government relations and industry recognition.

Arguably, the most important of these activities is government relations. GMA has operated an active government relations program with a firm working full time within Washington D.C. to pursue opportunities for geosynthetic materials. Working together with this firm, GMA has conducted lobbying efforts and engaged not only congressional offices, but multiple agencies including US Environmental Protection Agency (EPA), Department of Transportation, Bureau of Reclamation, the Department the Interior, the Army Corp of Engineers, the Council on Environmental Quality and other federal and state agencies. In each case, the overall goal of the discussions was the same; to promote the use of geosynthetic materials as cost effective, performance enhancing and environmentally friendly alternatives to traditional soil, sand, gravel and clay as construction materials. Coal ash storage has been an important issue in this effort.

Coal ash storage site failures at a power facility in Kingston, Tennessee in December 2008 and Oak Creek, Wisconsin in October 2011 and more than 50 documented cases of groundwater contamination near coal ash storage facilities all relate to the US EPA's issuance of a notice of proposed rulemaking in June 2010. These proposed rules outline new regulations for the storage of coal ash which will require the use of geosynthetic materials and expand the geosynthetic market significantly. This paper will present pertinent facts on the existing marketplace, discuss the current status of the regulatory, legislative and governmental processes and offer current opinions and projections on the potential effect of regulations on market size and impacts. The market growth will be reviewed in three segments: new site lining/barrier opportunities, capping and "normal" site closure opportunities and large scale site remediation and associated closures opportunities.

1. INTRODUCTION

It is difficult to present marketing information at a technical conference or via a technical journal. However, this paper aims to do exactly that. The written section of the presentation will largely contained historical information that is pertinent, presented chronologically. This is intended to provide context and an historical background. The "live" presentation portion of this paper will contain current information on the effects of the regulation of coal ash storage on the geosynthetic marketplace in North America.

2. HISTORY AND TIMELINE

The geosynthetics market as a whole and the geomembrane industry in particular received its first large growth spurt with the 1976 U.S. Congressional act known as RCRA [The Resource Conservation and Recovery Act]. RCRA created regulations to manage the store of both household and hazardous waste. The regulations were issued in two sections, the first specific to material deemed as hazardous waste, the second addressing the long-term fate of solid waste. Hazardous waste has since become known as "subtitle C" type waste and solid or most commonly household waste has become known by that specific section of the regulations "subtitle D." There is an additional waste stream known as construction and demolition waste or "C& D material" that is not regulated under RCRA but is instead addressed on a state-by-state or local regulatory basis.

The second significant regulatory impact waste management occurred in 1980 when the U.S. Congress passed the Comprehensive Environmental Response, Compensation and Liability Act more commonly known as "Superfund." Superfund was created to clean up uncontrolled hazardous waste sites. This regulation not only increased demand for geosynthetic materials but helped to spur on large growth in the capping applications, using geosynthetics as surface or near surface barriers to prevent rainwater infiltration.

3. COAL ASH, ITS REGULATION, OR LACK THEREOF, IN THE UNITED STATES

The proper place to begin this review is in calendar year 1980 with the passage by the U.S. Congress of what is known as the "Bevill Amendment," named for former Representative Tom Bevill (D-AL). This law amended RCRA by adding section 3001(b)(3)(A)(ii), known as the Bevill exclusion, to exclude "solid waste from the extraction, beneficiation, and processing of ores and minerals" from regulation as hazardous waste under Subtitle C of RCRA. It also required EPA to study the impact of coal ash on the environment. This study was completed and published in the Federal Register on May 22, 2000. The study reported "The Agency has concluded these wastes do not warrant regulation under subtitle C of RCRA and is retaining the hazardous waste exemption under RCRA section 3001(b) (3) (C). However, EPA has also determined national regulations under subtitle D of RCRA are warranted for coal combustion wastes when they are disposed in landfills or surface impoundments,..." However, the EPA determination for subtitle "D" regulation was not heeded and the absence of regulations of coal ash storage continued. Consequently just before 1 a.m. on Monday, December 22, 2008, a dike containing coal fly ash slurry ruptured at an 84-acre (0.34 km²) solid waste containment area at the TVA Kingston Fossil Plant in Roane County, Tennessee, USA. An estimated 1.1 billion U.S. gallons (4,200,000 m³) of coal fly ash slurry was released. Subsequent direct clean-up and remediation costs have been estimated at greater than 1.3 billion dollars.

Figure 1

This incident and other issues with groundwater contamination at or near coal combustion residual storage facilities has resulted in the US EPA considering new regulation of coal ash storage and significant companion actions on the legal, federal congressional and multiple governmental fronts.

Following the Kingston spill, on June 21, 2010 the EPA issued a "proposed rule" for the regulation of coal ash storage. . The proposed rule was actually at least three, perhaps as many as six unique and different regulatory schemes depending on how they were parsed. Two of the regulatory schemes were to regulate coal ash as a solid waste, under RCRA subtitle "D." or as a hazardous waste, using subtitle "C." Additionally, an option described as "D prime" but was also discussed in some detail. EPA held a series of nine public hearings on this topic. There have been volumes of comments, correspondence and information provided on this topic by participants across all range of the political spectrum. (In the opinion of this writer, EPA overreached in the attempt to obtain classification for coal ash as a hazardous waste material.) Further, EPA did itself and the United States a disservice by proposing multiple options rather than a single concise proposal.)

On October 12, 2011 after a period of internal consideration, EPA published a Notice of Data Availability [NODA] requesting additional comments and information on some selected topics pertinent to coal ash.

The U.S. EPA surveyed the operators and owners of coal-fired power generation facilities and received responses covering 240 facilities and 676 surface impoundments. Of the units that have been rated, 50 (of the 676) have been given the designation of "high hazard." This designation does not indicate a high probability of failure at a site; a site can receive a

“high hazard” designation based on its location-and the impact on the surrounding neighborhood or environment should a failure occur even if the estimated chances of failure are small.

On October 31, 2011 a failure occurred at a power generation facility owned by a WE Energies located on the shore of Lake Michigan in Oak Creek Wisconsin, south of Milwaukee.

Figure 2

This event resulted in a significant quantity of coal ash being released into Lake Michigan.

According to a report published by the State of Wisconsin Department of Natural Resources, the spill was the result of construction of a sediment retaining basin being constructed over old coal ash deposits. “...the FGD sediment basin would potentially be constructed in coal ash deposits (see figure 5). During construction, ash deposits were found in the western portion of the FGD sediment basin. These deposits were removed and replaced with suitable soil in accordance with the contaminated materials management plan. However, a liner plan was not submitted to the Department when ash deposits were discovered...” “A significant component of the bluff collapse material appears to be the coal ash deposited in a ravine in the 1950s – 1960s.”

4. CONGRESS ATTEMPTS TO ACT

On October 14, 2011 the U.S. House of Representatives passed H.R.2273 - Coal Residuals Reuse and Management Act, also known as the McKinley bill after the sponsor (Representative David McKinley (R-WV)). On October 20, 2011, Senator Hoeven (R-ND) and co-sponsors introduced to the 112th congress Senate resolution #1751, proposing legislation closely paralleling H.R. 2273; a modification of subtitle ‘D’ of the RCRA regulations, essentially regulating coal ash as a non-hazardous, solid waste. Multiple versions of legislation and regulatory schemes existed during this period and for several weeks, the regulation of coal ash was an active component of the 112th congress’s transportation bill, however, in the final negotiations, coal ash was dropped from that particular bill.

Subsequently, on August 3, 2012 the “Coal Ash Recycling and Oversight Act of 2012” (S.R.3512) was introduced to the Senate, sponsored by Senator Hoeven and 23 others (12 Republicans and 12 Democrats) . As of this writing, the congress is in recess, but it is anticipated that this bill may see action during the 112th congress. Clearly, some form of regulation for coal ash disposal will be propagated either through the legislative or regulatory pathway.

5. MARKET SIZE ESTIMATES

We further address the question of how much coal ash there is in existing storage facilities and how much is being produced and, what regulations might mean to the size of the North American geosynthetic marketplace.

Coal is used to supply approximately 45% of the annual demand for electricity in the U.S. It is estimated that 125 billion kilograms of coal ash is generated annually in United States. Of this quantity approximately 43% is “beneficially reused” or recycled into applications such as concrete, wallboard, pavement and other construction materials. Using an average bulk density for coal ash of 725 kilograms per cubic meter this equates to a volume of slightly greater than 172 million cubic meters per year total, with approximately 74 million cubic meters per year placed into long term storage/landfill operations. If one assumes a facility height of 15 meters, an annual area of just under 500 hectares (1235 acres) is needed for storage. While this is clearly a large number, the underlying assumptions are critical to understanding the market effect. One must settle on estimates for the following factors at a minimum; the number and capacity of existing facilities, an accurate bulk density of the specific ash in question, site selection, geotechnical, construction and other issues relative to the height/depth of the ash storage pile, additional land use and geometric concerns as well as a host of other factors, all highly variable.

The combination of this information and data set into an estimate of the effects of regulation on the geosynthetic marketplace is complex. Clearly regulation will expand the marketplace significantly. A critical unknown is the regulatory activity for existing facilities, both those currently receiving coal ash and those that are no longer receiving ash. Generally these sites have not been “closed” as thought of in the context of geotechnical, geosynthetic and environmental engineering. It is conceivable and in fact likely the regulators will concern themselves with the fate of the sites and locations where coal ash had been stored in the past. Consideration of the past performance of sites relative to groundwater contamination and the results of groundwater monitoring would lead one to anticipate regulation of older sites, even those that may not be currently accepting ash. A second equally important concern is the “stigma” attached with the potential designation of coal ash as a hazardous waste. During the recent short term, beneficial use has clearly declined and a designation of coal ash as hazardous waste would result in more materials diverted to landfill and storage operations..

Note to reviewers and readers: This is a fast moving topic where situations change as time and political positions evolve. It is the authors’ intent to report on the current situation and implications “at the time of the conference”; providing historical and background information to place the opinions and projections of the authors into context.

6. GEOSYNTHETICS IMPACT AND MARKET ESTIMATES

A brief snapshot of the past and more recent global geosynthetic marketplace is offered in the following paragraphs. Please note that all units presented in the following are either in U.S. dollars or percentages.

In calendar year 2001, the global demand for geosynthetics was \$3.2 billion. This was distributed geographically as follows: North America 42%, Europe 35%, Asia Pacific 16%, All Others 7%. Global sales by product type: geomembrane 45%, geotextile 22%, geogrid and high strength fabrics 17%, erosion control materials 10%, drainage materials 6%. Global sales by application; pavement 25%, erosion control 8%, drainage 11%, barrier products 22%, stabilization and reinforcement 22%.

In calendar year 2010, the global demand for geosynthetics was \$6.1 billion. This was distributed geographically as follows: North America 40%, Europe 18%, Asia Pacific 21%, All Others 21%. Global sales by product type; geomembrane 32%, geotextile 32%, geogrid and high strength fabrics 8%, erosion control materials 11%, drainage materials 17%. Global sales by application; pavement 18%, erosion control 13%, drainage 16%, barrier products 34%, stabilization and reinforcement 19%.

7. CONCLUSIONS

The combination of this information and data set into an estimate of the effects of regulation on the geosynthetic marketplace is complex. Clearly the regulation will expand the marketplace significantly. A critical unknown is the regulatory treatment for existing facilities, both those currently receiving coal ash and those that are no longer receiving ash. Generally these sites have not been “closed” as thought of in the context of geotechnical, geosynthetic and environmental engineering. It is conceivable and in fact likely the regulators will concern themselves with the fate of the sites and locations where coal ash had been stored in the past.

A second equally important concern is the “stigma” attached with the potential designation of coal ash as a hazardous waste. During the recent short term, beneficial use has clearly declined and a designation of coal ash as hazardous waste would result in more materials diverted to landfill and storage operations.

Shih Kai Su, Graduate Student, Department of Civil Engineering National Pingtung University of Science and Technology

Ying-Wei Liu, Professor, Department of Civil Engineering National Pingtung University of Science and Technology

ABSTRACT

The EN 12225 standard test method was adopted to evaluate the microbiological resistance of several natural and synthetic textiles. The bio-active soil criterion is the test cotton fabric should reduce 75% of its tensile strength after 7 days after burial within the test bio-active soil under controlled humidity and temperature conditions. After several trial procedures a commercial organic soil was chosen for use as the bio-active incubation soil for the standard test. The cotton fabric strength reduction, test materials and the most probable number (MPN) for total bacteria and fungi test count were evaluated for each incubation period. The test materials included the natural jute temporary erosion control mat (TECM), a reinforced polypropylene permanent erosion control mat (PECM), a polypropylene silt film geotextile, a black and white PP multi-filament woven geotextile, a reinforced polyester nonwoven geotextile, and a PVC coated polyester geogrid. After 28-days incubation the strength of the natural jute fabric was reduced by 90%. Fifteen percent strength reduction was measured for the PP PECM after nearly 4 months incubation. However, only 1.3% to 5.9% strength reductions were determined for the other tested geosynthetic materials. The total amount of bacteria was generally higher than that for fungi. The MPN values for the tested PECM and TECM were decreased as the burial duration increased. However, the MPN values increased with the increase in burial duration.

Keywords: Microbiological resistance test, Geosynthetic, Geotextile, Microbiology.

1. INTRODUCTION

Many geosynthetic applications require burying the geosynthetic product within the soil. Natural soils generally contain of large amounts of bacteria and fungi. This phenomenon is especially true for the soils in tropical areas. The primary resin used in geotextiles is mixed with anti-oxidants, screening agents, filters and/or other materials for a variety of purposes. Some of these additives might be excellent foods for the fungi and bacteria within soils. Burying geosynthetics within bioactive soils could influence the geotextiles' engineering properties. In addition, the search for biodegradable materials has also become an important environmental topic. Understanding and evaluating the microbiological resistance of several locally used geosynthetic and natural erosion control products is the purpose of this study. The EN 12225 soil burial standard test method was adopted to evaluate the microbiological resistance of the tested materials. The most probable number (MPN) of total bacteria and fungi was also used as the evaluation criteria in this study.

1.1 Soil Burial Test

BS EN 12225, Geotextiles and geotextiles-related product – Method for determining the microbiological resistance using a soil burial test was used to evaluate the biological resistance behavior of the tested materials. An environmentally controlled room was built for this study as shown in Figure 1. The tested soil was cultivated for one month to ensure the bioactivity reached the standard requirement. The cultivated temperature was controlled at 28 ± 2 °C with the relative humidity kept at $97 \pm 2\%$. The water content of the tested soils was kept at around 100%. Cotton fabric strips were buried 100 mm deep within the cultivated soils for 7-days. The fabric strips were then retrieved and cleaned with an alcohol/water mixture. The cleaned and retrieved cotton samples were then stored at a temperature of 20 ± 2 °C with relative humidity of $65 \pm 5\%$ for 72-hours before checking the strength reduction rate. Strength reduction greater than 75% or not was the criteria. Five soil containers were used to evaluate the tested soil activity. The average reduction rate was 79.28%. A minimum of 18 test samples for each tested material were buried approximately 100 mm deep to ensure good contact with the test soil. The containers permitted free oxygen exchange. The incubation temperature was controlled at 26 ± 1 °C with the relative humidity maintained at $95 \pm 5\%$ during the test. The water content of the test soil was kept at around 60% and checked every 4 weeks. The test

containers with test samples were incubated for 16 weeks at the specified climate conditions before retrieving and cleaning the fiber strips under standard procedure for further evaluation tests. The tensile strength of the control and retrieved strip samples were tested according to the EN 12226 strip tensile test method or ASTM D6637 method A for geogrid single rib tensile test.

Figure 1. Setup of incubation room.

1.2 Most Probable Number (MPN) Test

The most probable number (MPN) of bacteria and fungi test was also conducted for all tested materials and incubation soils at each period. This test procedure involved retrieving 1 g soil sample from the soil container and adding 10 ml of 100% no bacteria polluted water. The soil was suspended in diluted water for 101, 102, ..., 1010 ratios. For each diluted ratio of suspended water, take 0.02 ml suspended water added to 0.18 ml TSB and PDB incubation agents and placed within 96 well-plates. Five samples were required for each diluted ratio water batch. The mixed TSB and PDB agents were placed in well plate and kept in 30 °C incubation chambers for 3 days. The total amount MPN of bacteria and fungi for each diluted ratio suspended water was then determined using the following Equation (1). The unit of analysis is Colong-Forming Units per gram (CFU/g) for the test sample.

$$\text{MPN (cfu / gm)} = \frac{\text{MPN chart reading}}{\frac{\text{diluted ratio}}{\text{amount of water sample (ml)}}} \quad [1]$$

2. TEST MATERIALS

Several natural and geosynthetic fabrics were used in this study. The control material was a cotton fabric with unit mass of 219.59 g/m² and tensile strength of 10.80 kN/m. A temporary erosion control material (TECM), a reinforced jute erosion control fabric was used as another natural test material. Five geosynthetic geotextiles and related products were used in this study. The synthetic test products included a PVC coated PET geogrid, a green polypropylene silt film woven geotextile, a black and white PP multi-filament woven geotextile, a white reinforced polyester nonwoven geotextile and a PE reinforced polypropylene erosion control mat. The mass per unit weight and tensile strength of the tested materials are summarized in Table 1.

Table 1. General properties of the test materials.

Type	Mass per unit area (g/m ²)	Base Material	Strength per unit width (kN/m)
Jute-TECM *	559.68	Jute	4.90
PECM (PP)	263.93	PP	3.40
W-GT1(PP)	323.95	PP	75.80
W-GT2(PP)	465.67	PP	81.20
NW-GT(PET)	594.70	PET	108.40
GG (PET)	1536.44	PET	190.97

3. TEST RESULTS AND DISCUSSIONS

Five soil containers were cultivated for one month and used to evaluate the test soil activity. The incubation durations for the reference cotton fabrics were seven days and 14 days. The retrieved 7-day cotton fabric samples were cleaned and conditioned according the standard procedure. Three samples were retrieved from each container. The retained tensile strengths of the retrieved samples were tested according to the EN 12226 test standard. The average reduction rate in tensile strength was 79.28%. A picture of the samples before the tensile test is shown in Figure 2. Two containers of cotton samples were extended to 14 days. Figure 3 shows the retrieved 14-day cotton samples. The fabric structure of the samples was completely destroyed by the bacteria and fungi within the test soils. The selected commercial organic soils and incubation procedure satisfied the biological activity requirement for EN 12225 test standard.

Figure 2. Picture of 7-day incubated cotton strip samples (significant rot was observed).

Figure 3. Picture of 14-day incubated cotton strip samples (samples were completely destroyed by rot).

The biodegradation properties of the five geosynthetic products and one natural jute fabric were studied. The incubation duration was 4 months or more. Incubated samples were retrieved from the test containers to evaluate the tensile strength and total MPN of bacteria and fungi. The typical retrieval times included 7, 28, and 112-days. The maximum incubation time for the natural jute fabric was 28 days. Some geogrid samples were embedded within the test soils for 168 days. A minimum of six 50-mm samples were used for the EN 12226 tensile strength tests. Single rib samples were used for the ASTM D6637 method A test. The average tensile strengths and associated strength retained rates for the reference group and 3 different incubation durations for each test materials are summarized in Tables 2 and 3. It is clear that only 10% strength was retained for the test jute fabric after only 28 days incubation time. Low tensile strength was retained for the 14-day jute samples as shown in Figure 4. The strength of the polypropylene PECEM reduced near 15% after 112 days incubation time. Only 1.3% to 5.9% strength reductions were observed for the geosynthetic products after 112-days incubation time. The total MPN of bacteria and fungi for the test materials incubation soils are summarized in Tables 4 and 5. The total MPN for bacteria was higher than that for fungi. The MPN values for the test PECEM and TECM were decreased as the incubation duration increased. However, the MPN values increased when the incubation duration was increased. Further analysis is required. Some bacteria and fungi grew on the PP geotextile samples as shown in Figure 5, However very low strength reduction was observed for the tested samples.

4. SUMMARY AND CONCLUSIONS

The microbiological resistance of several locally used geosynthetic products and a natural erosion control product were studied. The BS EN 12225 testing method was used for the microbiological resistance evaluation using a soil burial test. The total most probable number (MPN) of bacteria and fungi for the test soils was used in this study. The retained tensile strengths of retrieved samples were tested according to the EN 12226 test standard and ASTM D6637 test method. A commercial organic soil was chosen as the bio-active soil for the standard test. Cotton fabric was used to evaluate the bio-activity of the cultivated test soils. The average strength reduction rate for the retrieved 7-day cotton fabric samples was 79.28%. The biodegradation properties of five geosynthetic products and one natural jute fabric were studied. The typical retrieval times included 7, 28 and 112-days. Only 10% tensile strength was retained for the 28-day incubation jute samples. The strength of the polypropylene PECM reduced to near 15% after 112 days incubation time. Only 1.3% to 5.9% strength reductions were observed for the remaining geosynthetic products after 112 days incubation time. In general, the total amount of bacteria was higher than that for fungi. The MPN values for the test PECM and TECM decreased as the incubation duration was increased. However, the MPN values increased with the increase in incubation duration.

ACKNOWLEDGEMENTS

This study is part of a generic research program on several natural and synthetic products by the Geosynthetic Laboratory of National Pingtung University of Science and Technology in Taiwan. The Geosynthetic Institute (USA)

recognized this laboratory as an accredited laboratory for BS EN 12225, BS EN 12226, and ASTM D6637 test methods. This study was partially supported by the National Science Council, Taiwan (NSC 99-2221-E-020-026). Mr. Chia-Shing Wu provided great support for the laboratory-testing program. The authors express their sincere appreciation to all members that contributed to this study.

Mine Water Treatment with Geotextile Tube System at Goldex Mine (Val d'Or, Qc, Canada)

Jocelyn Douh ret, ASDR Environment, Saint-Romuald, Quebec, CANADA
Andy Lister, TenCate, Toronto, Ontario, CANADA
Stephen Authier, ASDR Environment, Malartic, Quebec, CANADA

ABSTRACT

AGNICO Eagle operates Goldex Mine an underground gold mine in Val d'Or (Qc, CANADA) since April 2008. In 2009, Goldex decided to better handle mine water which was formerly directed to sumps. Solids from sumps were daily emptied mobilizing a full time scoop tram. Furthermore, water from the sumps was abrasive causing slurry pumps renewal.

A pilot test using a geotextile tube started in January 2010. High TSS mine water was conditioned in line with a coagulant and a flocculant prior dewatering with a geotextile tube. As results were convincing an automatic system was installed to feed two geotextile tubes in sequences.

Mine water average flow is about 60 m³ per hour with a 4 000 mg/L TSS level. Clean water comes out of the bags at a 10 mg/L TSS level. Once a geotextile tube is full, solids are removed by a scoop tram and reprocessed in the ore treatment process.

INTRODUCTION

AGNICO Eagle has been operating the Goldex underground Gold Mine in Val d'Or (QC, CANADA) since April 2008. The Mine is located in a semi-urban location at the west end of Val d'Or, QC. (Population 45 000).

In 2009, Goldex decided to better handle mine water. Mine water was formerly directed to sumps. Solids from sumps were regularly emptied mobilizing a full time scoop tram. Furthermore, water from the sumps was highly abrasive causing frequent slurry pumps renewal.

The gold mine extracts 8500 tons of ore per day. The Lowest level of the underground mine is situated at 2500 ft beneath the surface. Ore is extracted from the bottom of the gold reef.

Mine water comes from water infiltration at the surface as well as from the reef itself. This natural water is composed of 80% Mine Water. The water is also used for underground operations such as rock crushing, machinery cleaning as well as dust control. Mine water runs along the gallery eroding the mine shaft and transporting a high level of suspended solids. This water is collected in a sump located at the very bottom of the mine (level 76 under ground level).

Picture 2 : Sump collecting Mine Water

Picture 3: Sump pump

Mine Water is then pumped to the surface using high power pumps and booster pumps. This Mine Water is extremely abrasive, which increased the maintenance costs on the pumps. In addition the Mine Water was not clean enough to meet the discharge criteria into the local water course. Quebec regulation, Directive 019 from the Ministry of Environment, lists discharge criteria as shown in Table 1.

Table 1: Discharge Criteria under Quebec Regulation

PARAMETER	Monthly Average Concentration	Maximum Concentration
Arsenic	0,2 mg/l	0,4 mg/l
Copper	0,3 mg/l	0,6 mg/l
Iron	3 mg/l	6 mg/l
Nickel	0,5 mg/l	1 mg/l
Lead	0,2 mg/l	0,4 mg/l
Zinc extractible	0,5 mg/l	1 mg/l
Cyanures	1 mg/l	2 mg/l
Hydrocarbons (C10-C50)	-----	2 mg/l
TSS	15 mg/l	30 mg/l

Solids at the bottom of the sump were removed daily by a scoop tram dedicated to this full time.

Picture 4: Scoop Tram

With the above factors in mind, Goldex Mine decided to find a better solution to manage their mine water. Goldex Mine had one goal:

- Reduce mine water management cost by
 - o Reusing water
 - o Obtaining dryer solids

1.0 – PROPOSED SOLUTION AND PILOT TEST

A Rapid Dewatering Test (RDT) with a woven geotextile tube was conducted. The purpose of the RDT test is to identify the appropriate polymers, their dosage rate and the effectiveness of the woven geotextile. The chemical conditioning consisted of using a coagulant first to precipitate dissolved ions followed by a flocculant to create a strong flock that would allow the water to be released from the sediments and subsequently filter through the geotextile tube.

A pilot test was then proposed. The process consisted of:

- Constant Agitation of the slurry in the Sump
- Pump the Mine Water to the treatment station
- Coagulant injection
- Flocculant injection
- Static Mixer, mixes both coagulant and flocculant
- Treated mine water pumped to a geotextile tube
- Clean water is collected and recycled to the crusher

Picture 5: Chemical conditioning results

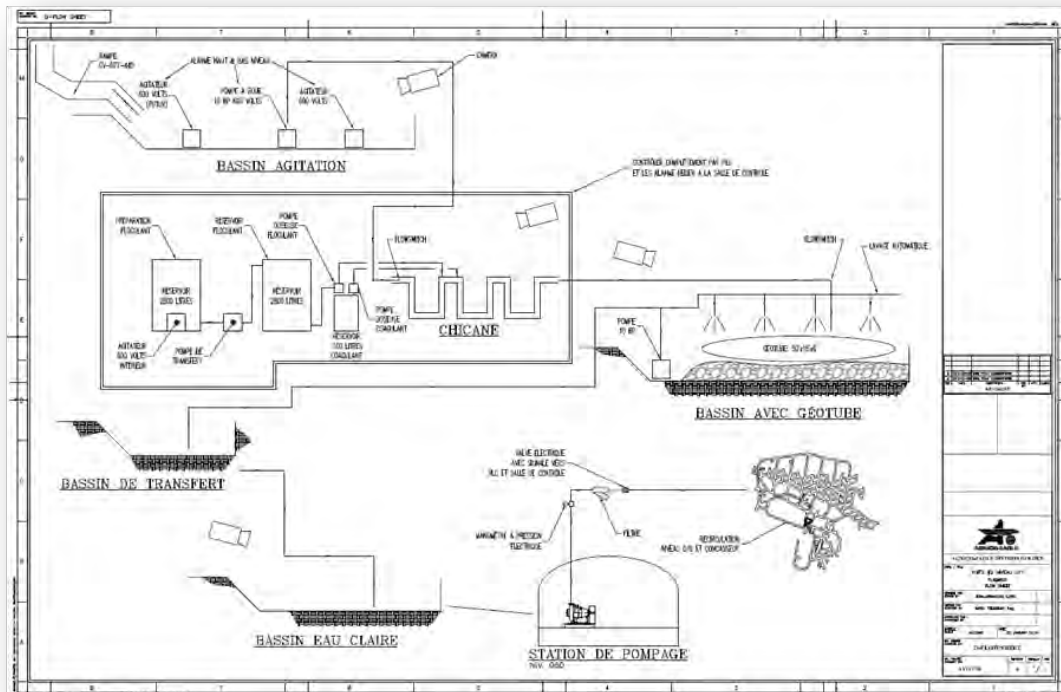

Figure 1: Principles of the process

A pilot test using a geotextile tube started in January 2010. High TSS mine water of 4000mg/l was conditioned in line with a coagulant and flocculent prior to pumping to the geotextile tube which was located in a nearby gallery (See Figure 1, Principles of the process). The dimensions of the geotextile tube were 30ft (9.14m) circumference X 50 ft(15.2m) long.

Picture 6: Chemical conditioning unit

Picture 7: Geotextile tube in a gallery

Water coming out of the geotextile tube was extremely clean with a TSS of 10mg/l

Picture 8: Clean water

2.0 – UNDERGROUND OPERATION

With the positive results of the pilot test an automatic polymer feed system was installed to feed in sequence two 30 ft (9.14m) circumference x 50 ft(15.2m) long geotextile tubes.

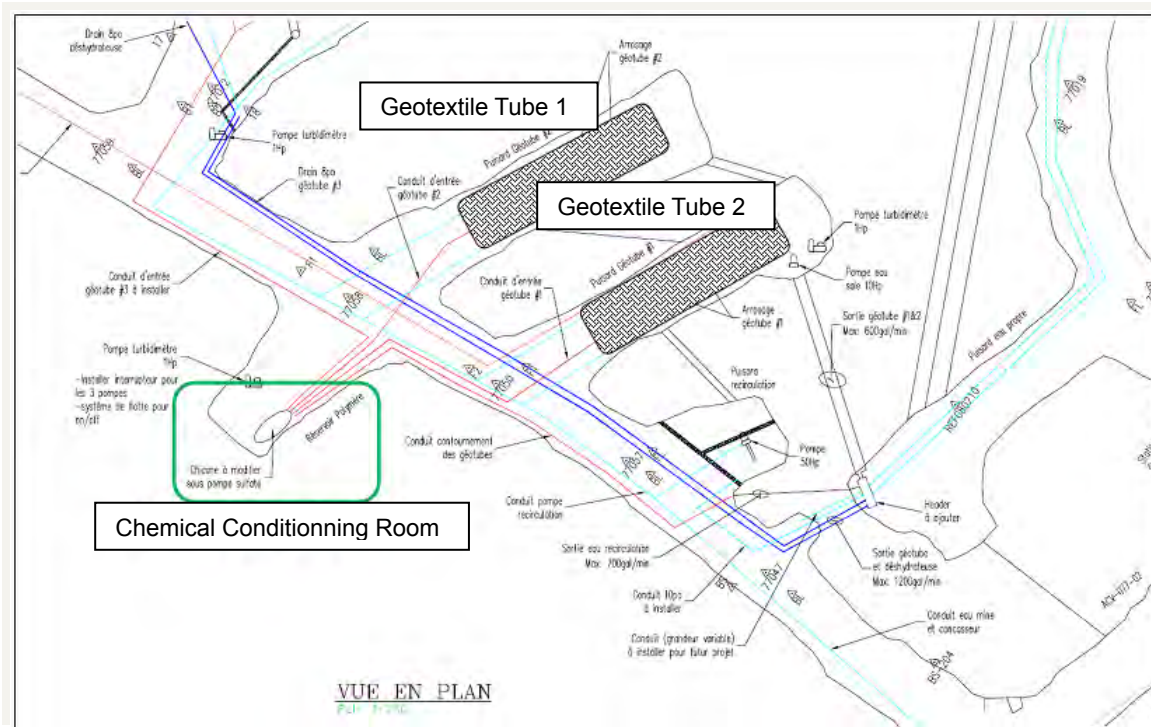

Figure 2 : Installation Plan

A more sophisticated and fully automated treatment unit was installed to ensure proper chemical conditioning of Mine Water prior to filtration and dewatering by the geotextile tube.

Picture 9: Polymer preparation unit

Picture 10 : Chemical dosing and mixing unit

Mine Water is pumped 40 minutes per hour at an average flow rate about 60 m³ per hour with a TSS level around 4 000 mg/L. Clean water comes out of the bags at a TSS level around 10 mg/L.

A sprinkler system was installed to spray water on the geotextile tube to prevent clogging.

Picture 11: Sprinkler System

Clean water coming out of the geotextile tube is used for crushing operation as well as equipment cleaning.

The geotextile tubes are filled 40 minutes every hour, 24 hours a day, 7 days a week during weeks. Solids are retained in the geotextile tubes. A complete fill cycle lasts approximately 1 month at which time the geotextile tubes are full holding 65 m³ of solids. The solids are then removed by the scoop tram and reintroduced into the ore treatment process. Table 2 shows performances of the geotextile tube solution regarding water treatment and solids dewatering.

Table 2: Performances of the geotextile tube solution

Parameters	Raw Water	Clean Water	Dewatered Solids
TSS Level (mg/L)	4000	10	n/a
Turbidity (NTU)			n/a
% solids	1 to 0,25	0,001	65
Specific Gravity (metric Tons/m ³)	1,6	1,0	3,5

3.0 - CONCLUSION

Geotextile tube solution with proper chemical conditioning allows for better Mine Water management.

Low maintenance clear water pumps then replaced the former slurry pumps. Clean water is re-used for mine operation and reduces the environmental impact of the mine on the local environment. The geotextile tube system also replaced a full time scoop tram with driver. Solids are removed once a month and follow the same mill process as ore extracted from the reef.

Using the geotextile tube solution, Mine water management costs were reduced by more than 50% compared to the previous manner.

Model Test of Stacked Permeable Geosynthetic Tubes

ABSTRACT

Geosynthetic tubes made of woven geosynthetic material provide an ideal medium for the dewatering of digested biosolids, dredged materials and industrial solid wastes and for the construction of levees. However, the dewatering process of a single permeable geosynthetic tube is time consuming. A better way is to stack permeable geosynthetic tubes one layer on top of another to use the weight of the tubes as surcharge. In order to improve the understanding of the performance of stacked permeable geosynthetic tubes, model tests of stacked permeable geosynthetic tubes resting on rigid foundation were carried out. A 2.0-mm-thick woven polypropylene geosynthetic sheet was used for the geosynthetic tubes. The deformation of the 2-layer geosynthetic tubes versus time curves are presented and analyzed in this paper. The time taken to achieve 80% dewatering efficiency for the stacking method is only 38% of that for the single tube method.

1. INTRODUCTION

In recent years, geotextile tubes have been used for dewatering waste sludge such as digested biosolids, sewage sludge, dredged materials, industrial solid wastes, fly ash and coal slurry. Traditionally, these high water content wastes are exposed to sunlight for the formation of desiccation crust. However, the process of sun drying is very slow and only effective for the top several centimeters. When geotextile tubes are used, the waste sludge is firstly filled into the geotextile tube by pumping. After that, water seeps through the permeable geosynthetic sheet and the water content of the solids inside the geosynthetic tube is reduced. In order to save space and accelerate the dewatering process, the geotextile tubes sometimes stacked together. The advantage and disadvantage of using permeable geosynthetic tubes for dewatering waste sludge have been summarized by Andrews (1999) and reproduced here as Table 1.

Table 1 Advantages and disadvantages of geotextile tube dewatering method (after Andrews, 1999)

Advantage	Disadvantage
<ul style="list-style-type: none"> • Able to dewater large quantities of sediments concurrently • Low operating costs • Can accommodate high flow rates and rapidly varying flows and solids concentrations, such as those produced from a hydraulic dredge • Provides immediate containment of material and reduces odors • Provides a method of increasing solids content quickly and efficiently • Replace small sludge lagoons, aerators and settling tanks, thus reducing the construction, maintenance and closing costs 	<ul style="list-style-type: none"> • Periodic removal of liquids required for maximum consolidation if sufficient drainage away from the tube is not provided • Water soluble contaminants can leach out over time.

In recent years, several analytical solutions for impermeable geosynthetic tubes have been proposed (Malik and Sysala, 2010; Cantré and Saathoff, 2010; Yan and Chu, 2010; Chu et al, 2011; Guo et al, 2011). The analysis of a permeable geosynthetic tube is more difficult than that of an impermeable one as the consolidation process of the soil in the tube during or after filling needed to be modeled too. One analytical method for single permeable tube proposed by Leshchinsky et al. (1996) was to assume that the consolidation process to be one-dimensional, that is, the width of the geosynthetic tube does not change during the consolidation process. The curve fitting methods to calculate the deformation of the permeable geosynthetic tube were also proposed by Shin and Oh, (2004), Yee et al. (2012) and Yee and Lawson, (2012). However, all these method were only applicable for single permeable geosynthetic tube. An easy and direct way to understand the performance of the stacked permeable geosynthetic tubes is by model test.

Usually model tests of permeable geotextile tubes were carried out in-situ because the field test considers the influence of weather and waves which are not easily simulated in laboratory. The engineering properties of dredged sediments ranged from beach sands to highly organic clays are usually indigenous to the environment from which they are dredged

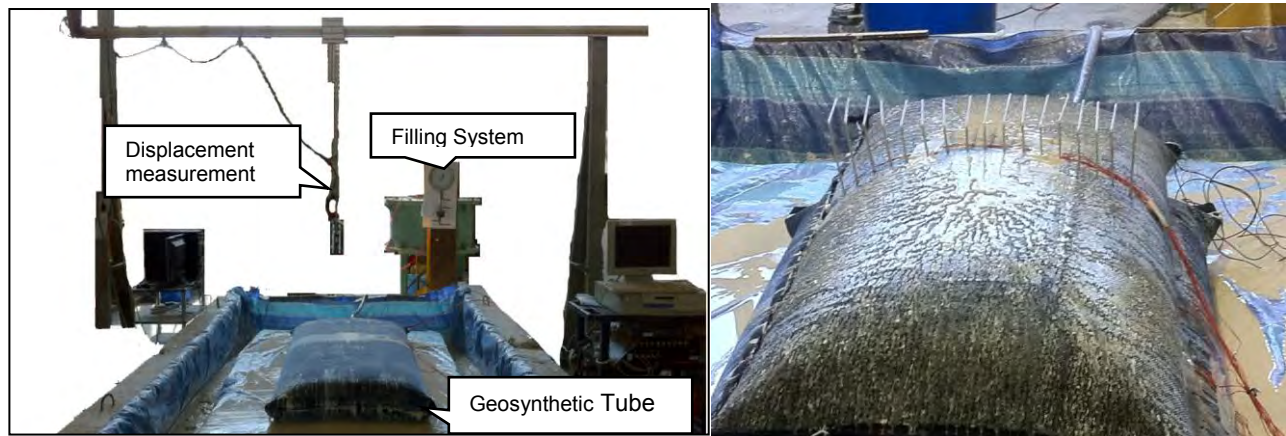

(Moo-Young and Tucker, 2002). Therefore, for coastal erosion projects, the model test of permeable geotextile tube was usually filled with dredge sand or silty clay materials on situ (Shin and Oh, 2003). However, the consolidated period will more or less be affected by the properties of the filling materials. Based on the field test conducted by Shin and Oh (2003), the dredge sand filled geotextile tube dropped off about 40% in height within 2 days from the time after being filled. But for silty clay, the tube dropped off 50% within a month after it has been filled. The basic engineering properties of consolidated soil after the model test such as water content and shear strength also have to be determined. The undrained shear strength of consolidated soil was usually tested by the laboratory vane shear test.

For dewatering sewage sludge using geotextile tubes, the dewatering time and the water content of consolidated soil are the two important dewatering performances. Normal dewatering operations require the dewatering time to be between one and two months (Lawson, 2008). The longer dewatering time constrains the speed and volume of waste that can be treated. Therefore, the acceleration of this dewatering process is necessary. Currently, there are two kinds of accelerate methods: 1) adding chemical dewatering accelerant; and 2) using electro-osmotic potential. The chemical dewatering accelerant can accelerate the dewatering time for the organic waste such as sewage sludge, lagoon solids but has no benefit with fly ash. The electro-osmotic potential dewatering acceleration method utilizes an electric potential between anode and cathode to accelerate the pore water moving through the fine-grained particles. The later method has been widely used in many kinds of sludge such as sewage sludge, waste water sludge, lagoon sewage and fine-grained residue from mine tailing.

A relatively large scaled model test of stacked permeable geosynthetic tubes resting on rigid basement was carried out in this paper. The permeable geosynthetic tubes are stacked together to use the weight of the tubes on top as surcharge to the tubes below. The tubes were made of 2-mm-thick, black color, polypropylene woven geosynthetic sheet supplied by Tok Si Engineering Co. Ltd, Taiwan. The tensile stress was 29kN/20cm and the maximum elongation was 20×27% tested by following ASTM D4595. The permeability of the geosynthetic was $1.00s^{-1}$ by ASTM D4491-99a, and apparent pore opening size (AOS) of O95 was 0.4mm by ASTM D4751. The slurry made from L2 Kaolin powder was used as filling material. Kaolinite was used because it had relatively high coefficient of consolidation. The deformation of the 2-layers geosynthetic tubes versus time curves were presented and analyzed.

2. MODEL TEST SET-UP

The experiments were performed in a box of 3.0 m wide, 4.0 m long and 0.4 m high as shown in Figure 1(a). The box was placed on the concrete floor. Two concrete beams and two wooden boards were used to form a box. Another flat wooden board was placed on the floor as the base for the geosynthetic tube. The box and the base were lined with double layers of plastic sheets to make it water proof and contain water that would seep out during the test.

(a) Panoramic view of the model setup

(b) Measurement of the surface between two tubes

Figure 1 Model test set up

The data loggers recorded the readings of strain gauges and water pressure transducers. The miniature pore water pressure transducers (PPTs) used in this model test was Druck® PDCR 81 type with an external diameter of 6.4 mm and height of 11.4 mm. Such a miniature size was necessary to minimize the influence of the measuring device to the overall soil behavior during model test. The PPTs has 5 m long and 2.3 mm diameter integral Teflon vented cable. Before a model test, all PPTs were calibrated by using water pressure generated in a triaxial cell. The reaction of the PPTs to the

applied pressure was linear and the capacity was 300 kPa. Two PPTs were used to test the pore water pressure during filling and dewatering stage. One was preinstalled on the inner top surface. Another was at the bottom.

The displacements of the HWG tubes during a test were measured by an automatic running scanner mounted on the frame. Two standing steel truss columns were fastened to the loading bearing concrete floor using bolts. A scanner was mounted on a horizontal track which was supported by the two columns. The scanner was attached to a motor so its movement could be controlled. The ILD1700-750 model laser sensor which was connected to a desktop computer recorded the time and the vertical distance to the top of the geosynthetic tubes at that time. The horizontal coordinate was calculated by the speed of scanner, 5 cm/s, multiply the recording time. Before the model test, the distance from wooden board to the laser sensor was scanned. Then the vertical coordinates of testing points on the HWG tube could be calculated as the difference between the distance to wooden board and the laser sensor readings. The contact surface between the two stacked geosynthetic tubes was determined by inserting a set of bended iron bars as shown in Figure 1(b). The bended right-angle part can be scanned by the laser sensor. The height of contact surface can then be calculated by the reading of the laser sensor subtracting the height of the iron bars. The iron bars were small enough so their disturbance to the top tube was negligible.

The kaolin powder was mixed with tap water into a slurry form. Firstly, the weighted dry kaolin powder and water were putted into a big mixer and blended for about 60 min. After mixing, the desired slurry was transferred from the mixer to a filling tank. This procedure was repeated several times until sufficient slurry was made. The filling tank had a height of 1.0 m and a diameter of 1.0 m.

Two sets of model tests on stacked permeable geosynthetic tubes (SPT) filled with slurry were tested. The details of the dimensions of the tubes and water content of the filling slurry are shown in Table.2.

Table.2 Information of stacked geosynthetic tube and filling slurry

Model test No.	Materials	Dimension of (W×L, m)		Water Content (%)
		Top tube	Bottom tube	
SPT1	HWG	0.70×1.35	1.0×2.0	71.6
SPT2	HWG	0.75×1.50	1.0×2.0	89.2

Figure 2 Filling process of Test SPT1

The model testing setup and testing procedure for Test SPT1 are shown in Figure 2. The bottom tube was filled and self-weight consolidated first in the same way as for the case of a single geosynthetic tube as shown in Figure 2(a) and (b). After the bottom tube was consolidated under self-weight, another tube was placed on top and fully inflated with the same type of slurry. The height of the tube after inflation was 0.677 m as shown in Figure 2(c) and (d).

3. TEST RESULTS

The measured cross-sections of the Test SPT1 are shown in Figure 3. Due to the limitation of the laser sensor, only the top profile of the each geosynthetic tubes could be recorded. The bottom geosynthetic tube of model SPT1 was inflated to almost sausage shape after filling for 4.51 hour as shown in Figure 3(a). Because of the dewatering process of the inflated slurry, the height of the bottom tube reduced until the top surface became flat as shown in Figure 3(a) by the profile measured at 44.6 h. At time of 99.03 h, a top tube was placed on to the bottom tube and inflated with slurry. The water content of the slurry was 71.2%. The height of the top tube after inflation was 0.677 m as shown in Figure 3(b). Under the weight of the top tube, the bottom tube compressed, but only by 2 cm, as shown in Figure 3 (b). The top tube consolidated till the top surface was flat as shown in Figure 3 (b) as the profile at time 113.2 h.

Figure 3 Cross-section changes with time for the Test SPT1

Figure 4 Cross-section changes with time for the Test SPT2

The displacements of the Test SPT1 tube versus time curve during filling and dewatering processes are presented in Figure 5. It can be seen that the self-weight consolidation of the bottom tube almost stopped 11h after filling. After the top tube was placed, the bottom tube settled about 2 cm in about 3h which was measured with the method discussed in

Figure 3. The small settlement of the bottom tube implies that the effect of the stacking of the top tube on the consolidation of the bottom tube was limited. Thus, stacking may not be effective in improving the dewatering effect of the bottom tube.

Test SPT2 was conducted using the same method as that for Test SPT1 except the water content of filling slurry of 89.2%. The measured cross-sections for Test SPT2 are shown in

Figure 4. The bottom tube in Test SPT2 was inflated in 1.87 hours and dewatered for 21.43 h (or total time 23.3 h) as shown in

Figure 4(a). At time of 96.93 h, the top tube was placed on top of the bottom tube and inflated till the total height of 0.606 m as shown in

Figure 4(b).

The displacements of the tube in Test SPT2 during filling and dewatering processes are shown in Figure 6. It can be seen that the self-weight consolidation process of the bottom tube were completed in about 6 hours after filling. After the placement of the top tube, the bottom tube settled about 1.9 cm in about 4 hours.

Figure 5 The height changing of Test SPT1

Figure 6 The height changing of the Test SPT2

4. DEWATERING EFFICIENCY

In fact, there is still no unified theory to predict the dewatering efficiency of permeable geosynthetic tube (Somasundaran, 2006). In this study, the dewatering efficiency, D_e , was calculated basing on the changes of displacement using Equation (8-1):

$$D_e = (H_0 - h) / (H_0 - H_{SF}) \quad (1)$$

where H_0 is the initial height of the bottom tube, h is the height at time t , H_{SF} is the final height of the bottom tube.

The dewatering efficiency for the Model Test SPT1 during self-weight dewatering stage was calculated with Equation (1) by taking H_0 = the height of bottom tube at the end of filling, and H_{SF} = the height of bottom tube before stacked. The dewatering time, t , was taken from the end of filling.

Figure 7(a) shows the dewatering efficiency versus time curve for Model Test SPT1 during self-weight dewatering stage. It takes about 3.6 hours for the 80% dewatering efficiency. Similar to the calculation of self-weight dewatering stage, the dewatering efficiency was calculated by taking H_0 = the height of bottom tube before stacked, and H_{SF} = the final height of bottom tube after test. The dewatering efficiency versus time curve for Model Test SPT1 during the stacking period is also shown in

Figure 7(a). The time was taken from the time when the top tube was placed. It can be seen that for the stacking method, only 1.56 hours was required to achieve 80% dewatering efficiency. Therefore, the stacking method is more efficient than the self-weight consolidation method as far as dewatering is concerned.

(a) Model Test SPT1

(b) Model Test SPT2

Figure 7 Dewatering efficiencies during self-weight dewatering and stacked periods

Figure 7(b) shows the dewatering efficiency versus time curves for Model Test SPT2 for both the self-weight dewatering and the stacking periods. The calculation method for Model Test SPT2 was the same as that used for Model Test SPT1. The time taken to achieve 80% dewatering efficiency was 4.0 hours for self-weight consolidation and 1.5 hours for the stacking period.

5. PROPERTIES OF KAOLIN AFTER TEST

After dewatering, the shear strength of the soil is improved as well. The engineering properties of the kaolin soil in the tube in the two model tests after dewatering were studied. At the end of the test, the permeable geosynthetic tube was cut off from one side in order to take soil samples for testing. The basic steps are shown in Figure 8 (a) to (d).

(a) Cut off the top tube

(b) Kaolin on top tube

(c) Remove the top tube

(d) Kaolin on bottom tube

Figure 8 Testing photograph of basic properties of Kaolin

Figure 9 w/c of kaolin in the bottom tube of Test SPT1

Figure 10 w/c kaolin in the bottom tube of Test SPT2

The water contents of the consolidated kaolin at different locations of the bottom tube from Test SPT1 are shown in Figure 9. It can be seen that water content distributions in the kaolin soil are not uniform. The values are higher in the center with an average of 52%, and lower on the two sides with an average of 50%. The water content of the soil along the top surface of the top tube had the lowest value of about 46%.

The water contents of kaolin in the bottom tube in Test SPT2 are shown in Figure 10. The average water content was 50.5% on the top, 52% on the two sides, and 54% at the center of the cross-section. The uneven water content distribution was due to not only the filter cake effect, but also the difference in the drainage length.

6. CONCLUSIONS

In this paper, the stacking method of permeable geosynthetic tubes is evaluated through laboratory model tests. The method uses the weight of the top tube as surcharge to the bottom tube. Through the model tests, the following conclusions can be drawn.

- (1) The stacking method is effective than the single layer of tube method. However, it is difficult to refill the bottom tube after consolidation.
- (2) The model tests results indicate that the time taken to achieve 80% dewatering efficiency for the stacking method is only 38% of that for the single tube method.
- (3) The water contents of the consolidated soil in the bottom tube were not uniform but with the higher values in the center and the lower ones at the boundary. In addition to the drainage length, the formation of filtration cake is another factor affecting the consolidation process of the soil in the tube.

Numerical Modelling of Geogrid-reinforced Unpaved Roadways

Wen-Chao Huang, Ph.D., National Central University, Jhongli City, TAIWAN, wenchaoh@ncu.edu.tw
Hung-Yun Liao, Research Assistant, National Central University, Jhongli City, TAIWAN

ABSTRACT

A partial layer of subgrade is usually excavated and backfilled with aggregates when geogrid reinforcement is used as a treatment method for improving soft subgrade as a roadway foundation. Use of geogrid reinforcement produces an adequate platform for the planned roadway construction site, where heavy traffic loading is constantly moving. This study presents different numerical modeling methods to explore the reinforcing mechanisms of the geogrid-reinforced unpaved roadways. Numerical models include finite element method and discrete element method. The finite element analysis results show that most of the settlement comes from subgrade layer, and the use of geogrid reinforcement can indeed limit the zone of yielding in the subgrade layer. Discrete element analysis results show that the local stiffness can be enhanced in the reinforced case when a perfect interlocking is achieved.

1. INTRODUCTION

During a recent survey on geotechnical problems that create difficulty for highway engineers, the issue of soft subgrades was mentioned in every response provided by construction and maintenance units. Soft subgrades usually result in high deformability, low permeability and low shear strength. In consequence, the bearing capacity of these subgrades can be very low. If, at the time of construction of the roadway and throughout the life of the pavement, moisture control such as drainage or drying is not practical or is insufficient, the wet subgrade soil is difficult to compact, unable to sustain heavy construction equipment traffic, and the compaction effort of the overlaying aggregate is ineffective. For the pavements built on such poor foundations, this leads prematurely to excessive permanent deformation, rutting and cracking. Currently, the methods to address soft subgrade conditions include excavation-substitution, soil improvement with chemical additives, and mechanical reinforcement with geosynthetics. The method selection depends on location, volume of traffic expected in service, availability of local material and time-cost consideration.

As far as employment of geosynthetics is concerned, geosynthetic materials include geotextiles, geomembranes, geogrids and geocomposites. They all have in common of being made of plastic polymers (under the form of fibers, threads or extruded sheets). In roadway engineering they can have different functions depending upon their manufactured type and base polymer. For instance, geotextiles are fabrics that can be used as separation layer, drainage layer or filter. Geotextiles have been used successfully in unpaved roads constructed on soft subgrades. In such situations, they prevent subgrade material from intruding into the overlying aggregate layer and help dissipate excess pore pressure that may build up under repeated load. As a result, compaction of the aggregate base is more effective and shear failure of the subgrade is less likely. Structural reinforcement effect is also obtained using geotextiles in unpaved roads where large deformation is allowable. Geogrids are large aperture plastic meshes that are used only for their reinforcement function. These are placed horizontally on the subgrade and backfilled with compacted aggregate. As a tensile-resistant reinforcement, geogrids can provide mechanical support and added stiffness to the aggregate layer. Geogrid reinforcement spreads the load more broadly to the subgrade, thus improved performance in terms of bearing capacity and deflection are obtained.

The reinforcement mechanisms of geogrid in an unpaved roadway include (1) tensile effect of the geogrid, (2) aggregate interlocking and lateral restraint, and (3) enhanced compaction of the aggregate material. In this study, the mechanical performance of using geogrid reinforcement in an unpaved roadway was discussed through numerical modeling including finite element method and discrete element method. The use of finite element method is to obtain the stress and strain variation in the soil mass, while the use of discrete element method is to understand the qualitative improvement of the aggregate material under different reinforcement conditions.

2. REINFORCEMENT MECHANISMS OF GEOGRID IN UNPAVED ROADWAYS

2.1 Tensile Effect of Geogrid

The tensile effect of geogrid as shown in Figure 1 is a major mechanism when there is weak subgrade or the geogrid reinforcement develops high tension strength. Application of vertical load to the aggregate layer surface produces compression of the aggregate and subgrade layers. As a result, the geosynthetic deflects and tensile forces developed.

The under-tensioned geosynthetic provides additional vertical support and lightens pressure on the subgrade. Consequently, it decreases the potential of bearing capacity failure and possible settlements of the subgrade layer.

Previous analyses suggest the tensile effect would be maximized when high modulus geosynthetics are used with very soft subgrade according to Bourdeau (1989). Miura et al. (1990) also performed laboratory tests to investigate the influence of geogrid tensile modulus. According to their experimental results, improved performance was related to the magnitude of strain measured in the geogrid during loading. Field test results also showed that the improvement was obtained in terms of rut depth reduction when using higher modulus geogrids, although not to the same level as would be obtained from the laboratory tests.

Figure 1 Unreinforced(left) and tensile effect in reinforced case(right)

2.2 Aggregate Interlocking and Lateral Restraint

Interlocking of aggregate and geogrid can be effective to improve the aggregate performance under cyclic loading. With repetitive loadings from the surface, the aggregate particles are rearranged and moved to a denser state. An appropriate size distribution of aggregate material and geogrid openings are needed such that the interlocking can be developed effectively.

Lateral restraint (Figure 2) is a reinforcement mechanism that does not require geosynthetic deflection. Under the vertical compressive pressure, particles in the aggregate layer and the soft subgrade tend to spread away from the loaded area. If the geosynthetic has sufficient interface shear resistance and tensile stiffness, friction or tangential interaction between soil and geosynthetic counteract this movement of the particles. This induces tension in the geosynthetic and enhances lateral confining stresses in the aggregate layer and the subgrade. Because confining stresses are increased, compressive stiffness and resistance of both the aggregate layer and the subgrade are improved by the lateral restraint mechanism.

Figure 2 Principle of lateral restraint action (modified from Perkins, 1997)

2.3 Enhanced Compaction of the Aggregate Material

Nimmergern et al. (1991) has indicated that as geogrid reinforcement was used in a roadway, the repetitive loading can produce an additional compaction effect to the aggregate base layer, hence increase the stiffness of the aggregate layer. When there is no geogrid reinforcement, the compaction effect may be deteriorated due to the presence of the weak subgrade layer underneath.

3. NUMERICAL MODELING

To understand the mechanisms of the geogrid reinforcement in an unpaved roadway, different numerical models were employed. Finite element models were formulated to obtain the stress and strain variations in the soil mass, while the discrete element models were established to simulate the aggregate base material under simplified unreinforced and reinforced conditions. The following sections discuss the details about the numerical modeling.

3.1 Finite Element Analysis (FEA)

In this study, finite element models were formulated to simulate a two layer system (i.e., a subgrade layer overlaid by substituted aggregate base layer) including optional geogrid reinforcement at the interface of the two layer system. Figure 3 shows a simplified axisymmetric geometry and surface loading pattern.

The layout of the FEA model is shown in Figure 3, a replication of the model established by Love et al. (1987), which is the cross section of a 2D plane strain model or axis-symmetric models with two layer unpaved system. The reinforcement is installed at the interface of aggregate layer and subgrade layer for the axis-symmetric models. A loading of $\frac{1}{2}$ widths 0.0375m is applied at the top of the aggregate layer. The detailed geometry of the analyzed model is included in Figure 3. Most of the material properties shown in Table 1 were determined based on the reference by Love et al.(1987), however, for the purpose of finite analysis, the Poisson's ratio of subgrade were suggested based on the assumption that the clay is undrained condition. Since there is also no volume change, the Poisson's Ratio was also assumed to be 0.49.

Figure 3 Layout of Finite Element Model

Table 1 Material Property in the Finite Element Model

Material	Young's Modulus (kPa)	Poisson's Ratio	Unit Weight (kN/m ³)	C_u (kPa)	ϕ (°)	Thickness (m)
Aggregate Layer	4000	0.35	19	1	36	0.05
Subgrade Layer	495	0.49	19	5.31	0	0.4
Geogrid Reinforcement	21000	0.49	-	-	-	0.001

3.2 Discrete Element Modeling (DEM)

Application of discrete element method to examine the mechanisms of geogrid reinforcement is also proposed. From the microscopic view of the aggregate particles in the sense of discrete element method, the reinforcing mechanisms such as lateral restraint, and the enhanced stiffness of the aggregate layer is the main purpose to be observed with the installation of geogrid reinforcement.

Because of the enhancement effect from geogrid reinforcements to the aggregate layer which consisted of mostly individual particles, it is of interest to investigate the effects through the application of discrete element method. The reinforcing mechanisms as mentioned previously are therefore to be investigated through the observation of aggregate movements qualitatively under either unreinforced or reinforced cases.

To simplify the unreinforced/reinforced condition in the discrete element model, the following models are established for analyses:

- (a) Aggregate particles rest on a given boundary wall.
- (b) Aggregate particles rest on pairs of smaller particles which is not subject to move in both the horizontal and vertical directions. This case is used to simulate the geogrid reinforced case.

The particles as mentioned above are simulated as cylinders (therefore simulating a 2D plane strain condition) in the models and generated randomly in a predetermined space (formed by boundaries – or walls), and then gravity force is applied to the system in order to simulate the effect of geostatic stress, another wall with limiting width simulating the foundation footing is moving downward at a certain velocity within a period of time until a given distance is achieved. The geometry of the discrete element model before loading is applied is illustrated in Figure 4. The aggregate layer consisted of 300 particles with radius ranging from 0.14 m to 0.28 m. The grids are assumed to be consisted of a series of two smaller particles with radius 0.1 m. The spacing of the grid is 1.2 m (center to center).

After the gravity force is applied to the system, it is found that the contact forces (shown in Figure 4 as black thick lines) are increasing with depth. In addition, the simulated reinforced case showed stress concentration above some “geogrid” locations. Due to this condition, the induced gravity force was also reduced in the locations adjacent to stress concentration areas, and thus the stress transferred to the subgrade layer is also reduced.

Figure 4 Discrete element model with gravity force applied

4. NUMERICAL MODELING RESULTS

4.1 Results of Finite Element Analysis

Figure 5 shows the surface and interface deformation, with a comparison between reinforced and unreinforced cases. It is found that the load plate settlement is reduced by around 40% (3.7mm to 2.2mm) with geogrid reinforcement. Also from the same figure it is noticed that most of the system deformation occurs in the subgrade layer, the settlement in the aggregate layer can be obtained by subtracting the total deformation at the top of the system by the deformation at the interface of aggregate and subgrade layer.

Figure 5 Aggregate layer surface deformation and aggregate-subgrade interface deformation for reinforced and unreinforced cases

From examination of the shear stress distribution above and below the reinforcement, it is found that the shear stress below the reinforcement is also reduced significantly by the presence of reinforcement as shown in Figure 6. The decrease in shear stress on the two sides of the reinforcement can be an advantage in the reinforced case, in that the induced shear stress in the subgrade is one source that made the system to reach failure. In addition, the vertical stress distribution also decreased from 19kPa (unreinforced) to 12kPa (reinforced) as shown in Figure 7, this result may also come from the geogrid reinforcement. Part of the vertical stress that needs to be developed in the subgrade layer in the unreinforced case now has been supported instead by the reinforcement due to the large stiffness of the geogrid reinforcement, therefore only a small amount deformation of the reinforcement is needed to mobilize this compensated vertical stress.

Figure 8 shows the development of the plastic strain in the system, it tells us what area in the system has reached the plastic deformation zone (blue zone represents yielding). From Figure 8, it is found that at the same loading step, the unreinforced case has a yielding zone both in the aggregate layer and the subgrade layer, while in the reinforced case, the yielding zone develops only in the aggregate layer and the boundary of the yielded zone has been limited as compared to the unreinforced case.

To summarize, the installation of the geogrid reinforcement in this case study plays an important role in decreasing the total deformation at the top of the roadway system, which is the main advantage of the installation of the reinforcement, the reason for that mostly comes from the compensation of stress reorganization of the geogrid reinforcement and therefore not only decrease the deformation in the subgrade layer from which most of the deformation comes, but also decrease the tendency of bearing capacity failure in the subgrade clay layer.

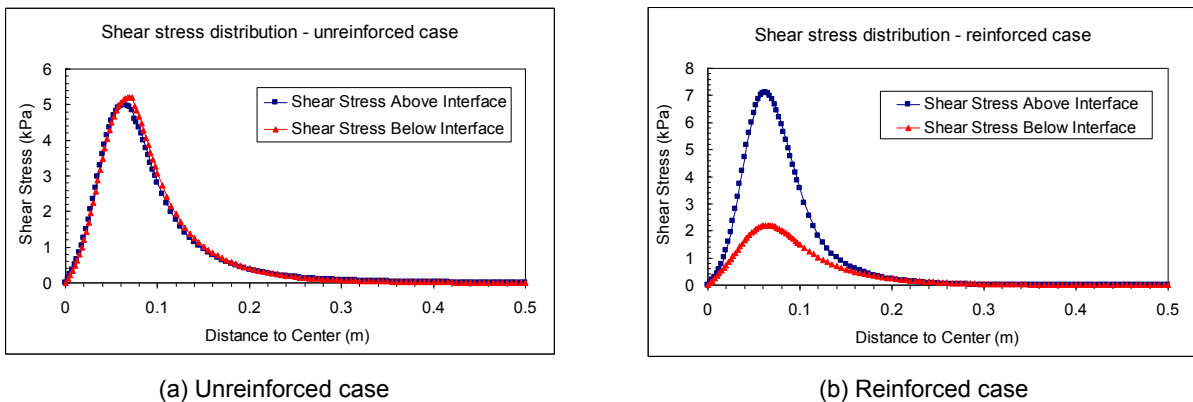

Figure 6 Shear stress distribution above (blue square) and below (red triangle) the aggregate-subgrade interface

Figure 7 Vertical stress distribution above (blue square line) and below (red triangle line) the aggregate-subgrade interface

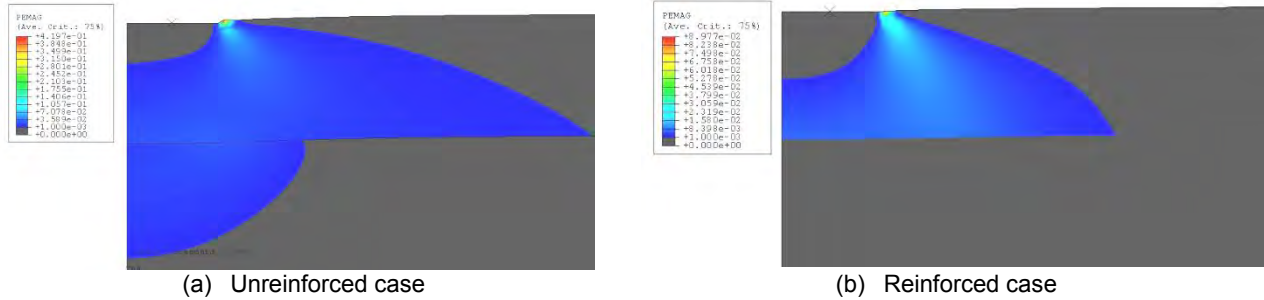

Figure 8 Yielding zone developments at the same loading stress. (grey zones represent “unyielding zone”, these two figures are at the same scale; blue zone represents yielding.)

One thing to note is that although the size of the FEM model is not realistic, however, the FEM model was established similar to a model proposed by former researchers. Once the FEM model was verified, the stress and strain fields can be observed and discussed in terms of its reinforcing mechanisms.

4.2 Results of Discrete Element Modeling

As mentioned in section 3.2, after force equilibrium is achieved in the gravity-applied system, the loading plate is then lowered at a constant speed and the development of contact forces between particles is recorded as shown in Figure 9. In the unreinforced case, the stress is distributed within a wider range and concentrated at the corner of the loading plate. In the reinforced case, the contact forces are more concentrated, especially under the loading plate. Most of the contact forces are balanced by the simulated geogrid reinforcement in the reinforced cases, while in the unreinforced case, the forces are balanced by the particle-wall friction which is not as effective as in the reinforced case.

Figure 9 Contact forces in unreinforced (top) and reinforced cases (bottom)

The contact forces are recorded when similar plate displacements are achieved. In the unreinforced case, the maximum contact force is about 820 kN at the edge of the loading plate. In the reinforced case, the maximum contact force is 1581 kN, which is evenly distributed below the loading plate. From the examination of contact forces developed in the above cases, it is therefore understood that the induced stiffness (equivalent of force divided by displacement) in the reinforced case is much larger than that in the unreinforced case. In the reinforced case, due to the limitation of lateral movement of the geogrid particles, the forces are balanced by the reaction provided by the geogrid reinforcement.

From the above results, we have expected that the reinforcing mechanisms from geogrid reinforcements are therefore developed gradually. First of all, with gravity force before the external loading is applied to the system, some of the contact forces are already balanced by the geogrid reinforcement (Figure 4, the arching effect on the right). The location might be somewhat random; however, this condition can reduce the potential stress increment onto the subgrade layer. Secondly, as the loading plate is moving downward onto the aggregate layer, the contact forces are balanced by the geogrid with the particles directly above it. Since the local stiffness of the aggregate material is enhanced due to geogrid reinforcement, the propagation of enhanced stiffness of the aggregate material is moving upward to the area below the loading plate as the loading plate is pushed down further. This procedure creates a limited force-concentrated area compared to the unreinforced case. In this area, the local stiffness is enhanced significantly due to the geogrid reinforcement. The requirement for interlocking of aggregate particle and the geogrid reinforcement is needed to ensure

the effectiveness of geogrid reinforcement. Without effective interlocking of aggregate particles and geogrid aperture, lateral restraint and tensile effect cannot be activated sufficiently.

When taking a look at the displacement vector in the cases shown in Figure 10, it is found that for all the cases, the particles that are right outside the loading plate have a tendency to move counterclockwise, the only different phenomenon that has been observed is the range of the heaving of the particles close to the surface. In the unreinforced case, the overall heaving of the particles extends to a greater depth and extends more horizontally to the right (this can be observed from the vector at the bottom of the unreinforced case), while in the reinforced case, the moving particles extend to only half of the space and the remaining particles almost stay immobilized.

Although the particles used in this analysis are cylindrical, not the real shape of the gravel layer, the main purpose of this study was to observe the reinforcing mechanisms from a microscopic point of view, in addition, the geogrid was assumed to be constrained in the lateral direction to simulate the lateral constraint of the geogrid material, this assumption was made based on the full shear strength development when interlocking was formed in the aperture of the geogrid. It was known that the tensile strength may be mobilized with increasing tensile strain, however, in this study, the tensile strength was developed as the “contact force” between the particles and geogrid increases. (which can be converted to tensile strength of the geogrid)

Figure 10 Displacement vectors of aggregate particles

The most important effect of the geogrid reinforcement can be observed in this analysis as well. From the vectors of the unreinforced case, it is found that at the bottom of the model, a noticeable horizontal displacement can be observed. In the reinforced case, it is found that the “lateral restraint effect” of the reinforcement has most significant effect below and right outside of the loading plate. Although the assumption of the “geogrid reinforcement” which is consisted of several “unmovable particles” may not be realistic in the actual practice, it provides us an insight from this extreme case.

When observing from the particle moving directions, it is shown that in the reinforced case, especially the rectangular area under the loading plate, most of the particles are confined horizontally, i.e. only vertical movements are permitted during loading. This condition explains the effect of lateral restraint and its consequences of enhanced confinement. As mentioned previously, the particles that are stuck in the geogrid apertures are confined laterally and vertically. As loading plate is moving downward, the lateral and vertical movement of the particles is less-limited such that particles below the loading plate started to express some degree of vertical and horizontal displacement. This condition can be observed apparently when comparing unreinforced and reinforced cases.

5. SUMMARY AND CONCLUSIONS

Geogrid reinforcement is a commonly used approach to deal with weak subgrade material in an unpaved roadway. The main reinforcing mechanisms of the geogrid reinforced unpaved roadway include (1) tensile effect of the geogrid, (2) aggregate interlocking and lateral restraint, and (3) enhanced compaction of the aggregate material. In this study, the mechanical performance of using geogrid reinforcement in an unpaved roadway was discussed through numerical modeling including finite element method and discrete element method. The conclusions are below:

- (1) Finite element analysis indicates that in an unpaved roadway, the settlement measured at the surface of the aggregate layer comes from the deformation of the aggregate layer and subgrade layer; however, most of the surface settlement comes from the settlement of the subgrade layer.
- (2) Finite element analysis indicates that the shear stress at the interface of the aggregate and the subgrade material is similar for the unreinforced case. However, for the reinforced case, the shear stress became smaller at the subgrade side of the geogrid reinforcement compared to the shear stress at the aggregate side of the geogrid reinforcement.

This indicated that the difference is compensated by the geogrid reinforcement and the induced shear stress in the subgrade layer subsequently decreased.

- (3) Discrete element analysis indicates that from the resultant contact forces recorded below the loading plate when comparing the unreinforced and reinforced cases, an approximate 50% increase of contact force to reach similar plate settlement is required for the reinforced case. Therefore, the local stiffness of the reinforced case was increased significantly when geogrid reinforcement is added. What was meant by local stiffness is that for reinforced case, most of the increased contact forces between particles were located right below the loading plate, only in the area below the loading plate and close to the geogrid reinforcement can we find the enhanced area extended slightly outward.
- (4) Discrete element analysis indicates that when checking from the movements of the particles, it is found that in the reinforced case, the aggregate particles tend to move within a limited range in the area under the loading plate both horizontally and vertically. Due to the assumption that the geogrid (which is consisted of unmovable particles) has very high stiffness, the aggregate particles are stuck (interlocked) in the apertures of the geogrid with very minor lateral deformation. When interlocking of aggregate material and geogrid aperture is formed at the interface, progressive interlocking between aggregate particles is initiated such that an enhanced confinement effect of the aggregate layer is appeared. The above condition explains that a higher resultant contact force may be required to reach similar plate settlement in the reinforced case.

ABSTRACT

This paper will present a comparison between results of field pullout tests and numerical simulations. The constitutive models and parameters used will be discussed. An earth dike was constructed in Poços de Caldas, Brazil, to contain 1,500,000 cubic meters of Bauxite residues. A geogrid-reinforced wall was built on the dike's top to reduce its width. PVA geogrids and local residual clayey silt were used. In order to verify the pullout behavior of the geogrid-soil system 16 large-scale pullout tests were conducted in an experimental fill. Pullout tests were simulated by finite element method. Hyperbolic elastoplastic model was used for the soil and linear elastic model was used for the geogrid. Soil parameters were determined by triaxial tests on undisturbed samples retrieved from the fill. An equivalent static distributed load was used to simulate compaction. Simulation results compare well to measured behavior.

1. INTRODUCTION

1.1 Description of the Dike

A dike was constructed in Poços de Caldas-MG, Brazil, by an aluminum company to contain 1,500,000 cubic meters of Bauxite residues. A nearby creek limited the space for the outer slope of the dike. To reduce the slope's width, a 5m high geogrid reinforced wall was built on the top of the dike. This solution led to significant reductions in volume of earth fills and in environmental impacts. Due to the high pH of the tailings material (NaOH contaminated sludge), special PVA geogrids were adopted, with a high chemical resistance. Figure 1 shows the dike and the reinforced soil wall.

Local clayey silt was excavated and used. Table 1 shows some properties of the soil. Heavy compaction equipment was used (roller and rammer compactors). Becker (2006) describes the construction details.

Two sections of the wall were monitored by telltales and topographic survey. A finite element analysis of the wall's construction was conducted (Sayao et al., 2010).

1.1 Experimental Fill and Pullout Tests

An experimental fill was built at the construction site to verify the behavior of soil-geogrid system by means of field pullout tests. The fill was 2.6m high, 3.5m wide and 10.8m long, excluding the end access ramps. The same soil and the same compaction procedures of the wall were used. A vibratory CA-25 roller was used in the center and rammer compactors close to the sidewalls. To avoid variation of vertical stress due to slopes, the fill was laterally supported by vertical walls of lumber boards, held up by steel piles on both sides (Figure 2a). To reduce wall's interference, geogrid samples were passed through metallic sleeves. This procedure was adopted by several authors (Juran & Chen, 1988, Bonczikewicz et

al., 1988, Farrag et al., 1993 and Perkins & Edens, 2003) and is recommended in ASTM D 6707. The space inside sleeves was empty thus keeping the beginning of the sample 0.15m away from the wall. Sleeves were design to be robust in order to resist high compaction stresses and field conditions. Telltales were used to monitor sample displacements and load cells were used to monitor pullout forces. The load was applied in stages with an average pullout speed of 0.7mm/min at the beginning of the samples. In Figure 2b one can see metallic sleeve and geogrid sample with telltales.

Table 1. Average characteristics of compacted soil

Characteristics	Value
Percent passing in sieve #40	84.9
Percent passing in sieve #200	74.2
Plasticity index (%)	18
Optimum water content (%)	30.4
Maximum dry unit weight (kN/m ³)	13.83

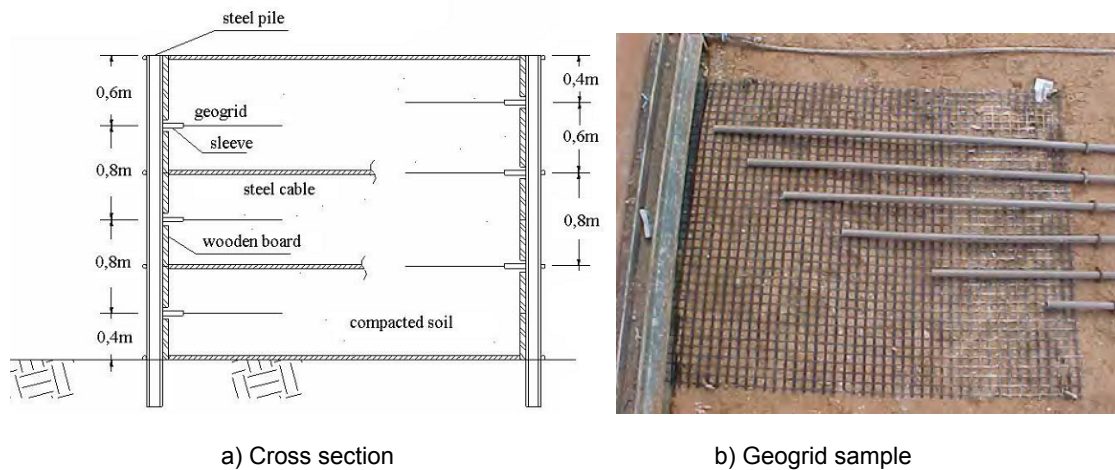

Figure 2. Experimental fill for pullout tests.

Three different types of polymeric geogrids were inserted in the fill (two of them were used in the wall). The samples were approximately 1.00 m long and 0.85m wide. Figure 3 shows results of tensile tests by manufacturer of geogrid Fortrac 55/25-20/30MP herein named 55A (ASTM D6637).

Figure 3. Load elongation curves of geogrid 55A (ASTM D6637).

Figure 4 presents the displacement distribution along the geogrid length, for tests with geogrid 55A. Some samples ruptured before pullout. Vertical stress and optimum water content of compacted soil are also shown. Strains were found to decrease along the specimen's length, due to geogrid flexibility. Consequently, the mobilized shear strength is non-uniform, being zero at the specimen's end. In many tests, slipping on the soil-geogrid interface occurred in the sample's initial portion while there was no displacement on the sample's end. Increase of vertical stress lead to a smaller mobilized length, as reported by Farrag et al (1993) and Lopes and Ladeira (1996).

Figure 4. Distribution of displacements at maximum pullout load for geogrid 55A.

2. NUMERICAL ANALYSIS

The first objective of numerical simulation of pullout tests was verifying the performance of constitutive models and parameters because it has simpler boundary conditions, mesh, and construction sequence than the reinforced soil wall.

During pullout tests, the soil-geogrid interface may reach its resistance. In soil-reinforced walls the stresses and tensile forces (T) are usually much smaller and there is not slipping in the soil-geogrid interface. To overcome this difficulty, intermediate test phases were simulated.

2.1 Finite Element Mesh and Construction Sequence

The software Plaxis 2D v8.2 was used. A mesh of isoparametric triangular elements of 15 nodes was used for plane strain analysis. Figure 5 shows the test setup. Figure 6 shows the mesh and boundary conditions of the first simulation attempt. The metallic sleeve was simulated as rectangle of linear elastic material with steel modulus. Inside this rectangle there is a smaller one made of linear elastic material of negligible modulus in order to allow free displacement of geogrid. The geogrid samples begin beside the low modulus material (point "A" in Figure 6b).

The first attempt of simulation sequence was:

- generation of initial stresses without upper layers;
- activation of first soil layer on geogrid and compaction equivalent stress;
- deactivation of compaction equivalent stress and activation of second soil layer; the process goes on until full soil height; and
- application of tensile force.

The sleeve movements were free in early simulations (Figure 6a). The simulation was later simplified by eliminating compaction procedure and by restraining sleeve movements (Figure 6b) because the residual tensile load induced in geogrid by these procedures was negligible.

Figure 5. Typical pullout test setup.

a) First simulation: finite element mesh and fixities b) Last simulation: detail of metallic sleeve and load application

Figure 6. Plane strain analysis of pullout tests.

2.2 Material Models and Parameters

Soil behavior was simulated by hyperbolic elastoplastic model that accounts for stress dependency of stiffness moduli (Hardening Soil Model). Six undisturbed blocks of compacted soil were retrieved from different layers in the wall. Table 2 presents soil parameters of Hardening Soil model obtained from consolidated drained triaxial compression tests with saturated specimens from undisturbed block no. 1.

Table 2. Strength and deformability parameters of soil.

Unit weight (kN/m ³)	Friction angle (°)	Dilatancy angle (°)	Cohesion (kPa)	E_{50}^{ref} ¹ (MPa)	E_{oed}^{ref} ² (MPa)	E_{ur}^{ref} ³ (MPa)
17.9	34.2	2.7	10.0	9.5	9.5	28.5

¹ E_{50}^{ref} is the secant stiffness modulus corresponding to the reference confining pressure 100kPa;

² E_{oed}^{ref} is the tangent stiffness modulus for oedometer conditions corresponding to the reference confining pressure;

³ E_{ur}^{ref} is the secant Young's modulus for unloading and reloading corresponding to the reference confining pressure.

The soil in the fill was unsaturated and the shearing probably was partially drained. As a first approach to the problem, it was decided to model drained shearing with effective parameters because the saturation degree of soil was about 90% and unconsolidated undrained triaxial tests did not show significant generation of excess pore pressure.

Water content, optimum water content and degree of compaction of tests no. 9, no. 10 and no. 15 (vertical stress of 14.3kPa) was very similar to values of block no. 1. Therefore, the results of those tests were selected for comparison with numerical analysis results.

In the considered tests, slipping on soil-geogrid interface and failure of soil took place before tension failure of geogrids. However, the stress level of geogrids in well-designed walls is much lower than in pullout tests. In order to account for that difference, numerical simulation represented the intermediate steps of pullout tests. Figure 7 shows an averaged displacement distribution curve of considered tests.

Geogrids were represented as linear elements without flexure or compression stiffness. The effect of confinement in geogrid stiffness is small. Therefore, it was neglected. A linear elastic model was used and the only parameter is elastic stiffness $J = 1210\text{kN/m}$ obtained from load elongation curves (Figure 2):

$$J = \frac{T}{\Delta L/L_0} \quad [1]$$

Where T is the tensile force per unit length, ΔL is the change in geogrid length and L_0 is the initial length.

Figure 7. Pullout test results and average curve, $T=20\text{kN/m}$ and $\sigma'_v=14.3\text{kPa}$.

3. SIMULATION RESULTS AND ANALYSIS

Figure 8 shows regions of equal vertical stress before the application of tensile loads. The vertical stress varies along the geogrid length and decreases close to the walls. This reduction is caused by shear stresses acting on wall's surface. A high stiffness metallic sleeve was not effective to minimize this problem because of stress concentration around itself.

Figure 9 shows regions of equal horizontal stress after the application of 20kN/m tensile load. The sleeve minimizes the wall's interference but causes stress concentration.

Load application causes strains and displacements in geogrid and surrounding soil. Figure 10 shows displacement vectors after 20kN/m tensile load application. Directions of displacement vectors close to the initial part of geogrid sample show little interference of wall.

Figure 11 shows a comparison between average pullout test results and finite element method simulation for 20kN/m tensile load. The magnitude of predicted displacements is in good agreement with field test results. Finite element simulation curve shows smaller displacements along geogrid except for the sample's initial region. In field's curve, that region shows a concentration of displacements and strains.

Figure 8. Regions of equal vertical stress before the application of tensile load.

Figure 9. Regions of equal horizontal stress after tensile load application, $T=20\text{kN/m}$ and $\sigma'_v=14.3\text{kPa}$.

Figure 10. Displacement vectors after tensile load application, $T=20\text{kN/m}$ and $\sigma'_v=14.3\text{kPa}$.

Figure 11. Displacement distribution along geogrid length, $T=20\text{kN/m}$ and $\sigma'_v=14.3\text{kPa}$.

Reducing geogrid stiffness and/or increasing shear resistance and stiffness of soil may cause strain concentration in pullout tests (Farrag et al., 1993, Lopes & Ladeira, 1996, Mallick et al., 1996 and Sugimoto et al., 2001). Several changes in parameters were made. Figure 12 shows predicted curves obtained by combinations of geogrid and soil stiffness increase and cohesion decrease. Although none of these sets of modified parameters resulted in significant

improvement of the displacement distribution curve, reducing geogrid stiffness and increasing cohesion and soil stiffness gave better results.

The constitutive model used for geogrid simulation is probably a significant cause of differences between experimental and predicted curves. In the finite element model, the geogrid is assumed to interact with surrounding soil only by transfer of shear stress by interface elements. The passive resistance developed against transverse ribs is neglected. In other words, the geogrid is represented like a geotextile.

Figure 12. Displacement distribution curves for several sets of parameters, $T=20\text{kN/m}$ and $\sigma'_v=14.3\text{kPa}$.

The analysis of load level effects agrees with that conclusion. As the load increases the displacements also increase and the role of passive resistance becomes more significant for higher displacements. Figure 13 shows that increasing tensile loads lead to greater difference between predicted and experimental curves.

The low stiffness of geogrid's transverse ribs may have contributed to reduce the differences between test results and predictions.

Figure 13. Effect of tensile load level on displacement distribution, $\sigma'_v=14.3\text{kPa}$.

4. CONCLUSIONS

Finite element simulation of field pullout tests was conducted. Constitutive models, parameters and boundary conditions were discussed. A Hyperbolic elastoplastic model was used for simulating soil behavior. For simulating geogrid behavior, a linear-elastic model that does not account for passive resistance on transverse ribs was used.

The constitutive model used for geogrid simulation is probably a significant cause of differences between experimental and predicted curves. The transfer of shear stress by interface elements is the only interaction between geogrid and surrounding soil. The passive resistance developed against transverse ribs is neglected. However, in spite of the fact that the numerical simulation was not able to reproduce stress concentration in the initial part of geogrid samples, overall predicted displacements compared well with test results. Therefore such model seems to be adequate for working stress conditions found in well designed walls and in early stages of pullout tests (particularly if transverse ribs have low stiffness), rather than for ultimate pullout conditions.

ABSTRACT

Observation and numerical modeling of MSE test wall is presented here. The 6m wide and 3.2m high wall with 10cm thick precast concrete face elements and reinforcement length of 2.15m was built on construction site of Motorway 5C in Bosnia and Herzegovina. Welded wire mesh Q335 was used as reinforcement. Compared to other MSE test walls, the presented work is unique due to the choice of backfill material consisting of course crushed stone aggregate ranging from ~0-100mm in size whereas most of other published studies used sandy backfill. Two weeks after the construction, the top of the wall was loaded with additional overburden weight 1.5m in height (~30 kPa). The forces in reinforcement were measured with a series of embedded sensors and deformation with an inclinometer installed in the middle of the wall length, including geodetic survey of wall face. Experimentally observed results are compared to the analysis results obtained from numerical model created using Plaxis software.

1. INTRODUCTION

The field monitoring of mechanically stabilized earth (MSE) wall behavior for work and ultimate stress states combined with numerical analysis can increase the cost-effectiveness and facilitate the ability to successfully predict the behavior of such structures. For this purpose, monitoring and numerical modeling of MSE test wall is presented. The 6m wide and 3.2m high wall with precast concrete elements face was built on construction site of Motorway 5C, section Drivusa-Gorica in Bosnia and Herzegovina. Welded wire mesh was used as reinforcement. Compared to other published test MSE walls, the work presented here is unique in the fact that the backfill material consists of course crushed limestone aggregate with D50=32mm, whereas the most of other published studies use sandy backfill.

The most comprehensive published research of behavior of flexible retaining structures was done by Allen and Bathurst (2003). They gave an overview of the results for 20 field structures made of reinforced soil as an official report published by Washington State Department of Transportation. Their results of measurements and conclusions along with the ones obtained on individual test walls made by other authors (see Allen et al. (2004) and Bathurst et al. (2002)), to a large extent, influenced the development of not only design codes, but also the development of innovative computation methods that enabled more rational reinforced earth structures (see Fannin and Holtz (2011), Koerner (2005), Palmeira, E. M. (2009), Rowe and Skinner (2001)). A practical example is semi-empirical "K Stiffness" method (Allen et al. (2003b, 2004)), which provides reinforcement forces prediction that are substantially smaller than the ones predicted by limit equilibrium based methods. In addition, Holtz and Lee (2002) made report on research conducted on the internal stability of reinforced soil walls. Using the results of monitoring of 6 walls with different reinforcement elements and types of backfill material, they made recommendations for improving the modeling techniques for the level of working stress. Carruba et al. (1999) analyzed the behavior of wall reinforced with flexible reinforcing elements (PE and PP geogrids), with monitoring done on application of surcharge load stage-wise. The authors used clayey gravel as backfill material. Back analysis was done using software package Abaqus, with the Drucker-Prager constitutive model and the associative flow rule. Bergado et al. (2003), analyzed the behavior of reinforced embankment built on soft soil. The embankment was reinforced with galvanized and PVC coated hexagonally shaped geogrids. Doing back analysis, authors analyzed the dominant mechanism of interaction for working stress state, with conclusion that dominant mechanism being direct shear. One of the interesting examples with different backfill material published is the detailed monitoring of reinforced

soil structures is 12.0 m high wall with backfill material of rammed clay, reinforced with HDPE geogrid (Yang, G. et al. 2009). Within this case study, the behavior of the wall for working stress condition was analyzed.

Practically, all studies mentioned above were made on the walls with fine grained (sandy) backfill material. The interaction of such material and reinforcement compared to the backfill composed of coarser granular material is significantly different, as confirmed by many of published articles dealing with research of interactions in various conditions (pullout, direct shear) (see Hsieh et al. (2011), Minazek et.al (2010)). Application of modern numerical methods in predicting stress-strain behavior and at the same time dealing with complex soil reinforcement interaction, cannot be considered satisfactory without confirming the results to measurements made on real structures. A wide variety of reinforcement elements and backfill material types further complicates this problem. As a result, the only way to reach reliable conclusions is to create sizeable databases of field wall case studies.

2. MATERIALS AND WALL GEOMETRY

The MSE test wall was constructed next to the slope of service road between two bridge piers on construction site of Motorway 5C, section Drivusa-Gorica in Bosnia and Herzegovina. It was placed on well-compacted coarse granular material ($\phi=45^\circ$ and $c=0$) with leveling pad consisting of C20/25 concrete beam 40x40cm, reinforced with 6 ($\phi=12\text{mm}$) longitudinal steel bars placed in corners and transverse reinforcement made of $\phi=8\text{mm}$ stirrups spaced 20cm c-c.

The wall face consisted of 10cm thick precast concrete panel elements 100x80cm (including half elements 50x80cm) as shown in Figure 1. Elements were made of high-strength concrete ($W/C=0.35$) with early strength of C30/37 achieved after one day. Self-compacting smart dynamic concrete (SDC) with admixtures based on polycarboxylate was used. Elements were reinforced with $\phi=8\text{mm}$ steel bars spaced 15cm c-c both placed in the midsection of thickness. In addition, two anchorage reinforcements in form of $\phi=12\text{mm}$ stirrups 25x80cm (extending 20cm out) were placed in each element to allow proper connection of facing with the soil reinforcement (see Figure 2).

Standard steel welded wire mesh (WWM) Q335 ($f_y=500/560\text{MPa}$) is used for soil reinforcement with 8mm bars spaced at 15cm c-c in both directions. They are fabricated as 6m long and 2.15m wide (see Figure 2). Course crushed limestone aggregate ($\phi=48^\circ$ and $c=0$), with grains ranging from ~0-100mm ($D_{50}=31.5\text{mm}$) was used as backfill material (Figure 3). The gradation test result is shown in Figure 4. The constructed wall was 6m long with reinforcement embedded 2.15m (to allow use of whole WWM) and 3.2m high (4 rows of prefabricated elements).

Figure 4. Backfill material gradation curve ($D_{50} = 31,5$ mm)

3. MEASUREMENTS AND CONSTRUCTION SEQUENCE

In order to measure soil stiffness after application and compaction of backfill material layer, circular plate, with 30cm diameter, was used (see Figure 5). The test was carried out in general accordance with HRN U.B1.046. The load was applied in five increments. Settlement readings were taken at 0.50 minute intervals for the first 2 minutes, and 1 minute intervals thereafter, until detectable movement of the plate has stopped, i.e. until the average settlement rate is less than 0.05mm per 3 minute interval. The Range of Pressures starts from 0 kPa to 250 kPa. Two tests were conducted on different heights of the wall. First one, for the height of 0,8 m (test 1), and second for 1,4 meters (test 2). The results of average settlements for 5 load increments are shown in Table 1 below.

Table 1 : Static load plate test results

Load and settl. Test No.	Load increments [kN/m ²]					
	0	50	100	150	200	250
	Settlements [mm]					
Test 1 [level 0,8 m]	0	0,09	0,44	0,825	1,36	1,8
Test 2 [level 1,4 m]	0	0,12	0,35	0,6	0,9	1,2

Note that the soil backfill reference deformation modulus for numerical model was obtained using back analysis results of this test.

An Interfels Standard Inclinator Casing is used for wall lateral displacements measurements (see Figure 5 and Figure 6). It was installed in the middle of wall length (to avoid boundary effects). Casing, which is 3,0m long, with outside diameter of 70mm, and inside one 65 mm was installed before wall construction. Casing is placed 1,5m below bottom of the wall in stiff foundation soil, in order to ensure prevention of movement of its base (fixed reference). Bottom cap is used to prevent fine particles infiltration, which may strongly affect the readings. Standard coupling unit 400mm long, with outside diameter of 77mm, and inside one 70 mm was used to connect extension casings during construction. Area around casing was protected by fine sand to avoid damaging (i.e. punching by courser grains). In addition to inclinometer, geodetic survey of vertical midsection of wall was performed using 8 fixed points spaced 40cm apart, in order to monitor horizontal displacements (see Figure 7).

The 4 rows of precast concrete elements were placed (6 elements in each row). The total of 8 WWM were used during wall construction (2 per element) placed 40cm apart. Each 40cm layer of backfill material between WWM was placed in 2 intervals (20cm each). After each interval, material was compacted using combination of 2 ton roller compactor (Figure 3) and vibratory plate compactor for difficult spaces (i.e. around inclinometer) to ensure proper stiffness of backfill.

Figure 5. Static load plate test

Figure 6. Inclinometer deformation measurements

A total of 16 strain gauges, were mounted to WWM bars on different locations (see Table 2) to measure forces. A total of 16 strain gauges (SGs), were mounted to WWM bars on different locations (see Table 2) to measure forces. The SGs were standard 350 Ohm gauges manufactured by HBM, put in a Whetstone bridge and amplifier system. After the wall was erected, two of the SGs malfunctioned and their readings were dismissed. The malfunction was probably due to mechanical damage caused during construction process. Calibration of the applied forces was conducted in the laboratory using tension loading frame. The error in measured forces is estimated to be up to 10% and can be, among other effects, due to slight differences in mounting of SGs on the mesh.

Two weeks after the wall was erected, 1.5m high overburden load (~30kPa) was added as shown on Figure 8. This load corresponds to the required design traffic load for regional roads in Bosnia and Herzegovina. Week after the loading was completed, inclinometer readings, geodetic survey of wall face and force measurements in reinforcement bars were performed again for comparison with the initial ones.

Figure 7. Geodetic survey of wall face

Figure 8. Wall with 1.5m overburden load (~30kPa)

4. OBSERVATIONS RESULTS

The results of force measurement without and with overburden load for 14 locations are listed in Table 2. They are compared with forces obtained by numerical analysis in the following section of the paper.

The geodetic survey of wall face as well as inclinometer readings show no horizontal displacements of the wall (only negligible values that are on the margin of error). The wall will be stepwise loaded with additional overburden load till its failure in future, and these results will be published elsewhere.

Table 2. Force measurement.

Sensor (height; depth [m])	Without overburden load kN/m	With overburden load kN/m
A1 (0,2; 0,4)	4,8	8,8
B1 (0,2; 1,15)	4,2	7,6
C1 (0,2; 1,90)	4,2	7,2
A2 (0,6; 0,4)	2,7	3,5
B2 (0,6; 1,15)	3,6	5,9
C2 (0,6; 1,90)	3,0	5,0
A3 (1,0; 0,4)	5,8	10,0
B3 (1,0; 1,15)	3,9	6,4
C3 (1,0; 1,90)	5,2	9,7
B5 (1,8; 1,15)	2,6	6,9
A6 (2,2; 0,4)	1,9	4,2
C6 (2,2; 1,90)	5,3	11,1
A8 (3,0; 0,4)	1,3	2,6
B8 (3,0; 1,15)	2,0	4,2

5. NUMERICAL MODELING

Numerical analysis was performed using Plaxis Geotechnical Software Package. A plane strain numerical model of reinforced earth wall built on stiff foundation soil is made of reinforcing element, soil elements and boundary conditions (loads and displacements). Triangular finite elements with 15 nodes, 12 Gauss integration points and average dimension of 10,0 cm were used. Soil geogrid contact was modeled by interface elements. Hu and L. Pu J. (2004) stated that use of interface elements in modeling is very important for obtaining realistic solutions to the many soil-structure interaction problems. Interaction coefficient of 1,3 was adopted according to pullout laboratory test conducted on similar reinforcement and backfill material (see Minazek (2010)). The soil is modeled by Mohr-Coulomb constitutive model with non associative flow. Table 3 defines the parameters of the granular backfill material and material supported by the wall as well as foundation soil. The foundation soil was considered as stiff with deformation modulus 5 times greater than the backfill one. Surcharge was modeled with 1 step of loading according to real constructive sequence.

Table 3. Soil parameters

Parameter	Granular backfill	MC (loose) – surcharge soil	Foundation soil
γ [kN/m ³]	22,0	21,0	24,0
φ'_p [°]	48	29	45,0
c' [kPa]	0,0	0,0	0,0
ψ [°]	15	0	0,0
E_{ref} [MPa]	60,0	15,0	300,0
E_{incr} [MPa/m']	2,0	-	-
ν [-]	0,3	0,3	0,2
R_i^*	1,3	-	-

*Note that $\varphi_i = R_i \cdot \varphi_{soil}$

The stiffness characteristics of the backfill material are determined by back analysis on numerical model of static plate load test. The axisymmetric numerical model of this test is shown in Figure 11b, and results in Figure 12. Dilatancy angle for modeling non associative flow was determined according to Bolton's empirical equation for plane strain conditions, which relates the mobilized friction angle (φ'_p) to the critical state friction angle (φ'_{cv}) and dilation angle (ψ): $0,8 \cdot \psi = \varphi'_p - \varphi'_{cv}$. Numerical model with finite element mesh is shown in Figure 11a. The reinforcement is modeled as an elastic geogrid slender element, with axial stiffness $EA = 1,11 \cdot 10^5$ kN/m', determined for maximum elastic strain of steel (in air tensile test).

Figure 11. a) Numerical model and wall geometry;

b) Numerical model of plate load test

Facing elements are modeled as plate elements, with bending stiffness defined with thickness of the facing elements. For thickness of 10,0 cm, the stiffness is determined as: $EA = 3 \cdot 10^6 \text{ kN/m}$; $EI = 2500 \text{ kNm}^2/\text{m}$

Figure 12. Results of plate load test numerical model : a) load – displacement curve; b) vertical displacements

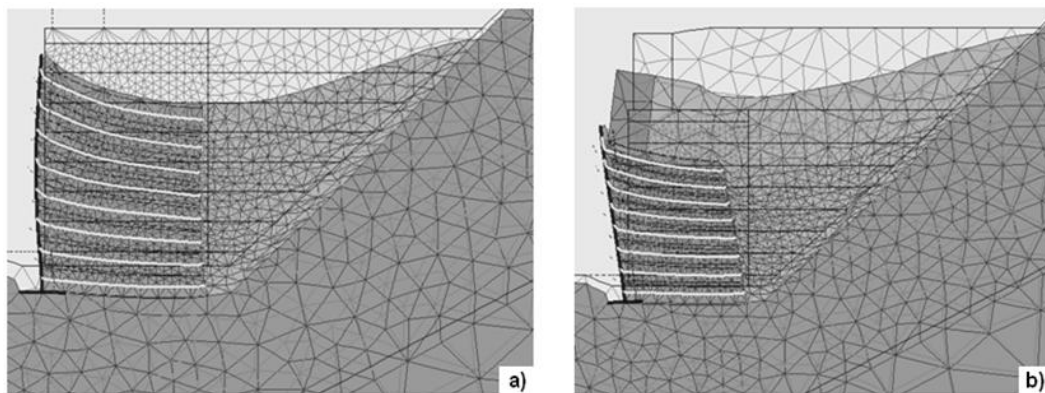

Figure 13. Deformed mesh (not in scale), a) Without overburden load; b) With overburden load

Figure 14. Lateral displacements, a) Without overburden load; b) With overburden load,

The trend of wall displacements is shown in Figure 13, while the magnitudes of lateral displacements are shown in Figure 14. Maximum horizontal displacement after placing overburden load is 1,0 mm, while the deformations of the wall self weight, range of about 0,5mm.

Table 4. Maximum reinforcement forces from numerical model.

Level (in meters from bottom of the wall)	Without overburden load kN/m	With overburden load kN/m
3,0	2,1	8,4
2,6	3,0	8,0
2,2	3,2	7,0
1,8	5,5	9,5
1,4	5,8	10,3
1,0	4,6	5,8
0,6	3,0	4,5
0,2	3,8	5,4

Finally a comparison between calculated and measured force distribution along geogrid was analysed. Figure 15 shows force distribution along geogrid calculated numerically, with indication of measured forces on the location of strain gauges.

Figure 15 : Force distribution along reinforcement and comparison with measured values

6. CONCLUSIONS

Reinforced Earth Wall (REW) with WWM and course crushed limestone aggregate backfill was built in order to study the behavior of such structure under loading. The wall was surcharged with 1,5m of overburden load. Wall behavior was modeled by means of finite element analysis and comparison with actually measured values is showing fairly good agreement.

A very unique combination of WWM on relatively small vertical spacing, with course crushed limestone aggregate backfill makes the wall to behave as a stiff block with no internal displacements except the reinforcement elongation (which is less than 2,0mm). This fact, together with previous research results mentioned in introduction, can be used for analysis of two aspects of wall behavior. First one is the investigation of inclusions vertical spacing influence on REW behavior, and second one, for investigation of interaction mechanism between course crushed limestone aggregate and welded wire meshes.

A very simple Mohr-Coulomb soil constitutive model was able to predict the behavior of reinforced earth structure. The wall will be stepwise loaded with additional overburden load till its failure in future, and results obtained from that study will be published elsewhere

ACKNOWLEDGEMENTS

The authors would like to express deep gratitude to following companies for providing location, financial support, construction equipment and manpower for this project: PC Motorways of Federation of Bosnia and Herzegovina, Euro-Asfalt, STRABAG, SGS BH, BASF, Geokonzalting.

On the Role of Human Error in Failure of Three Geosynthetic Reinforced Earth Walls

Dhani Narejo, Ph.D., P.E., GSE Environmental LLC, USA, dnarejo@gseworld.com.

ABSTRACT

The paper presents three case histories of geosynthetic reinforced earth walls that failed due to human errors in their construction. "As-designed", "as-built" and "failed" scenarios are presented for each of the walls, emphasizing the connection between the error and the wall failure. In one case, the geogrid was installed in the wrong direction and incorrect soil was placed in the reinforced zone. In another case, surface runoff was directed into the drainage stone behind the wall face. In yet another case, a drainage swale shown on the plans was left out. Such human errors occur during construction when neither the design engineer nor a construction quality assurance inspector is engaged to ensure compliance with the wall plans and specifications. The failure mode varies depending on the nature of the error, but water is involved in all three walls as an additional cause of the failure. Noncompliance with the specifications may be intentional in a few cases in order to save money. Unintentional errors, however, are seen to occur in a majority of the cases. The cost of rebuilding the walls can be quite significant even when no lawsuits are involved. Most of the human errors can be easily prevented by requiring the presence of the design engineer or quality assurance inspector during the wall construction. A quality assurance inspection requirement is especially important for walls in the residential market, where errors are more common.

1. INTRODUCTION

Geosynthetic reinforced earth walls (GREWs) are one of the most popular soil retaining structures in the world and particularly in the USA. Ease of construction, aesthetic value, and lower construction cost are some of the important reasons for world-wide acceptance of GREWs. Well-designed and well-built GREWs are known to perform exceptionally well as one can see by visiting a few of the thousands of these walls in many towns and cities. The geosynthetic industry knows very well also that a small number of GREWs of questionable quality are built every year even in those markets that should be highly mature and sophisticated, such as the USA. This would indicate that similar problems would be more widespread in other emerging markets. Human errors should be a common factor in all types of projects such as buildings, roadways, landfills, bridges, and so on. An important difference is that these projects have a much stronger role of construction quality assurance than GREWs. Probably the ease of construction of GREWs, and the fact that this is a highly price-conscious industry, has contributed to lax standards for quality assurance. As a result, there are probably more problems, and even failures, of GREWs than highways, bridges and buildings. This state of affairs is less common in DOT (department of transportation) GREWs where construction quality assurance is already well established.

Retaining wall failures can be placed in two categories: those caused by deficiencies in design, and those caused by deficiencies in construction. The design procedures and construction materials are rarely ever to be blamed for the quality issues in GREWs. However, design practice of GREWs, especially in certain residential markets, is questionable with regard to remote designs, poor or no construction drawings, and little or no geotechnical investigation. The export of the design of GREWs by some manufacturers is a worrisome trend. Many contractors and project owners consider a detailed design and stability analysis to be unnecessary and a waste of money when walls are small and are located in residential areas. Design engineers are often happy to go along providing electronic designs all over the world without ever seeing the site. The entire industry must share the blame for the quality issues and take necessary actions to improve design and construction standards for GREWs. The recent inspector certification program by the Geosynthetic Institute is a welcome step in that direction. However, additional contractual standards are necessary to improve other aspects of GREWs such as the design practice. Certain minimum standards of quality for design and geotechnical investigation need to be established.

This paper presents case histories of three GREWs that failed due to one or more errors during construction. Later, the walls were rebuilt as before, except that the construction flaw(s) was removed. Therefore, these walls became like large-scale field experiments in the effect of the quality of construction on the performance of the walls. The paper emphasizes "designed", "built", "failed" sequence for each of the projects with the hope that others can benefit from such cases. Little emphasis is placed on an engineering analysis of the failures as the flaw is obvious in each case and the rebuilt walls – with the flaw(s) removed - are performing as expected. There are some interesting observations to be made about the endurance of these walls when challenged by adverse conditions. The purpose of this paper is to share these unintended experiments with the reader so that a consensus can be achieved about the need for construction quality

assurance of GREWs in residential and commercial construction where such a program is urgently needed. Fortunately, all three projects were settled amicably among the parties involved without a lawsuit.

2. CASE HISTORY 1

2.1 Description

This first case history is about a wall in a storm water detention pond in Houston, TX. Three sides of the detention basin were sloped while the fourth side required a wall due to right-of-way restrictions. The soil at the site is clayey silt or silty clay with a medium plasticity index. A 12 ft vertical cut for the wall was free-standing, showing the clayey soil being desiccated from the severe drought of 2011/2012 that occurred throughout Texas. The pond is to accept the surface water run-off from a large commercial building that is located in a mixed zoning community. The geotechnical investigation showed that the design engineer can use a ϕ' of 28° based on published relationships between friction angle and plasticity index of clayey soils. The engineer performed internal, external and global stability analysis using a commercially available slope stability and wall design software. With an ϕ of 34° for the reinforced soil and geogrid design strength of 2575 lbs/ft, factors of safety obtained for all failure modes were well above the required minimums. Other important features of the wall include a block fascia with a front batter of about 7° , 8" gravel drainage zone behind the blocks, 9 ft geogrid length at every 2 ft vertical spacing, and a low permeability cover soil to seal-off the top of the wall. A full set of drawings and design report was given to the wall contractor although these were not required by the contract agreement. The design engineer visited the site prior to the construction but no visit was performed during the construction as none was required and everyone agreed that the wall was quite simple. The wall was built during the peak drought season and the pond was put into service.

The wall failed after being in service for about six months. The engineer visited the site and took some photos as well as made some observations as summarized in Figure 1. Figure 1(a) shows a partial view of the design cross-section of the wall emphasizing only the differences with Figure 1(b) which shows as-built wall. Figure 1(c) shows the wall failure in one location while the rest of the wall, although distorted, did not fail. Note in Figure 1(a) that the design required the geogrid to be installed in the machine direction while the wall was built with the geogrid installed in the x-machine direction as seen in Figure 1(b). Note also that the reinforced soil required in the design is structural fill with zero percent fines while that used in the construction is the silty clay that was excavated from the pond. Interestingly, a third party quality assurance technician was at the site to monitor compaction of the backfill soil in the reinforced zone. The site geotechnical engineer – different from the wall design engineer – had also visited the site during the wall construction. The primary contractor for the site was closely involved with the wall construction.

The wall failed after a heavy rainstorm that was preceded by several months of drought. The failure mode was clearly block-geogrid connection rupture which took a triangular shaped zone of soil out, leaving the geogrid hanging in the air. While the strength of the clayey soil was great during the drought, the rainfall went right into the body of the wall due to the cracks, wetting the soil. Therefore, the strength of the reinforced soil decreased over time, caused by a dissipation of the negative pore water pressure. This could be easily seen from the failed section which was moist and showed large lumps of high plasticity clay. There was one area where the blocks actually sheared off from the geogrid. The rest of the wall showed a wavy deformation along the length, with severe cracks extending back to the end of the reinforced zone. It was decided by all the parties unanimously that the entire wall must be demolished and rebuilt according to the plans. The same wall-builder rebuilt the wall and the same soils inspector was hired to perform the wall inspection. The only difference was that the inspector and the design engineer ensured that the wall was built according to the specifications and plans.

2.2 Lessons Learned

Several important lessons could be learned from this case history, among them the following:

- i) This failure could have been easily prevented if a construction quality assurance inspector or the wall design engineer had been contracted to inspect the wall construction. Just one site visit could have sufficed in this particular case.
- ii) A soils compaction testing technician was at the site but was ineffective in this case. This shows that the wall inspection must be performed by parties given specific responsibility and training to perform this work.
- iii) Mistakes occurred despite the wall-builder, contractor, design engineer and soils inspector all having considerable experience in their respective areas of expertise.
- iv) It is possible that the problem could have been limited to deformation – but no failure – had the geogrid been installed in the correct direction. It appears that GREWs can be built with cohesive soil provided water is kept out and some deformation is accepted. The top and back of the walls built with clayey soil must be sealed against water. This can be achieved with a geosynthetic clay liner at the top and a drainage

geocomposite at the back.

- v) All parties quickly agreed to cooperate, thereby preventing an expensive lawsuit. Even then this was an expensive failure for several parties involved, whose insurance had to cover the reconstruction cost.

(a) As Designed

(b) As Constructed

(c) A Photo of the Failure

Figure 1 – For Case History 1, Wall As Designed, As Built and a Photo of the Failure.

3. CASE HISTORY 2

3.1 Description

The second case history is about a wall built in front of a large commercial building in Dallas, TX. The original ground had a slight negative slope in front of the building. A parking lot was built in front of the building that also accommodated heavy shipping and receiving traffic and one of the entrances to the building. It was necessary to build a small wall– 8 ft maximum height - in order to obtain the required grades for the pavement. The need for this wall was realized after the fill had already been placed. But it was easy enough to move the fill back slightly in order to make room for the wall. Ideally, the wall should have been built first, or at the same time as the placement of the fill. The engineer assumed a friction angle of 33° for the reinforced soil, 28° for the retained soil and 30° for the foundation soil based on the information available at the time of the design. Internal, external and global stability analyses were performed with a commercially available software and the effect of heavy truck traffic was considered in the design. The contractor agreed to use pea gravel for the entire reinforced zone of the wall. Adequate drainage pipe was placed behind the fascia blocks and day-lighted every 20 ft. The design engineer visited the wall during the construction but before the pavement was built. A geogrid with a long-term allowable design strength of 1918 lbs/ft was specified by the engineer with 2 ft vertical spacing and a minimum length of 5.5 ft. Since most of the wall was only 6 ft high, 5.5 ft geogrid length showed adequate factors of safety for all failure modes.

The pavement behind the wall failed about 18 months after the construction. Although the wall designer was relieved to hear that it was not the wall failure, the primary engineer for the project appeared to be quite concerned about the wall. The wall contractor had left the back of the wall open to receive surface flows from the parking lot. Figure 2(a) shows a partial cross-section of the design of the wall as submitted to the wall contractor while Figure 2(b) shows the same for the wall as constructed. Figure 2(c) shows a photo of the failure of the pavement behind the wall. Notice that the design called for extending the pavement all the way to behind the wall cap so that the surface flows would go over the wall face. The wall, as-built, collects all the flow from the parking lot in the gravel behind the blocks. Pea gravel has a limited capacity to handle fines that could have been brought in with vehicular traffic over time and entered the pea gravel. It is not difficult to visualize a scenario where the drainage/reinforced soil zone got contaminated over time with fines, preventing water flow outward and inducing seepage inward towards the parking lot. Truck traffic over wet and/or poorly compacted soil was likely the cause of the pavement failure. The wall remained intact and was able to resist load from trucks as close as 2ft to the wall face.

An independent civil engineer was hired by the primary contractor to investigate the pavement failure as well as the design of the wall. The engineer concluded that the pavement failure could have occurred due to several reasons including a poor compaction of the fill soil and seepage from the water entering the back of the wall. Leaving the back of the wall open to storm flows is an obvious flaw while the soil compaction is difficult to verify with the same level of

certainty. Had the wall contractor followed the plans, there could have been no doubt that he was not responsible for the problem with the pavement. Based on conversations with various parties, the author assumes that the wall and the adjacent pavement was removed completely and reconstructed. The reconstruction cost was very likely shared by the primary contractor and the wall contractor as in the case of the first case history. An experienced wall contractor made an error in his eagerness to be creative. The engineer made one visit to the site at his own expense as the agreement required no visit from the engineer.

3.2 Lessons Learned

This case study reinforces the lessons learned from the previous case history about the role of human errors in GREW failures. However, one can never overemphasize the following:

- i) A construction quality assurance inspector could have easily noticed the problem with the wall construction and alerted the design engineer or the owner.
- ii) The design engineer visited the site only once during the wall construction, which does not appear to be enough. The design engineer should have also visited the wall after the construction of the building and the parking lot were completed.
- iii) Water is a common threat in many of the wall problems and should not be underestimated. Specifically, the top of the wall, and even the back of the wall, should be sealed from water by a combination of low permeability soil, GCL, and a drainage geocomposite.
- iv) Wall contractors assume a significant risk when building walls differently from the stamped plans. Even when a change is necessary, it is important to contact the design engineer and have the plans changed so that the plans and the construction are in complete agreement.
- v) Heavy truckloads immediately behind walls should be considered not only in the design process but also in construction details, including compaction requirements.

2.2(a) – As Designed

2.2(b) – As Built

2.2(c) – A Photo of Pavement Failure

Figure 2 – For Case History 2, Wall as Designed, As Built and a Photo of Failure.

4. CASE HISTORY 3

4.1 Description

The third case history is about a wall in a new residential development in San Antonio, TX. The hilly terrain at the site is characterized by about 6" of brown clay underlain by limestone with approximately 12 to 50 SPT blows per inch within the top seven feet. House building pads are developed at the site by extensive cut and fill operations requiring walls ranging from a few feet up to 40 feet in height. Since walls are founded in a competent limestone, global stability of the walls is not a concern. On the other hand, almost all the fill at the site is uncontrolled and obtained from either limestone blasting at the site or imported from adjacent sites with similar soils. The friction angle of these clayey gravels is more than 45 degrees and unsupported vertical cuts of up to 8 ft in these fill material can be observed at the site. However, these same soils are highly erodible when exposed to storm water flows. Therefore, ravines and gullies as deep as 5 ft could be observed at the site. The wall in question has a maximum height of 9 ft and occurs at the end of the property line which is also the toe of a 10-degree 500 ft upward slope. The depth of the fill ranges from about 9 ft at the wall to zero feet at about 200 ft up the slope. Even after the fill, there is a significant slope of about 10 degrees for about 500 ft in some areas. The wall was designed based on NCMA (National Concrete Masonry Association) guidelines for block walls with geogrid reinforcement. A friction angle of only 34 degrees was used for the reinforced soil which was the same as blasted limestone. For the retained and foundation soils, a friction angle of 30 degrees was used. A 3H:1V slope was assumed for the backfill. Therefore, the design was based on a highly conservative assumption of the soil properties.

The wall failed gradually over a time period of two years due to the erosion of the reinforced and retained soil. The failure mode was an overtopping of the fascia due to water pressure. Although the wall was designed conservatively, one of the main problems at the site, that of the erosion, was not addressed by the wall contractor as required by the contract with the owner. Figure 3(a) shows a partial cross section of the wall as designed by the wall engineer. The reader may note in the figure a drainage swale that is intended to accommodate the surface water flows behind the wall. Figure 3(b) shows the way the wall was built, that is, without the drainage swale. In the absence of the drainage swale, small rills and ravines formed initially on the slope above the wall. The erosion then continued to worsen to the point where eventually entire wall sections got washed out as is shown in Figure 3(c). This was the only location at the entire site where the wall failed due to erosion. This was also the only place where there was a long slope above the wall without a drainage swale. At the other location with much higher walls, either slopes were short or there was a drainage swale with an erosion control mat. In this case, the drainage swale was skipped to save money. There was also a change in the ownership of the entire site involved during the peak of the housing crisis in the USA.

After a long back and forth, the property owner and the wall contractor reached an agreement to rebuild the wall with a drainage swale. The same materials and methods were used as in the original wall. The only difference was that a drainage swale was placed immediately behind the blocks as indicated on the original construction drawings. The author has seen the wall after being exposed to a few heavy rainfalls. The erosion that caused the failure of the wall seems to have stopped at least for now. It is expected that the plot above the wall will have a housing pad soon which will solve the erosion problem. The contractor had to remobilize the crew from a long distance and completely rebuild large sections of the wall at a significant expense and as per the plans. Building the wall right at the first time would have cost less money and maintained amicable relations with the site owner.

4.2 Lessons Learned

The lessons learned from this case history reinforce the same from previous two case histories, i.e., intentional or unintentional errors in wall construction can lead to wall failures. Here are some specific lessons from this case history:

- i) Water was involved in this failure as in the case of the previous two failures. Design engineers and wall contractors must consider surface and sub-surface water that may challenge a wall.
- ii) No design engineer ever visited the site in this case and no construction quality assurance inspector was hired to inspect the wall in order to ensure a compliance with the project specifications. Therefore, a noncompliance with the design went unchallenged until the wall failed completely.
- iii) Erosion of the backfill soil is a common problem in many walls and one that is often not properly considered at the design stage and during construction.
- iv) The cost of rebuilding the wall was many times higher than the cost of putting the drainage swale as required by the project specifications.
- v) Non-cohesive soils with very high shear strength, such as blasted limestone spoil, are also highly erodible requiring protection at the top of the wall.

5. CONCLUSIONS

Geosynthetic Institute has an ongoing program that tracks reinforced soil wall failures. The June 2012 newsletter (GSI, 2012) of the institute mentions 154 failures in the database. Several authors including Koerner & Koerner (2012) and Yoo & Jung (2009) present an analysis of reinforced soil wall failures. High seepage stress and poor drainage are two factors that are frequently associated with GREW failures. This paper emphasized the role of human errors and how water exploits weaknesses in walls. Errors in most cases are simple and can be easily prevented by requiring the engineer's representative or a quality assurance inspector to be present to monitor the wall construction. The following conclusions can be drawn based on the three case histories:

- Water was a factor in the failure of all three walls. This manifested in either poor surface drainage (case histories 2 and 3) or dissipation of negative pore pressures in the clayey reinforced soil.
- Two of the three cases (case histories 1 and 2) were of unintentional errors while one case (case history 3) involved cost savings as the motive.
- In all three cases, the walls were removed and rebuilt at a considerable cost to the parties involved in the construction. None of the cases resulted in a lawsuit which significantly lowered the overall cost of the resolution.

- Failures occurred after six to eighteen months of service under extremely adverse conditions of a defective construction. Even then the walls performed the intended function before giving in under additional loads from water.
- Surface water drainage and subsurface seepage are generally not adequately considered in the design and must be carefully designed and implemented.

Paving Fabric Interlayer Systems for Pavement Enhancement

Ray Myers, Asphalt Interlayer Association, USA, rmroads@gmail.com

ABSTRACT

Pavement interlayers represent one of the largest geosynthetic applications, in part due to the tremendous amount of research and documented proof of performance. However, much of this technical work was done 20-30 years ago and the commercial market for this technology peaked shortly thereafter. Today, because of transportation agencies personnel turn over and a lack of performance monitoring, much of the pavement life extension afforded by this technology has been overlooked, forgotten or misunderstood. This presentation will discuss the combination of benefits provided by geosynthetic pavement interlayers compared to other, less cost effective pavement construction and maintenance strategies. Many agencies are turning to open graded friction courses to reduce hydroplaning and road noise. This technology can result in added exposure to water in the pavement structure and more rapid pavement deterioration. It will be shown how interlayers can mitigate this issue. A geosynthetic interlayer remains a very attractive value proposition for pavement preservation, especially in light of the rapidly rising cost of road building materials. The presentation will redirect attention to this excellent pavement strategy for both new pavements and for pavement rehabilitation. The technology and the associated benefits of different geosynthetic pavement interlayers will be reviewed. Then, to allow designers and end users to make intelligent pavement design choices, the costs of the different systems are compared to the cost of traditional pavement strategies. It will be shown how geosynthetic pavement interlayers are more appropriate today than ever as public agencies and private owners try to meet their transportation/pavement maintenance needs with very limited dollars.

1. INTRODUCTION

The inclusion of a geosynthetic pavement interlayer system can address and mitigate many pavement distress factors. These systems may be used in both new pavements and those undergoing rehabilitation. The lowest cost and easiest to install system is the traditional nonwoven paving fabric, which is combined with asphalt cement to become a pavement membrane interlayer. More specialized geosynthetic interlayer systems are also available and will be briefly discussed at the end of this paper. The basic functions of geosynthetic interlayer systems will be discussed along with a brief explanation of how the systems are installed. These systems should be viewed like any other pavement enhancement tool—there are appropriate situations where they should be used to gain the optimum and most cost effective benefit for the pavement. Consistent with the theme of the conference session for which the paper is written, engineers should not forget the 40 plus years of successful application of the paving fabric interlayer system and the hundreds of thousand lane miles of pavement enhancement achieved. The usage is somewhat lower today than 15-20 years ago, but that is mainly due to the fact that the system was proven effective in the 80's and 90's and not a lot of research has been necessary since then. So, without so many current papers on the subject, the newer generation of pavement engineers forgets that this basic system is often the most cost effective pavement treatment available to them. However, the properties of the materials are the same, the installation is improved, and the pavement enhancement performance is the same or better. Also, with the current cost of asphalt concrete reaching very high levels and the paving fabric cost staying low, the paving fabric interlayer system is more cost effective today than any time in the past. With asphalt concrete cost now frequently rising above that of Portland cement concrete, those wishing to continue to use asphalt concrete should be looking for ways, like those discussed herein, to enhance the life of flexible pavements, to improve the life-cycle cost.

The history of modern paving fabric usage dates back to 1968 with the development of the nonwoven needle-punched fabric. This fabric was made using polypropylene fibers formed into a strong felt-like fabric structure of about 4.1oz./sq.yd.(140 gm./sq.m.). The way in which the fabric is applied to the pavement is 0.25 gal./sq.yd (1.14 l./sq.m.) of asphalt cement tack coat is uniformly sprayed onto an existing pavement and then the paving fabric is immediately laid into this tack coat.

Fig. 1 Paving fabric placed into fresh tack coat

Fig. 2 Asphalt concrete placed over paving fabric

Next, an asphalt concrete layer of at least 1.5 in.(38mm) is placed onto the fabric interlayer. There are two reasons for the minimum 1.5 in.(38mm) overlay thickness. First, the heat from the asphalt concrete re-melts the asphalt cement tack coat and draws it up to saturate the paving fabric and to bond to the overlay. Secondly, the 1.5 in. (38mm) thickness provides the necessary internal shear strength of the layer so that it will not shove or buckle in high shear stress areas of the pavement. Once the overlay is in place the interlayer becomes the thick, fabric reinforced asphalt cement layer that provides the functions of a moisture barrier and a stress absorbing interlayer. This paper will not go into the details of geosynthetic pavement interlayer installation. Please refer to the detailed installation instruction manuals available from every credible supplier of these materials. There is also the Asphalt Interlayer Association (AIA) with the website of www.aia-us.org where information on the specification and installation of these systems is readily available. Installation is not difficult, but all the considerations in the installation manuals must be followed to end up with a successful application. Admittedly, some areas of the country have more experience with the installation of geosynthetic pavement interlayer systems than other areas.

2. THE MOISTURE BARRIER FUNCTION

The first important function of the paving fabric is that of a pavement moisture barrier. When properly saturated with asphalt cement, the paving fabric interlayer is approximately four orders of magnitude less permeable than the pavement layers adjacent to it. The AASHTO M 288 paving fabric specification calls for a nonwoven fabric of 4.1oz./sq.yd.(140 gm./sq.m.), as it has been shown that this thickness and weight of fabric is required to absorb and reinforce the recommended asphalt cement tack coat of 0.25 gal./sq.yd (1.14 l./sq.m.), the amount necessary to form a proper moisture barrier. It is important to note here that the integrity of the moisture barrier is highly dependent on the good uniform application of the proper amount of asphalt cement tack that will saturate the paving fabric. Insufficient tack amount or a spotty spray application pattern will not result in a continuous moisture barrier with the system. As a pavement moisture barrier, the paving fabric interlayer, or any composite geosynthetic interlayer with a paving fabric, provides many benefits to the pavement. Pavements are quite permeable, with 30-40% of rainwater typically infiltrating asphalt concrete and 50-67% infiltrating Portland Cement Concrete pavements (Cedergren, 1974). The amount of water that infiltrates pavements is critical to pavement performance yet this information is not widely known or fully appreciated by most pavement engineers. Infiltrated water also frequently comes from over-zealous irrigation systems or washing systems that throw a lot of water onto pavements. The infiltrated water can cause significant damage to the pavement, dramatically shortening the pavement life. FHWA documents claim the road life can be shortened by up to 50% if the road section is saturated even 10% of the time (Cedergren, 1974). This damage can be pore water pressure that overrides the load spreading capability of the base and/or subbase aggregate support, limiting the vehicle loading to small areas and this exceeds the bearing capacity of the subgrade soil, failing the road. Free water in an aggregate can cause accelerated subgrade soil intrusion into the base aggregate and pumping of fines through cracks and joints to weaken and create voids under the road. Pumping action of water trapped within a pavement can also cause stripping of the lower asphalt concrete layers—an effect where the asphalt cement binder is mechanically scrubbed off the asphalt concrete stone and the layer can crumble apart. Also, water in the pavement support layers can cause damage due to the expansion and contraction associated with freezing and thawing in northern climates. Beyond these more obvious water related pavement concerns, when the subgrade and/or subbase layer has a higher moisture content, its strength and bearing capacity can be greatly compromised and, without the design bearing capacity support originally assigned to the subgrade, the road begins to fail rapidly.

The paving fabric membrane interlayer also minimizes the exposure of oxygen to the asphalt concrete layers below it. This keeps them from oxidizing, a primary cause of why older asphalt concrete layers become brittle and crack. In some areas of the United States, the subgrade soils beneath pavements are highly expansive clays. The incorporation of a paving fabric membrane interlayer within pavements over these soils, can maintain a constant moisture content in these soils year around, keeping them from experiencing pavement damaging shrinking and swelling.

There are other common sense ways to view the use of a paving fabric membrane interlayer “tool” as a pavement moisture barrier layer. In new pavements the incorporation of a pavement moisture barrier will prevent the infiltration of surface water down into the pavement structural support layers. Since this surface water is the primary source of moisture in pavements, the elimination of this source will take away the need to drain the infiltrated water from the pavement support layers. The paving fabric moisture barrier will therefore allow the designer to use base and/or subbase aggregates that are more dense-graded and more poorly drained as opposed to the more expensive aggregates with gradations designed to make them more free-draining.

To demonstrate this, look at how AASHTO assigns coefficients of drainage depending on the permeability of aggregate layers (AASHTO 1993):

<u>Quality of Drainage</u>	<u>Water Removed Within</u>	<u>Drainage Coefficient (Cd)</u>
Excellent	Two hours	1.20
Good	One day	1.00
Fair	One week	0.80
Poor	One month	0.60
Very Poor	Will not drain	0.40

The drainage coefficient is multiplied times the structural number of each aggregate layer. Therefore, as may be seen, aggregates that drain infiltrated water rapidly and keep the road base moisture levels low are, by AASHTO pavement design, assigned higher structural properties by applying high drainage coefficients (Cd). Conversely, dense-graded, slowly draining aggregates have their structural strength discounted by the assignment of low drainage coefficients. Examples of typical AASHTO pavement base designs are as follow:

Two different 10 inch thick aggregate base layers of moderately hard crushed stone with the same structural number (SN) of 0.12 per inch are multiplied times the drainage coefficient to show the dramatic effect of their ability to drain:

Excellent draining aggregate—10” X 0.12 SN X 1.2 Cd = 1.44 SN total structural contribution to the road

Poorly draining aggregate--10” X 0.12 SN X 0.6 Cd = 0.72 SN total structural contribution to the road

However, if the paving fabric moisture barrier never allows the water to saturate these aggregates, the highest drainage coefficients may be applied to even dense graded, low permeability aggregates. So, now instead of being discounted half their strength, the lower quality, poorly draining aggregates may be assigned as much strength as the more expensive free-draining aggregates. This provides not only a more cost effective way to utilize base aggregate layers, but it is also a green way to conserve resources since the aggregate fines are not screened and wasted at the quarry. It is difficult to design the ideal aggregate gradation where it is highly permeable yet dimensionally stable and easy to work with and compact. More dense graded aggregates, allowed when a paving fabric is incorporated, are more easily compacted and can be more stable layers for pavement construction. It is still very important to use a separation/stabilization geotextile beneath the aggregate base so that the subgrade soil does not contaminate and weaken any aggregate gradation. The separation/stabilization geotextile will also allow a lesser structural section since it improves the strength of both the subgrade soil and the aggregate base layers.

Another way common sense may be used is to potentially limit the use of highway edge drains. Edge drains are often built into new or rehabilitation highway projects to help control the moisture levels beneath pavements. If it is a groundwater problem, this needs to be addressed with geosynthetic cutoff drains and/or fairly deep edge drains. However, as discussed above, most of the water coming into the pavement structural layers is coming through the pavement surface. For a pavement edge drain system to work, the aggregate base needs to be open and free-draining to be able to rapidly move the infiltrated water to the edge of the highway. In new pavements this means using the more expensive, select graded aggregate. In pavement rehabilitation projects, the base aggregate is rarely

free-draining, by original design or due to subgrade soil contamination over the years. Therefore, transportation engineers are fooling themselves if they think retrofitting edge drains to these roads will pull the water out as rapidly as needed. Instead, the common sense alternative is to cap the pavement with a paving fabric membrane interlayer and never allow the water to enter the road structure in the first place. There is usually an overlay project accompanying a retrofit edge drain project anyway, so the low cost addition of the paving fabric interlayer is usually only one-third to one-fifth the cost of installing edge drains. The other problem this eliminates is the maintenance hassle with edge drains. They are difficult to keep functioning properly and many of these systems in roads right now are not working due to clogging, system collapse, overgrown or damaged outlet structures, etc.

A common pavement treatment today is mill and fill, where the existing pavement is milled down, often two to four inches, and a replacement layer of asphalt concrete is placed where the old layer was taken out. Obviously, there will be some short term benefit to the pavement, like an improved ride and a “younger” more flexible top pavement layer. However, using this methodology, the pavement engineer has not solved any of the real problems that made that original, same thickness pavement fail in the first place. So the agency is just inviting the same rapid deterioration cycle to repeat itself. If a paving fabric interlayer was placed at the bottom of this new, replacement asphalt concrete layer, a real structural benefit would be realized by the pavement as the pavement support layers would now be maintained at a lower moisture level and would thus have greater strength. This is the only way to effect a real positive change with a mill and fill strategy. The paving fabric interlayer may be placed at the bottom of the filler asphalt or up to half way from the bottom of the filling, if two overlay lifts are to be placed.

From a safety standpoint, many transportation agencies are using a highly drainable asphalt concrete surface layer. This keeps the surface drier to prevent hydroplaning and it also enables a quieter ride as less tire-to-road contact is made. These drainable layers are well suited for the inclusion of a paving fabric interlayer below to keep this rapidly infiltrated water from penetrating the entire pavement structure. The surface water is stopped at the paving fabric layer and routed to the edge of the pavement, instead of down through the pavement where the water can cause rapid pavement deterioration.

One inexpensive way to incorporate the benefit of a moisture barrier in a pavement is to apply the paving fabric interlayer beneath a chip seal surface treatment. The installation method is different because of no heat from an overlay, but instructions are readily available on how to accomplish this installation below a chip seal. This fabric reinforced chip seal maintains an effective moisture barrier for many years, whereby a plain chip seal surface treatment without the fabric interlayer, typically cracks back open within a couple of years negating any moisture barrier properties the chip seal might have had. An added benefit is the fabric forms a fibrous seat under the chip and actually holds the stone better for much less stone loss from the chip seal due to traffic. The fabric interlayer can also stop the surface bleed through of excessive crack filler from the underlying pavement to the new surface. Chip seal surface treatments over a paving fabric are reported to last two to four times as long as traditional chip seals and the moisture barrier properties are much better and longer lasting. Some agencies use chip seal surface treatments as interlayers, where they are immediately overlaid, or they are left to traffic for some time before the overlay is placed. Again, with no tensile strength to keep the moisture barrier from cracking open and without the fabric layer to create a stress absorptive layer, the chip seal does not work as well as a membrane interlayer as the paving fabric. The fabric and chip seal combination can be left for years and then overlaid to still realize its benefits beneath a future asphalt concrete overlay.

A comprehensive discussion on the effectiveness of paving fabric membrane interlayers as pavement moisture barriers may be found in the Electronic Circular 006 of the Transportation Research Board at <http://gulliver.TRB.org/publications/circulars/ec006.html> . This document discusses the research proving how impermeable the system is as well as the benefits to pavements.

3. THE STRESS ABSORPTION FUNCTION

The second major function of the paving fabric system is as a stress absorbing interlayer. The paving fabric system can absorb movements from cracks and joints in the underlying, existing pavement. This helps eliminate the hard contact/bond between the existing pavement and the overlay that can cause reflective cracking. Obviously, there are limitations to how much movement the paving fabric interlayer can absorb and dissipate. Looking at the 40 years of widespread, successful utilization of this system, it is extremely effective at mitigating slight to moderate fatigue cracking, and longitudinal cracking and joints, like highway widening cracks. The system is also effective at treating transverse cracks and joints, but these often have too much differential vertical movement associated with them to be mitigated for extended periods. The most difficult cracking to treat is thermal cracking, because it is generally not reflective, bottom up cracking. Instead, thermal cracking can reoccur within the new asphalt concrete overlay as it shrinks and expands. Thermal cracking needs to be addressed in the new overlay mix design.

It is interesting to hear the variety of opinions on the effectiveness of paving fabric interlayers at mitigating reflective and fatigue cracking. Most users understand the limitations of the system and are very happy with the performance they have seen. Notable transportation agencies consider the inclusion of a paving fabric interlayer equivalent to placing an additional 1.2 to 1.5 inches of asphalt concrete overlay thickness when looking at how long the overlay lasts before additional work is needed on the pavement (Smith, 1984 and Maxim, 1997). Another way the performance of the paving fabric has been measured is, agencies believe its inclusion doubles the life of an equivalent thickness overlay. Some agencies have mistakenly turned to using a paving fabric interlayer when they have an existing pavement that is so bad that they know their standard overlay will not work. Paving fabrics are not miracle layers and unfortunately, these agencies expected too much and became dissatisfied with the performance over these poor condition roads. Then when they are not satisfied with the performance where it should not have even been placed, they get a mindset that “paving fabrics do not work on our roads” although an agency next door may have very successful results properly applying these interlayers. Like any other pavement treatment, the earlier the treatment is applied in the deterioration cycle of the pavement, the longer the overlay will last—the whole idea behind pavement preservation. Paving fabrics placed over early to moderate fatigue cracking, block cracking, and longitudinal joints and cracks are extremely effective and many agencies have realized these benefits. Performance of the system is tied to suitable applications and pavement preparation. Many agencies forget about the importance of the moisture barrier function of paving fabrics and only measure their success by counting cracks. The paving fabric interlayer is quite flexible and durable and when cracking does eventually return to the overlay, the paving fabric interlayer typically remains intact and maintains its waterproofing capability. Even in areas of severe thermal cracking, it is reported that when thermal cracking occurs in the surface layer, the paving fabric membrane stays intact. Beyond maintaining its moisture barrier function, the intact interlayer does not allow foreign matter to fall into the crack to progressively wedge it wider, so the cracks stay smaller and more manageable.

Design guidelines, available from paving fabric manufacturers, describe which existing pavement conditions are suitable for the application of a paving fabric interlayer system. There are limitations as to how large of a crack the system may be installed over, as well as limitations on the vertical movement of adjacent sides of existing cracks or joints. Some crack filling preparatory work is recommended. If a pavement is not suitable for paving fabric placement, steps such as the placement of a leveling course of asphalt concrete can bring the existing pavement up to a condition where the paving fabric system will be the most effective. If there is rutting in the existing pavement, a leveling course or milling is required to establish a drainable surface on which the moisture barrier shall be placed. Milling to reshape a crown in a pavement, or to allow the new pavement elevation into an existing curb and gutter system is common, but, often, an excessive amount of milling is taking place that actually destroys pavement structure that could be supporting traffic. There is no problem placing a paving fabric interlayer system directly over a milled surface.

Often overlooked by pavement engineers is the tremendous benefit a flexible pavement may realize just by being layered as opposed to being a single thick, monolithic layer. Some of the earliest work on paving fabric interlayers showed that a layered pavement can withstand over 10 times the amount of flexural loading before the initial development of the typical bottom-up fatigue cracking (Maxim, 1997). This is because a thick, monolithic pavement generates a very high level of tensile stress at the bottom of this single layer every time the pavement flexes under load. A pavement made up of two layers, separated by the well bonded paving fabric interlayer, will experience much lower tensile stress at the bottom of each thinner layer. An analogous situation is how a piece of plywood may be flexed many more times than a clear wood board without cracking, simply because, even though the wood layers are well bonded together and strong, slight stress absorptive movement can occur between layers to minimize the tensile cracking stresses at the bottom of each layer. A highly effective, yet often overlooked application for paving fabric interlayers is their use within new asphalt concrete pavements or within thick pavement overlay layers, to greatly delay the development of the first fatigue crack development.

4. GENERAL PAVING FABRIC INFORMATION

4.1 Specifying the Paving Fabric Interlayer System

There are generally only three weight classes of paving fabric used in the US. The predominant style is what is recommended by the national guideline specification, AASHTO M 288, 2006, with a minimum weight of 4.1oz./sq.yd.(140 gm./sq.m.). A lighter version at 3.7oz./sq.yd.(125 gm./sq.m.) is used on some lighter duty roads, parking lots, and sometimes with a chip seal surface treatment over the fabric. Less frequently utilized are weights of about 5.0oz./sq.yd.(170 gm./sq.m.), and occasional fabrics up to 6.0oz./sq.yd.(203 gm./sq.m.). This heavier weight may provide more stress absorption but one must be careful to specify and install the heavier amount of asphalt cement tack consistent with this heavier fabric. If any weight fabric is not fully saturated to form the bond to the overlay, the new pavement could experience some shoving and the moisture barrier is not fully implemented. Ready

to use specifications are available to the engineer or owner and the author generally recommends the AASHTO M 288 specification be used.

4.2 Recycling the Paving Fabric Interlayer System

There are varying stories out there as far as the recyclability of an installed paving fabric interlayer when a pavement is milled. Large field trials have been run showing that paving fabric interlayers may be successfully milled and the resultant small pieces of paving fabric mixed back into a variety of asphalt concrete mixes. The system needs to have been installed properly, with the correct amount of tack coat so that all layers are well bonded and if the agency must mill through the interlayer, the milling should target $\frac{3}{4}$ to 1 in. (19 to 25mm) below the interlayer. This will mean the cutting is near vertical and there is no chance of going in and out of the interlayer level due to inconsistent overlay thickness over the interlayer. There have also been stories of milling operations where pieces of the paving fabric were milled up and later caused problems at the entrance screen to the secondary crushing operation. In these cases, it is probable that the fabric system was not installed properly and too little tack was used. This light tack causes poor layer bonding and pieces of partially dry fabric that could pull up during the milling. Some paving/milling contractors have solved the problem of handling these occasional larger pieces of fabric in their operations and are fine with milling through paving fabric layers. All that being said, the smart move is to **not** mill through the paving fabric interlayer, unless it is absolutely necessary. Not because of potential problems, but because the agency/owner has already paid for a stress absorbing and moisture barrier layer in their pavement. Asphalt concrete layers below the paving fabric are less oxidized and may not need replacement. Milling should stop at least 0.5 in. (12mm) above the interlayer so that it may remain intact and continue to offer its many benefits to the new overlay(s) placed over it. There seems to be far too much milling today, which may be partially because the paving contractor gets paid to mill it up, obtains the millings, generally for free, and then puts the millings back into new asphalt concrete that is sold on a project. If there is no grade problem, perhaps only enough milling should be done that is needed to reshape the road surface and not excessive milling that often destroys good existing pavement support structure that must then be replaced by new pavement at a high cost.

4.3 Paving Fabric Value Proposition

Looking at the cost benefit of paving fabric interlayers, the installed cost of the system varies somewhat based on the size of the project, location, etc. However, the installed system around the US in 2012 generally runs between \$1.50 and \$2.00 per square yard. The cost of asphalt concrete, which can also vary with the size of the project, is generally around \$4.00 to \$5.00 per inch thickness per square yard. Therefore, the fabric only costs about as much as 0.3 to 0.5 in. (7.5 to 12.5mm) of asphalt concrete yet it is widely proven to give the benefit of an additional 1.2 to 1.5 in. (30 to 38mm) of asphalt concrete. This shows how the paving fabric interlayers can greatly reduce or extend a transportation agency's overlay budget. If only a minimal, 1.5 in. (38mm) overlay is allowed, adding the low cost of the paving fabric can double the life of the overlaid pavement before additional maintenance treatments will be necessary. So, the agency/owner may choose to take the savings up front, or they may wish to lower the annual cost of the pavement. Transportation agencies frequently choose to save some up front, to pay for the paving fabric, **and** gain additional savings on extended pavement life.

5. SUMMARY OF PAVING FABRIC INTERLAYER BENEFITS

- The paving fabric interlayer system provides an effective, long lasting pavement moisture barrier and all the pavement benefits discussed.
- The moisture barrier function can be a very useful pavement design tool when the pavement structure and the hydraulic conditions are considered holistically.
- The moisture barrier function can solve some climatic problems and subgrade and base problems that typically shorten the life of pavements.
- As a moisture barrier, the system is more effective at preventing pavement moisture damage and saves money over the use of edge drains and over the use of select free-draining base aggregates.
- As a stress absorbing membrane the paving fabric interlayer can effectively minimize both the development of fatigue cracking in new and rehabilitated pavements and can retard the development of reflective cracking.
- A paving fabric interlayer is the most cost effective enhancement for flexible and composite pavements, considering all the benefits it provides.

--The paving fabric interlayer may be used beneath a chip seal surface treatment to create a pavement moisture barrier and to greatly extend the life and enhance the quality of the chip seal treatment.

--Paving fabrics may be recycled, but why destroy the existing interlayer that can go on helping a new overlay(s) and protecting the pavement from moisture.

--There is a large amount of reports on proof of performance, demonstrating both the crack retardation and moisture barrier benefits in pavements.

--There is also a vast amount of helpful design and installation information, including sample project specifications, available from the manufacturers of the products and from the Asphalt Interlayer Association.

6. OTHER GEOSYNTHETIC INTERLAYER SYSTEMS

This paper has focused on paving fabrics, the lowest cost interlayer with the longest history of use. There are other geosynthetic interlayers that have built on the success of the basic paving fabric system. One class of product is called paving mat and is made, at least partially, out of fiberglass fibers. These mats are somewhat thinner than a traditional paving fabric and require less tack coat to saturate.

Fig. 3 Paving Mat Installation the fabric

Therefore, the paving mats cannot absorb as much stress from the slight movements from underlying cracks and joints as the thicker, traditional paving fabric interlayer system. The paving mats can develop strength at lower elongation if they are placed into a pavement situation where that need occurs. Depending on the needs of the project, pavement engineers should consider this another interlayer tool, if they need higher modulus and generally lower impermeability and less stress absorption, compared to traditional paving fabrics. According to their manufacturers, these paving mats are more readily recycled, because they are more brittle, have lower tear strengths, and will shear apart easier upon milling. But, again, why mill the interlayer that was previously paid for and that could continue to benefit the new overlay(s). Paving mats are a bit more difficult to install and their initial cost is higher, so, the total installed cost may be twice or more than the traditional paving fabric, but this cost is still low compared to the additional amount of asphalt concrete that would be required to supply comparable pavement performance when all the interlayer benefits are considered.

Another class of geosynthetic interlayers is paving grids. These products are made with distinct opening sizes with the intent of interlocking with the asphalt concrete overlay. The grids are strong, made from fiberglass or polyester bundles of strands, so they have high strength at low strains. These products may have advantages in higher shear areas of pavements, such as at bus stops, before stop signs, toll booths, etc., because they add shear strength to the asphalt concrete overlay. Some paving grid manufacturers claim to have a higher degree of success than traditional paving fabrics at retarding reflective cracking, particularly over more aggressive cracks or joints. Some of these grids are composited with a traditional paving fabric so that the moisture barrier benefits discussed above may be realized as well. The project engineer has a choice of a waterproofing grid composite or a grid only that does not create a pavement moisture barrier. With the higher cost of these grid products and the higher cost to install these products, the overall installed product cost may be as much as 4 to 6 times the cost of an installed traditional paving fabric. However, the unique pavement situations where these grids or grid/fabric composites are applied can still make them cost effective solutions in pavement rehabilitation. This is because expensive, thick asphalt concrete overlays cannot overcome rapid failure in some pavement distress situations.

Fig. 4 Paving grid/paving fabric composite and overlay

There are two classes of strip membrane interlayers. The first is basically a paving fabric factory coated with rubberized asphalt, available up to 36 inch (0.9 meter) widths. This product class is used as strip stress absorption over cracks or joints and is used as a continuous bridge deck membrane waterproofing layer. A heavier, higher strength strip membrane is also available, and is used for treatment of more aggressive cracks and joints, generally beneath at least a 2 inch (50mm) overlay. These strip products are very effective at reflective crack retardation, but since they are generally not placed full width on the pavement, they are not an effective moisture barrier, other than how they seal the specific crack they are treating.

Fig. 5 Strip membrane over a joint before overlay

Fig.6 Strip membranes for a bridge deck waterproofing

Guideline specifications for all these more specialized geosynthetic pavement interlayers are available directly from the manufacturers and have not yet been published by AASHTO.

7. CONCLUSION

In summary, geosynthetic pavement interlayers are very useful tools that should always be considered both in analyzing new flexible pavement designs and in rehabilitation projects involving asphalt concrete overlays or chip seal surface treatments. It is important to note that although the discussion has been “pavements” and “roads”, these geosynthetic pavement interlayers are applied to parking lots, storage and commercial yards, all classes of roads, bike paths and trails, and airport pavements. Wide pavements, such as parking lots greatly benefit from the areal moisture barrier function of some of these systems. These interlayers should not be viewed as additional cost on a project. Instead, geosynthetic interlayers can save up front costs by getting the same performance out of thinner overlays. In addition, these interlayers can greatly extend the life of new asphalt pavements and asphalt concrete overlays, and traditional paving fabrics can greatly extend the life of chip seal surface treatments. Also, as shown, the moisture barrier function opens the door to the use of more cost effective construction materials, to lower the costs of new construction. Technical reports and installation guidelines are available for anyone wishing to further explore how these cost effective interlayer systems can save their pavement budget dollars. Many of the references below are provided as sources of information on these interlayer systems. Although most of the laboratory and in-pavement research was performed years ago on these interlayer products, the proof of their pavement enhancements is being realized every day by transportation agencies and private pavement owners. Over 250,000 lane miles of pavement have been enhanced by geosynthetic pavement interlayers and usage is still very strong, much of it by repeat users that have enjoyed how the interlayers have lowered the costs and extended the life of their pavements. Due to the frequent employment turnover by pavement engineers and administrators, the performance of roads with and without geosynthetic interlayers is rarely monitored and documented properly for the benefit of the

next engineer in that position. Current pavement engineers and administrators should take the time to investigate all the literature available on pavement interlayers and maybe even look into their own agency records to see why they have not had to invest as many maintenance and rehabilitation dollars on some of their roads—they might just have a geosynthetic interlayer below.

Permanent Geosynthetic Wrapped Face MSE Retaining Wall

Paul C. Frankenberger, P.E., TenCate Geosynthetics Americas, USA, p.frankenberger@tencate.com
John M. Lostumbo, P.E., TenCate Geosynthetics Americas, USA, j.lostumbo@tencate.com

ABSTRACT

Mechanically Stabilized Earth Retaining Walls (MSERWs) are commonplace on building sites and roadways. The typical MSERW uses a precast concrete facing panel or a masonry block facing unit. However, a new MSERW facing has been developed using geosynthetics. The first permanent geosynthetic wrapped face MSERWs using synthetic grass combined with structural geogrid soil reinforcement have been installed on a toll road construction project. MSERWs were needed to support the new roadway in limited access space. Although there are many types of MSERWs, geosynthetic wrapped face walls provide vertical grade separations at significantly lower cost. The long term design life of the geosynthetic face has always been the limiting factor in their use for permanent MSERWs. The benefit of using the synthetic grass geosynthetic wrapped face MSERWs was an economical, aesthetic and permanent structurally sound green wall face with no maintenance for the design life of the structure.

1. INTRODUCTION

Concrete and steel are standard materials in the construction of roads, bridges and retaining walls. With the introduction of MSERWs in North America in the early 1970s, concrete facing panels attached to steel soil reinforcements became the standard of practice. Later in the 1980s, concrete segmental block units were added as popular MSERW wall facing materials. Over the past 25 years, use of MSERWs with concrete segmental block units and geosynthetic reinforcement increased wall production and reduced overall wall costs. The development of polymer based geosynthetics such as geogrids offered a cost-effective, corrosion-free alternative to steel soil reinforcement. The use of MSERWs has been discussed and presented in several papers and the design methodology is well established. This paper expands beyond the limits of the concrete facing unit using geosynthetics composed of synthetic grass as the permanent wall face. A photo of one of the completed permanent geosynthetic wrapped face MSERWs is shown in Figure 1. The focus of this paper is on the synthetic grass facing as shown in Figure 2.

Completed permanent geosynthetic wrapped face MSERW.

2. WALL DESIGN

2.1 Project Overview

On the Nuevo Necaxa – Tihuatlan Toll Road Section of the Mexico DF – Tuxpan Highway in Puebla, Mexico, significant grade changes were encountered on the new highway alignment through beautiful mountainous terrain. Vertical retaining walls were needed to support the new roadway in the limited access space. Given the steep 70-degree terrain and large number of retaining walls required, MSERWs were designed to satisfy the project economics. A cross section of the

MSERW is shown in Figure 3.

Figure 3. Cross section of MSERW.

Although there are many types of MSERWs, a geosynthetic wrapped face MSE retaining wall provides vertical grade separations at significantly less cost. However, the long term design life of the geosynthetic face has always been the limiting factor in their use. The solution on this project was an MSERW designed using TenCate Miramesh[®] SG (synthetic grass face geogrid mesh) attached to TenCate Miramesh[®] GR (green biaxial geogrid mesh) with Tencate Miragrid[®] XT (geogrid soil reinforcement). A typical section of the wall face is shown in Figure 4. The MSE wall is an economical and structurally sound permanent green wall face with no maintenance. Figures 3 and 4 show drainage composites used in the wall design. Drainage is an important factor in the MSERW design but is beyond the scope of this paper.

Figure 4. Typical section of synthetic grass wall face.

2.2 Soil Properties

The soil properties used in the MSERW design are shown in Table 1.

Table 1. Soil properties in MSE wall.

Soil Properties	Reinforced Zone	Retained Zone	Foundation Zone
Friction Angle (degrees)	38	38	35
Cohesion (psf)	0	0	333
Unit Weight (pcf)	128	128	128
USCS Classification	GW	GW	SM

2.3 Geosynthetic Properties

The long term design strengths of the geosynthetic reinforcements are shown in Table 2. The Primary Geogrid is the geogrid soil reinforcement. The Secondary Geogrid is the synthetic grass face geogrid mesh.

Table 2. Long term design strengths.

	Primary Geogrid	Secondary Geogrid
Ultimate Tensile Strength (lbs/ft)	9,500	1,790
Reduction Factor for Creep	1.6	3.16
Reduction Factor for Durability	1.1	1.1
Reduction Factor for Installation Damage	1.05	1.05
Long Term Design Strength (lbs/ft)	5,140	490

3. SYNTHETIC GRASS FACE GEOGRID MESH

3.1 Development

In the author's experience, the challenge in vegetated geosynthetic wrapped faced wall construction has been that over-seeding and hydro-seeding may not be as effective as desired. Many factors contribute to the complete vegetated geosynthetic wrapped face wall including; time to vegetation growth, homogeneous growth coverage, maintenance of irrigation system, direction of wall to sunlight exposure and seed mix selection (Tencate Geosynthetics North America, Miramesh... 2010). It takes time to achieve established grass growth especially in the case of a near vertical wall face. The typical pattern for grass growth is on top of the short ledges in the wall batter and then the grass cascades over the next lift. Initially, a geosynthetic was developed to provide high resistance to sunlight at the exposed vegetated face and also to satisfy the long term tensile strength needed as secondary reinforcement to prevent surficial slope failure. The material is a green biaxial geogrid mesh which is capable of permanently retaining soil at the wall face, yet open enough to promote vegetation growth. The mesh is coated and offers a 75 to 100 year design life exposed to sunlight. However, the goal was to create a geosynthetic wall facing that looked fully vegetated at the completion of wall construction.

A two-year development process was begun to develop a unique geosynthetic wall facing by tufting synthetic grass into a secondary reinforcement geogrid. Using TenCate's experience of grass yarn development, a review was conducted on high ultraviolet (UV) resistant fibers, new grass yarn, new tufter and capability of high pile height. The concept was to take the original green biaxial geogrid mesh and tuft in an 18-inch strip of synthetic grass which would represent the lift height of the face of an MSERW. The remaining material would not contain the synthetic grass, but extend back into the wall face to provide the necessary strength as secondary geogrid reinforcement at the wall face.

Initially, synthetic grass yarns were tufted in a backing geotextile attached to the green biaxial geogrid mesh but a typical coating to hold yarns in place cannot be applied as this would block all water flow and be detrimental to the design of the wall. However, the yarns were cut-pile and were not stable enough to maintain their relative position in the backing. The pile length of the yarn was increased and an additional substrate, a woven primary backing, was used to tuft the yarns for additional support. After testing, it was determined the flow rate of the 18-inch woven section that was tufted had insufficient water flow and could promote soil infiltration. In the final design a high flow heavy nonwoven was used that would not impeded water flow through the system but would adequately hold the synthetic grass tufts into place (see Figure 5). This resulted in synthetic grass face geogrid mesh, a composite product that would offer the necessary reinforcement for wall facing and provide a fully vegetated appearance immediately after completion. The nonwoven allows sufficient drainage and retains soil backfill, and the color of the grass can be changed depending on the desired color of the wall face.

Figure 5. Back of synthetic grass tufts in nonwoven geotextile.

The synthetic grass face geogrid mesh is a unique geosynthetic composite utilizing synthetic grass, nonwoven geotextile backing and green biaxial geogrid mesh as shown in Figure 6. The polymer for the backing is a homopolymer polypropylene, which offers one of the best combinations of UV stability and tenacity. The polymer for the grass blade is low density polyethylene and was chosen for its softness and drapability so that it more resembles the look and feel of actual grass. The synthetic grass yarn also provides significant UV protection to the geogrid. Both the synthetic grass and the nonwoven support membrane are made from inert polymer resins in the polyolefin family. They have hindered amine light stabilizers that are custom tailored for each specific polymer to allow the best weathering and color fastness properties over time.

Figure 6. Synthetic grass face geogrid mesh.

3.2 Laboratory Testing

The next stage was to test for UV durability of the geosynthetic when exposed to sunlight using fluorescent ultraviolet (QUV) testing. The data obtained from QUV testing at the Geosynthetics Institute, Folsom, PA, USA demonstrated that the synthetic grass significantly reduced damage of exposure to the reinforcing geogrid. The synthetic grass face geogrid mesh testing has shown 40 percent strength retained when exposed to high sustained UV levels approaching 40,000 hours of exposure (see Figure 7). We currently have more than 42,000 hours (almost 5 years) of accelerated UV test data with and without the tufted synthetic grass.

Figure 7. QUV test results on synthetic grass reinforcement (performed by Geosynthetic Institute, Folsom, PA, USA).

3.3 Design Life

Currently, the industry standard for measuring the UV resistance of geosynthetics is to use the xenon arc light source following ASTM D4355 or the fluorescent UV light with condensation to simulate weathering, ASTM D7238. For buried geosynthetics, the industry standard has been a minimum UV resistance of 70% strength retained after 500 hours per ASTM D4355. Correlating UV exposure from these test methods to field exposure is difficult. UV intensity and degradation rates are directly related to geographical location and other factors. However, it is possible to use the erythemal UV irradiance data of various geographic locations to develop a correlation between simulated UV exposure testing and field exposure (TenCate Geosynthetics North America, UV Durability... 2010).

Using the QUV simulated UV weathering (ASTM D7238), the intensity is about twice as much as using the xenon arc light source (ASTM D4355). Based on the intensity of the UV light source and the range of erythemal UV irradiances encountered in various geographic regions of North America, the equivalent exposure time for a design life of 75 years to 100 years ranges from about 18,000 hours to 23,000 hours. As shown in Figure 5, the result of the synthetic grass face geogrid mesh UV resistance is 62% strength retained at 18,000 hours and 59% strength retained at 23,000 hours per QUV testing. These are conservative values, since the irradiance levels are based on full sun exposure of a horizontal surface. Vertical surfaces, like a MSERW, will be shaded for a significant percentage of the day compared to a horizontal surface. This provides more strength than the LTDS of the material, so it may be used as a permanent wall face with design life of 75 to 100 years as shown in Table 3.

Table 3. Synthetic grass face geogrid mesh design strength.

Ultimate Tensile Strength (lb/ft)	LTDS (lb/ft)	Retained Strength at 75 year UV Exposure (lb/ft)	Retained Strength at 100 year UV Exposure (lb/ft)
1,790	490	1,110	1,056

4. WALL CONSTRUCTION

4.1 Project Overview

A total of six permanent geosynthetic wrapped face MSERWs were constructed by the general contractor, CONNET. The total wall area is 236,000 square feet with 105,000 square yards of geogrid soil reinforcement and 55,000 square yards of synthetic grass face geogrid mesh. The geogrid soil reinforcement was installed in 18-inch vertical lifts. The typical geogrid soil reinforcement length is 70 percent of the wall height. The tallest wall reaches a height of 40 feet with a maximum wall length of 984 feet and wall area of 39,370 square feet.

4.2 Facing Installation

Temporary forms were used at the wall face in the installation of the permanent geosynthetic wrapped face MSERW. The temporary form is required in order to achieve proper compaction at the wall face and is used to set the wall batter. On this project, some of the walls have a batter of 90°. The synthetic grass face geogrid mesh was placed vertically inside the temporary form with the green biaxial geogrid mesh extending back into the wall fill. The soil was placed in 8-inch vertical lifts and compacted to 95% modified proctor density. On this project, the contractor chose two different types of form systems: wire forms and wood forms.

4.2.1 Wire Forms

Wire forms typically consist of prefabricated L-shaped 18-inch high wire baskets that are 10-foot long and available through various steel fabricators. The detail of a typical wire basket form is shown in Figure 8. On this project, the contractor field-bent black steel wire mesh to create L-shaped wire baskets (see Figure 9.) Galvanized steel is not required since the wire basket is only considered a temporary form. The high pile height of the synthetic grass face geogrid mesh is designed to hide the wire basket form.

Figure 8. Detail of typical wire basket form.

Figure 9. Field-bent black steel wire basket form.

4.2.2 Wood Forms

Wood forms may be used to create the vertical wall face. The wood forms consist of 18-inch high sturdy wood members connected to steel brackets embedded in the wall (see Figure 10). As each lift is constructed, the wood forms are pulled from the wall face and moved up in consecutive wall lifts. Wood forms were used to construct many of the walls on the project as shown in Figure 11.

Figure 10. Detail of typical wood form.

Figure 11. Wood forms used at wall face.

5. CONCLUSION

MSERWs were constructed on a toll road project through mountainous terrain. These permanent MSERWs were constructed entirely of geosynthetic materials. The wall facing consists of synthetic grass face geogrid mesh to provide a design life beyond 75 years. The benefit is a structurally sound permanent geosynthetic wrapped face MSERW that is economical and aesthetic with no maintenance.

ACKNOWLEDGEMENTS

Polyester Geogrids as Asphalt Reinforcement - A Proven Technology

Bernd Thesseling, Applications Engineer, Huesker Synthetic GmbH, Germany, thesseling@huesker.de
Greg Kiggins, Product Manager, Huesker Inc., USA, gkiggins@hueskerinc.com

ABSTRACT

The conventional method for rehabilitation of cracked concrete or asphalt pavements is the installation of new asphalt layers. But a new overlay does not make the cracks disappear; they are still present in the old asphalt layers. Because bituminous bound materials are unable to withstand the high tensile stresses that result from external forces like traffic and temperature variations, these cracks rapidly propagate into the new asphalt overlay. This phenomenon, known as reflective cracking, is one of the major problems associated with the use of asphaltic overlays.

In order to tackle the problem of reflective cracking and to therefore prolong the service life of a pavement, a reinforcement grid made of high modulus polyester has proven to be a very effective solution. Geosynthetics as asphalt reinforcement have consistently shown outstanding results in addressing the issue of crack initiation and propagation, eliminating the damage caused by water intrusion that ultimately leads to the failure of the pavement structure. The increased pavement life achieved by the use of this technology not only prevents excessive disruption to traffic flow and local business, but it also demonstrates strong environmental and economic benefits.

Through basic theory and practical experiences this paper will demonstrate the success and extended pavement life that can be achieved in both highway and airfield applications. Special attention is given to the performance on site, e.g. the loss of tensile strength due to the paving procedure (influence of paver and truck passes), but also to milling of reinforced asphalt and its recycling.

1. INTRODUCTION

Asphalt reinforcement has been used worldwide for many years to delay or even prevent the development of reflective cracks in asphalt layers. Using asphalt reinforcement can clearly extend the fatigue life and therefore the maintenance intervals of rehabilitated asphalt pavements. Currently there are a number of different products and systems made of different raw materials (e.g. polyester, fiberglass, carbon fiber, polypropylene...) available in the market. It is not disputed that each of these systems has a positive effect in the battle against reflective cracking; however there are differences in the behavior and effectiveness of each system.

2. CREATING AN ASPHALT REINFORCEMENT OVER ALMOST 40 YEARS

The idea of a reinforcing fabric for asphalt road construction first emerged in the early 1970s (Figure 1). The first experiences with geogrids were in the construction of earthworks and foundations, so the idea to use them in asphalt pavements was a logical next step. The initial intention was that the embedded Geotextile layer was able to pick up the tensile stresses in the asphalt and prevent cracks from forming. However, it was soon realized that this principle did not work, but the product proved very useful at delaying the formation of reflection cracks in resurfaced roadways. Even then polyester was a preferred raw material because of the compatibility of its mechanical properties with the behavior of asphalt. Since then many products made from different raw materials have been developed.

Figure 1. One of the first attempts to use a Geogrid in asphalt pavements at the early 1970s.

3. BASICS REFLECTIVE CRACKING AND ASPHALT REINFORCEMENT

It is well known that cracks appear due to external forces, such as traffic loads and temperature variations. The temperature influence leads to the binder content in the asphalt becoming brittle; cracking starts at the top of a pavement and propagates down (top-down cracking). On the other hand, high stresses at the bottom of a pavement, from external dynamic loads, such as, traffic, lead to cracks that propagate from the bottom to the top of a pavement (bottom-up cracking).

A conventional rehabilitation of a cracked pavement involves milling off the existing top layer and installing a new asphalt course, but cracks are still present in the existing (old) asphalt layers. As a result of stress concentrations at the crack tips caused by external forces from traffic and natural temperature variations, the cracks will propagate rapidly to the top of the rehabilitated pavement.

Deteriorated concrete pavements are typically rehabilitated by installing new asphalt layers over the old concrete slabs. Temperature variations lead to a rapid crack propagation especially at the expansion joints to the top of the new asphalt overlay.

In order to delay the propagation of cracks into the new asphalt layers an asphalt reinforcement comprised of high tenacity polyester can be installed. The reinforcement increases the resistance of the overlay to high tensile stresses and distributes them over a larger area, thereby reducing the peak shear stresses at the edges of the cracks in the existing old pavement. The reinforcement also provides a normal load to the crack surfaces, thereby increasing the aggregate interlock (shear resistance) between both crack surfaces and thus increasing the resistance to reflective cracking.

High modulus polyester (PET) is a flexible raw material with a maximum tensile strain less than 12%. The coefficients of thermal expansion of polyester and asphalt (bitumen) are very similar. This leads to very small internal stresses between the PET fibers and the surrounding asphalt (similar to reinforced concrete). For this reason Polyester does not act as an extrinsic material in the asphalt package, however at this point it should be mentioned that the aim of a PET-grid as asphalt reinforcement is not to reinforce asphalt in such a way as one reinforces concrete. The installation of a PET-grid as asphalt reinforcement improves the flexibility of the structure and avoids peak-loads over a cracked existing layer into the overlay and through this mechanism reflective cracking is delayed.

As found by De Bondt (De Bondt 1999) the bonding of the material to the surrounding asphalt plays a critical role in the performance of an asphalt reinforcement. If the reinforcement is not able to sufficiently adopt the high strains from the peak of a crack, the reinforcement cannot be effective. In his research, de Bondt determined an equivalent "bond stiffness" in reinforcement pull-out tests on asphalt cores taken from a trial road section. The equivalent bond stiffness of a bituminous coated PET-grid was found to be, by far, the best of all the commercial products investigated.

Furthermore, asphalt reinforcement must resist as much damage as possible from the stresses and strains applied during installation and overlaying / compaction of the asphalt. Very high forces can also be applied to the individual strands of the reinforcement by aggregate movement in the hot blacktop during compaction.

In a research at the RWTH (Rheinisch-Westfaelische Technische Hochschule) Aachen University in Germany, called "Effectivity of asphalt reinforcement systems under consideration of installation damage" (Sakou 2011), it was found that products with a brittle raw material like fiberglass can lose a significant part of their tensile strength when trafficked by

asphalt delivery trucks and after the asphalt compaction. The results of the demonstrated research are also confirmed by results of tests performed according to EN ISO 10722-1 “Geosynthetics: Procedure for simulating damage during installation” (tBU 2003). In both tests Polyester as raw material exhibited a very good resistance to installation damage.

4. INFLUENCE OF DAMAGE DURING INSTALLATION ON THE TENSILE STRENGTH OF ASPHALT REINFORCEMENT PRODUCTS

The properties of asphalt reinforcement (e.g. tensile strength, tensile strain) are influenced during their installation, the paving procedure (paver and truck passes) and the compaction of the asphalt (Figure 2). The result, specifically the loss of tensile strength of the asphalt reinforcement grid during the paving procedure, is known as installation damage.

After an asphalt reinforcement product is placed, many asphalt delivery trucks have to pass over the grid. Additionally there is the compaction of the hot mix asphalt, during which the individual filaments or strands of the asphalt reinforcement are largely influenced by the movement of aggregates, in particular of coarse and sharp-edged aggregates. Next to the reinforcement characteristics (flexible or brittle raw materials), the degree of installation damage by roller compaction not only depends on the number of passes and the type of compaction (e.g. rubber tired, static, dynamic), but the weight of the compactor and the condition of the base layer (e.g. smooth, rough/milled) as well.

To successfully counteract reflective cracking, installed reinforcement products must resist the installation influences without damage and without significant loss of strength.

There is currently a lack of experience and knowledge concerning the real residual properties (what could be termed “effective tensile strength”) of asphalt reinforcement products following their installation and the subsequent paving installation procedure.

In the context of a diploma thesis at the RWTH Aachen University (Sakou 2011), a test procedure to describe installation damage was developed. One of the aims was to analyze and quantify the “effective tensile strength” for two different asphalt reinforcement products with different raw materials (polyester and fiberglass) after the influence of installation damage.

Figure 2. Influences on asphalt reinforcement products during the asphalt installation

4.1 Diploma Thesis at the RWTH Aachen University Considering Installation Damage

As part of the work to assess the resistance of asphalt reinforcement products to installation influences, site-appropriate tests were performed at the institute's installation test track. As one goal, comparable tensile strengths of the tested products after the following influences were intended to be achieved:

- Only the influence of trafficking asphalt trucks
- Only the asphalt compaction
- Combination: Trafficking of asphalt trucks and compaction of the asphalt

4.1.1 Test Procedure

To determine the impact of truck traffic only, undamaged specimens of the reinforcement products were placed on a clean and even road and loaded by a truck. The applied load was carried out by 35 passes with a speed of 20 ± 5 km/h without any steering movements or braking activity. Considering a truck with 5 axles who drives backwards to the paver and forward again this corresponds to 3.5 delivery trucks driving over the grid.

In preparation for the tests, an asphalt binder course (AC 16 B S) was installed on the base of the test track first. Onto the binder course, the reinforcement grids have been placed according to the manufacturer's installation guidelines. Some of the pre-damaged specimen (truck passes) have also been used in the test-track for further exposure to simulate the double load-effect, truck passes and compaction. To differ between undamaged, pre-damaged and the different loading types, the specimen had been placed into separate sections. Subsequent to the installation of the reinforcement specimen a 50mm asphalt wearing course was installed and compacted with 6 roller passes (2 static and 4 dynamic).

To test their tensile strength after the asphalt installation and compaction, some of the specimen had to be removed after the installation of the wearing course. For this reason these specimen have been wrapped into an aluminium foil and coated with a separating agent to create a very bad interlayer bond.

To investigate the different influences the test track was divided into different sections:

- A - An undamaged fiberglass reinforcement was installed, followed by the installation and compaction of an asphalt wearing course. (→ Load influence: Compaction only)
- B - A Polyester reinforcement was installed, followed by the installation and compaction of an asphalt wearing course. (→ Like „A“, load influence: Compaction only)
- C - A pre-damaged fiberglass grid was installed. Subsequently the asphalt wearing course was installed and compacted. (→ Load influence: Truck passes and compaction)
- D - A pre-damaged Polyester reinforcement was placed. Subsequently the asphalt wearing course was installed and compacted. (→ Like „C“, load influence: Truck passes and compaction)

4.1.2 Results

In the context of the research the final material characteristics (e.g. tensile strength) have been tested with the wide width tensile test according to EN ISO 10319. To compare the separate types of tests (variants) the property "residual strength" was chosen. The residual strength is defined as the maximum tensile strength after the installation damage tests, expressed as a percentage of the maximum tensile strength of the undamaged reference material.

The results revealed the considerable difference between the influence from truck traffic and asphalt compaction on the tensile strength of the specimens. It must be mentioned, however, that for the damaged fiberglass grids the test samples had to be taken from the side of the specimen, as the middle parts had been completely destroyed during the installation damage test, and were therefore impossible to test (Figure 3).

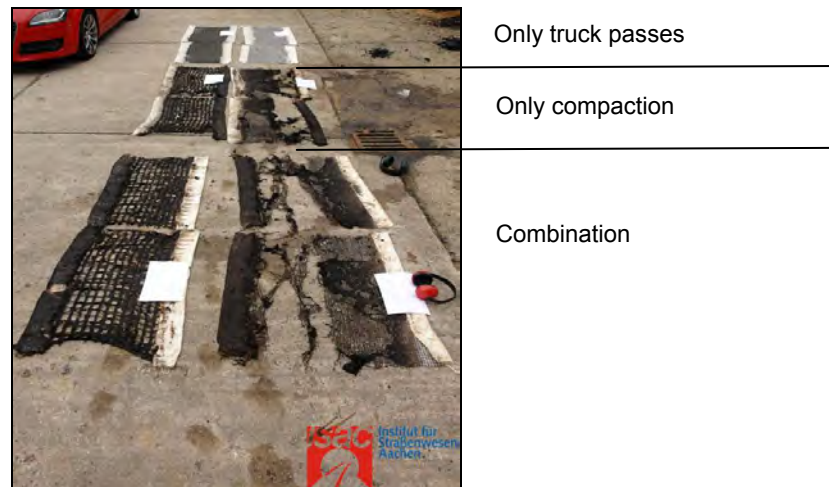

Figure 3. Results of installation damage test
Left: PET-Grid; Right: fiberglass grid

After the load influence "truck passes" only, the polyester grid showed a residual strength of 85%, while the fiberglass grid had only 44% residual strength. After the load influence "compaction" only, the polyester grid showed a residual strength of 71%, while the fiberglass grid had only 21%.

The polyester grid specimens which were subjected to both loading influences - asphalt compaction and truck passes - still had a residual strength of 70% while the fiberglass grid subjected to both loading influences revealed further damage with a residual strength of only 11% only (of the measurable areas, see Figure 3).

4.1.3 Summary

After a series of testing, it can be safely concluded that installation damage plays an important role on the "effective tensile strength" of asphalt reinforcement products. It was found that the polyester grid lost max. 30% of its tensile strength after loading from truck passes and asphalt compaction. In contrast to the performance of the polyester grid, the fiberglass grid showed a loss of strength up to approximately 90%. The fiberglass grid was damaged significantly more than the Polyester grid reinforcement.

4.2 Conclusion Regarding Installation Damage on Asphalt Reinforcement Products

As previously mentioned, asphalt reinforcement products must resist as much damage as possible from the stresses and strains applied during installation and compaction of the asphalt. Very high forces can also be applied to the individual strands of the reinforcement by aggregate movement within the hot asphalt during compaction.

From the research at the RWTH Aachen University, products with a brittle raw material (like fiberglass) can lose a significant part of their tensile strength when trafficked by asphalt delivery trucks and after the asphalt compaction. The results of the research are validated by results of tests performed according to EN ISO 10722-1 "Geosynthetics: Procedure for simulating damage during installation" (tBU 2003). Furthermore, it is expected that for fiberglass grids the results would be worse on a milled surface.

The tests reveal that polyester grids exhibit a very good resistance to installation damage compared to other products made with more brittle raw materials.

5. PRACTICAL EXPERIENCE: MUNICIPAL ROAD "ROSENSTRASSE" IN GERMANY

The following project shall give an example of the successful use of asphalt reinforcement in roads. The project is located in the Northwest German town of "Ochtrup". The road is a highly trafficked road. The majority of vehicles are trucks, because the road is one of the main connections to the nearby border of the Netherlands. Before rehabilitation, the road exhibited severe alligator cracking, longitudinal and transverse cracking in large scale. The original design called for milling, approximately 50 mm of the surface followed by installation of a new 50 mm asphalt surface course. Due to the problematic condition of the existing base, the expected lifetime of the new surface was only 2 years.

The more durable (but also much more expensive) solution would have been to remove the cracked binder and base course. An alternative to this solution was the installation of a Polyester Geogrid as asphalt reinforcement over the cracked binder course, where the thickness of the new wearing course would remain 50 mm. Therefore, the economical advantage had to be proven by a longer lifetime, which should be the main goal in most of these applications. The layers would have the same thickness, therefore the economical advantage results from the longer lifetime of the surface over the old cracked area.

After milling off the 50 mm surface course the asphalt reinforcement grid was installed, and covered again with a 50 mm 0/11 AC asphalt layer. The whole project was finished in the summer of 1996.

5.1 Project Update: June 2002

Six years after the repairs were carried out, the District's Chief Executive was asked for a condition report on the "Rosenstrasse". In his answer, he commented as follows: "I'm happy to inform you that the repairs have fully stood the test of time. The use of the asphalt reinforcement system under the 0/11 asphalt layer has meant that, to this day, no cracks have appeared in the asphalt-concrete surface. This method was chosen at the time to avoid the necessity of the additional work required for the binder and base course."

5.2 Project Update: September 2009; Assessment by TÜV Rheinland

The TÜV Rheinland is a leader in independent assessment services. In 2009, the TÜV Rheinland was commissioned to document the cracking and assess the condition of "Rosenstrasse" along the portion of the road that was repaired in 1996.

The appraisal compared the current condition with the condition that existed before repairs were carried out. This comparison allowed conclusions to be drawn about the effectiveness of the asphalt reinforcement system for delaying the occurrence of cracks propagated from the lower asphalt layers.

On August 24th 2009, a visual inspection was done in accordance with Working Paper No. 9 (by the German FGSV; Research Association for Transportation in Germany). The TÜV used the image documentation of the construction measures used in May 1996 as the basis for its assessment. The District's Chief Executive responsible at that time provided additional necessary information.

5.2.1 Result

After 13 years of use, the cracking condition value (ZWRIS) for the section of the road repaired with the Polyester grid in 1996 was determined to be excellent. The visual inspection of the road surface revealed almost no damage with the exception of two areas. The damage in these areas, however, was due to subsequent repair work on the drainage system. A few lateral cracks were discovered at one point on the outer edge of the road. Small cracks along the road surface were also found at a few other points on the outer edges (Figure 4).

The photos documenting the condition of the site in 1996 (Figure 5) show that the distance between the reinforcement system and the road edge was always around 150 - 300 mm. TÜV Rheinland also confirmed: "The entire remaining road area is free of cracks."

Figure 4. Lateral crack at the edge

Figure 5. Fitted reinforcement (detail)

5.2.2 Conclusion

The condition assessment by TÜV Rheinland revealed that the "Rosenstrasse" in the city of Ochtrup has, in spite of constant heavy traffic, remained in good condition to this day. The deployment of the asphalt reinforcement system to effect repairs has completely stood the test of time. This measure has shown that a Polyester asphalt reinforcement can keep the condition of rehabilitated roads at a high level over extended periods of time.

6. PRACTICAL EXPERIENCE: SALGADO FILHO AIRPORT, PORTO ALEGRE (BRAZIL)

In 2001 the existing access to an aircraft maintenance hangar (used by aircraft as large as the Boeing 777, with a weight over 250 tons) had to be resurfaced after more than 40 years of use. The existing pavement was made of 5.0 × 3.5 m concrete slabs, 250 mm thick. The slabs were resting on a layer of gravel.

The rehabilitation design involved the installation of an asphalt leveling layer first. In order to prevent the propagation of the expansion joints from the concrete slabs into the new surface, an asphalt reinforcement made of high modulus polyester was to be installed. A 50 mm asphalt surface course was installed on top of the polyester reinforcement.

Because it was not possible to block the access for an extended period of time, the rehabilitation work had to be finished in just one night. In order to stay within this very tight time frame, it was decided to only reinforce the heavily loaded inner portion of the pavement. The outer portions, which are not typically subjected to the heavy loading of aircraft traffic, were left unreinforced.

What initially was thought to be a purely practical solution developed into an ideal demonstration of the effectiveness of an asphalt reinforcement grid. By only reinforcing a portion of the pavement and leaving the remainder unreinforced, a direct side-by-side comparison of the performance of the reinforced and unreinforced sections was possible.

In October 2007, approximately 7 years after the rehabilitation, the first assessment of the pavement took place. At that time the designer, the technical manager of the airport, and an employee of the reinforcement manufacturer were present.

The expansion joints in the concrete beneath the unreinforced pavement areas had already propagated to the top of the surfacing. The vegetation, visible in the developed cracks, led to the conclusion that these cracks had existed for some time. In contrast, the PET-grid reinforced areas did not show any indications of cracking (Figures 6 and 7). Because the unreinforced section was not subjected to aircraft traffic, the propagation of the expansion joints in these areas can be conclusively attributed to the horizontal stresses that resulted from changes in temperature. The areas reinforced with the polyester grid were subjected to both temperature-induced and aircraft traffic-induced stresses.

For further details the reader is referred to a paper prepared by Monser and Montestruque (Monser et al. 2010).

7. AN EYE ON SUSTAINABILITY

In the context of the construction industry, different construction techniques and designs for specific projects must be compared for their ECO_2 (Embodied carbon dioxide) emissions as an indicator for their sustainability. As a matter of fact, the ECO_2 is only one of the criterion for successful projects, along with social and economic considerations. However the request for sustainability is now appearing more and more important on both the client's and contractor's side.

7.1 Examples of ECO_2

The amount of ECO_2 per kg of material can vary significantly as seen in Table 1. The more processing and energy that is required to create the final product, the higher the ECO_2 emission. Processes that are especially energy intensive like the production of cement (for cement concrete) produce a high amount of CO_2 .

Cement manufacturing releases CO_2 into the atmosphere both directly and indirectly. Direct emissions of CO_2 occur when calcium carbonate is heated, producing lime and carbon dioxide. Indirect emission occurs if the energy used for cement manufacturing involves the emission of CO_2 .

Table 1. Examples of embodied carbon dioxide (ECO₂) in construction materials

Material	kg ECO ₂ / kg of material	Note
Aggregate	0.0052	gravel or crushed rock
Aluminium	9.16	-
Asphalt	0.076	6% binder content
Bitumen	0.55	-
Cement	0.74	UK weighted average
Concrete 16/20	0.10	unreinforced
Reinforced Concrete RC 40/50	0.188	high strength applications / precast
PVC General	3.10	-
Polyester	1.93	derived from HDPE
Steel	1.46	average UK recycled content
Steel	2.89	Virgin steel

7.2 Comparison of Embodied Energy for Reinforced and Unreinforced Asphalt Overlays

The report "Sustainable geosystems in civil engineering applications" commissioned by the Waste and Resource Action Plan (WRAP, 2010) has analyzed geosystems as alternatives to standard designs used by civil engineers. Parallel to geosystems for ground engineering the report has identified that:

"Reinforcement of the asphaltic or bound layers can increase the life of the surface layers, again by contributing to a strengthening of the bound layers. Such strengthening increases their ability to resist cyclic fatigue, thermal stresses during extremes of winter and summer temperatures, as well as increasing resistance to near surface crack propagation."

The report clearly identifies that asphalt reinforcements can extend pavement life by limiting reflective cracking and thus providing more sustainable pavements as a result. This paper aims to demonstrate the above referenced effect by comparing the ECO₂ based on the material consumption per year of lifetime of two construction techniques. One construction technique is the conventional rehabilitation of cracked overlays by milling and repaving; the second is a rehabilitation using a polyester asphalt reinforcement geocomposite in the same process.

The use of appropriate geosynthetic solutions in asphalt reinforcement applications can provide a reduced carbon footprint. Due to the reduction in fill/asphalt thicknesses there are related savings in carbon footprint, including a reduction in transport emissions and reduction in asphalt production emissions. A simple comparison between a reinforced and an unreinforced solution was done by Hessing (Hessing 2011). It was shown that, compared to the unreinforced overlay, savings up to of 60% ECO₂ can be achieved in the design life of a maintained reinforced asphalt pavement. Extending the pavement life and thus reducing the need for maintenance and the corresponding ECO₂ achieve this substantial savings.

8. MILLING AND RECYCLING

Even the best asphalt reinforcement cannot guarantee that an asphalt road will have an infinite life. The ease of removal of surfacing by milling is an increasingly frequent topic for discussion.

For this reason the impact of a polyester asphalt reinforcement on milling activities was investigated under defined conditions by the Institute of Road and Traffic Engineering at the RWTH Aachen University (RWTH 2008).

On the University's own 26m long, 1m wide test bed, RWTH staff can lay and remove lengths of road construction using ordinary methods typically employed on site. A rail-mounted paver machine with a high performance compacting screed installed the road materials. The surface was given its final compaction by a tandem vibratory roller.

For the milling tests a small milling machine with a milling drum width of 500mm was used.

The aim of the investigation was to analyze and evaluate the milling characteristics of the reinforced road construction in terms of process engineering and the machinery used. In addition to investigating particle size distribution and the type and size of reinforcement fibers in milled asphalt, the possibility of recycling the removed asphalt containing reinforcement fibers in the form of asphalt granulate in bitumen-bound layers was examined.

8.1 Test Procedure

A 60mm asphalt binder course (AB 0/16S) and an asphalt base were laid over a frost protection layer on the test bed. After a resting time of about one week, the PET asphalt reinforcement was installed in accordance with the manufacturer's installation instructions. This was then overlaid with a 40mm asphalt surface course (AB 0/11S).

8.2 Removal - Milling Tests

A milling depth of about 50mm was selected to ensure that the asphalt surface course and the first 10mm of the asphalt binder course (including reinforcement) were removed by the milling machine in a single milling operation (Figure 8). This procedure was recommended by the manufacturer for the removal of reinforced roads.

Result: During removal of the material no detrimental effect on the milling operation was observed. Over the full test length, the millings were finely graded. The fibers of asphalt reinforcement produced from the milling process were evenly distributed in the millings. The fibers had an average length of about 100mm.

Figure 8. Milling the asphalt including the reinforcement

Figure 9. Virtually no fibers on the milling drum

After completion of the milling operations, the milling drum was checked for adhering fibers. It was clear that over the whole test bed almost no (only 2) fibers had been trapped in the milling drum (Figure 9). During this test, no detrimental effects on the milling process were observed.

8.3 Recyclability: Effect of the Reinforcement Fibers on Marshall Stability

As part of tests on the recyclability of PET grid-reinforced asphalt, the effect of asphalt reinforcement fibers was investigated. Marshall test specimens were made from the asphalt binder layer material with and without asphalt reinforcement fibers and their Marshall stability and flow values were determined. The reference sample was defined as the asphalt binder course that was laid on the test bed. The asphalt reinforcement fiber content was the major difference between the two variants and the purpose of the test was to determine the effect of these fibers on Marshall Stability.

Result: There were only relatively small differences with respect to bulk density and void content between the Marshall test specimen used for the tests. The values for Marshall Stability and flow were virtually identical.

The results for the Marshall test parameters are shown in the following table.

Table 2. Results of Recyclability test

	Reference sample	With reinforcement fibers
Marshall Stability	8.4 kN	8.5 kN
Marshall Flow	3.6 mm	4.3 mm

No negative implications were observed in the course of the asphalt testing to determine the effect of asphalt reinforcement fibers on recyclability based on the Marshall Stability and Flow parameters.

9. LIMITS IN USING AN ASPHALT REINFORCEMENT GRID

There are limits in the types of asphalt problems that can be solved by using asphalt reinforcement. For example, the impact of asphalt reinforcement on the bearing capacity of a pavement has not been quantified. When a road has insufficient bearing capacity, it is necessary to carry out rehabilitation measures other than utilizing asphalt reinforcement, such as subgrade/base enhancement or increasing the asphalt thickness.

Another limitation of asphalt reinforcement involves large vertical movements in pavements. It is generally difficult to prevent crack propagation resulting from the large vertical movements that can be caused by concrete slabs which are not stable in their position or frost heave, even when using an asphalt reinforcement system.

In such cases, it is necessary to eliminate or minimize these movements prior to the installation of a reinforcement grid and the new asphalt layers (e.g. undertake injection below the slabs, or "crack and seat" the slabs to achieve a stress relief). One has to consider that reinforcement grids made of brittle raw materials (e.g. glassfibers) cannot resist shear forces. For this reason they tend to deteriorate quickly, especially when subjected to vertical movements (of concrete slabs, for example) that create shearing forces, even when they are minimal.

Manufacturers of grids made of brittle materials often point out that because of their fragility and brittleness (i.e. the low shear strength of fiberglass and the resulting high risk of damage) these grids should not be placed directly onto milled surfaces. The behavior of fiberglass reinforcements when placed directly over the sharp edges of cracks, especially during compaction, has not been clarified and requires further investigation.

10. CONCLUSION

Reflective cracking occurs in rehabilitated asphalt pavements. High tenacity Polyester as raw material is often chosen because of the high compatibility of its mechanical behaviour to the modulus of asphalt and its good behavior under dynamic loads. A bituminous coated Polyester asphalt reinforcement grid can show excellent results in delaying reflective cracking. This has been shown by numerous theoretical investigations and practical examples from the past several years.

Through research undertaken to complete a diploma thesis which analyzed and quantified the "effective tensile strength" for two different asphalt reinforcement products with different raw materials (polyester and fiberglass), it was shown that installation damage can have a noticeable influence on the properties of an asphalt reinforcement grid.

An investigation at the Institute of Road and Traffic Engineering of the RWTH Aachen University showed that milling and recycling of polyester grid-reinforced pavements does not negatively affect the milling process or the quality of the recycled asphalt.

Prediction of Tensile Strength Behaviour of Coir Geotextiles

Dr .S. Chandrakaran, Professor, Department of Civil Engineering NIT Calicut
D.S.Shamla, Student, Department of Civil Engineering NIT Calicut

ABSTRACT

Tensile strength and elongation properties are the major requirements of geotextile used in various geotechnical applications. The present study deals with the prediction of the tensile strength behavior of the coir geotextiles by two empirical modeling methods- a multiple linear regression equation and an ANN (Artificial Neural Network) model. Warp yarn strength, warp yarn elongation, ends per metre (EPM), picks per metre (PPM) and scorage of the yarn were used as input parameters. Both the models were able to predict the geotextile strength with reasonably good precision although the ANN model demonstrated higher prediction accuracy. Warp yarn strength, number of warp yarns and ends per metre are the two most dominant factors determining the strength of geotextiles in warp direction. The scorage of the weft yarn and picks per metre have significant effect on the assistance and the strength of the geotextile in the warp direction.

1. INTRODUCTION

Geotextiles are woven / non-woven or knitted structures of natural /synthetic textile fibre used in various geotechnical, civil engineering and soil conservation applications. They can perform different functions like filtration, separation, drainage, reinforcement, erosion control etc.

Natural fibre geotextiles like jute and coir have recently gained increasing popularity in the field of geotechnical engineering all over the world, due to growing environmental concern. "Coir" is the agricultural fibre obtained from the husk of the coconut fruit which surrounds the base shell. It is a natural biodegradable material with a highly crystalline structure with the spiral angle of the micro fibres ranging between 30° - 45°. This leads to a greater extensibility than in most other natural fibres. Its high lignin content contributes to higher durability and slow bio-degradation compared to other natural fibres. It is also very long lasting, with infield service life of 4 to 10 years. Because of growing awareness of sustainable development coir geotextiles are increasingly used world over for various Civil Engineering applications such as slope stabilization, erosion control, sub-grade stabilization for low volume roads etc. Hence coir geotextile is recognized as an ideal material that is capable of offering an ecologically sustainable solution to many of the environment- related issues.

2. MATERIALS AND METHODS

For predicting the tensile strength of coir geotextiles two methods have been adopted- by developing a Linear Regression Equation and an Artificial Neural Network (ANN) model. The predicted results were compared with the existing experimental results.

3. MULTIPLE LINEAR REGRESSION

Multiple Linear Regression (MLR) is a well known statistical procedure trying to find a linear relationship between two or more explanatory variables and a dependent variable by observing data. It can be used for forecasting output values. Dependent variable (y) can be explained by the equation below:

$$y = a + \sum b x + \epsilon \quad [1]$$

Before using ANN, a multiple linear regression model is constructed. MLR is used as a verification and comparison model of ANN in the literature. It is claimed that ANN generally gives better results than MLR (Mithat Zeydan, 2010). Geotextile strength is defined as the dependent variable and explanatory variables are: number of warp yarns per fabric width, ends per metre (EPM), picks per metre (PPM), warp yarn strength, and scorage of the weft yarn.

4. STRENGTH PREDICTION BY ANN

Artificial Neural Network (ANN) is a very potent modelling tool, which mimics the functioning of biological neurons. The goal of this type of network is to create a model that can precisely map the functional relationship between inputs and outputs using historical data. Neural networks are composed of simple elements operating in parallel. These elements are inspired by biological nervous systems. As in nature, the connections between elements largely determine the network function, typically, neural networks are adjusted, or trained, so that a particular input leads to a specific target output. The figure below illustrates such a situation. There, the network is adjusted, based on a comparison of the output and the target, until the network output matches the target. Typically, many such input/target pairs are needed to train a network.

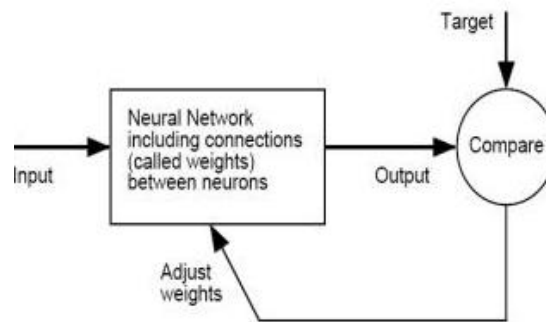

Fig .1Neural network model

The work flow for the neural network design process has six primary steps:

0. Collect data
1. Create the network,
2. Configure the network,
3. Initialize the weights and biases,
4. Train the network,
5. Validate the network and
6. Use the network.

In ANN, one or more hidden layers are positioned between one input layer and one output layer. Each layer is composed by a number of neurons or processing elements. Each neuron receives a signal from the neurons of the previous layer and each of these signals is multiplied by a separate weight known as synaptic weight. The weighted inputs are then summed up and passed through a transfer function, which converts the output to a fixed range of values. The output of the transfer function is then transmitted to the neurons of next layer. Finally the output is produced at the neurons of the output layer.

Back-propagation, a supervised learning algorithm, is the most popular among the existing ANN training algorithms namely forward pass and backward pass. In the forward pass, a set of data is presented to the network as input and its effect is propagated, in stages, through different layers of the network. Finally, a set of outputs is produced and the error vector is calculated. In the backward pass, this error signal is propagated backwards to the network and the synaptic weights are adjusted in such a manner that the error signal decreases in each iteration process. As the objective of the present endeavour is to predict the fabric strength, back-propagation algorithm was employed as it is apt for the prediction modelling. The algorithm uses the input-output data during training to optimize the synaptic weights, so that the error signal between actual and predicted output becomes minimum. Once the training is completed, the developed model can predict the output for any set of input pattern.

For ANN modelling, nn tool in MATLAB R2009a was used. 129 sample data had been collected for both multiple linear regression model and ANN, from the previous work done by Subaida et.al (2008). From the available 129 input-output data sets, 109 data sets were randomly chosen as training data and used for the development of ANN and linear regression models. Remaining 20 data sets were kept as testing data to evaluate the prediction performance of the models. ANN and regression predictions were done for various parameters of the coir geotextiles. By trial and error five parameters of the coir geotextiles were finally chosen for the prediction. Statistical parameters like mean absolute error% and coefficient of determination were used to judge the prediction performance of the developed models. Absolute error% was calculated by using the following expression.

$$\text{Absolute error\%} = \frac{\text{Actual value} - \text{Predicted value}}{\text{Actual value}} \times 100 \quad [2]$$

5. RESULTS AND DISCUSSION

5.1 Regression and ANN Models

The regression equation developed for the prediction of coir geotextile strength in warp direction is shown below

$$\text{Geotextile strength} = (0.1285 \times \text{No. of Warp Yarns}) - (0.9766 \times \text{Scorage}) + (0.2216 \times \text{Ends Per Metre}) - (0.1161 \times \text{picks Per Metre}) + (0.0472 \times \text{Warp Yarn Strength}) + 3.9611 \quad [3]$$

The summary of prediction performance of ANN and regression model is shown in Table1.

Table 1 Summary of fabric strip strength prediction results by ANN and regression models

Statistical Parameter	Training Data		Testing Data
	Co-efficient of Determination (R^2)	Co-efficient of Determination (R^2)	Mean Absolute Error (%)
ANN	0.98	0.94	1.9
Regression	0.91	0.94	2.4

It is noted that, in case of training data, the prediction performance of ANN model is better than that of regression model. The correlation coefficients between experimental and predicted values are 0.98 and 0.94 for regression and ANN models, respectively. Moreover, the absolute error of prediction was much lower for ANN model (1.90 %) as compared to that of regression model (2.4 %). It signifies superior modelling competency of ANN over the regression method. The scatter plot of experimental geotextile strength and predicted geotextile strength are depicted in figures 2 and 3.

It is observed that the actual and predicted geotextile strength values are more closely associated in case of ANN model. Table 2 shows the detailed prediction results of ANN and linear regression models in the testing data sets.

Fig 2 Scatter plot showing the experimental results and predicted geotextile strength by regression model

Fig 3 Scatter plot showing the experimental results and predicted geotextile strength by ANN

Table 3 Detailed fabric strip strength prediction results for testing data by ANN and regression models

Experimental Strength(KN/m)	Predicted Strength(KN/m)	
	ANN Model	Regression Model
10.33	12.4658	10.096
13.42	12.4792	10.61
14.91	13.2351	12.1762
14.16	13.314	12.4332
16.97	17.9458	20.4868
16.8	17.6161	20.7438
32.02	32.8168	32.0836
31.14	34.5435	32.8546
11.7	14.0295	14.714
12.42	14.0295	14.714
4.71	6.2618	6.5147
9.04	6.2799	6.7717
21.36	19.7181	19.2084
19.72	19.7181	19.2084
25.07	21.9174	22.4815
21.93	21.9174	22.4815
33.54	34.573	34.312
35.76	31.6971	33.541
33.15	29.8096	33.284
35.7	34.1469	34.055

It is observed that the performances of both the models are reasonably close to each other. Comparable prediction error shows that the ANN model was adequately trained and was able to achieve generalization.

5.2 Analyzing the Influence of Input Parameters

The influence of various input parameters on the geotextile strength was analyzed by curve fitting tool in Microsoft Excel and graphs were plotted with each parameter against the geotextile strength. All the parameters were kept at their middle value, except for the parameter whose influence is being estimated. Now, the parameter, whose importance is being evaluated, is varied from its minimum to maximum level and the corresponding change in the dependent variable or geotextile strength is noted. The influence of various parameters against the geotextile strength is shown in graphs plotted below.

Fig 4 Effect of EPM on geotextile strength

Fig 5 Effect of PPM on geotextile strength

Fig 6 Effect of warp yarn strength on geotextile strength

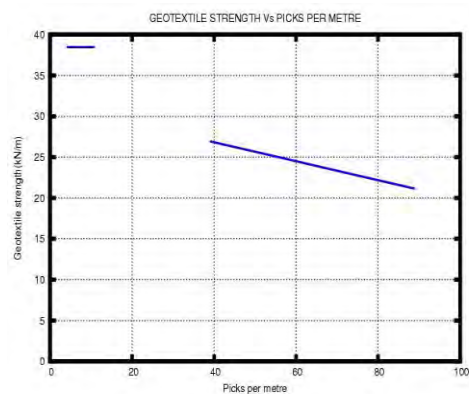

Fig 7 Effect of number of warp yarns on geotextile strength

Fig 8 Effect of scorage of the weft yarn on geotextile strength

6. CONCLUSION

The tensile strength of coir geotextile has been predicted with two methods –by developing linear regression model and ANN model. Reasonably good accuracy was obtained by linear regression and ANN models using warp yarn strength, warp yarn number, ends per metre, picks per metre and weft yarn scorage as inputs. The prediction accuracy is consistent and better for ANN model than that of linear regression model. The absolute error in percentage obtained for the tested data was 2% for ANN model and 2.5% for multiple linear regression model. The co-efficient of determination for the trained data is 0.97 and 0.91 respectively for ANN and regression models. For the tested data the co-efficient of determination obtained are 0.97 and 0.95 for ANN and regression models correspondingly. From the analysis of various parameters show that warp yarn strength, no: of warp yarns and ends per metre are the two most dominant factors determining the strength of geotextile in warp direction. The scorage of the weft yarn and picks per metre have significant effect on the assistance and the strength of the geotextile in the warp direction.

ABSTRACT

The unconfined compression strength test results performed on recycled-content expanded polystyrene (EPS) blocks indicate that EPS blocks consisting of recycled-content expandable polystyrene (PS) can be produced to meet the current ASTM D 6817 standard compressive resistance requirements. Additionally, the results also indicate that the overall recycled content may not significantly influence the compressive resistance values of recycled-content EPS blocks compared to virgin EPS blocks as demonstrated by the test results for a target density of 21.6 kg/m³, which showed compressive resistance values for 15% and 30% recycled-content blocks similar to the compressive resistance values obtained for a virgin EPS block with 0% recycled-content expandable PS. The compressive resistance results for the higher target density of 38.4 kg/m³ indicates the potential for an optimal recycled-content block that yields a higher compressive resistance than a virgin EPS block with 0% recycled-content expandable PS.

1. INTRODUCTION

Expanded polystyrene (EPS)-block geofoam made of virgin expandable PS is being successfully used in many civil engineering applications such as lightweight fill in roadway embankments over soft ground (Stark et al. 2004a, 2004b) and in landslide stabilization and repair (Arellano et al. 2010, Arellano et al. 2011a, 2011b); as a compressible inclusion to reduce lateral pressures on earth-retaining structures and earth pressures on underground utilities; as seismic buffers for building walls, bridge abutments, earth-retaining structures, and underground utilities; and as a buffer to reduce the increase in stresses due to thermal expansion of bridge integral abutments. At present, however, widespread use of recycled-content EPS is limited because no tool is available that can predict the key mechanical properties required to design recycled-content EPS blocks.

The primary obstacle to more widespread use of recycled-content EPS in civil engineering applications is the current lack of material prediction models that can provide the stress-strain-time-temperature behavior of recycled-content EPS. EPS blocks in civil engineering applications must typically support loads to prevent an ultimate limit state failure (collapse failure) as well as a serviceability limit state failure (failure due to excessive deformation). Therefore, the load-bearing capacity of EPS blocks is critical in civil engineering applications (Arellano and Stark 2009). The mechanical properties of EPS, which consist of the stress-strain-time-temperature behavior, are important in evaluating the load-bearing capacity of EPS blocks. Although recycled-content EPS is currently used in packaging material, this application is not as load-bearing critical as in civil engineering applications.

The overall goal of the research described herein is to develop stress-strain-time material prediction models for recycled-content EPS blocks that will allow engineers to perform structural response predictions in various civil engineering applications. Specifically, the proposed models will provide the stress-strain-time behavior of recycled-content EPS blocks thus allowing engineers to perform structural response predictions for various potential applications of recycled-content EPS, such as allowing engineers to determine the suitability of recycled-content EPS in lightweight fill applications that include roadway embankments, slope stabilization and repair, and levees.

This paper presents the preliminary results of unconfined compression strength tests completed for the purpose of evaluating the stress-strain properties of recycled-content EPS blocks. First, an overview of the recycled-content EPS manufacturing process and a description of the samples tested and tests performed are provided. After that, the unconfined compression test results of the recycled-content EPS samples are summarized and discussed. Lastly, conclusions based on the unconfined compression strength results are summarized.

2. OVERVIEW OF RECYCLED-CONTENT EPS BLOCK MANUFACTURING PROCESS

The recycled-content EPS block geof foam manufacturing process consists of the following primary steps: 1) recycling of pre- and post-consumer polystyrene (PS) and expandable PS, 2) pre-expansion of expandable PS beads, and 3) block molding. An overview of each step is subsequently provided.

Step1: Recycling of pre- and post-consumer polystyrene (PS) and expandable PS

Pre-consumer and post-consumer polystyrene (PS) and expandable PS material is sent into an extruder which melts and mixes the polystyrenic material, i.e., pre- and post-consumer PS and expandable PS. As the polystyrenic material exits the die of the extruder, it is cooled and solidified by water and the extruded polystyrenic material is cut into pellets by a pelletizer. Pre-extrusion and palletization of the recycled-content polystyrenic material facilitates mixing and further processing.

The polystyrenic material pellets undergo an additional extrusion process, whereby the pellets are impregnated with the blowing agent pentane and are transformed into recycled-content expandable PS beads. Virgin PS may also be added, but not required, during this additional extrusion process. Recycled-content expandable PS beads are defined herein to consist of the combination of polystyrenic material pellets and any virgin PS. The recycled-content expandable PS beads utilized in this research contain 60% recycled-content polystyrenic material (30% pre-consumer PS & expanded PS and 30% post-consumer PS & expanded PS) and 40% virgin PS.

Step2: Pre-expansion of recycled-content expandable PS beads

Before pre-expansion, the recycled-content expandable PS beads produced in Step 1 are combined with virgin expandable PS beads at the appropriate ratios to obtain a desired overall recycled-content block of 15% and 30%. The recycled-content expandable PS beads and virgin expandable PS beads are physically mixed together in a large ribbon blender. The overall recycled content of the block is defined as the ratio of the recycled-content expandable PS mass to the total (recycled-content and virgin) expandable PS mass used to mold the block. The 15% overall recycled content block was made by blending 25% of the recycled-content expandable PS beads produced in Step 1 with 75% of virgin expandable PS beads. The overall recycled content is calculated as $(25\% \times 60\% \text{ recycled-content PS beads}) + (75\% \times 0\% \text{ recycled-content virgin beads}) = 15\%$ overall recycled-content block. Similarly, the 30% overall recycled-content block was made by blending 50% of the recycled-content expandable PS beads produced in Step 1 with 50% of virgin expandable PS beads. The overall recycled content is calculated as $(50\% \times 60\% \text{ recycled-content expandable PS beads}) + (50\% \times 0\% \text{ recycled-content virgin expandable PS beads}) = 30\%$ overall recycled-content block.

The combined recycled-content and virgin expandable PS beads are placed in a pre-expander which injects steam to soften the PS beads and causes the blowing agent pentane within each bead to partially vaporize. The softened beads will expand to 50 times their original size due to the action of the blowing agent. The expanded beads are called pre-puff. The PS beads are pre-expanded to the appropriate pre-puff density needed to get an overall target EPS block density. In this stage, the steam properties, pressure in the expander, and expansion time will have an influence on the properties of the pre-puff and the final quality of the final EPS-block. The pre-puff is cured for 24 hours for physical stabilization.

Step 3: Block Molding

The stabilized pre-puff is moved into a molder and heated again with steam that is injected into the mold. "The residual blowing agent in the closed cells of each pre-puff particle causes some slight additional expansion of each particle. Because the outer skin of each pre-puff particle has been softened by the heat of the steam there will be thermal 'welding' (called bead fusion or simply fusion) at the contact points between the individual, expanding pre-puff particles (Horvath 2011). The fusion process transforms the pre-puff from individual grains to an EPS block with fused beads. In this stage, multiple factors, including the steam properties, pressure in the mold, molding time and the weight of pre-puff, will influence the final quality of the overall EPS-block.

As indicated in the summary of the block manufacturing process above, many variables such as steam temperature, steam pressure, pentane content, recycled content, density, curing time can impact the overall properties of the block. However, based on the experience with virgin EPS blocks, the primary variables that influence the mechanical properties of EPS blocks is the type (molecular weight) of PS used in the blend and overall EPS block density. Additionally, one hypothesis of this research is that the overall recycled content of an EPS block will have an influence on the mechanical properties. In this research, the pentane content was kept constant at 4%, and the other factors such as steam temperature, steam pressure and curing time were kept consistent throughout the study. Therefore, the results presented herein will focus on density and overall recycled content of the block.

3. DESCRIPTION OF SAMPLES AND TESTS PERFORMED

Unconfined compression, flexural, and creep tests will be conducted in order to obtain the mechanical properties of recycled-content EPS block geofoam. This paper presents the unconfined compression test results.

As previously noted, the recycled-content EPS block study focuses on the effect of density and overall recycled content on the stress-strain behaviour. ASTM D 6817 provides the physical property requirements for seven types of EPS blocks that are primarily based on density. However, this study is limited to evaluating the properties of recycled-content EPS blocks at two target densities of 21.6 kg/m³ and 38.4 kg/m³, which are the density requirements for ASTM types EPS22 and EPS39, respectively. ASTM 6817 provides minimum compressive resistance values for strains at 1%, 5%, and 10%. Therefore, the compression strength evaluation for recycled-content EPS blocks consists of comparing the recycled-content EPS block measured compressive resistance values to the ASTM required compressive resistance values.

Three different overall recycled-content EPS blocks were evaluated. As described in Step 2 of the manufacturing process, EPS blocks with an overall recycled content of 15% and 30% were tested. However, in order to provide a better comparison, blocks with only virgin expandable PS and no recycled-content expandable PS were also tested.

One 610 mm by 610 mm by 100 mm block sample was prepared for each combination of the two target densities and three overall recycled-content block types that were to be tested. Therefore, six different block samples were prepared for this study. The blocks were cured for 24 hours. ASTM C 165-05 recommends that a minimum of four specimens be tested and ASTM D 6817-11 recommends the use of 50 mm cube specimens. Therefore, four 50 mm cube specimens were prepared from each block sample for compression strength testing. The specimens were conditioned per ASTM D 1621.

Density measurements were obtained on each specimen based on the ASTM D 1622 procedure. The uniaxial unconfined compression test load frame S-610 manufactured by Durham Geo Slope Indicator was used to conduct the uniaxial unconfined compression tests. A displacement rate of 5.0 mm/min, which is equivalent to 10% strain per minute, was used in the compression tests based on the ASTM D 6817 procedure. WINSAS™ data acquisition software was used to record the compression platen displacement and the corresponding load during the tests. The “zero deformation point” method proposed in ASTM C 165-05 and ASTM D1621-10 was used to correct the compressive resistance values obtained from the tests. According to Horvath (2011), because platen-seating errors on an EPS test specimen surface that may not be perfectly smooth, planar and perpendicular to the direction of load application results in a slight concave-downward shape at the beginning of a stress-strain curve, correction of the stress-strain curve is required.

4. UNCONFINED COMPRESSION STRENGTH TEST RESULTS

Tables 1 through 6 show the measured densities and unconfined compression strength tests results as well as the average values obtained on the four specimens tested from each block sample and the corresponding standard deviation.

Table 1. Measured densities and compressive resistances of Sample A (15% recycled content, target density 21.6 kg/m³).

Specimen No.	Measured density (kg/m ³)	Compressive resistance (kPa)		
		1%	5%	10%
1	20.38	74	121	136
2	20.00	67	115	130
3	19.91	69	115	132

Table 6. Measured densities and compressive resistances of sample F (0% recycled content, target density 38.4 kg/m³).

Specimen No.	Measured density (kg/m ³)	Compressive resistance (kPa)		
		1%	5%	10%
1	36.89	194	299	326
2	38.85	198	314	343
3	38.63	201	308	337
4	36.91	202	299	327
Avg.=	37.82	199	305	333
Std. Dev.=	0.92	3.11	6.36	7.08

Because of limited experience molding recycled-content EPS blocks as well as inherent density variations that typically occur within a block, the measured densities obtained on the specimens are different from the target densities. Based on the experience with virgin EPS blocks, the density of an EPS block is related to the unconfined compression strength (Horvath 1995, Stark et al. 2004a). Therefore, in order to compare the unconfined compressive strength results obtained from the recycled-content EPS block specimens with the ASTM D 6817 compression strength requirements, linear regression analyses were performed to develop a relationship between the measured densities and compressive resistance values obtained from all specimens. Figures 1 through 3 provide the compressive resistance values at 1%, 5%, and 10%, respectively, versus density for the various overall recycled-content block samples tested. The linear regression relationships are also included in these figures as well as the requirements for ASTM types EPS22 and EPS39, which represent the two target densities of 21.6kg/m³ and 38.4 kg/m³ desired of the recycled-content EPS blocks.

From the linear regression relationships shown in Figures 1 through 3, normalized compressive resistance values were determined for each of the two ASTM target densities. Tables 7 and 8 provide the normalized compressive resistance values for target densities of 21.6kg/m³ and 38.4 kg/m³, respectively. As indicated by Tables 7 and 8 and as shown by Figures 1 through 3, the block samples met the ASTM minimum compressive resistance values for both target densities and for all overall recycled contents tested. Therefore, the unconfined compression strength test results indicate that recycled-content EPS blocks can be molded to meet the ASTM D 6817 compressive resistance requirements.

Figure 1. Regression relationships between density and compressive resistance at 1% strain.

Figure 2. Regression relationships between density and compressive resistance at 5% strain.

Figure 3. Regression relationships between density and compressive resistance at 10% strain.

Table 7. Normalized compressive values for target density of 21.6 kg/m³.

Sample	C (0%)	A (15%)	B (30%)	ASTM EPS22
Target density (kg/m ³)	21.6	21.6	21.6	21.6
Recycled content (%)	0	15	30	0
1% Compressive Resistance (kPa)	77	83	71	50
5% Compressive Resistance (kPa)	137	134	130	115
10% Compressive Resistance (kPa)	150	151	149	135

Table 8. Normalized compressive values for target density of 38.4 kg/m³.

Sample	F (0%)	D (15%)	E (30%)	ASTM EPS39
Target density (kg/m ³)	38.4	38.4	38.4	38.4
Recycled content (%)	0	15	30	0
1% Compressive Resistance (kPa)	203	226	189	103
5% Compressive Resistance (kPa)	311	329	304	241
10% Compressive Resistance (kPa)	340	354	333	276

Figure 4 shows a comparison of normalized compressive strength with recycled content variance. At the target density of 21.6 kg/m³, the compressive resistance behaviour is not very sensitive to recycled content because the compressive resistance values for recycled content of 0%, 15% and 30 % are similar for each strain range of 1%, 5%, and 10%. Therefore, the compressive resistance data at a target density of 21.6 kg/m³ indicates that blocks consisting of a higher recycled content than the blocks tested herein, i.e., greater than 30% recycled content, may also meet the ASTM D 6817 requirements.

At the target density of 38.4 kg/m³, the compressive resistance behaviour shows a greater compressive resistance at 15% recycled content compared to both 0% and 30% recycled content. Therefore, the compressive resistance data for the higher target density of 38.4 kg/m³ indicates a possible optimum recycled content that can produce a higher compressive resistance. As with the target density of 21.6 kg/m³ data, the 38.4 kg/m³ data also indicates that blocks consisting of a higher recycled content than the blocks tested herein may also meet the ASTM D 6817 requirements.

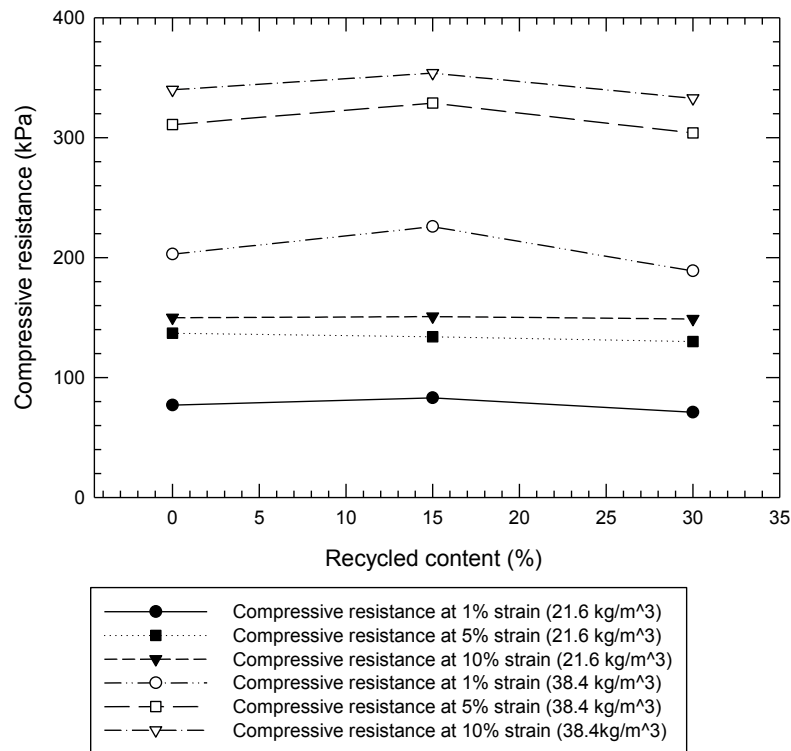

Figure 4. Comparison of normalized compressive strength with recycled content variance.

5. CONCLUSION

The unconfined compression strength test results performed on recycled-content EPS blocks indicate that EPS blocks consisting of recycled-content expandable PS can be produced to meet the current ASTM D 6817 standard compressive resistance requirements. Additionally, the results also indicate that the overall recycled content may not

significantly influence the compressive resistance values of recycled-content EPS blocks compared to virgin EPS blocks as demonstrated by the test results for a target density of 21.6 kg/m³, which showed compressive resistance values for 15% and 30% recycled-content blocks similar to the compressive resistance values obtained for a virgin EPS block with 0% recycled-content expandable PS. The compressive resistance results for the higher target density of 38.4 kg/m³ indicates the potential for an optimal recycled-content block that yields a higher compressive resistance than a virgin EPS block with 0% recycled-content expandable PS.

The research program includes supplemental compression resistance tests as well as flexural and creep tests. The results of these tests will facilitate accomplishment of the overall research goal, which is to develop stress-strain-time material prediction models for recycled-content EPS blocks that will allow engineers to perform structural response predictions in various civil engineering applications. Unlike traditional waste materials used in civil engineering applications, the benefit of the EPS recycling process is that it can be modified to achieve the desired engineering properties. Thus, the successful characterization and use of recycled-content EPS will contribute to wider acceptance of other recycled materials, such as plastics and glass that can be recycled in a controlled manner, in civil engineering applications. Importantly, extending the use of recycled-content EPS blocks to civil infrastructure applications will decrease the volume of polystyrene that ends up in landfills and will contribute to more sustainable infrastructure systems.

ACKNOWLEDGEMENTS

The authors thank Rapac, LP for providing the recycled-content expandable PS beads and NOVA Chemicals, Inc. for providing the virgin expandable PS beads and for molding the recycled-content EPS blocks.

Preliminary Evaluation of Thermally Induced Strains and Pressures Developed in a GRS Integrated Bridge System

ABSTRACT

An emerging technology that uniquely integrates commonly constructed bridge superstructures with geosynthetic reinforced soil bridge abutments is currently being promoted by the Federal Highway Administration. This technology enables rapid construction of single-span bridges without the expense of deep foundations, expansion joints, and approach slabs while eliminating the development of a “bump at the end of the bridge”, which generates long term maintenance costs. A 42.7 m long single-span bridge was constructed in Ohio using this integrated system approach. It is currently the longest GRS IBS in the US. To study the thermally induced interactions between substructure and superstructure, the bridge abutments and superstructure were heavily instrumented with vertical pressure cells, lateral pressure cells, strain gage, and survey targets. This paper provides a description of the construction process, a summary of the instrumentation utilized, and select data collected over a three year monitoring period.

1. INTRODUCTION

Since many of the existing single span bridges are reaching or have exceeded their expected service life, there is an increasing need to replace many of these bridges (Adams et al., 2007). Reducing the cost of construction is increasingly critical given the lack of funding at the county, state, and federal level to address the current bridge replacement need. Typically, bridges are constructed on deep foundations to minimize movement and vertical deformations, but deep foundation design and construction can be expensive due to the cost of the specialty contractors, among other things. Bridge abutments are typically designed using a conventional, integral, or semi-integral configuration in line with current practice, but each of these methods inherently has issues (Tatsuoka et al., 2009). The Federal Highway Administration (FHWA) at the Turner-Fairbanks Highway Research Center in McLean, Virginia developed and continues to refine Geosynthetic Reinforced Soil (GRS) Integrated Bridge System (IBS) technology (Adams et al., 2007, Adams et al., 2011a; Adams et al., 2011b), which uniquely integrates a commonly constructed bridge superstructure with a GRS abutment substructure. GRS IBS technology can potentially accommodate the construction or replacement of single span, low volume bridges without the need for deep foundations, expansion joints, or approach slabs, and without developing a “bump at the end of the bridge”.

While this project specifically targets GRS IBS technology, is important to note that conventional GRS bridge supporting structures have been constructed successfully in the U.S. and abroad for many years. Lee and Wu (2004) provide an excellent review of the configurations for and performance data collected on numerous GRS bridge-supporting structures. More recently, Adams et al. (2011b) summarized the performance of in-service GRS abutments (specifically GRS Integrated Bridge Systems between 2005 and 2010), and this report indicates that GRS IBS technology has the potential to advance the state of single span bridge design and construction. Also included in this report (Adams et al., 2011b) is a performance overview of several other bridges built with GRS abutments in the private and public sectors within the U.S. and Canada in addition to various case studies of GRS walls built during the past 20 years to validate the long-term performance of these structures. This paper will provide details regarding the construction of the largest GRS IBS to date and preliminary data collected during the first three years of this project. The long term goal of this research project is to evaluate the thermally induced interactions between the superstructure and the GRS approach behind it. There is some indication that the early-age substructure interactions are stable, which contrasts with the problematic ratcheting effect observed in conventional, integral, and semi-integral abutment bridge designs. Additionally, it is important to point out that this technology is constructed without the construction costs and long term maintenance expenses associated with deep foundations, expansion joints, and approach slabs.

2. GEOSYNTHETIC REINFORCED SOIL (GRS) INTEGRATED BRIDGE SYSTEMS (IBS)

The structural components of a GRS IBS include a reinforced soil foundation, the GRS abutment, and the GRS integrated approach (Adams et al., 2011a). Each GRS abutment is constructed using 1) controlled fill between each reinforcement (a clean, crushed aggregate that meets AASHTO standards), 2) tight geosynthetic spacing (typically 20.3

cm with a 30.5 cm maximum), and 3) excellent compaction with special attention paid to the areas near the face of the wall since the load is placed directly behind of the face of the abutment. The tight spacing specified for a GRS IBS is non-negotiable to ensure the interaction between each geosynthetic reinforcement and soil layer is not compromised. The use of controlled, high quality fill material with excellent compaction also ensures that any movements are minimal and within the tolerable limits of the structure. In addition to the GRS abutment, the approach fill is also constructed using GRS techniques to minimize subsidence of the approach fill relative to the diaphragm wall.

When the superstructure design includes a reinforced concrete deck on steel girders (as was the case in this project), the girders are positioned on a reinforced concrete footing that is cast directly on the GRS abutment, and a diaphragm wall is formed at the beam ends similar to an integral or semi-integral abutment configuration. Because the concrete footing is cast directly on the GRS abutment, traditional bridge bearings between the superstructure and the GRS abutment are not installed. As a result, thermal movements of the superstructure induce some lateral movement in the upper portion of the GRS abutment with dissipation of the lateral stresses due to the flexibility of the system. Whether using steel or concrete superstructure elements, the GRS approach fill is compacted directly against the diaphragm wall. Based on performance monitoring of this arrangement conducted by the FHWA, there is no requirement of an expansion joint or approach slab. The specific requirements for the integrated approach are outlined by Adams et al. (2011a) in the most recent interim implementation guide for this technology. In addition to reduced construction cost and time, this design can easily be modified for unforeseen site conditions, construction is less dependent on weather conditions, and the IBS is easier to maintain because there are fewer components susceptible to deterioration (e.g. bearings). However, based on current field experience with this technology, GRS IBS should be limited to single span bridges with low scour potential if crossing over water.

As of January 2012, the FHWA reports that a total of 68 state DOT projects in 28 states are currently at some stage of development (conceptual to construction). In 2005, Defiance County, Ohio teamed up with the FHWA during the early stages of GRS IBS field deployment (Adams et al., 2007). As of 2011, the County Engineer in Defiance reports that they have constructed 25 single span bridges with span lengths ranging from 3.1 m – 42.7 m, and benefited from a 25% – 50% cost savings on these projects in comparison to more conventional technologies they have utilized in the past. Figure 1(a) displays the design profile of the GRS IBS constructed over the Tiffin River in Defiance, Ohio as part of this project. It is the largest single span GRS IBS constructed to date (42.7 m in length). Figure 1(b) displays a photograph of the actual bridge that was instrumented and is currently being monitored by UNC Charlotte as part of the research study.

Figure 1. Geosynthetic Reinforced Soil (GRS) Integrated Bridge System (IBS).

3. INSTRUMENTATION PLAN

Since this IBS does not include an expansion joint or approach slab in the design or construction of this bridge, one might expect surface cracks to develop in the same way the “bump at the end of a bridge” develops for more conventional designs. However, long term monitoring of GRS IBS bridges constructed over recent years indicates that cracking does not develop and the deformations measured post-construction are insignificant and within allowable deformation criteria. To evaluate the thermally induced interactions between the superstructure and GRS substructure,

both components were heavily instrumented with a network of sensors that measure strain, vertical pressure, lateral pressure, and abutment/footing deformation (Figure 2).

Figure 2. Project instrumentation.

Five steel girders were instrumented with 36 vibrating wire strain gages (Figure 2(a)) to measure the thermally induced deformations in the steel. It is important to note that vibrating wire technology was utilized for all sensors in this study to collect static measurements of strain and pressure as a result of thermal changes to the system. Dynamic loading conditions were not assessed and there are no stationary traffic loads that exist on this bridge, located on a rural county road. The mounting blocks for the strain gages were arc-welded to the girder sections at the steel fabrication plant, and the strain gages were installed just before the girders were erected on site. Strain gages were installed at the top and the bottom of the web on each girder as displayed on Figure 3. The 12 strain gage configuration displayed in Figure 3 was installed at the center of the bridge and approximately 1.7 m from the face of each GRS abutment. The gages were positioned on the inside of each girder to ensure they were not exposed to direct sunlight. The cables were aligned on the top surface of the bottom flange and fed into nonstructural pipe that was secured to the underside of the girders near the north abutment where the main data acquisition enclosure was located. Only one gage failed during the installation process (97% strain gage survivability).

At two elevations within each GRS abutment (see Figure 1(a)), three vibrating wire vertical pressure cells (Figure 2(b)) were installed. At each elevation, one cell was centrally located under the concrete footing and the other two cells were positioned approximately 2.7 m on either side of center. At each elevation, a small hole was drilled through one of the blocks on the side wing wall, and a pipe was fit through the hole to bring the cables from the inside of the abutment to the face of the wing wall. Plumbing was installed on the side of each abutment to protect these cables from vandalism and flood debris.

Three vibrating wire lateral earth pressure cells (Figure 2(c)) were installed on the back of the superstructure concrete diaphragm adjacent to the GRS reinforced approach fill to measure the horizontal soil pressure at each end of the bridge as the girders expand and contract with the normal thermal cycle. A layer of mortar was positioned between the cell and diaphragm wall to ensure a smooth transition between the bearing surface and the cell. A thick, nonwoven geotextile was glued to the face of the lateral pressure cells to protect the cells from excessive contact pressures as the stone backfill was compacted. These cables were also fed through a PVC pipe positioned inside the wing wall. One of the pipes installed on the wing wall of the south abutment is displayed in Figure 1(b).

Figure 3. Strain gage installation configuration.

The Campbell Scientific data acquisition system includes a CR1000 data logger, three AVW200 vibrating wire spectrum analyzer modules, four AM16/32 multiplexers, an RF401 spectrum data radio modem, a Raven cellular modem, an Omni cellular antenna, and a power supply. All strain gages installed on the steel girders and all pressures measured on the north abutment were wired directly to the multiplexers connected to the logger on the north abutment. The remaining pressure cells on the south abutment were collected by a multiplexer on that side of the bridge, and the data was radioed to the logger on the opposing side of the bridge. Combined, these peripherals enabled UNC Charlotte to successfully establish a remote connection to the data acquisition system in Ohio and eliminated the need to implement a second data logger on the south abutment, which would have required a second cell phone connection. Deep cycle batteries charged by solar panels provide continuous power to the monitoring systems on site.

Three reflective survey targets (see Figure 2(d)) were mounted on each girder footing and nine targets were installed on the face of each GRS wall above the countermeasure (a total of 24 targets between the two sides of the bridge) to measure girder settlement, global GRS abutment settlement, and wall deflection. A permanent total station mount installed on site provides a fixed point of reference for the ongoing measurements collected by Defiance County (i.e. horizontal angle, horizontal distance, and vertical distance readings) to determine the three-dimensional coordinates for each target with time. Baseline readings were collected at the completion of each abutment and just prior to girder placement. Survey readings were recorded for all major loading events during the construction process and continue to be monitored.

4. GRS IBS CONSTRUCTION

The earth work and construction associated with the GRS abutments for this project was completed using a 4-6 man crew of county personnel, and it took them approximately 2 – 4 construction days to complete each GRS abutment. The abutments were constructed using 1) controlled fill between each reinforcement, 2) tight geosynthetic spacing, and 3) excellent compaction with special attention paid to the areas near the face of the wall since the load is placed directly behind the face of the wall. The FHWA recommends a setback distance of at least 20.3 cm (Adams et al., 2011a). The GRS abutment facing was constructed using solid core concrete masonry units (CMUs) on the bottom 1.5 m of the wall and hollow core CMUs for the remaining height. CMU dimensions were 20.3 cm by 20.3 cm by 40.6 cm. Figure 4(a) displays the construction of the initial reinforced layers.

The GRS layers were backfilled with AASHTO No. 89 crushed stone (Figure 4(a)) and compacted using method specifications (e.g. three passes with a vibratory plate tamper and a hand tamper along the edges) in accordance with Adams et al. (2011a). Compatible fill should be well graded or open-graded gravel to ensure excellent compaction directly behind the face of the wall, facilitate alignment of the facing, and limit post construction lateral deformation (Adams et al., 2011). At the completion of each compacted layer, a woven geotextile reinforcement (wide width tensile strength = 70 kN/m) was positioned between each course of block, creating a frictional connection that resulted in a vertical spacing equal to 20.3 cm.

d) steel girders set on GRS abutment

e) constructed GRS approach

f) Concrete deck pour

Figure 4. Project construction phases.

The lengths of the primary reinforcement varied from 2.6 m (at the bottom) to 5.5 m at the top of the abutment, and a secondary geotextile reinforcement was installed to create the bearing bed for additional support beneath the footing, and within the approach fill behind the girders to minimize settlement (see Figure 1(a)). Due to the bearing loads on the top of each GRS abutment, the top three courses of the hollow core CMUs (just below the girder footing) were reinforced by filling their cores with concrete and installing rebar dowels. Before the footing was formed and poured, a layer of geofoam was placed on the top of the facing block and a single row of solid block was positioned behind it on top of the stone fill to help carry the front load of the footing without direct application to the facing (Figure 4(b)). The left side of the concrete footing in Figure 4(b) lines up with the front face of the wall. The geofoam is positioned between the CMU and the footing to the left of the solid block, and the top GRS layer is displayed behind the solid block in this photograph. Details of this general configuration are discussed in Adams et al. (2011). Figure 4(c) displays a photograph of the final footing cast directly on the GRS abutment with the exposed reinforcing steel for the back of the concrete diaphragm.

Using a large crane, local contractors positioned the steel girders on the reinforced concrete footing. The contractors attached the cross-bracing, installed the necessary steel reinforcement across the girder ends, and formed the concrete diaphragm with two additional concrete pours on top of the footing, encasing the ends of the girders (displayed in Figure

4(d)). The lateral pressure cells were installed mid-height on the back of the diaphragm before the construction of the GRS approach and wing walls was completed. Figure 4(e) displays the completed GRS approach, and Figure 4(f) displays the concrete cast in place deck. Two data acquisition enclosures were permanently installed on the north abutment (far abutment in Figure 4(f)) to handle all 36 strain gages and the nine pressure cells on the north side. A third data acquisition enclosure was installed on the south abutment to collect the pressure cell data on the opposing abutment and send it wirelessly to the logger on the north abutment. In both cases, these enclosures were conveniently located behind the guardrail for safety and accessibility. The anticipation of high flood waters prevented the positioning of these enclosures anywhere below the top of the abutments.

5. DISCUSSION OF PRELIMINARY RESULTS

Data continues to be collected from all 54 sensors at a two minute sampling rate. While considerable data has been collected and analyzed, the following figures have been selected for display in this paper due to space limitations. A more detailed evaluation of the full data set is in the process of being prepared for publication. All data displayed in the figures herein have been processed through a 30-day moving average digital filter to attenuate daily thermal fluctuations. This post-processing stage was performed to better illustrate the long term behaviors of the GRS IBS for the purpose of evaluating the interaction between the superstructure and the GRS integrated approach behind each end of the bridge.

Figure 5 displays the average ambient temperatures for both the top and bottom strain gages as a function of time over the three year monitoring period. The long term ambient temperatures clearly follow typical thermal cycles, and there is very little difference measured between the gages installed on the web near the top flange versus the gages installed on the web near the bottom flange (locations of these gages are displayed in Figure 3) throughout the majority of the year. During the summer months, a temperature differential of a few degrees Celsius (at most) develops throughout the depth of the girder (see the peaks of the curves displayed in Figure 5). This is consistent with expected temperature distributions in composite bridges, which are characterized by a linear profile in the deck and a near uniform temperature throughout the girder that only develops a significant nonlinear increase near the deck during summer months due to the substantial thermal gradient in the deck induced through intense solar radiation (Kennedy and Soliman, 1987).

Figure 5. Ambient temperature as a function of time.

Figure 6 displays hysteresis curves for the average lateral pressure measured on the south abutment as a function of the average ambient temperature over a three year monitoring period. Each year of monitoring is labeled separately so the stress history of the lateral earth pressure cells installed on the south end of the superstructure is clearly illustrated in Figure 6. The stress history begins on the 2009-2010 curve at approximately 13°C (the initiation of data is indicated with a circle on Figure 6). The curves cycle over the three year time period with each year indicated by a different symbol. The yearly cycle transition occurs during the month of October, and each of the two transitions are indicated with a square on Figure 6 (e.g. the transition from 2009-2010 data to 2010-2011 data occurs at approximately 17°C when the average lateral pressure reads approximately 10 kPa). When the temperatures decrease, the abutments are

experiencing an 'active' state, and when the temperatures increase, the abutments are experiencing a 'passive' state of pressure. The equivalent figure for the north abutment displayed similar trends.

In general, Figure 6 displays the increase and decrease in lateral pressure as the steel expands and contracts with the thermal cycle, respectively. During the first two years, the steady decrease in lateral pressure was impacted by a spontaneous increase in lateral pressure after the average ambient temperature fell below freezing temperatures. This jump in lateral pressure developed during the 2009-2010 and 2010-2011 cycles between the temperatures of 0°C and -5°C in Figure 6. When ambient temperatures began to increase and they surpassed the freezing mark, the average lateral pressures displayed in Figure 6 re-established their initial trends. This behavior is illustrated by the large loops displayed on the left side of Figure 6.

Figure 6. Average lateral pressure on south abutment as a function of ambient temperature.

There was a high density, nonwoven geotextile that was glued to the heads of the lateral earth pressure cells attached to the diaphragm wall before the backfill was placed. The geotextile was included to help prevent high contact pressures from developing between the stone and the stainless steel cell (i.e. it served as a bearing pad for the fill). It is hypothesized that the thickness of the geotextile enabled the material to retain moisture, and the geotextile exhibited freeze-thaw behaviors as the temperatures dropped below freezing and was then re-elevated above 0°C. The freeze-thaw behaviors of the geotextile created an increase in the lateral pressure that was likely not attributed to the thermally induced interactions between the superstructure and the substructure. During the 2011-2012 winter, the temperatures recorded were mild in comparison to the two previous years, which explains why the same trend did not occur during this cycle.

Since there is a gradual decrease in the average lateral pressure rather than a sharp elimination of lateral pressure when the temperatures decrease and the steel to contracts, the GRS approach fill appears to move with the superstructure within the limits of thermal deformation experienced by the steel. This would explain why long term monitoring of several GRS IBS bridges does not show surface cracking at the superstructure-substructure interface as one might expect. The two systems appear to be working together as thermally induced deformations take place.

Since the data indicates that the GRS fill remains in contact with the superstructure during these thermal cycles, one might be concerned about a 'ratcheting' effect that could develop during subsequent years. The geo-phenomenon referred to as 'ratcheting' is best defined by describing the behavior of a more common integral abutment configuration. For an integral abutment configuration constructed on deep foundations, rigid body rotation is experienced as the system moves inward during colder temperatures and outward during the warmer temperatures (Horvath, 2005). According to Horvath (2005), as the superstructure of a typical integral abutment configuration contracts during the winter, an active earth pressure wedge develops and follows the abutment inward. Due to the inelasticity of soil, the displacement is not fully recovered during the summer months, and at the end of each annual thermal cycle, a net inward displacement of each abutment commonly exists (Horvath, 2005). During the subsequent bridge expansion, increased lateral earth pressures can develop and more closely approach the theoretical passive state with dangers of exceeding the margin of safety built into the design (Horvath, 2005). This increase in lateral pressure with each thermal cycle is referred to as 'ratcheting', and the potential for structural failure increases with time even though it could take years to develop

(Horvath, 2005). In the case of the GRS IBS constructed as part of this project, the data does not show significant increases in lateral pressure from year to year. In fact, the lateral pressures displayed during the 2011-2012 cycle on this figure decrease relative to the 2010-2011 cycle. The authors will continue to monitor this interaction between the superstructure and the adjacent reinforced GRS approach.

Figure 7 displays the average thermal strain as a function of time for all top and all bottom gages over the three year monitoring period. Strain movement in the positive direction indicates tension and strain movement in the negative direction indicates compression. The data presented on this figure reflects actual strains in the steel girder computed using the manufacturer provided conversion displayed in Equation 1 (Geokon, 2012):

$$\mu\epsilon_{actual} = R_1 - R_0 B + T_1 - T_0 \alpha \quad [1]$$

Where: R_1 = the gage reading at time t
 R_0 = the initial gage reading at the chosen reference time t=0
 B = the gage factor of the sensor
 T_1 = the measured temperature at time t
 T_0 = the measured temperature at the reference time t=0
 α = the temperature coefficient of expansion for the instrumented material ($12.2\mu\epsilon/^\circ C$ for steel).

Since the purpose of this study is to determine the thermally induced interactions between substructure and superstructure, the theoretical thermal axial strain in an unrestrained steel girder was also calculated and displayed on the figure as an idealized reference model to characterize the relative end restraint in the superstructure over time. The ambient temperature and thermal expansion coefficient for steel were utilized to calculate the thermal strain for the theoretical unrestrained condition displayed. If the temperature of a fully unrestrained steel beam increased, the steel would expand without any internal stress in member. If, on the other hand, the same steel beam was fully restrained as the temperature increased, deformation would be prohibited, but the internal stress in the member would increase accordingly. Since composite action and the potentially large thermal gradient in the concrete deck are not accounted for in this reference model, comparison should be limited to only examining the relative behavior of the superstructure restraint over time. With each thermal cycle, the variance between the thermal strain measured at the top and bottom decreases. Additionally, the variance between the measured strain data (indicated with symbols on Figure 7) and the idealized reference model decreases with each thermal cycle. Initially, there is a large difference between the top and bottom strain, but these values converge with each thermal cycle. The convergence may be associated with drying shrinkage of the concrete deck. In general, the data presented on Figure 7 indicates that, contrary to ratcheting, the end restraint in the superstructure remains consistent and may even be experiencing slight relaxation over the first three seasons of operational service.

Figure 7. Thermal strain as a function of time.

Figure 8 displays the average thermal stress as a function of time for all top and all bottom gages over the three year monitoring period. Since a long-term static monitoring approach was taken, it is assumed that all stresses are thermal in

nature (i.e. they are not load induced). In the absence of load-induced stresses, thermal stress can be directly measured and calculated using vibration wire strain gage technology with Equation 2 (Geokon, 2012):

$$\sigma_{thermal}(t) = \sigma_{apparent}(t) = R_1 - R_0 BE \quad [2]$$

Where: E = the elastic modulus of the instrumented material

Note that the calculated thermal stresses are computed relative to the measured response on October 1, 2009. Although the data presented seems to show a bias toward higher tensile stresses in the winter months than compressive stresses in the summer, this is an artifact of the datum developed by the initial conditions. Similar to Figure 7, an idealized reference model was developed to provide the theoretical thermal axial stress associated with a fully restrained steel beam. The theoretical thermal axial stress is displayed in Figure 8 for comparative evaluation of end restraint behavior over time. An increase in stress indicates tension and vice versa. If a steel beam is fully restrained at the ends, any increase in temperature will cause an equivalent compressive axial stress in the beam and vice versa. Again, this reference model neglects the critical composite action between the concrete deck and steel girders as well as the thermal gradient in the superstructure so it should not be used as a direct means of evaluating superstructure performance. However, it can serve as a temperature-normalized baseline to compare the relative superstructure response over each thermal cycle. As noted for Figure 7, the variance between the top and bottom thermal stress responses decreases with time in Figure 8 as well. The difference in long-term thermally induced stresses and/or strains measured in the top and bottom gages throughout the superstructure are generally attributed to composite action and flexure. Over several thermal cycles, both the magnitude of stresses and the difference in thermal stress along the depth of the cross section is reduced, indicating a reduction in relative end restraint and flexure in the superstructure. Since the thermally induced stresses decrease over time relative to the fully restrained reference model, the end restraint in the superstructure is tending toward the idealized unrestrained response.

Figure 8. Thermal stress as a function of time.

6. CONCLUSIONS

1. The long term ambient temperatures clearly follow typical thermal cycles with minimal differences observed between the gages installed on the web near the top versus the bottom locations. A temperature differential equal to a few degrees Celsius (at most) develops during the summer months. This behavior is consistent with expected temperature distributions in composite bridges, which are characterized by a linear profile in the deck and a near uniform temperature throughout the girder that only develops a significant nonlinear increase near the deck during summer months due to the substantial thermal gradient in the deck induced through intense solar radiation.
2. The lateral pressures increase and decrease as the steel expands and contracts with the thermal cycle, respectively, but during the first two years, there was a spontaneous increase in lateral pressure when the average ambient temperature fell below freezing temperatures. When ambient temperatures re-elevated, the

average lateral pressures re-established their initial trends. The nonwoven geotextile installed between the pressure cell and reinforced fill was likely the cause of the erratic behavior observed. It is hypothesized that the geotextile retained moisture and exhibited freeze-thaw behaviors adjacent to the lateral earth pressure cells.

3. Since there is a gradual decrease in the average lateral pressure rather than a sharp elimination of lateral pressure when the temperatures decrease and the steel contracts, the GRS approach fill appears to move with the superstructure within the limits of thermal deformation experienced by the steel. The two systems appear to be working together as thermally induced deformations take place. This could explain why long term monitoring of several GRS IBS bridges does not show surface cracking at the superstructure-substructure interface as one might expect.
4. Since the data indicates that the GRS fill remains in contact with the superstructure during the thermal cycles, one might be concerned about a 'ratcheting' effect that could develop during subsequent summer months. The lateral end pressure data do not show significant increases from year to year as one might expect. In fact, the lateral pressures displayed during the 2011-2012 cycle on this figure decrease relative to the 2010-2011 cycle. However, these behaviors will continue to be monitored.
5. The variance between the thermal strain measured at the top and bottom of the web decreases with each thermal cycle. Additionally, the variance between the measured strain data and the idealized reference model decreases with each thermal cycle. Initially, there is a large difference between the top and bottom strain, but these values converge with each thermal cycle. The convergence may be associated with drying shrinkage of the concrete deck. Contrary to ratcheting behavior commonly experienced by an integral abutment configuration, the end restraint in this GRS IBS superstructure remains consistent and may even be experiencing slight relaxation over the first three seasons of operational service.
6. GRS IBS technology can potentially accommodate the construction or replacement of single span, low volume bridges without the need for deep foundations, expansion joints, or approach slabs, and without developing a "bump at the end of the bridge". As of 2011, Defiance County has constructed 25 single span bridges with span lengths ranging from 3.1 m – 42.7 m, and benefited from a 25% – 50% cost savings on these projects in comparison to more conventional technologies they have utilized in the past.

ACKNOWLEDGEMENTS

This research was funded by the Federal Highway Administration. Mike Adams (FHWA) and Warren Schlatter (Defiance County Engineer) should be recognized for their continued support and pursuance of innovative technology. We would like to thank the Defiance County personnel involved in this project for their hard work and cooperation during the construction process.

Radial Load Tests for the Evaluation of Stress-Strain Relation of Geocells

Ansgar Emersleben, Dr.-Ing., Clausthal University of Technology, Institute for Geotechnical Engineering, GERMANY, Ansgar.emersleben@tu-clausthal.de

ABSTRACT

Geocells represent an alternative for the stabilization of soils with low bearing capacity. The use of geocells is recently increasing, especially in areas where good quality aggregate material is hard to find and/or expensive. The performance of geocell stabilized soils is mainly dependent on the stress-strain relation of the geocells. The stress-strain relation is commonly evaluated by tensile tests similar to other geosynthetics. This test method is unsuitable to evaluate the stress-strain relation of the geocell including the junctions or the cell geometry at construction site conditions. Therefore radial load tests were developed to determine the stress-strain relation of geocells for load support applications at in-situ conditions. In this paper the set up and the procedure of new radial load tests are described. Furthermore, the stress-strain relation of different geocells evaluated in tensile tests and in radial load tests are compared and analyzed. The influence of the geocell junctions on the stress-strain relation and the overall performance of geocells are presented.

1. INTRODUCTION

1.1 Geocells

According to DIN EN ISO 13426-1 (2003) geocells consist of single synthetic strips that are connected along specific lines or special points by different means in a way that a field of connected cells develops. Mainly polyethylene (PE), polypropylene (PP) and polyester (PET/PES) are used as raw materials. Polyvinyl alcohols (PVA) or Aramid (AR), which are sometimes used as raw materials for geogrids, are not of particular importance for the manufacturing of geocells. The connection between the single synthetic strips depends on the used raw material and can be realized by extrusion, thermal bonding, adhesive, hot melting or sewing. The connected cells build permeable expanded elements in a honeycomb shape. They are installed on site and filled with soil material which is finally compacted.

According to DIN EN ISO 10318 (2006) geocells are categorized as geotextile related products. In connection with a non-woven located below the geocells they can also be considered as geocomposite.

1.2 Application Areas of Geocells

Since their development in the seventies the application areas of geocells has increased significantly. Besides the classical soil stabilization, geocells are used for erosion control, retaining walls and other applications for example flood walls (Figure 1).

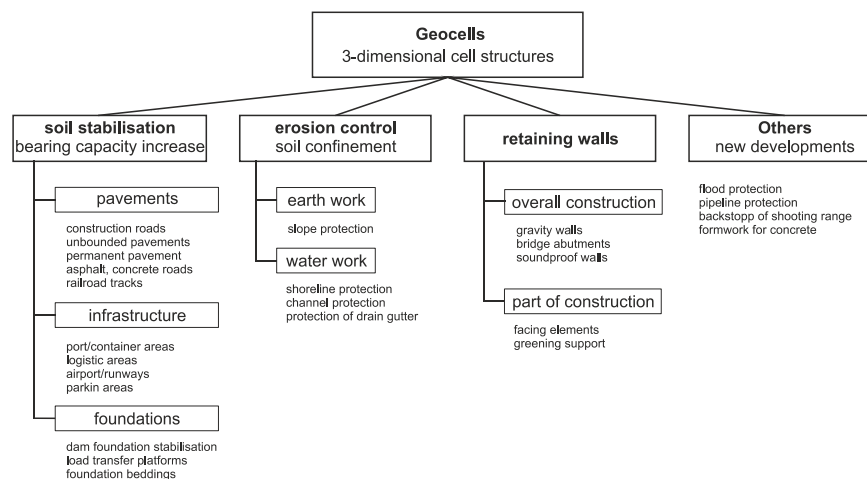

Figure 1. Geocell application areas (Emersleben 2010b).

1.3 Working Mechanism of Geocells

In a vertically loaded geocell horizontal earth pressure is activated due to the friction between infill material and geocell wall. The resulting strains in the cell walls mobilize hoop stresses in the cell walls and horizontal resistance in the adjacent cells. The amplitude of the activated hoop stresses depends on the type and magnitude of the applied load within the cell.

Due to the hoop stresses and the lateral passive earth resistance the horizontal deformation of the fill material is restricted and the stiffness of the fill material is increased. Mhaiskar et al. (1993) and Kazerani et al. (1987) determined (when verifying test results using the finite element method) a stiffness increase of a geocell stabilized soil compared to a non-stabilized sand by a factor of 2 to 3. Similar increase has been observed in field tests by Emersleben and Meyer (2010c).

The stiffness of the geocell composite results in a stiff plate effect which increases the load distribution angle. Due to this the vertical stresses are distributed on a larger area which reduces the vertical deformation (e.g. Dash et al. 2003; Chang et al. 2007; Sitharam et al. 2008) (Figure 2).

Figure 2. Working mechanism of geocells (Emersleben 2010b)

1.4 The Influence of Stress-strain Response on the Working Mechanism of Geocells

Regarding load support applications, the working mechanism and thereby the influence of geocells on the load distribution and load deformation behavior is dependent on many different factors, as for example geocell geometry, density of infill material, position of geocell within the pavement, cover thickness, loading geometry and material stiffness (Emersleben 2010b).

According to recent literature one of the most important factors is the tensile stiffness respectively the elastic modulus of the geocell material (e.g. Pokharel et al. 2009). An increase in elastic modulus of the cell material results according to Krishnaswamy et al. (2000), Mhaiskar et al. (1996) and Dash et al. (2003) in an increase of the measured bearing capacity.

According to Mhaiskar et al. (1996) especially the material stiffness in the small strain range is of importance as strains are mobilized already under small applied loads.

Krishnaswamy et al. (2000) investigated in tests with grid cells for dam foundations that with increasing material stiffness larger slip circles are developed.

Dash et al. (2003) however points out that the stiffness of the geocell material must be investigated in association with the surface structure of the geocell and the interconnected geocell system.

1.5 Evaluation of Stress-strain Response of Geocells

The stress-strain response of geocells is usually evaluated by standard tensile tests on the used raw material or on geocell strips according for example on DIN EN ISO 10319 or ASTM D 4595. Additional tests to evaluate the seam and peel strength of the junctions are usually carried out on basis of DIN EN ISO 13426-1 and ASTM D 4473 (Figure 3).

Figure 3. Wide strip tensile test and seam peel test according to European Standard DIN EN 10319 and DIN EN 13426-1

Both tests are adequate to evaluate the tensile strength of the raw material and the ultimate strength of the junction, as needed for example for erosion control applications, but do not simulate the in-situ situation of a geocell as presented in Figure 2. The radial load situation within the loaded cell is not considered in the tensile tests presented above.

Because of that an alternative test, called radial load test (RLT) was developed by the authors to evaluate the stress-strain relation of geocells at in-situ load conditions and to compare these relationships with stress-strain behavior of wide strip tensile and peel strength tests (Emersleben 2010b).

Used materials, conducted tests and results are described and analyzed in the following chapters

2. GEOCELL MATERIAL

Three different geocell types were used in the laboratory tests. The geocells can be differentiated by their manufacturing process as well as the used raw material. Geocells manufactured by a high density polyethylene (PEHD), a thermally bonded nonwoven and a mixture of PEHD and polyester (PES/PEHD) with different tensile strengths was used. The use of geocells manufactured by different raw materials was mainly considered for the variation of tensile stiffness. Besides the different stiffness, the used materials have a different surface texture. The rough structure of the surface of the PEHD geocells was achieved by a number of between 22 and 31, 0.35-0.85 mm deep sinkings per cm². Additionally perforated PEHD cells were tested, where holes with a diameter of 10mm were punched into the cell walls. The opening area of the holes represents 16 % of the whole cell area. The surface structure of the PES/PEHD cells is smooth while the geocells made of a non-woven (PES-V) is rough. An overview of the main geocell parameters are given in table 1.

Table 1. Basic parameters of tested geocells.

	PEHD perforated	PEHD non-perforated	Nonwoven PES-V	PES/PEHD (1)
Material surface	structured, perforated	structured	smooth	smooth
h^1 [cm]	15	15	15	15
h_{eff}^2 [cm]	8	15	15	15
t^3 [mm]	1.70	1.70	1.50	1.80
A^4 [cm ²]	1.36	2.55	2.25	2.7

¹ h = cell height; ² h_{eff} = cell height without perforations; ³ t = material thickness; ⁴ A = cross section area

For the determination of the stress-strain properties, tensile tests in accordance to DIN EN 10319 were conducted. The tests were conducted to determine the ultimate tensile strength of the raw material. For evaluation of the peel strength tensile tests on basis of DIN EN 13426-1 were conducted. The test results of both tests for a strain rate of 20 mm/min are given in Figure 4.

Figure 4. Comparison of tensile test and peel strength test results for different geocell materials.

Despite a comparable manufacturing process and identical raw material, the tested perforated and non-perforated PEHD geocells showed a significant difference in the stress-strain properties which was a result of the perforation within the geocell structure and the resulting stress distribution within the cell area.

Test results of the ultimate tensile strength for perforated PEHD cells in peel- and tensile tests are comparable. In contrast to this the measured peel resistance for the PES-V cells, the non-perforated PEHD cells and the PES/PEHD geocells resulted in smaller values than the measured material tensile strength (Fig. 4). Especially the PES/PEHD geocells showed a significant difference in peel resistance and tensile test data. Compared to the other geocells, the PES/PEHD geocells showed the highest tensile strength while their junction strength is least.

3. RADIAL LOAD TESTS

3.1 Basic Principal

Based on the overall accepted load transfer mechanism within a geocell system (Figure 2) used in load support applications, neither the tensile strength of the raw material nor the seam strength are sufficient to describe the stress-strain relationship of geocells at in-situ conditions. Both tensile tests and seam strength test are carried out two-directional, but at in-situ load situation the geocells are loaded in radial direction. In addition only the maximum seam strength of the geocells can be evaluated in the two-directional tests. Due to the missing consideration of the opening angle of the junctions in two-directional tensile tests, the influence of the junctions on the stress-strain behavior and with it the in-situ stress-strain behavior cannot be simulated adequate (Figure 5).

Figure 5. Radial load situation in single loaded geocell, manual manufactured geocell without junction (left side), industrial manual manufactured geocell with junction (right side).

3.2 Test Device

In the radial load tests a single geocell is loaded by a pneumatic pressure bag. The air pressure bag consists of an air filled membrane with an internal steel cylinder. The steel cylinder prevents internal stresses and ensured a uniform stress distribution on the geocell walls. The pressure bag has a height of 30 cm and diameter of 25 cm. The dimensions of the pressure bag were optimized to investigate 15 cm high cells with a diameter of 20 – 23 cm. The air pressure in the bag is controlled by an electronic valve with an automatic control program. Static tests can be executed in a load- or strain-controlled way up to 500 kPa. Dynamic loads tests can be executed with varying amplitudes and load frequencies up to 4 Herz (Emersleben and Meyer 2009).

Indirect strain sensors were incorporated by using a rotary potentiometer. Strains were measured by a string with plastic properties placed around the loaded cell. From the elongation the activated geocell strains were analyzed (Figure 6).

Figure 6. Schematic overview of radial load test on single geocell

3.3 Test Installation and Procedure

For the test setup the air pressure bag was installed in the centre of a test box. The box had a height of 30 cm and a width and length of 1.27 m.

The geocell is placed in the middle around the pressure bag. Afterwards the strain sensor was installed. The measurement wire was placed around the geocell in mid height, fixed and connected to the potentiometer located outside of the test box. To protect the measurement wire, the wire was placed in a plastic rod. To simplify the arrangement small holes were drilled in the cells through which the wires were taken to the potentiometer. Index tests indicated that this does not influence the test results. A preload was applied to the geocells to ensure a force-fit of single cells and the pressure bag. This also allowed control of the junction/seam opening angle (Figure 7).

Figure 7. Installed geocell on air pressure bag and connected strain measurement system

The static tests were used for the detailed investigation of interactions and load carrying mechanisms of different geocells. They were, compared to the tensile tests, deformation controlled based on the test specimen circumference and a strain rate of 20 mm/min. Load was applied until failure of the cells or strains exceeded values of 20 – 25 %.

4. RESULTS OF RADIAL LOAD TESTS

4.1 Interpretation of the Radial Load Test Results on Geocells Without Junctions

With a radial-symmetrical horizontal load of an unconfined single cell the horizontal loads must be taken by hoop forces in the geocell material. The mobilized hoop forces ($F_{rad,\epsilon}$) can be calculated on basis of a modified boiler formula ("Long Term Hydrostatic Pressure Resistance Formula" or "Barlow's Formula") according to DIN 2413 (German Institute for Standardization) (see Equation 1).

$$F_{rad(\epsilon)} = \frac{\sigma_{h(\epsilon)} \cdot d_{\epsilon,z(\epsilon)} \cdot A}{2 \cdot t} = F_{zug(\epsilon)} \quad (1)$$

where $F_{zug(\epsilon)}$ = measured tensile force in tensile test at strain level ϵ ; $F_{rad(\epsilon)}$ = calculated tensile force on basis of radial load test results at strain level ϵ ; $d_{\epsilon,z(\epsilon)}$ = diameter of the geocell at strain level ϵ ; t = material thickness of the geocell material; A = material cross section without consideration of perforations; $\sigma_{h(\epsilon)}$ = applied radial pressure on geocell.

Studies of Wesseloo (2009) under identical test conditions show that the stress-strain behavior of a plastic membrane is not influenced by the load direction (axially or radial).

Transferring the results from Wesseloo (2009) to the radial load and tensile tests presented in this paper leads to the conclusion that at the same stress level the mobilized strains within the geocell material should be identical. Figure 8 presents a comparison of the tensile strength measured in the tensile tests and the calculated hoop strength according to equation 1 for different geocells without junctions.

Figure 8. Comparison of measured tensile strength in tensile tests and back calculated tensile strength on basis of radial load test results for different circular manufactured geocells without junctions.

The results show that at similar strain level the calculated and measured forces/stresses in the geocell material are comparable. Minor deviations between the calculated and measured forces/stresses can only be observed for PES-V geocells. For these geocells a different material behavior was observed in radial load and tensile tests. In the tensile tests a material failure was observed as a result of creep behavior in the material. In radial load tests single nonwoven layers were separated, whereupon the materials cross section and hence the tensile strength decreased.

The results indicate that radial load tests on geocells without junction's leads to the same result as width tensile tests. Radial load tests are adequate to evaluate stress-strain behavior of geocells under in-situ load conditions.

4.2 Radial Load Test results on Geocells with Junctions

Radial load test results for different geocells are presented in Figure 9. Considering the junctions of the geocells and their opening angle at site conditions the non-perforated PEHD geocells shows the best stress-strain relationship while the non-perforated PES/PEHD geocells shows the worst stress-strain behavior. The difference between perforated PEHD geocells and nonwoven geocells made of PES-V is marginal.

The results show the huge influence of the junctions on the stress-strain behavior of geocells. This effect cannot be simulated in width tensile tests or seam tests.

Figure 9. Results of radial load tests of single geocells with junctions.

4.3 Influence of Geocell Junctions and Their Opening Angle

The in-situ site installation process results in different opening angles of the geocell junctions/seams. The achievable opening angle for PEHD and PES/PEHD geocells is approx. 90° and for PES-V geocells approx. 130° . Varying opening angles even for similar geocell geometries are the result of material stiffness and the type of joint. Radial load tests on geocells with junctions (commercially manufactured) and without junctions (manually made geocells) were conducted to determine the influence of the junctions on the stress-strain behavior. Figure 10 indicates the influence of joints on the stress-strain behavior of the perforated and non-perforated PEHD geocells.

Geocell strains of industrial manufactured cells (with junctions) are larger than strains measured for manually made cells (without junctions), independent of the geocell material.

In contrast to the manually made geocells industrial manufactured geocells increase their opening angle during initial loading. Due to the continuous opening only small stresses are activated within the cells walls. Only for almost fully opened junctions, applied loads result in geocell strains accompanied by significant strength increase. In contrast handmade geocells without junctions are characterized by an immediate strain and stress activation. This result in improved stress-strain properties compared to industrial manufactured cells.

Perforated and non-perforated PEHD geocells and PES/PEHD geocells with similar opening area and opening angles (90°) were chosen to test the influence of the junctions. It was investigated that the joints have a large influence on the geocell stress-strain behavior (Fig. 10).

Figure 10. Comparison of pressure-strain behavior of circular manufactured (glued) geocells without junctions and industrial manufactured (original) geocells with junctions.

With increasing geocell material stiffness a higher influence of the joints was observed. The material stiffness is expressed as extensional stiffness according to equation 2. To consider the significant influence of the perforations of the geocell material (different cross section area) the extensional stiffness is expressed in the unit force (kN) which is different from the usually know expression according to ASTM.

$$J = E \times A \quad (2)$$

where J = extensional stiffness at strain ε ; E = Elastic modulus at strain ε based on tensile tests; A = material cross section.

The reduction of maximum applied pressure due to the junctions can be expressed up to a strain of 2 % by a linear function according to Figure 11. With increasing geocell stiffness the difference of the horizontal pressure which can be applied on the single geocell without and with junction, is significantly increasing. This is based on the fact that with increasing geocell material stiffness the achievable opening angle of the junction at site installation is smaller than for geocell materials with smaller material stiffness.

Figure 11. Influence of the junctions on the applied radial pressure dependent on the geocell stiffness.

5. COMPARISON OF TENSILE AND RADIAL LOAD TESTS

5.1 Comparison Between Wide Strip Tensile Tests and Radial Load Tests

Figure 12 shows a comparison between results of wide strip tensile tests according to DIN EN 10319 and radial load tests. Considering the geocell junctions/seam in the radial load tests and their influence on the stress-strain response the tensile strength measured in radial load tests is significantly smaller than the tensile strength measured in wide strip tensile tests. The consideration of the junctions leads to different results not only in the amount of tensile strength. Width tensile tests do not represent the stress-strain behavior of geocell at in-situ conditions and are therefore not representative to describe the stress-strain behavior of geocells in load support applications.

While the PES/PEHD geocells shows the highest tensile strength in the wide strip tensile test, the tensile strength was the smallest in the radial load test. As a result of the high material stiffness (based on width tensile tests) and the poor quality of the junctions the angle of the junction is not really high (Figure 10).

Figure 12. Comparison between wide strip tensile tests and radial load tests on different geocell materials.

5.2 Comparison Between Seam Peel Strength Tests and Radial Load Tests

Figure 13 shows a comparison between results of wide strip tensile tests according to DIN EN 13426-1 and radial load tests.

Compared to the radial load tests the tensile strength of the seam peel strength tests is smaller for all tested geocell materials. The main reason for this effect is the fact that the opening angle of the junction which occurred at side conditions cannot be sufficient simulated in seam peel strength tests. Because of that the stress-strain response of seam peel strength test is smaller than in radial load tests.

Results show that seam strength tensile tests do not represent the in-situ stress-strain behavior of geocell at in-situ conditions and are therefore not representative to describe the stress-strain behavior of geocell in load support applications.

Figure 13. Comparison between seam peel strength tests and radial load tests on different geocell materials.

5.3 Influence of Different Tensile Tests on the Elastic/Stiffness Modulus of the Geocells

The influence of the conducted test on the tensile stiffness of the different geocell materials is presented in Table 2. The highest modulus can be observed for the tensile tests, because the influence of the junction is not considered. The smallest modulus can be observed for the radial load tests which represents the real in-situ conditions.

It can also be seen that the seam peel strength test is only adequate to measure the maximum peel strength but cannot be used to evaluate the stress-strain behavior in an exact way. The back calculated stiffness modules are more than four times smaller than those from the radial load tests.

Table 2. Tensile stiffness modulus of geocells at 5 % strain in kN.

test type	PEHD perforated	PEHD non-perforated	PES-V	PES/PEHD
Tensile test DIN EN 10319 [kN]	24.3	55.2	21.4	67.7
Seam peel strength test DIN EN 13426-1 [kN]	3.00	7.74	5.41	2.68
Radial load tests [kN]	18.4	35.6	19.0	9.8

6. SUMMARY

The paper presents a new test method called radial load tests to measure the stress-strain response of single geocells at site conditions. First time the opening angle of the geocells seams/junctions is considered in stress-stains measurement. The presented results show that especially the opening angle of the junction has a significant influence on the stress-strain behavior. Comparison of radial load test results with commonly known wide strip tensile and seam peel strength tests show that the measured radial tensile strength is smaller than the measured wide strip tensile strength but larger than the seam peel strength. This is based on the fact that the seams/junctions of the cells are not considered in width tensile strength and the opening angle of the junctions cannot be simulated adequate in the seam strength tests. Results show that the developed radial load tests are the first tensile test which really simulated in-situ conditions of installed geocells and thus leads to a stress-strain response, which simulated the in-situ behavior of geocells in the best way.

Rehabilitation of Raw Water Reservoir for Franklin WTP

Bill Shehane, P.E., Seaman Corporation, USA, bshehane@seamancorp.com

ABSTRACT

The city of Franklin, Tennessee, a suburb of Nashville, initiated a rehabilitation project for their existing raw water reservoir to fix leaks caused by several deep fissures in the earthen basin. Because of the leaks, the reservoir ran complete dry during an extended drought season. When the Tennessee government released economic stimulus dollars, this site was among the top 10 projects earmarked to receive funding. After a failed attempt at using a natural clay liner, the city selected a potable water grade geomembrane to solve its water containment issues. This paper will go over the reservoir history, sizing options, liner material options, construction overview and lessons learned during the project.

1. INTRODUCTION

During the summer of 2007, the city of Franklin, Tennessee and its surroundings were experiencing a severe drought. Due to the high heat and low flows in the Harpeth River, Franklin struggled to meet water supply demands in the area. The city's raw water reservoir, which can hold 322 million liters (85 million gallons), was completely dry for several months. As a result, the 7.6 MLD (2.0 MGD) Franklin water treatment plant was inoperable for periods of time. Water is normally pumped from the Harpeth River into the raw water reservoir, where it is later treated before consumption.

Over the next 2 years, the drought officially ended and upgrades were put in the city's water distribution system. This helped to ease worries about Franklin's water system, except for the reservoir. It was estimated that up to 3.8 million liters (1 million gallons) of untreated water per day leaked from the reservoir, even after temporary installations of clay along the cracks in the bottom.

Figure 1: Reservoir in 2008 after the major drought of 2007

2. RESERVOIR HISTORY

The Franklin reservoir was originally built in the 1950's and during that time the water treatment plant was designed for only 3.8 million liters per day (1 million GPD). The reservoir served as a source of water during the warm summer months, where water was pumped from the Harpeth River. The reservoir was 121,000 square meters (30 acres) in size and designed to hold up to 380 million liters (100 million gallons) of water. During the 1960's, the water treatment plant was upgraded to handle 7.6 million LPD (2 million GPD). Over the years, volume within the reservoir was lost due to accumulated filter backwash solids reducing the capacity to only around 300 million liters (80 million gallons). Also, the original clay liner was no longer working and there were continuous leaks in the bottom.

The reservoir's problems had been common knowledge for years among past and current city officials, who had planned for the city to pay \$3.9 million on a rehabilitation project. However, in late 2009 Franklin received \$2.5 million from the Recovery Act/State Revolving Fund – a \$1.5 million loan to be paid over 20 years and \$1 million that will never have to be repaid. As a result, the city of Franklin only had to come up with \$1.4 million for the rehabilitation project.

3. SCOPE OF PROJECT

AECOM Engineers was hired to investigate and design alternatives, optimize sizing of the reservoir and recommend life cycle synthetic liner materials for an improved and enlarged reservoir for water conservation at the treatment source.

3.1 Liner System Alternatives

Eight different types of liner systems were evaluated and based on a design life of at least 20 years. They are as follows:

- Geosynthetic clay liner (GCL) with 30 cm (12") of soil cover
- HDPE liner left uncovered
- HDPE liner with 30 cm (12") of soil cover
- LLDPE liner with 30 cm (12") of soil cover
- Reinforced Chlorosulfonated Polyethylene (CSPE) left uncovered
- Reinforced Ethylene Propylene Diene Monomer (EPDM) left uncovered
- Reinforced Polypropylene (fPP-R) left uncovered
- Reinforced Ethylene Interpolymer Alloy (EIA-R) left uncovered

These eight alternatives were narrowed down to two, based on evaluations of long-term liner systems that had been in service for 20 years or more. In addition, it was decided that 30 cm (12") of soil cover on top of the geomembrane or GCL was too costly over a 142,000 SM (35-acre) site. The two options chosen were CSPE (Hypalon) and EIA-R (XR-3 PW/XR-5 PW). In addition, AECOM decided to specify a 36-mil thickness in the reservoir bottom and 45-mil thickness on the side slopes. A thicker geomembrane was recommended on the sides for higher abrasion resistance from potential wave action.

3.2 Resizing of the Reservoir

Alt.	Scope	Water Volume (MG)	Excavation C.Y.	Off-Site Spoil C.Y.	Avg MG/Yr WTP Production	Years @ 0.0 MGD WTP of past 31	Average Days per yr @ 0.0MGD WTP	Estimated Grading & Modifications Cost - No Liner	5yr savings (loss) including sludge/liner**
A.	Existing - Minimum Rehab	85.5	-	-	1,201	8	28.6	\$100,000	\$1,459,370
B.	Raise Spillway 1.0 ft	95	-	-	1,206	7	25.9	\$175,000	\$1,465,539
C.	Raise Spillway 1.5 ft	100	-	-	1,208	6	26.5	\$200,000	\$1,474,840
D.	Raise Spillway 2.0 ft, raise berm 8"	105	1500	-	1,211	5	27.8	\$250,000	\$1,474,613
E.	Raise Spillway 2.0 ft, raise berm 12" & cut for balanced cut/max spoil ~654	109	20,800	-	1,212	5	25.4	\$475,000	\$1,404,466
F.	Raise Spillway 2.0 ft & cut to "level" Bottom ~ 652.2 ft	113	40,600	20,000	1,214	5	22.8	\$700,000	\$1,334,418
G.	Raise Spillway 3.0 ft, add cut to berm, cut 4' below 652.2 "leveled bottom", & low	155	204,000	154,000	1,229	0	0	\$2,850,000	\$647,475

Figure 2: Seven alternatives to increase the water volume of the reservoir

AECOM looked at seven alternatives to increase the overall capacity of the reservoir from 300 million liters (80 million gallons) to a potential 590 million liters (155 million gallons) - see Figure 2. With a combination of raising the spillway 61 cm (2 feet), raising the berm 20 cm (8 inches) and excavating soil in the bottom, the optimum design volume came to be 400 million liters (105 million gallons) - Alternative D. This was based on the estimated grading and modifications cost at \$250,000 and only 1,150 cubic meters (1,500 CY) of excavation required.

3.3 Removal of the Filter Backwash Solids

Another means of increasing the capacity of the reservoir was removal of the existing filter backwash solids. There was a significant volume of material due to over four decades of use, with the solids now being diverted to the sanitary system. The filter backwash solids had high levels of aluminum and copper and was considered a "special waste" if taken outside the reservoir, since it was processed. The options were as follows:

- No action – poor bearing/volume soil
- Beneficial reuse for up to 24 million SM (6,000 acres) of cropland
- Take to a Class 1 landfill
- Take to a Construction and Demolition (C+D) landfill as a day cover

The option chosen was to haul the filter backwash solids to a C+D landfill, which required 1,900 dump truck loads or a total of 25,000 cubic meters (33,000 CY).

Figure 3: Disposal of filter backwash solids

During the solids removal, numerous areas of soft spots were found. To fix this, large rip rap from the side slopes was used in these areas for stabilization of the soil. This was a great use for the rip rap, since it had to be removed from the sides of the reservoir anyway before installation of the geomembrane liner and geoweb system. The haul off and rough grading of the reservoir bottom took approximately 3 months to complete.

3.4. Geomembrane Liner and Geoweb Installation

Even though the reservoir will be holding “raw water” from the Harpeth River, the facility owner wanted the liner system to be NSF 61 certified for potable water. After one month of fine grading the reservoir bottom, installation of the geomembrane liner started. Since the geomembrane was a heavily reinforced coated fabric with excellent physical properties such as puncture resistance, a geotextile below the liner was not needed.

Figure 4: Geomembrane liner installation

The EIA-R was prefabricated into panels 27.5 meters (90') wide by 55 meters (180') long, making them over 1,500 SM each (16,200 SF). Fabrication of the geomembrane was performed by Colorado Lining International's New Caney, TX facility and installation of liner and geoweb was by Geosynthetics, Inc. (GSI). A total of 95 prefabricated geomembrane panels were delivered to the job site. This allowed for only 2 field seams per acre required, which dramatically reduced the amount of CQA testing in the field.

A thicker 45-mil reinforced EIA-R was installed on the side slopes since they will experience greater exposure to the elements and a 36-mil reinforced EIA-R was installed on the reservoir bottom. Liner installation was completed in approximately 2 months and required over 142,000 square meters or 1.5 million square feet (35 acres). Sand tubes made out of the EIA-R were also placed along the bottom to prevent wind uplift when the reservoir is empty.

Due to concerns from potential wave action when the reservoir is full of water, AECOM recommended a geoweb with stone be installed along the top of the side slopes and on top of the geomembrane liner. After the geoweb was in place, a concrete anchor trench was installed. The geoweb with stone was also placed below the 61 cm (24") diameter influent pipe to prevent scouring and as a ramp down to the toe of slope for vehicle access when needed.

Figure 5: Installation of geoweb along the side slopes

To control any solids and sediment coming from the 61 cm (24") influent pipe, a 60-meter (200') long floating baffle system was installed. The baffle was also made out of an EIA-R potable grade geomembrane. A bench was installed inside the area of the baffle to help confine the sediment and also provide a specific area for clean out when needed.

4. CONSTRUCTION COMPLETION AND LESSONS LEARNED

The Franklin reservoir rehabilitation project went out for bid in December of 2009 and the notice to proceed was given on April 1, 2010. The reservoir was operationally complete in October of 2010, with the final construction cost being over budget by only 1% (\$3,946,762). The general contractor was Summit Construction based out of Nashville, TN. Once completed, the reservoir achieved a total of 430 million liters (113 million gallons) of storage which was 8% over the original design of 400 million liters (105 million gallons).

Some issues and lesson learned that came up during construction included:

- Subsurface conditions can vary greatly and were worse than expected in some areas
- Unit grading quantities can vary from design estimates
- Constructability of the geoweb "keyway" was more difficult than expected
- Geoweb needs concrete at the toe for more stable installation
- Baffle curtain should be anchored in some way at the bottom due to high flows

This rehabilitation project was able to improve and enlarge the raw water reservoir for water conservation at the treatment source by using a high performance geomembrane liner for leakage abatement. There was sustainable reuse of the filter backwash solids that were disposed of as a regulated solid waste and used as a daily cover at a C+D landfill. The project also had sustainable reuse of the interior rock rip rap, which was used as structural fill material to improve

low bearing soft spots in the reservoir bottom. The city of Franklin has potential plans to expand this water treatment facility and the impoundment for a future growth effort.

ABSTRACT

Due to the particular morphology of some Italian Regions, it is very difficult to find areas suitable for a new waste disposal site location. As a consequence, lots of waste disposal sites are in mountain areas and many of them have been enlarged with respect to their predicted dimensions.

The article describes the application of reinforced soil structures for the expansion of one mountain-located landfill and the use of geosynthetic materials for the lining systems.

A case history is presented: a needful embankment on the waste body for the construction of the upper new part of the landfill lining with natural and geosynthetic materials.

Because of the site conditions and other design requirements (stability, Italian regulations, lack of appropriate soil materials), realization of the works has been rendered very difficult in some circumstances; some problems could have been overcome thanks to the usage of geosynthetics materials as described in the paper.

1. INTRODUCTION

Due to the particular morphology of some Italian Regions (i.e. mountains very close to the sea, and basically the whole seaboard and flattish areas urbanized), it is very difficult to find areas suitable for a new waste disposal site location. As a consequence, many waste disposal sites are in mountain areas and many of them have been enlarged with respect to their predicted dimensions.

1.1 Main characteristics of the Facility

Bossarino landfill is located near the town of Savona in Liguria Region, in a small valley with lateral slopes that are very steep in some zones. The landfill is a non-hazardous solid waste (industrial waste) landfill. In the old part of the landfill, whose altitude ranges from about 80 m to about 200 m above sea level, waste disposal operations started in the 90s. Until 2009 about 2,100,000 m³ of waste materials had been placed.

At the bottom and at the slopes of the landfill, the subsoil is constituted of rock materials (mostly schists), weathered in the upper meters that were removed profiling the slope. Slopes can reach the inclination of 35° and more, and the mean inclination of the bottom, in the longitudinal axis, can vary from 7° to 14°.

An extension of about 1,500,000 m³ (1,100,000 m³ for waste) of the existing landfill, by superelevation up to 260 m above sea level, was authorized in 2007 (see Figure 1 and Figure 2).

1.2 Construction Problems and the New Project

In 2009, topographic surveying showed that the top plan of the existing plant was smaller than the designed one. This was caused by some settlements of the waste body larger than those expected. Principally these were due to chemical changes in stored waste over time: the increase of the biodegradable fraction and its decomposition.

The top plan of the existing landfill is the base of the new upper part, so a smaller base means a smaller quantity of waste.

As the maximum altitude of the expansion cannot be varied (it is a bond of the extension authorization), the only solution was to enlarge the existing top plan and obtain an area similar to the previous design, through the construction of an embankment on the waste body.

Because of the site conditions (very narrow operational spaces and impossibility to enlarge the landfill area) and the need to continue the waste disposal operations without involving extended areas that already have a vegetation cover,

the best engineering solution was to build the embankment with the technique of reinforced soil as described in the present paper.

This solution allowed to create an additional waste basin between the existing landfill and the new external slope of the landfill in the upper part of the embankment.

Figure 1. Plant of Bossarino landfill with the authorized superlevation

Figure 2. Cross section A-A

2. DESIGN CHARACTERISTICS

The choice of a reinforced soil structure instead of concrete retaining walls or non reinforced embankments is due to many reasons:

- Lack of external materials: soil derives only from excavation both from the cover of the existing waste and from the natural mountainside (on which the new upper part of the landfill will lay). This same material has to be used for daily cover, edge embankments, tracks, etc. The use of reinforced earth allows a reduction in materials for fill and backfill;
- Soil reinforced walls are flexible structures capable of bearing high differential settlements (typical of waste) without loss of functionality;
- Topographic surveying of the landfill showed a reduction of construction slopes due to settlements. The use of reinforcing elements allows the construction of steep slopes that, after settlement, are still steeper than the ones of non- reinforced natural soils, so the reduction of the top of the waste fill is lower with the same extent of landtake;
- Establishment of vegetation on reinforced slopes, like natural slopes can be easily achieved through the use of protection mats that increase the soil's resistance to erosion;
- An important aspect is the cost effectiveness of the system. Reinforced slopes allow considerable economies in earthworks by reducing the quantity of earth fill and the extent of landtake. Moreover in the upper part of the work, the backfill of the embankments is made by extra waste that means extra earnings for the plant.

2.1 Geometry

According to the morphology of the existing landfill, reinforced and non reinforced slopes were designed.

The total volume of the embankment is about 225,000 m³, of which 40,000 m³ is of waste placed in the basin in the upper part of the construction.

The maximum total height is about 40 m with stabilization berms in intermediate position along the slope. The construction angle of the slopes ranges from 45° to 60° for the reinforced soil structures and 35° for simple compacted soil.

Reinforcement is given by geogrids with characteristic strength of 80 kN/m, vertical spacing of 50 cm and length of 5 m (embankment toe) or 10 m.

There are also basal reinforcements with characteristic strength of 300 kN/m at the toe of each embankment. The length is variable according with the distance between the excavation profile and the edge of the embankment.

A plan view of the reinforced wall and a typical cross section are represented in Figure 3 and in Figure 4. It is important to point out that in the cross section is shown the final long term slope profile; the inclination angle is lower than the construction one due to consolidation settlements. These settlements are the product of mechanical (i.e.: self-weight and surcharge due to overlying landfill expansion) and biodegradation-related phenomena.

The evolution of settlements, as describes in the following, is monitored using benchmarks placed during construction activities and through periodic topographic surveyings.

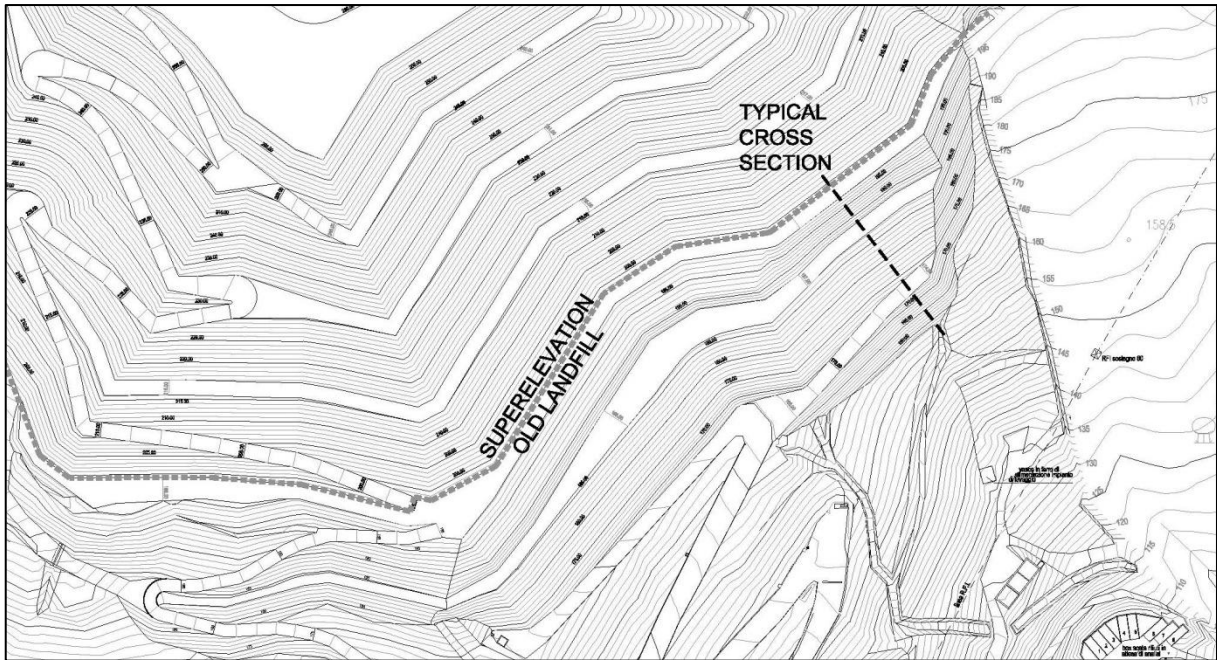

Figure 3. Plan view of the reinforced slope

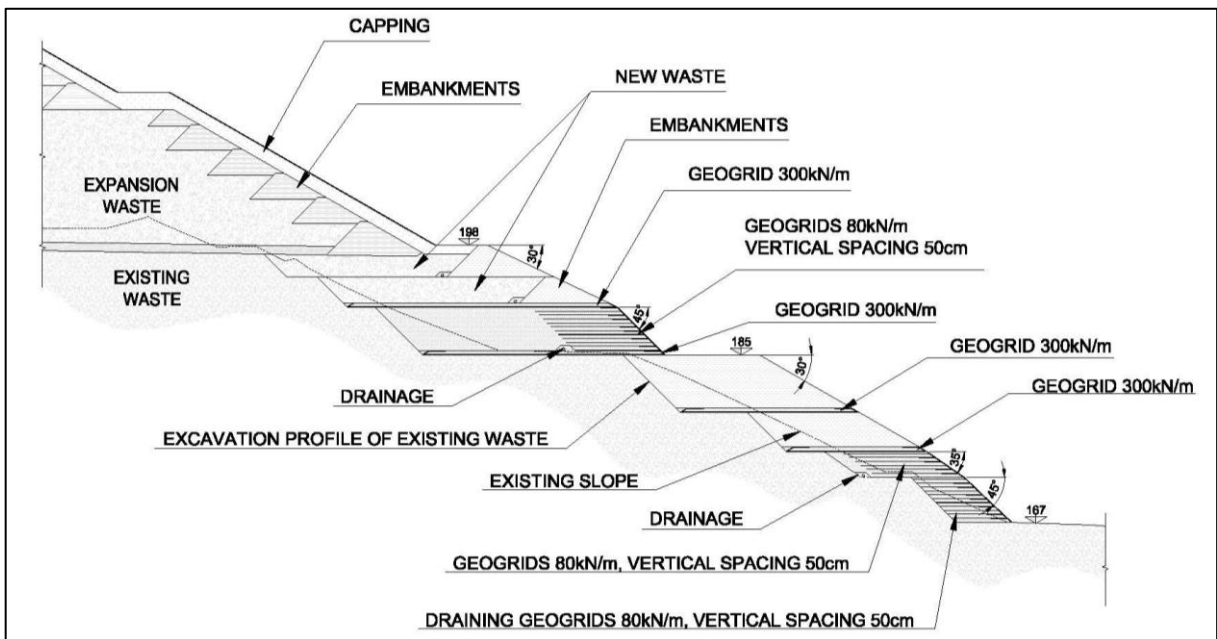

Figure 4. Typical cross section of the reinforced slope

To obtain maximum flexibility and better environmental integration, no hard facing was designed. Instead an external temporary formwork (a lightweight “climbing” shutter of tubes and boards) was erected to support the face during construction. The grids were turned up the face of the formwork and returned into the embankment directly below the next reinforcement layer.

In order to increase the soil’s resistance by providing immediate protection of exposed areas from the direct effects of wind and rainfall impact and by protecting seeded topsoil from washing out before vegetation grows, erosion protection mats are used in the external facing as shown in Figure 5.

Figure 5. Detail section of the slope

2.2 Drainage System

Pore water pressures are controlled by drainage trenches at the back of the reinforced zone and by a particular underdrain.

The trenches are formed with a slotted HDPE pipe of 200 mm diameter, 30-70 mm size gravel and woven geotextile.

Besides, the toe of the slope is reinforced with a geogrid with built-in water drainage that quickly dissipates excess water pressures. This is a precautionary device as the soil used as fill material of the reinforced earth structure was predominantly coarse-grained with a little fraction of cohesive soil. Less than 15% of the particles should pass the U.S. No. 200 sieve according with U.S. Federal Highway Administration (2001).

In fact, such structures are negatively affected by the development of high excess pore water pressures caused by the applied load within the soil mass; the increase in pore pressures causes a reduction of short term strength characteristics. Besides, the effective stress reduction connected with the pore water pressure increase causes a reduction of pull-out resistance. In staged construction, such as that used in reinforced earth technique, pore pressure build-up can accumulate at each lift increasing the level of the risk as the construction proceeds. References on the behavior of draining geogrids embedded in cohesive soils are given in Zornberg & Mitchell (1994; 1995); Boardman, (1998); Zornberg & Kang (2005); Feng et al. (2008); Ghionna et al., (2010).

2.3 Lining of the Waste Basin

According to Italian regulation (D.Lgs. 36/2003), the waste basin in the upper part of the embankment is provided with sealing and drainage systems.

The sealing system is made up of the following layers (from bottom to top): GCL, HDPE geomembrane and a protection geotextile (mass per unit area of 600 g/m^2) and is laid on the bottom and on the sidewall and extended to the top of the lateral embankment (anchored under the culvert at the top).

The drainage layer is made up of a bottom gravel layer (0.5 m thick), slotted HDPE pipes and protection geotextile (areic mass of 125 g/cm^2).

It must be noted that the fabric encased GCL can substitute the mineral clay liner required by Italian regulation. In fact, it is said that particular solutions can be adopted in the realization of the lateral containment barrier provided, if they guarantee a performance equivalent to that of the mineral layer of 1 m with a permeability of 10^{-9} m/s .

However the GCL is a further lining in addition to the one at the bottom of the existing landfill.

The equivalence between the compacted clay liner (CCL) and the GCL liner can be easily demonstrated through the Darcy equation, which leads to the following:

$$k_{GCL} \times \frac{H+T_{GCL}}{T_{GCL}} = k_{CCL} \times \frac{H+T_{CCL}}{T_{CCL}} \quad [1]$$

where k_{GCL} and k_{CCL} are respectively the permeability of the geocomposite clay liner and mineral clay liner, T are their thicknesses and H is the height of the leachate above the liners (Koerner and Daniel, 1993).

2.4 Material Properties

There are two natural materials involved in the design of this work: fill and backfill of reinforced and non-reinforced slopes and waste.

The soil used in all models as the retained fill and backfill of reinforced earth was site material derived from excavation both of the cover of the existing waste and of the natural mountainside on which the new upper part of the landfill will lay. The waste material of the considered landfill is formed from the following main components: car fluff, industrial sludges, plastic fibers and fiberglass, contaminated soil from polluted sites and residues from waste treatment plants. The waste disposal operations contemplate, before compacting the waste, the mixing of different types of waste with hydraulic excavators or dozers in order to make the material homogeneous.

Unit weight and apparent frictional parameters were defined through back analyses, the composition of waste and specific site test such as unit weight site determination, standard penetration tests, field vane tests, surface seismic tests, and plate loading tests.

Beside natural materials, geosynthetics are involved in stability calculations. To assess the interface strength parameters (friction angle and cohesion), shear tests were made. In particular all the interfaces between geosynthetic materials and between natural material and geosynthetics present in the bottom and side sealing were investigated.

In Table 1 soil and waste characteristic parameters (average values) and interface characteristic parameters (minimum values) are shown.

Table 1. Characteristic parameters of materials

Material	γ [kN/m ³]	ϕ [°]	c' [kPa]
Fill and backfill of reinforced and non-reinforced slopes	19	31	0
Waste (industrial)	14	30	0
Natural subsoil (schists)	25	22	170
Lining (old landfill)	-	16	25
Slope lining (expansion)	-	22	0
Bottom lining (expansion)	19	27	0

Design parameters are obtained by reducing characteristic parameters by the appropriate partial coefficient given by Italian regulations (N.T.C. 2008).

2.5 Fabrics Properties and Design Strength

Three types of fabrics were selected for reinforced slopes:

- Draining geogrids with base tensile strength of 80 kN/m, with 50 cm vertical spacing;
- Geogrids with base tensile strength of 80 kN/m, with 50 cm vertical spacing;
- Geogrids with base tensile strength of 300 kN/m.

Grids are made of high tenacity polyester yarns encased in a durable sheath of polyethylene.

British Standards (BS 8006) were used to reduce reinforcement base strength as Italian regulations do not consider partial load factors. To define the reinforcement design strength, the unfactored strength of the reinforcement is reduced by the reinforcement material factor f_m which is the product of basic components:

$$f_m = f_{m1} \times f_{m2} \quad [2]$$

$$f_{m1} = f_{m11} \times f_{m12} \quad [3]$$

$$f_{m2} = f_{m21} \times f_{m22} \quad [4]$$

Where:

f_{m1} is a partial material factor related to the intrinsic properties of the material and is made up from the following component factors:

f_{m11} is related to the consistency of manufacture of the reinforcement and how strength may be affected by this and possible inaccuracy in assessment

f_{m12} is related to the extrapolation of test data dealing with base strength. This factor may vary with the required service life of the structure

f_{m2} is a partial material factor concerned with construction and environmental effects and is made up from the following component factors:

f_{m21} is related to the susceptibility of the reinforcement to damage during installation

f_{m22} is related to the environment in which the reinforcement is installed

2.6 Static Stability Analyses

Both internal stability of the embankment and global stability of landfill, taking into account also the geosynthetics interfaces and the foundation subsoil, were checked considering the ultimate limit states according to Italian regulations. Stability analyses were performed using traditional limit-equilibrium methods (2D).

The analyses helped to determine the characteristic strength of the reinforcements according to the strength parameters of the fill materials supplied.

References on the stability analyses of reinforced structures are given in Ghionna and Olivetta (2005) and in Ghionna and Veggi (2007).

2.7 Seismic Stability Analyses

The stability analyses were carried out taking into account seismic condition as well. According to Italian regulation, the analyses was performed considering the ultimate limit states and by simplified pseudo-static methods. For the purpose of the pseudo-static analysis, the seismic action shall be represented by a set of horizontal and vertical static forces equal to the product of the gravity forces and a seismic coefficient. Seismic coefficient is proportional to PGA (peak ground acceleration) that in this case is equal to 0.059 (g) as the part of Italy in which the landfill is located is lightly seismic.

Seismic coefficient takes into account also topography, soil stiffness and kind of structure. The use of a simplified method, like the pseudo- static one instead of a dynamic analysis, was considered adequate thanks to a low seismic action.

References about seismic stability analyses of landfills are given in Augello et al. (1995), Bray et al. (1995), Siegel et al. (1990), Singh et Murphy (1995).

3. CONSTRUCTION

The construction of the embankment began in May 2010. The waste basin on the upper part of the embankment was ready for waste disposal operations in June 2011 and the end of the whole embankment occurred in October 2011.

In situ and laboratory tests on the embankment and on the reinforcements (Proctor standard tests, Plate Load Tests, in situ density tests, pullout tests) were performed to ascertain if the final properties of the embankment match the design specifications. For reasons of shortness, the description of the tests conducted and the discussion of the results obtained are not included in the present paper, but they could be presented in the future.

Figure 6a) shows the beginning of the construction of the toe of the embankment with draining geogrids. Please note the utilization of removable climbing formwork. An intermediate phase of construction is shown In Figure 6b).

a) toe of the reinforced earth structures

b) intermediate phase of construction

Figure 6. Embankment construction

Figure 7 shows the embankment at the end of construction (October 2011) and during the construction of the toe of the superelevation of the landfill that is partly supported by the reinforced soil embankment.

Figure 7. Front photography; slope at the end of construction

According to the project, a monitoring system was built during construction (see Figure 8).

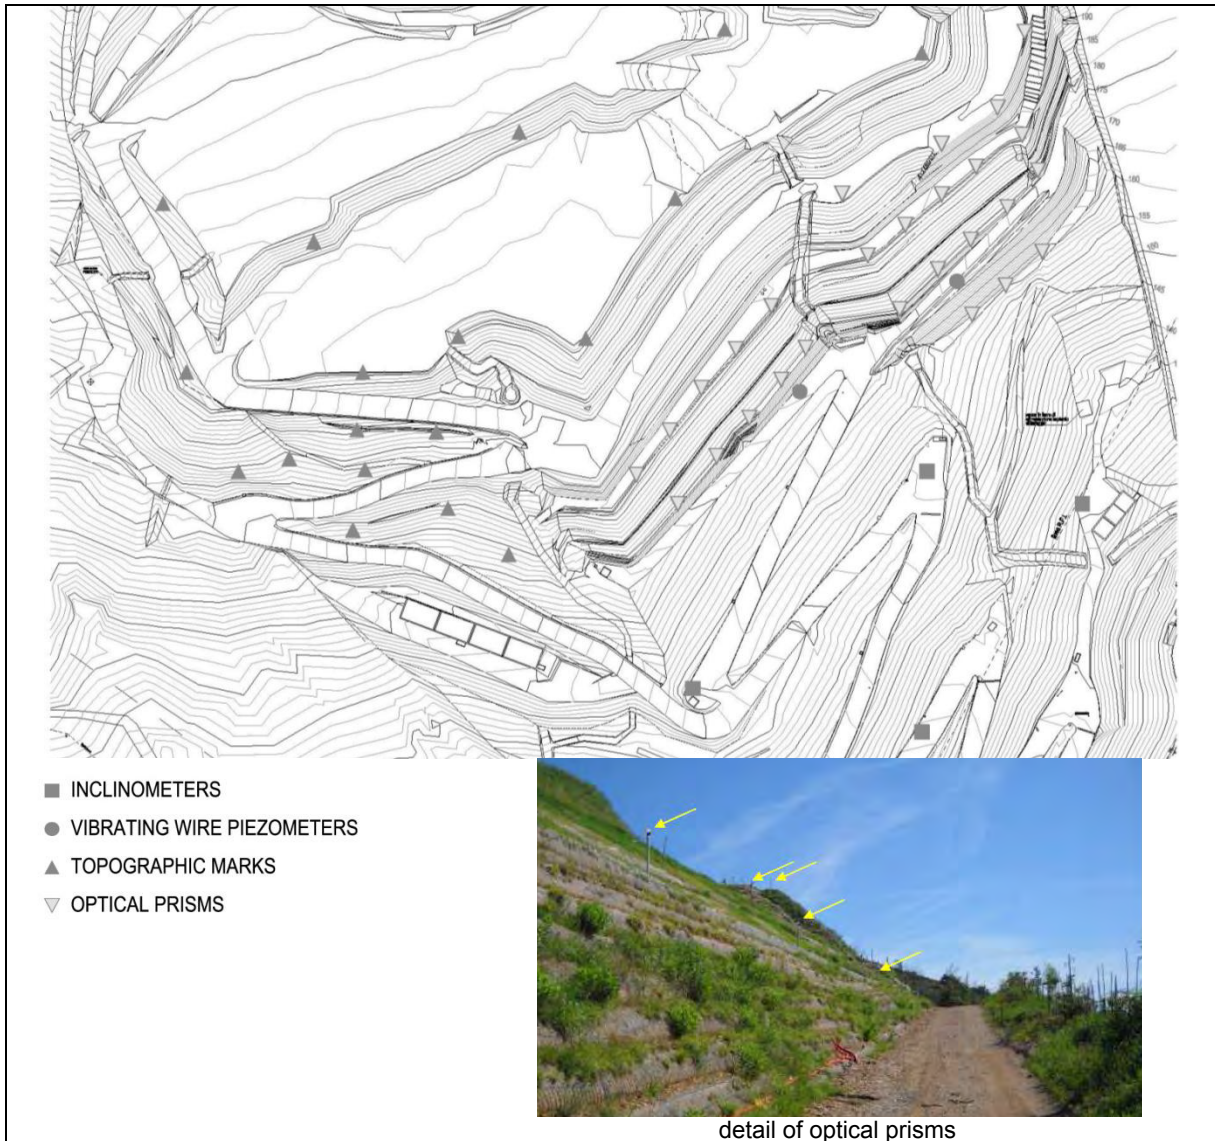

Figure 8. Plan of the landfill (2012) and monitoring system

The monitoring system had the function to check:

- vertical and horizontal settlements by means of about thirty topographic marks (optical prism) placed at the toe of the embankment, at intermediate positions and at the top. Topographic survey was planned once every fifteen days. Collected data were used to verify if the evolution of settlements and the velocity of deformation match the design calculated values. It was also programmed a topographic survey of the entire embankment and of the surroundings every three months.
- the increase of leachate pore pressure in the waste body under the embankment. For this purpose from street level at 170 m above sea level, two boreholes were drilled to a depth of 25 m and in each borehole two vibrating wire piezometers to a depth of 16 m and 25 m were placed. A data logger registered leachate pressure every 6 hours. The piezometers measured also the temperature of the leachate which is useful for understanding if some anaerobic biodegradation was ongoing.
- horizontal displacement along the base of the embankment through four vertical inclinometers installed in boreholes drilled to a variable depth of 20–30 m from the landfill surface. Surveying was programmed every fifteen days.

Surveying activities will be carried on up to landfill closure for a continuous check of stability conditions.

Today the superelevation is operational, the waste layers have a thickness ranging from 15 m to 20 m below the expansion bottom.

4. CONCLUSION

The article describes an example of the application of reinforced soil structures for the expansion of a mountain-located landfill and the use of geosynthetic materials for the lining systems.

In this case history the use of this kind of work allow the recovery of a volume for waste disposal with environmental and economic benefits.

In fact the use of reinforced soil structures is a typical application for solving problems due to particular morphology of the site or to different constraints (i.e. bonds of authorization, limits of properties, impossibility to find natural materials with proper geotechnical characteristic and so on).

It is also pointed out that the replacement of earth materials with geosynthetic, when the regulations allow that, provides many advantages: ease of construction, certainty of technical characteristics, landtake reduction and in some cases minor costs.

Others similar case histories with different purposes (solution to geotechnical problems) are known as described for example in Veggi and Parla (2009) or in Ghionna and Veggi (2007).

These examples confirm the validity of the application of reinforced soil structures in the environmental field.

Remediation of Industrial Wastewater Sludge by Electrokinetic Geobox

V. K. Tyagi, Managing Director, Hi-Tech Geosynthetics Pvt. Ltd., New Delhi, India, vipkolon@yahoo.com

ABSTRACT:

A pilot-scale study was conducted on in situ decontamination of industrial wastewater sludge containing relatively high concentrations of target metal contaminants such as cadmium (6.85 mg/kg), chromium (117.5 mg/kg), copper (335.7 mg/kg) and lead (64.1 mg/kg). A new type of geosystem (a cellular geobox) composed of geocomposites (electrokinetic geosynthetic, GEK) was developed for waste remediation. A low-level direct current results in physicochemical changes in the applied media, leading to species transport by coupled mechanisms, such as electromigration, electro-osmosis, electrophoresis and electrolysis of water. The modified geotextile and geocomposite with functions of filtration, drainage, conduction, and ion exchange capacity accelerated the contaminant removal rate. The electrokinetic removal efficiencies of abiotic heavy metals exceeded 85% for the mobile and weakly bound fractions, such as the exchangeable and carbonate fractions, and were higher than 69% for the strongly bound fractions, such as the organic/sulphide and residual fractions. The final product can be used as landfill material.

1. INTRODUCTION

The wastewater sludges obtained from industrial treatment plants often contain various contaminants, such as toxic heavy metals. They cannot be disposed of directly at landfill sites or reused as composts because of their toxicity. Furthermore, there may be the danger of a further significant increase in contamination potential and of the bioavailability of toxic heavy metals in the sludge because of the formation of more easily extractable forms of heavy metals from the less mobile forms originally present in the sludges (Lake 1987).

The use of electrokinetic techniques for remediation of low-permeability soils and sludges contaminated with heavy metals, organic compounds and radionuclides can be highly effective, efficient and economical (Acar and Alshawabkeh 1993; Acar et al. 1995). An electrically conductive geosynthetic, also known as an electrokinetic geosynthetic (GEK), is basically a geocomposite material combining the electrokinetic function with the existing conventional functions of geosynthetic materials. The superiority of GEK over conventional metallic electrodes lies in the absence of corrosion problems, permitting polarity reversal and providing required drainage. It can also act as ion exchange membrane by adding an ion exchange resin during the polymerisation process.

The conceptual scheme of electrokinetic remediation is shown in Figure 1. The geosynthetic material used for manufacturing the geosystem (i.e. the Geobox) was a woven geotextile made of composite multifilament yarns of inert polymeric (polyester), with carbon black added as impurity material. Traces of impurities of polymers from the family of polythiophenes, oligothiophenes and pentacene were also mixed to increase the conductive properties of the geotextile. The carbon black is mixed with polyester resin through 3D chaotic mixing. The percolation threshold of carbon black is 2.5%, which enables the polyester to decrease its resistivity from 1×10^8 ohm cm to a range between 1×10^3 and 1×10^2 ohm cm (1×10^3 ohmcm being the resistivity of steel). This final product is passed through a normal extrusion process to produce conductive polyester yarns. The yarn is then passed through weaving looms to make the woven geotextile. The same resin can be used to make nonwoven geotextiles or geocomposites.

The traces of polythiophenes, oligothiophenes and pentacene have been added to make the polyester intrinsically conductive. This has been done to impart a permanent conductivity effect to the geotextile. Passing the polyester resin through the electrochemical doping process does this. Normal polyester is an electrical insulator. The introduction of a charge carrier (by the addition or removal of electrons) into the conduction or valence bonds of polyester increases the electrical conductivity dramatically. The resin is suspended in an electrolytic solution (a mixture of tri-fluoroacetic acid, propionic acid and sulphonic acid) along with separate counter and reference electrodes. An electrical potential difference is created between the electrodes, which causes a charge (and the appropriate counter-ion from the electrolyte) to enter the polyester in the form of electron removal (p-doping). The woven geotextile was stitched to give a box shape with a three-chamber configuration, as shown in Figure 2. The stitching was done in such a manner that bodkins can be inserted in the grooves created to impart sufficient rigidity for box-type configurations. This box-type shape was configured to enhance the stability of the geosystem (as compared with geotubes) against the external environmental forces (wave, current and tidal forces) normally encountered in the field. The cellular configuration was envisaged to store sludge, provide anode purging and cathode electrolytic solution in separate compartments. The outer side was rendered impervious by applying a layer of bitumen coating. The objectives of this study were to monitor the effectiveness of the electrokinetic geosynthetic (GEK) system for the removal of contaminants in sludge, and to

investigate the factors that were most critical in determining the efficiency of electrokinetic processing for the removal of various contaminants in sludge.

Figure 1. Conceptual scheme of electrokinetic remediation

2. MATERIALS AND PROCEDURES

2.1. Experimental Set-Up

The experimental set-up consisted of five main components: the cellular geobox, the electrode chambers, the electrodes, the electrolyte solution containers and the power supply system. The geobox, made of woven geotextile, has overall dimensions 2.5 m x 3 m x 1 m. The properties of the woven geotextile are listed in Table 1. The central portion (1.5 m x 1 m x 1 m) formed the sludge chamber. At both sides of the sludge chamber, a woven geotextile acted as the semi-permeable ion-exchange membrane and also as secondary electrodes. In addition to the woven geotextile, conducting geocomposite drains (properties given in Table 2) were used. The apparent opening size (AOS) of the nonwoven geotextile was chosen to enhance the transport of ions towards the electrode compartments and to restrict the sludge particles from flowing into the electrode compartments. The experimental conditions maintained in the geobox are shown in Table 3.

Table 1. Properties of woven geotextile used for fabricating geobox

Property	Standard	Value (unit)
Grab tensile strength	ASTM D 4632	8130 N
Grab elongation	ASTM D 4632	30–40%
Trapezoidal tear strength	ASTM D 4533	2357 N
Puncture strength	ASTM D 4833	2067 N
Apparent opening size	ASTM D 4751	100 μ m
Permeability	ASTM D 4491	10^{-2} cm/s
Mass per unit area	ASTM D 5261	1000 g/m ²

Material: Polyester with traces of carbon black, polythiophene, oligothiophene and pentacene and ion exchange resin (di-vinyl benzene with styrene).

Table 2. Properties of geocomposite drain

Property	Standard	Value (unit)
Core:		
Mass per unit area	ASTM D 3776	850 g/m ²
Thickness	ASTM D 1777	9.5 mm
Compressive strength	ASTM D 6364	8500 N/100 cm ²
Filter:		
Grab tensile strength	ASTM D 4632	3000 N
Grab elongation	ASTM D 4632	60–90%
Trapezoidal tear strength	ASTM D 4533	1200 N
Puncture strength	DIN 54307	6000 N
Apparent opening size	ASTM D 4751	80 μ m
Permeability	ASTM D 4491	101 cm/s

Nonwoven geotextile material: Polyester with traces of carbon black, polythiophene, oligothiophene and pentacene and ion exchange resin (di-vinyl benzene with styrene). Core material: Polystyrene

The nonwoven geotextile component part of the drain intercepted finer soil particles before they entered the electrode compartment, and the drainage part ensured faster collection of contaminant in the main electrode compartment. This enhanced the efficiency of the removal system. Conductive geocomposite drains were also provided inside the sludge chamber to ensure free drainage of sludge in the extreme situation of sludge cake formation due to loss of moisture. They also acted as separate channels for electrokinetic removal of contaminants as they also acted as ion-exchange

membranes. One side of the geobox was used as the anode to prevent the electrode-electrolysis reaction, and other side was used as the cathode. The primary electrodes were composed of graphite and stainless steel cylinders. These cylinders were again coated with conductive high-density polyethylene (HDPE) polymer sheath through a p-doping process. Graphite and stainless steel were used to impart structural rigidity and to reduce the overall polymer coating thickness. The conductive polymer was provided to resist corrosion and chemical degradation. The electrode compartments contained electrolyte solutions in sufficient quantity to avoid sudden variations in electrolytic composition. Valves were provided to provide water for electroosmosis and to allow gas to escape from the electrodes. The outer sides of the geobox were made impervious by impregnating them using a bitumen spray. Two small cylinders were used as electrolyte solution reservoirs, which allowed the measurement of water transported from the anode side. The electrolytic solutions were passed through the treatment unit and were recirculated after conditioning in both electrode compartments by peristaltic pumps (1–250 rev/min, four heads), and a d.c. power supply (5–220 V, 0.01–2 A, 500 W) was used. Although electrolysis of water in an anode compartment naturally generates hydrogen ions, an anode-purging solution of 0.05N H₂SO₄ was used to boost the hydrogen level and enhance its reactivity with respect to the metal contaminants in the sludge bed. In the cathode compartment, hydroxides were precipitated by hydroxide ions derived from the electrolysis of water, and these precipitates inhibited the removal of contaminants in the sludge bed. A 0.5N H₂SO₄ solution was used as cathode electrolyte solution to buffer the effect of hydroxide ions produced in the cathode department. Constant current was applied to maintain the net rates of the electrolysis reactions at a constant level and to minimise complicated current boundary conditions during the experiments. The parameters are shown in Table 3.

Table 3. Experimental conditions in geobox for electrokinetic treatment

Parameters	Conditions
Target metal contaminants	Cd, Cr, Cu, Pb
Applied current (A)	2
Area of sludge bed (m ²)	1.5
Length of sludge bed (m)	1.5
Duration (h)	72
Anode purging solution	0.05N H ₂ SO ₄ solution 100 l
Cathode electrolyte solution	0.5 N H ₂ SO ₄ solution 100 l

The sludge chamber has been filled with industrial sewage in slurry form by hydraulic pumping through the inlet valve. The slurry was mechanically mixed to maintain water content of 80% by weight. 1300 l (1.3 m³) of sludge volume was maintained in the sludge chamber. The slurry level was at 0.9 m. The anode and cathode electrolyte solutions were pumped into the electrode compartments for 1 h, without electric current, for initial stabilisation of the system. The 0.9 m level was maintained for the electrolytes in the electrode compartments. As the experiment progressed, the overall voltage drop over the sludge and electrode compartments, pH variations and porewater volume transported by electro-osmotic flow were measured. After 7 days of operation, the electro-osmotic flow became constant, in line with the pH of the sludge bed. Samples were obtained from different locations of the sludge bed at regular intervals, and the residual concentrations of the various forms of metal contaminant in the sludge compartments were determined.

2.2. Contamination Measurement Methods

Heavy metals occur in sludge in various abiotic (physiochemical) forms, such as soluble, adsorbed, exchangeable, precipitated, organically complexed and residual phases. They may also exist in biotic forms, such as extracellular and intracellular species. The variety of heavy metal forms significantly influences their environmental mobility and bioavailability, and finally determines the potential for environmental contamination (McBride 1994). Heavy metals existing as loosely bound fractions, such as the adsorbed, soluble and exchangeable forms, tend to be easily moved and dispersed. Metals associated with organic ligands or embedded in crystal lattices are not easily separated or mobilised. Sequential extraction analysis has been suggested to determine the speciation of heavy metals in any given matrix (Tessier et al. 1979; Khalid et al. 1981; Bardi and Aston 1983; Gibson and Farmer 1986; Domingues and Silva 1990; Davidson et al. 1994).

2.3. Preparation of Sludge Samples

The sludges used in this experiment were anaerobically digested sludges taken from an industrial wastewater treatment plant in Mumbai, India. Sludges were collected at two different plant locations, i.e. before and after the dewatering process, and they were mechanically mixed to maintain a water content of 80% by weight. The sludge was hydraulically pumped through the inlet valve into the geobox at 65% of its volume.

2.4. Analysis of Sludge

The analytical procedure involved two extraction steps. The first step involved the sequential extraction of the abiotic fraction of the sludge heavy metals before and after the electrokinetic treatment. The sequential extraction method used in this experiment was suggested by Tessier et al. (1979) and later revised by the Environmental Biochemistry Research Group at Imperial College, UK (Li et al. 1995). The second step was based on an extraction scheme for determination of biotic speciation of the heavy metals. This method involved sieving, elutriation, EDTA extraction, washing and acid digestion, for determining the distribution of heavy metals, between their soluble, precipitated, extracellular and intracellular components (Hayes and Theis 1978). A volume of 100 ml of sludge was passed through a 150 mm sieve for separation of biomass and particulates; the sieve residue was washed with 500 ml of deionised water. A volume of 600 ml of diluted sludge was placed in a conical upflow clarifier for separation of the biomass from inert particulates. The overflow rate of the desired upflow clarifier was calculated using Stokes's law (specific gravity of sludge particle: 1.02). Elutriation was continued until the final elutriate volume collected from the upflow clarifier was about 5 l. As the chelating agent, EDTA is known to have a stronger affinity for heavy metals than for the extracellular polymers of the microbial cell wall, it was used to extract only the extracellular phase of the heavy metals from the biomass after elutriation. The procedure for subsequent extraction is shown in the flowchart in Figure 3, and the various chemical extractants used are shown in Table 4. The electrophoretic transport of microbial cells after electrokinetic treatment was examined by determining the number of microbial cells at different locations in the sludge.

3. ELECTROKINETIC PROCESS

3.1. Brief Overview

The electrical transport induced in the sludge is used for the removal of contaminants and the introduction and

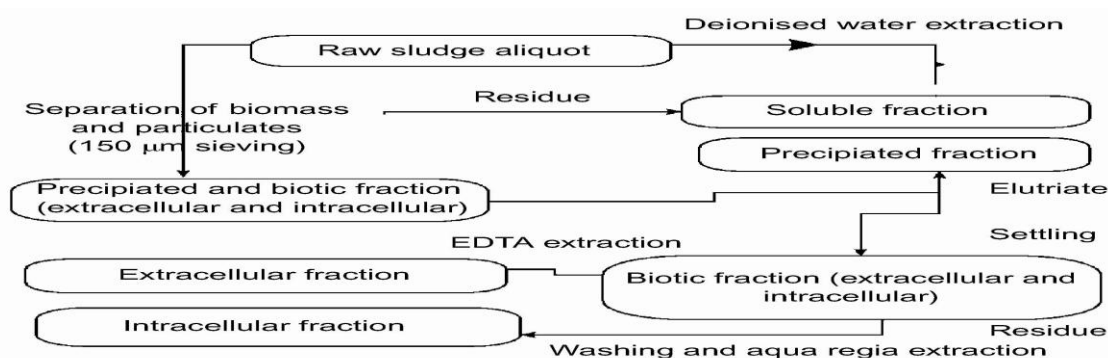

Figure 3. Subsequent fractionation scheme for analysis of biotic phases of heavy metal in the sludge

distribution of reagents into the sludge matrix. The reagents may be used for contaminant degradation, enhancement of contaminant solubility, immobilization of contaminant or attainment of an optimum pH in the sludge during the treatment process. The application of low-level direct current results in physicochemical changes in the medium, leading to species transport by coupled mechanisms, of electromigration, electro-osmosis, electrophoresis and the electrolysis of water. In the electrokinetic cell there is an anode half-cell and a cathode half-cell. Water undergoes electrolysis at each electrode.

At the anode, water is oxidised, producing an acid front and oxygen gas. Reduction of water occurs at the cathode, where a base is produced and hydrogen is released. The acid front migrates towards the cathode through the medium. This, in turn, causes contaminant to be desorbed and/or dissociated, resulting in the initiation of electrophoresis and electromigration, i.e. the transport of charged suspended solids and soluble ions under the influence of the applied potential gradient. The applied potential gradient also leads to electro-osmosis, i.e. the flow of an ionic liquid to a charged surface. Finally, the contaminants are transported towards the cathode and anode depending on their electrical charge

Table 4, Various chemical extractants used in sequential and subsequent extraction schemes for determination of abiotic and biotic speciations of heavy metals

Fractions	Chemical extractants
Abiotic	
Exchangeable	0.5 M MgCl ₂ + NH ₄ OH/HOAc (pH ¼ 7)
Bound to carbonate or specially adsorbed	1 M NaOAc + NH ₄ OH/HOAc (pH ¼ 5)
Bound to Fe and Mn oxides	0.04 M NH ₂ OH HCL in 25% HOAc
Bound to organics and sulphides	0.02 M HNO ₃ + 30% H ₂ O ₂ + 3.2 M NH ₂ OAc in 20% HNO ₃ (pH ¼ 2)
Residual	HF/HClO ₄ /HNO ₃ (4:2:15)
Total digestion	HF/HClO ₄ /HNO ₃ (4:2:15)
Biotic	
Soluble	Deionised water
Precipitated (insoluble)	Aqua regia; HNO ₃ /HCL (1:3)
Extracellular	10 ⁻⁴ M EDTA
Intracellular	Aqua regia
Total digestion	Aqua regia

(i.e. cationic or anionic), and the direction of porewater flow. Contaminants collected at the electrodes can then be extracted and subsequently treated for reuse. The dissolution and precipitation of ions may result from chemical reactions during electrokinetic treatment. These processes have a significant effect on contaminant removal. The acid front produced at the anode by electrolysis of water is able to dissolve most metal ions. However, relative dissolution of different species depends on the pH of the pore fluid and the solubility product of each species (Alshawabkeh and Acar 1994). Convective forces also contribute to front migration, but to a lesser extent. As precipitation of many metal ion species occurs at pH values greater than 6.0, and electrokinetic processing automatically raises the pH at the cathode, it becomes imperative to buffer the cathode compartment to facilitate the removal of contaminants (Alshawabkeh and Acar 1992). A reduction of pH to less than 4 results in the retention of cationic species in a stable form. It also facilitates the electrolysis of water, resulting in reduced production of OH ions. Cathode water electrolysis will also reduce the power requirement and overall treatment cost by decreasing the electrical potential difference applied across the mass (Acar and Alshawabkeh 1996). Electro-osmotic flow is important in some processes, such as removing organic contaminants and enhancing metal or radionuclide removal from the sludge.

3.2. Various Parameters for Electrokinetic Experiment

A possible range of electric potential to drive the electrokinetic remediation is from 10 V/m to about 250 V/m (but preferably from 20 V/m to 100 V/m). In this experiment, the voltage was varied between 25 V/m and 40 V/m. The current was maintained at a constant value of 2 A. The operating current was determined by measuring the temperature of the sludge chamber until constant chamber resistive heating was achieved owing to the passage of current. The electromigration of ions increases as the current increases, and the electro-osmotic flow enhances owing to the increase in voltage. The ionic current between the electrodes in the pore fluid depends on the voltage applied in the sludge. Depending on the type of ions being transported, the current and voltage induced in the sludge, and the sludge and pore fluid chemistry, the ion transport may vary between 0.5 and 5 cm/day.

4. RESULTS AND DISCUSSION

4.1. Initial Concentrations and Speciations

The initial concentrations of abiotic and biotic forms of metal contaminants present in the sludge are shown in Table 5. Figure 4 presents the relative availability of different phases of heavy metals. The total concentrations of target heavy metals were relatively high even though the sludges were taken from a industrial wastewater treatment plant. The recoveries of the sequential and subsequent extraction procedures were in the ranges 96–100% and 96–98%, respectively, as shown in Table 6. In line with the results of the abiotic heavy metal sequential extraction analysis, most of the heavy metals existed in the organic/ sulphide and residual fractions and resulted from the anaerobic digestion of the sludge in the wastewater plant prior to coagulation and settling (Lake 1987). The results of subsequent fractionation showed that the main portion of the biotic heavy metals was distributed between the precipitated (insoluble) and intracellular components of the sludge, with the exception of cadmium. Extracellular heavy metals (EDTA extractable) accounted for less than 6% of the total amount of the heavy metals present. Likewise, soluble metals were also insignificant fractions in all cases (less than 2.5%), again with the exception of cadmium, 10% of which was soluble. It may be presumed that microbial uptake actively competed with precipitation in the removal of heavy metals from the digester supernatant. This phenomenon has been verified by the demonstrated ability of microbes (and especially bacteria) to concentrate metal ions around the cell wall by complexing with proteins and acid grouping that serves as bonding sites (Hayes and Theis 1978). The inability to release these metals during EDTA extraction further suggested active transport of these metals to the cell interior.

4.2. Concentration of Metals After Electrokinetic Treatment

Figures 5 and 6 show, respectively, the concentration variations of abiotic and biotic heavy metals in the sludge compartment after electrokinetic treatment. The dissociation and desorption of metal species occurred continuously along the migration direction of the acid front during the treatment, and metal contaminants seemed to be gradually transported towards the cathode by electromigration and electro-osmotic purging. Charged polymers on the microbial cell surface contain ionisable groups, which result in an amphoteric surface. Their surfaces carry a net negative charge at high pH and a net positive charge at neutral pH (Ebersole and McCormick 1993; De Flaun and Condee 1997). Thus the microbial cells migrate towards the anode or the cathode in an electric field, depending on their surface charges, as

Table 5. Fractionation of heavy metals using two different extraction schemes

Extraction method	Fractions	Concentration (g/g)			
		Cd	Cr	Cu	Pb
Sequential extraction (abiotic fractionation)	Exchangeable	0.85	0.0	10.6	0.0
	Carbonates	1.1	1.4	5.0	5.1
	Fe/Mn oxides	4.0	2.7	15.9	2.9
	Organic/sulphides	0.0	38.2	245.0	33.4
	Residual	0.8	68.7	51.7	18.9
	Sum	6.75	111.0	328.2	60.3
	Total digestion(a)	6.85	117.5	335.7	64.1
	Recovery(b) (%)	98.5	94.4	97.7	96.7
Subsequent extraction (biotic fractionation)	Soluble	0.8	0.1	9.6	0.1
	Precipitated (insoluble)	5.3	77.7	246.7	36.3
	Extracellular	0.0	4.0	16.7	3.5
	Intracellular	0.4	11.6	28.6	10.6
	Sum	6.5	93.3	301.6	50.5
	Total digestion	6.7	94.6	308.7	52.4
	Recovery (%)	97.0	98.6	97.7	96.4

(a) The concentrations were determined by the final step of sequential extraction using HF/HClO₃/HNO₃ solution. (b) (Sum of concentrations of all fractions/concentration determined by total digestion) x 100%. (c) The concentrations were determined by the extraction of aqua regia solution.

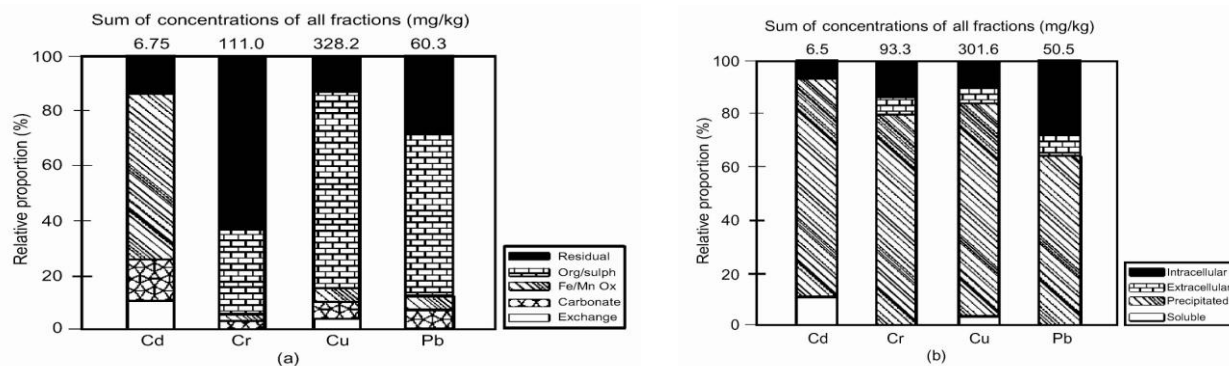

Figure 4. Relative proportioning of heavy metals in the untreated sludge: (a) abiotic speciations analyzed by sequential extraction: (b) biotic speciations analyzed by subsequent extraction

controlled by the surrounding pH. On the reverse side, the porewater in the sludge compartment flowed towards the cathode by electro-osmosis during the treatment period. Accordingly, the largest number of microbial cells appeared in the zone near the cathode rather than in the middle of the sludge compartment resulting from the coupled effect of the electrophoretic transport of microbial cells and the electro-osmotic flow. For this reason, the extracellular fractions of heavy metals accumulated in the same zone as the microbial. High effectiveness of the electrokinetic removal of metal contaminants is not expected on the basis of the sequential extraction analysis result, because 72–95% of most of the target metals (Cr, Cu and Pb) were predominantly partitioned in the strongly bound fractions, such as the organic/sulphide and residual fractions, again with the notable exception of Cd.

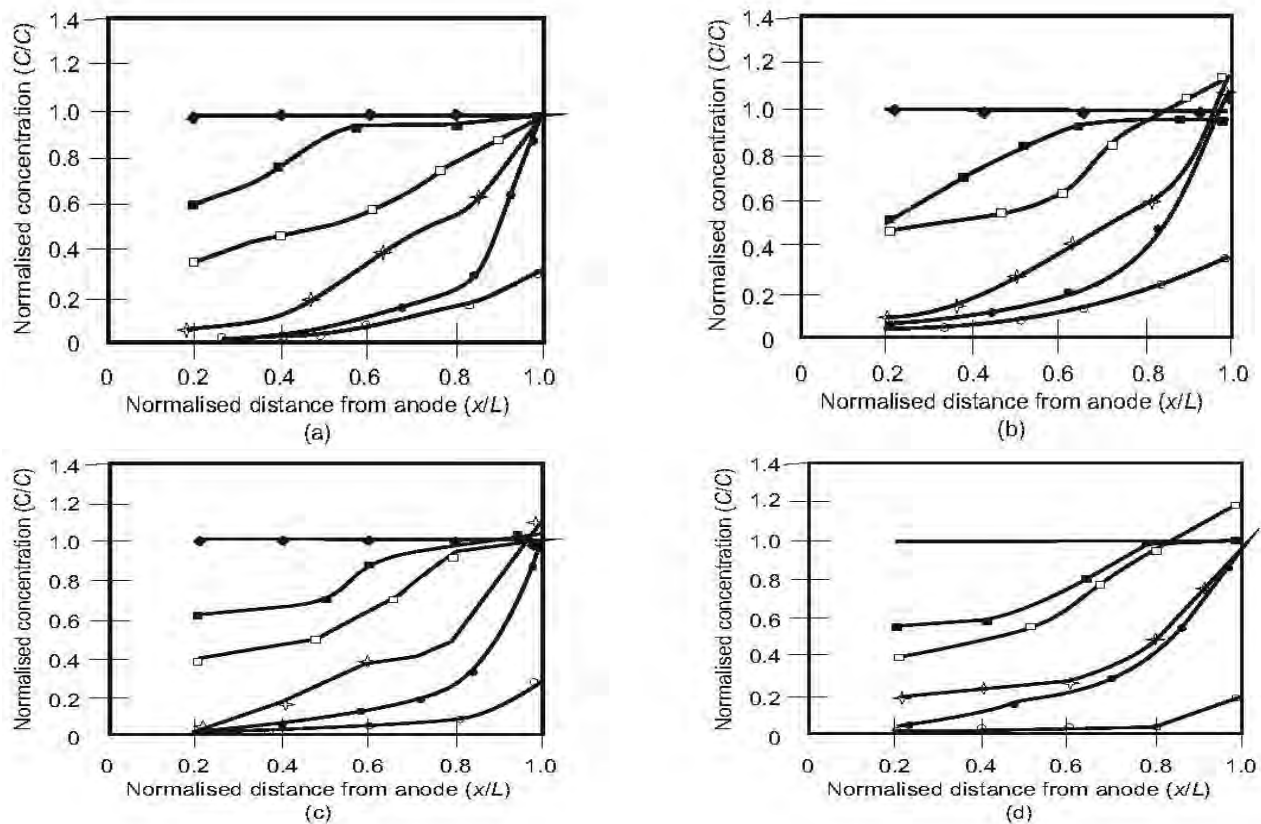

Figure 5. Concentration profile of abiotic metals in the sludge chamber after electrokinetic treatment (x distance from anode; L length of sludge chamber) for: (a) Cd; (b) Cr; (c) Cu; (d) Pb. r , initial; s , exchangeable fraction; d , carbonated fraction; Fe/Mn oxide fraction; h , organic/sulphide fraction; j , residual fraction

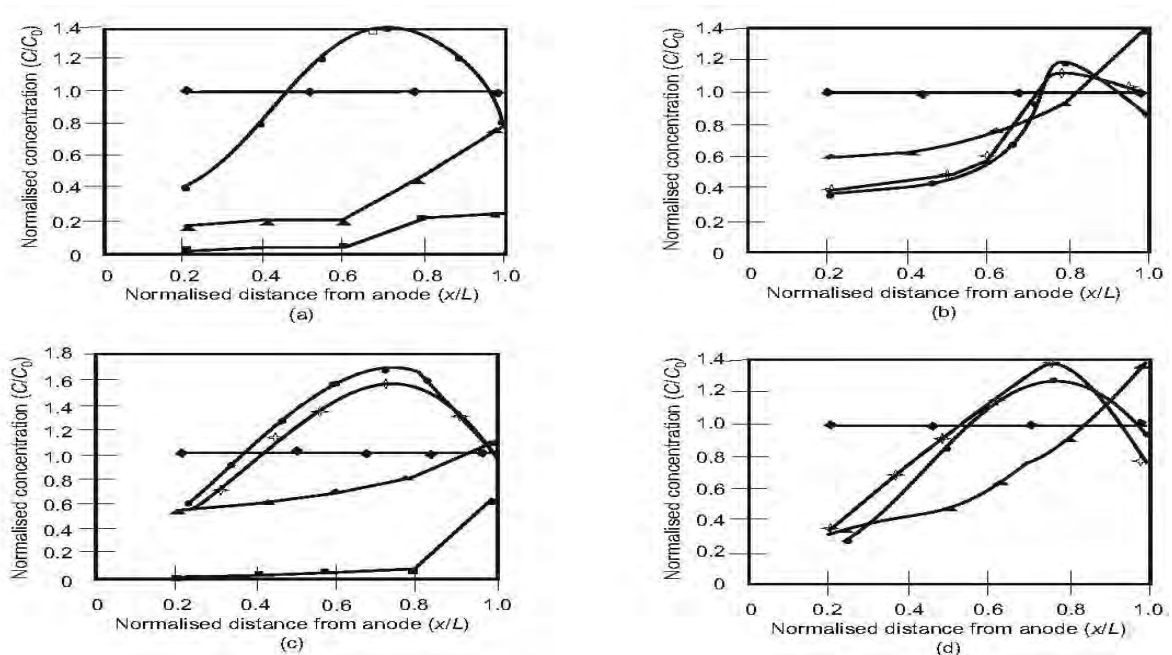

Figure 6. Concentration profile of biotic metals in the sludge chamber after electrokinetic treatment (x distance from anode; L length of sludge chamber) for: (a) Cd; (b) Cr; (c) Cu; (d) Pb. r, initial; j, soluble fraction; m, precipitated (insoluble) fraction; , extracellular fraction; d, intracellular fraction conditions.

5. CONCLUSIONS

From the results of a pilot-scale study on the electrokinetic removal of heavy metals from industrial wastewater sludges, using a geobox that included an electrokinetic geosynthetic (GEK), the following conclusions may be drawn:

Electrokinetic geosynthetic (GEK) materials offer a technically viable and efficient solution for remediation of contaminated wastewater sludge.

The sludge contained high concentrations of heavy metals in the chemical form of various speciations. To estimate the environmental impacts of metal contaminants in sludges, the concentrations and speciations of metal contaminants were determined by sequential and aqua regia extraction methods. Except for Cd, most target metals (Cr, Cu and Pb) exist predominantly in the organic/sulphide and residual fractions (72–95%).

The removal efficiencies of heavy metals were significantly dependent on their speciations in the sludge. The more strongly bound fractions, such as organic and residual fractions, were less effectively removed by electrokinetic treatment.

The variation of the sludge pH significantly influenced the removal efficiency of the electrokinetic technique. As the acid front generated by the electrolysis of water in the anode compartment migrated towards the cathode, the overall sludge pH decreased gradually. The complexed and/or adsorbed metal species were dissolved and desorbed along with the migration of the acid front.

Removing Human Error from Geomembrane Leak Location Surveys

Matthew P. Kemnitz, Leak Location Services, Inc., USA, mkemnitz@llsi.com

ABSTRACT

Human error can drastically affect the accuracy, completeness and validity of geomembrane leak location surveys. Geomembrane leak location surveys have been commercially available since 1985 and industry standards have been developed for the various implementations. However, industry standards do not eliminate human error in applying the standards, taking the data and correctly interpreting the data. Proper use of technology, with extensive field experience and a thorough understanding of the technology, can reduce human error to a negligible level.

1. SURVEY DATA

At the heart of geomembrane leak location surveys is the process of taking the data, plotting the data and interpreting the data. If the data is taken incorrectly or inaccurately it can be useless. Without solid data acquisition, leak location surveys are often ineffective. The data must be read accurately, written correctly, and entered into the data plotting program correctly, each step entailing error. If the above can be done without errors there is still the aspect of interpreting the data. This takes time and experience that can only be fully mastered in the field. With a human interface, the human elements of reading a meter, writing down the data and interpreting tables of numbers or keyboarding the readings into the correct places in the data plotting software provide multiple opportunities for error.

1.1 Data Acquisition

One way data can become inaccurate is during the recording of the data. Simply writing down the information collected on a notepad is unreliable. There are multiple issues associated with this method that relate to human error. The data can be written down incorrectly, out of order or it can simply become destroyed or lost in certain field conditions. On an area of only 4,000 square meters (2-acres) there can be up to 6,000 readings to be recorded. This calculation is based on a grid pattern that accurately depicts a leak signal per the ASTM standard. Per ASTM D 7007 the leak signal shall be represented by five or more data points in the data. With larger grid spacing, leaks of smaller sizes can be missed. The likelihood of all of the readings to be written down accurately and in the correct order is very low. Assuming a one percent error on the copying of the data the number of errors increases with size and can be detrimental to the overall survey. (Table 1)

Table 1. Number of errors in relation to the size of the area surveyed.

Area(m ²)	Area(Acres)	# of Readings	1% Error
929	0.23	667	6.7
9,290	2.30	6,667	66.7
46,452	11.48	33,333	333.3
92,903	22.96	66,667	666.7
139,355	34.44	100,000	1,000.0

It can be expected that the larger the area the longer the survey will last and thus the potential for error increases even more due to fatigue and tediousness.

Pencil and paper recording of data from an instrument has long since been replaced by digital data acquisition systems and computers using microprocessors and software. Computer data acquisition systems as seen in Figure 1, take the reading, convert it to digital data and store the data practically instantaneously with no errors. The data is stored in the order that it was taken. The leak location technician does not have to concentrate on the physical recording of the data because it is automatically stored. Instead they can concentrate more on how they physically are taking the data and making sure their technique is sound and site conditions are ideal.

Figure 1. Leak location survey being performed on soil-covered geomembrane using a digital data acquisition system.

1.2 Plotting the Data

Once all of the data has been collected it should be plotted. This can be done many different ways, but the best way is the one with the least amount of human input. Inputting the data by keyboard increases the chance of error by incorrectly keying in the data and can lead to erratic data points and leak signals being missed. Without oversampling, one incorrect input can lead to a leak being missed. Using a computer system that automatically downloads the data and graphs it automatically eliminates the need for inputting the data by hand. By removing this extra step from the leak location survey process a significant amount of time is saved and the chance of the recorded data being input into the data plotting software incorrectly is eliminated.

1.3 Interpreting the Data

Using graphing software that accurately imports the data and converts it to easily understandable graphs can greatly aid in the interpretation of the data for leak signals. Since graphical representation of the data is the final step in the use of the data, it is important that the software being used is adaptable. Plotting the data on a fixed scale can cause larger signals to be off-scale, and suppress smaller signals. Figure 2 shows that the graphing software needs to be able to adjust in such a manner as to make the smaller leak signals visible. Figure 3 shows a plot of the same data on a better scale. By using graphing software and knowing how to fully use its capabilities, leaks similar to that shown in Figure 2 will be detected. Without the use of good graphing software the leak location surveyor would need to interpret all of the data by themselves. This can lead to complications and take much more time than is necessary. The idea is to be able to efficiently and effectively find leaks within a site. Being able to interpret the data onsite and to verify signals the same day greatly reduces the effect that site condition changes have and improve the accuracy of the leak signals locations. Data interpretation is a learned skill. It takes time to learn and cannot be fully understood in a few short weeks. Data must be viewed and interpreted consistently over multiple different surveys to better understand how each survey is different and how this relates to the data's interpretation. The operator must be thoroughly experienced in interpreting the data, knowing how site conditions can affect leak signals and knowing how to recognize false signals.

Figure 2. Leak location data showing two leak signals. The larger signal masks the smaller signal.

Figure 3. Leak location data showing two leak signals. The smaller signal is visible after adjusting the scale.

Figure 4. Leak #30 (Smaller leak signal.)

Figure 5. Leak #31 (Larger leak signal.)

2. FIELD EXPERIENCE

Lack of experience is another big factor that leads to human error. Simply understanding how to take the data correctly is not sufficient for finding all the leaks. The leak location surveyor also needs to thoroughly understand how to set up the survey to obtain the optimum results. Because of the many possible scenarios of landfill construction, this cannot be taught in a classroom. Extensive and frequent field experience is the only way to fully understand the intricacies of leak location surveys.

2.1 Survey Setup

Setting up for a leak location survey is actually done well before the leak location technician arrives onsite. Before arriving the technician should already know the layering sequence of the cell as well as the general geometry and possible grounding paths within the cell to be surveyed. They should also know how the cell will be surveyed and what equipment will be needed to perform a successful leak location survey. If grounding paths are present they will be able to advise the client on how to remove or greatly decrease the effect of the grounding path on the leak location survey. The intent is to best prepare for a leak location survey before arrival to the site. This is done so that when the survey is performed, every foreseeable detriment to the survey can be addressed in order to produce optimum results. This type of preparation greatly improves with field experience. Once the survey technician is onsite the remainder of the setup is just as important. Questions such as, "Are there pipes buried under the cover material?", "In which direction do they run?" and "What effect do they have on the survey?" all need to be answered so an optimum grid pattern can be placed for the best results.

2.2 Understanding the Technology

Equipment does become damaged whether it's from shipping or from day to day use. If the equipment is not working properly and the survey technician doesn't realize it, they can essentially be taking data for nothing. The ability to intimately understand how the equipment works will keep this from happening because they will know when something is not working properly. There are situations where there are multiple leaks in the near vicinity of each other. The graphing software may show what looks to be just noise or one leak signal to most technicians. An experienced leak location technician will know that this one signal can mask smaller nearby signals. This is remedied by exposing the leak signal shown in the data then testing the area around the initial leak signal to ensure there is no additional damage to the geomembrane. Figure 6 shows three leak signals which are relatively close to one another. The largest leak signal masks or distorts the first two leak signals as shown in Figure 6. It does not do any good to just find a leak at a site. It is far better to find all leaks of sizeable interest. The more experience someone has the more problems they have come across and the more solutions they have utilized. This helps the survey proceed correctly as well as reduce time to a minimum which always pleases the client.

Figure 6. Leak location data showing what looks to be noise or one possible leak signal.

2.3 Continued Education

Continued education and further improvements on current technologies can help to reduce human error and further improve the effectiveness of leak location surveys. This can be done through training by frequently updating techniques to involve newer adaptations that advance survey techniques. Training is an on-going process that cannot be done once over a short time period if favorable results are to be expected. Frequently updated training topics and techniques will help to keep leak location surveys advancing along with the rest of the geosynthetics industry.

2.4 Review of Work

Openly sharing problems will help to avoid their reoccurrence and improve the quality of work of others. Peer review of work has been around for hundreds of years and can be used as a type of quality-control system. Through the review of work an increased awareness of possible pitfalls and complications can be better recognized and combated before they become an issue. Many instances have occurred where a leak location survey has been attempted by an initial company and the results have been inconclusive and no leak signals have been found for a specific cell. A second company was then called out to perform a leak location survey on the same cell and leak signals were found. This is due to an oversight where part of the setup was not done properly. Had the initial company had a peer review their work this setup error could have been avoided.

3. CONCLUSION

Removing human error in leak location surveys is imperative to the quality of landfills and surface impoundments throughout the world. Leak location surveys can be physically demanding and tedious and the likelihood of errors can be high. However there are ways to reduce these errors to a minimum that will not significantly affect leak location surveys. The proper application of industry standards coupled with sound technology and extensive field experience can minimize human error to an insignificant level.

ABSTRACT

In this research, results from a series of large scale dynamic model tests on geocell reinforced and unreinforced homogeneous sand beds are presented. The placement density of sand in all the tests was maintained at 70%. The loading was applied through a circular steel plate which replicates the load application from a passenger car. A single axle wheel load of 40 kN was assumed on the pavement surface of which 7 kN was calculated to be applied on the subgrade layer. The influence of the width and height of the geocell reinforcement on the cyclic behavior of the loading system was studied and the performance improvement in terms of traffic benefit ratios and cumulative plastic deformations/rutting was determined. A traffic benefit ratio was observed to be as high as 45 for the case of geocell size $h/D=1$, $b/D=4$ at 10% plate settlement. The cumulative permanent deformations were reduced by 8 fold for the same case against the unreinforced case at 5% plate settlement.

1. INTRODUCTION

In India, a statistical survey by rural development of India shows that around 80% of road network is comprised of rural roads (Rural roads, 2012) whose performance is always inferior and questionable. Besides, engineers are often forced to seek alternative designs using inferior materials, commercial construction aids, and innovative practices for better performance of pavements. One such category of commercial construction aids is utilization of geosynthetics. Geosynthetics includes a large variety of products manufactured of different polymers are adopted in numerous geotechnical and transportation applications. Often, it is important to estimate the efficacy of such inclusions in natural ground to improve the design methodologies and construction practices prior to their utilization.

Research on geocell reinforcement for pavement applications started about five decades ago. This reinforcement technique was first adopted by the US Army Corps of Engineers for improving the bearing capacity of poorly graded sand by using it as a lateral confinement (Webster, 1979). Lateral confinement, increased bearing capacity, and tensioned membrane effects were identified as the important reinforcement mechanisms for geogrid and geocell reinforcement (Giroud and Noiray, 1981, Dash et al 2001, Han et al. 2008a). The geocell reinforced bases exhibit bending resistance, tensile strength, and shear strength, and intercept the failure planes from the subgrade (Zhou and Wen, 2008). Understanding these mechanisms originated from mostly static plate load tests, however, limited research has been focused on these mechanisms under cyclic loading. The following sections discuss the cyclic behavior of geosynthetic reinforcement and factors affecting the performance of the geosynthetics under repeated loading.

2. BACKGROUND

Ever since the reinforcement forms were used, many kinds of geosynthetics like geotextiles, geogrids and geocells have come into existence. Many researchers have studied these reinforcement forms (geogrids and geocells) under static loading for pavement applications, however, a very few studies are available on cyclic loading (Barksdale, 1989; Cancelli, 1999; Collin, 1996, Dash et al. 2001; Dash et al. 2003; Sitharam and Sireesh, 2005). Generally, geosynthetics are used as pavement base or subbase reinforcement. Base course lateral restraint is the main reinforcement mechanism of geosynthetics in paved roads as described by Bender and Barenberg (1980). Further, Kinney and Barenberg (1982) demonstrated that the geotextile-reinforcement can be used in unpaved roads. When the planar geosynthetic reinforcement is placed at the bottom of the asphalt concrete layer, it leads to the highest reduction in the vertical deflection (Hosseini et al., 2009). Hosseini et al. (2009) reported that the overall performance of the asphalt pavement was improved when an effective bonding was maintained between the asphalt concrete and the geogrid. The

settlement over the loading area of reinforced pavement was also reduced when compared with unreinforced pavement under cyclic loadings.

To quantify the benefits with geosynthetic reinforcements in pavements under cyclic loading, a non-dimensional term called traffic benefit ratio (TBR) has been introduced. TBR is expressed in terms of extension of life or by savings in base course thickness. TBR is defined as the ratio of the number of cycles necessary to reach a given rut depth for a test section containing reinforcement, divided by the number of cycles necessary to reach the same rut depth for an unreinforced section with the same section thickness and subgrade properties. This is in consistent with the non-dimensional parameter called improvement factor defined in the case of static loading system on geosynthetic reinforced beds (Dash et al. 2001; Dash et al. 2003; Sitharam and Sireesh, 2005).

Several researchers investigated the cyclic behavior of different forms of geosynthetic reinforcements and provided TBRs. Haas (1985) reported a TBR of about 3.3 for geogrid reinforced beds in a large test tank. Similarly Barker (1987) used geogrid reinforcement under a moving single wheel system and observed a TBR of 1.2. Al-Qadi (1994) studied a combination of geogrid and geocell reinforcements in a test tank and observed TBR ranging from 1.7 to 3.0. Similar observations were made by many other researchers where the TBR was observed to be ranged from 1 to 4 under single axle wheel loads (Barksdale, 1989; Cancelli, 1999; Collin, 1996). Recently, Pokharel (2010) performed large-scale cyclic plate loading tests on geocells and observed that the NEOLOY polymeric alloy (NPA) geocell improved the strength and life of the unpaved road sections over weak subgrade. The reinforced sections had much higher percentage of elastic deformation (more than 90%) as compared with the unreinforced sections and also the NPA geocell.

The effect of the properties of infill material on the performance of unpaved and paved road sections subjected to cyclic loading shows that both the strength of the subgrade and the quality of infill material play a vital role in improving the performance of the geocell-reinforced road sections (Kazerani and Jamnejad, 1987). Higher performance was observed with geocell reinforcement with dense infill on a good subgrade. Similar observations were reported by Han et al., (2008a). Han et al (2008b) also reported that the placement of geocell from the surface of loading is very crucial. In static load tests, it was observed that the depth of placement of geocell should be maintained about 1 to 5% of the width of the loading area (Dash et al., 2001; Sitharam and Sireesh, 2005).

Literature study reveals, based on the limited information available on geocells, that the cyclic behavior of geocell reinforced beds are not yet understood completely. Hence, in this study, an attempt has been made to understand the cyclic/repeated load response of the geocell reinforced sand subgrades.

3. MATERIALS AND METHODS

3.1 Sand

The soil used in this investigation was dry sand. The particle size distribution of the sand was determined by dry sieve analysis as per ASTM D 422. The particle size distribution of the sand is shown in Figure 1. The sand is classified as poorly graded sand with letter symbol SP according to the Unified Classification of Soil (UCS). The physical properties such as specific gravity, maximum and minimum void ratios of sand were determined according to ASTM D 854-00, ASTM D 4253 and ASTM D 4254 respectively. The properties of sand are depicted in Table 1.

3.2 Geocell

Geocell is a strong, lightweight, three dimensional honeycomb-like cellular confinement systems, which is made of ultrasonically-welded HDPE strips that are expandable on-site to form a honeycomb-like structure. It acts as a foundation reinforcement mat for improvement of bearing capacity of weak soils. It is a polymer of High density polyethylene (HDPE) material with a density ranging between 0.935-0.965 g/cm³ and with surface treatments of texturing which consists of a multiple of rhomboidal indentations over the entire strip area and material where the polyethylene strip shall be perforated with horizontal row of 10 mm diameter holes. The geocells used in this study are having weld at regular intervals of 400 mm and 75, 100 and 150 mm depths. A typical geocell mattress used in the present study can be seen in the Figure 2.

Table 1. Properties of sand used in investigation

Properties	Values
D 10 ,mm	0.20
D 30, mm	0.32
D 60, mm	0.48
C_u	2.40
C_c	1.07
Specific gravity	2.63
E_{max}	0.74
E_{min}	0.51

Figure 2. Typical geocell used in the study

4. TEST SETUP

The sand beds with 70% relative density were prepared in a test tank measuring inner dimensions of 1m × 1 m x1 m (length x width x height). A rigid thin steel plate of 150 mm diameter (D) and 15 mm thickness was used to apply the repeated traffic loading. The size of the plate was chosen such a way that the area of the plate resembles the area of tire pressure. Loading was given by graphical user interfaced MTS MPT software with the help of hydraulic power unit (HPU), hydraulic service manifold (HSM) and sophisticated double acting linear dynamic 100 kN capacity actuator which is attached to a 3.5 m high, 20ton capacity reaction frame as shown in Figure 3.

Figure 3. Test-cum-Loading system used in the present study

5. TESTING PROCEDURE

Test procedure can be explained under three sub topics:

1. Preparation of relative density calibration chart
2. Preparation of sand bed
3. Cyclic load tests

5.1 Preparation of Relative Density Calibration Chart

To determine the density with which sand is to be poured in the tank, a special technique called sand raining technique or sand pluviation technique was used. To achieve this, a special device is designed. This device has a hopper with a flexible pipe connected to its bottom. A 40 mm internal diameter and 300 mm long pipe with an inverted cone welded at its one end was intern attached to the bottom of the flexible pipe. The sand passes through the pluviator disperses at bottom by a 60° inverted cone. This pipe is fitted with a movable scale to arrange different heights shown in Figure 4.

Relative density calibration chart was obtained by conducting a series of tests with different heights of fall of sand pluviation. Natural densities were measured physically by collecting samples in small containers whose weights and volumes were known. With the known values of the minimum and maximum void ratios of sand used in the investigation, a calibration chart was prepared for the height of fall against the corresponding relative density. For any required relative density, the corresponding height of fall can be read directly from the calibration chart shown in Figure 5.

5.2 Sand Bed Preparation

The sand was placed in the test tank using pluviation technique as discussed above. In this study, the relative density of sand was maintained at 70 %. The test bed density was frequently monitored by taking samples at different depths during pluviation using flat cups. The densities were well within the range of 1% error. The modulus of the test beds were also examined with a 10 kg capacity Lightweight Deflectometer (LWD). From LWD tests, the average modulus of the test bed at 70% relative density was found to be 28.2 MPa. This modulus is compared with the pressure-settlement data obtained from an unreinforced bed which was found to be 27.8 MPa (average).

Figure 4. Devices used in the preparation of test beds

Figure 5. Calibration curve for the sand used in the study

5.3 Cyclic Load Tests

Upon filling the test tank up to the desired height, the fill surface was leveled and the loading plate was placed on a predetermined alignment such that the loads from the actuator applied would be transferred concentrically to the footing to avoid eccentricity. To facilitate this, a recess was made into the footing plate at its centre to accommodate a ball bearing through which vertical loads were applied to the plate. In the case of reinforced beds, upon ceasing the pluviation at predetermined depth, the geocell was stretched on the leveled subgrade and continued the sand pluviation to fill the geocell mattress.

The plate was located carefully at the centre of the actuator against the reaction frame to avoid eccentric loading. The cyclic load was applied to a loading plate using a computer-controlled servo hydraulic actuator, with a maximum load of 7 kN and a minimum on 0.7 kN using a continuous haversine loading pattern as shown in Figure 6. The load was estimated based on the field data using a strain type total pressure cells buried under subbase layer just above the subgrade. Similar loading pattern was also adopted by Edil et al (2007) for the case of geocell reinforced granular subbase layer. Since the intermediate layers have not been simulated in this model tests, the pressure exerted on to the subgrade was directly applied through a plate. A 10% of load (0.7 kN) was constantly applied on the plate to make the cycle a closed loop. The load form was applied at a frequency of 0.77 Hz. Multi-Purpose Test Ware (MPT) software was set up to control and acquire the applied load data as well as the deformation data.

A series of repeated load tests were conducted to verify the efficiency of the geocell layers in the subgrade. These tests include single geocell layers with different sizes with respect to the plate diameter. The width of geocell (b) was varied at 3 times the plate width (D) represented as geocell width ratio, b/D . Similarly the height of the geocell was varied as $h/D=0.5, 0.67$ and 1.0 . The relative density of the sand was maintained at 70% in all tests. The depth of the reinforcement layer from the bottom of the plate was maintained at 0.1 times the diameter of the plate according to Sitharam and Sireesh (2005) and Dash et al (2001). All the tests were conducted until reaching the settlement about 20% of the plate diameter. The equivalent diameter of geocell pockets, d_c was maintained at about $1.6D$ in all the tests.

Figure 6. Loading pattern used in the study

6. RESULTS AND DISCUSSION

Figure 7 depicts the response of the geocell reinforced bed under cycling loading conditions. It can be observed that the total settlement ratios are large for the initial loading cycles, while their magnitude attenuates thereafter.

The settlement ratios are reduced as the amount of geocell reinforcement increases, hence, the unreinforced subgrade exhibits the highest settlement ratios. To quantify the reduction in settlement ratios and the efficacy of geocell, cumulative permanent deformations (CPDs) were calculated from a sequence of experiments. First, the permanent deformation was calculated for each loading cycle, by subtracting the elastic component of the settlement from the total settlement. The permanent deformations per loading cycle were then added cumulatively, to obtain the cumulative permanent deformations / settlements with increasing number of loading cycles. Figure 8 demonstrates the variation of cumulative permanent deformations with the number of loading cycles for all the cases considered in this study. The variation of the traffic benefit ratio, TBR, as defined earlier, for different geocell configurations is also presented in Figure 9.

Figure. 7 Typical pressure-settlement pattern from repeated loading for the case of geocell reinforced bed ($h/D=1$, $b/D=4$)

Figure 8. Variation of cumulative permanent deformations with number of loading cycles for various cases

Figure 9. Variation of traffic benefit ratios with settlement ratios for different geocell sizes

The unreinforced subgrade was tested for only few loading cycles as the prescribed maximum amount of settlement ($s/D > 50\%$) was reached at this stage. It is clear from Figure 9 that the permanent deformations of geocell reinforced beds are much less when compared to the unreinforced subgrades. This reduction is as high as 8 fold between unreinforced case and geocell reinforced case ($h/D=1, b/D=4$). It is to be noted here that the permanent deformations are higher for the case of $h/D=0.5$ with $b/D=4$. The higher permanent deformations, in this case, can be attributed to the least flexural stiffness of the geocell mattress available compared to the other cases. It can also be inferred from this figure that for obtaining higher structural support for the pavement layers, the geocell height should be adequate enough to provide resilient behavior. The geocell with $h/D=1$ is providing highest resilient behavior during the repeated traffic loading in this study.

From Figure 9, the traffic benefit ratio (TBR) at 10% settlement ratio are observed to be as high as 45 for $h/D=1; b/D=4$ case; 35 for $h/D=0.67; b/D=4$ case, 12 for $h/D=0.67; b/D=3$ case and 8 for $h/D=0.5; b/D=4$ case of geocell reinforced sections. Hence, it can be summarized that the geocell of sufficient size (b) and thickness (h) will provide a higher traffic benefit ratio for a given level of traffic loading conditions.

Further study is required to understand the optimal benefits from the critical geocell geometry. It is also important to determine the depth of this kind of reinforcement and number of layers of reinforcement for optimum performance.

7. CONCLUSIONS

From a large scale cyclic model tests on unreinforced and geocell reinforced beds, following conclusions can be drawn:

1. Geocell can be used as reinforcement in pavement subgrade layers to increase the stiffness of the subgrade.
2. Geocell reinforcement reduces the plastic settlements, referred as rutting on the pavement surface by providing lateral confinement to the infill soil. The reduction in permanent deformation is observed to be as high as 8 fold for the case of geocell size $h/D=1, b/D=4$ versus the unreinforced bed at 5% plate settlement.

3. The traffic benefit ratio, TRB was observed to be as high as 45 for the case of geocell size $h/D=1$, $b/D=4$ versus 8 for the case of geocell size $h/D=0.5$, $b/D=4$ at 10% plate settlement. The lower TRB for the thin geocell layer is attributed to the flexural stiffness of the geocell mattress offered to support the cyclic loading. Hence, it is important to choose an optimum size geocell for higher structural support for a given traffic loading system.

4. Further systematic study is required to completely understand the geocell material in pavement layers such as base and subbase layers with aggregate infill.

ACKNOWLEDGEMENTS

The authors would like to express their appreciation to STRATA Geosystems India Pvt. Ltd. for providing the geocell material for this research.

Secondary Containment Retrofitting Using a Bituminous Geomembrane

Kurt Liebe, P.E., Chevron, USA, KLiebe@Chevron.com

Tarik Hadj-Hamou, Ph.D., P.E., Strategic Engineering and Science, THadj-Hamou@sesinonline.net

ABSTRACT

The City of Portland (OR) requires that bulk fuel terminals install impervious secondary containments (i.e. liners) around tanks or facilities built after 2004. To satisfy this requirement when planning to replace a group of tanks with two large tanks at its Willbridge Terminal in Portland, (Oregon) Chevron compared different liner options. The site is essentially flat and numerous tanks, pipelines, and ancillary structures exist within the secondary containment so any earthwork to cover a liner or promote drainage would have been very difficult. The number of penetrations, pipe support, and pipes crisscrossing the facility favored a liner that could be pieced together and seamed easily. An exposed liner consisting of a 160 mil Bituminous Geomembrane was ranked as the optimum solution. The City of Portland approved the design and the liner was installed in 2010 and has worked to the satisfaction of the Terminal operators. The paper describes the selection process, design, installation, and performance of the geomembrane thus far.

1. INTRODUCTION

1.1 Background

The Chevron Willbridge Terminal (the Terminal) is located in Portland, Oregon near the Willamette River and stores refined petroleum products. There are currently 11 light product tanks, 10 lube oil tanks of smaller diameter, and 3 waste tanks. In service for over a hundred years, the tanks at the Terminal are of varying sizes and fabrication styles (from riveted to welded plates as shown on Figure 1). Products are received and shipped via truck, pipeline, and marine vessels.

To manage inventories and dispense the products a large number of pipes crisscross the Terminal as shown on Figure 2. Drain inlets, pumps, electrical panels, electrical conduits and other appurtenances are also located with the secondary containment. The Terminal does not offer much topographical relief and is essentially flat. The stormwater drainage system consists of a series of drain inlets connected by pipes to an oil-water separator prior to connecting to the City of Portland sewer system. The soil at the Terminal is mostly sand and therefore stormwater rarely ponds around the tanks.

In 2008 Chevron decided to refurbish part of the Terminal and replace a series of small and relatively old tanks with two new tanks. The location of the two new tanks is shown on Figure 3. These two tanks (Tanks 163 and 163) were designed with the most current Chevron State of Practice and include double bottoms which mean that they are constructed on top of concrete slabs. However, replacing existing ASTs with new ones triggered the 2004 Stormwater Management of the City of Portland Department of Public Works and described in the next section.

1.2 Regulations

At the Federal level, secondary containment system for aboveground storage tanks (AST) at terminals and refineries are regulated by the Clean Water Act as amended by the Oil Pollution Act of 1990. The requirements are detailed in the Spill Prevention, Control, and Countermeasures (SPCC) and Facility Response Plan regulations.

At the state level, Oregon has adopted the International Fire Code that governs AST containing motor vehicle fuel. A permit from the state fire marshal is required for gasoline and diesel fuel tanks with a total storage capacity of more than 1,000 gallons (gal).

At the local level (City of Portland) the requirements for secondary containment are detailed in the City of Portland Stormwater Design Manual (2004). The requirements for bulk fuel terminals are:

- A secondary containment equal to 100 percent of the product's larger container or 10 percent of the total volume stored, whichever is larger;
- An impervious floor within all containment areas. Floors shall be sealed to prevent spill from contaminating the groundwater;

The local requirements are in fact more stringent than the Federal and State requirements for the secondary containment since they specify that an "impervious floor" shall be installed. To achieve this requirement, Chevron contemplated the options available to construct and or install an "impervious floor" around Tanks 163 and 164 at the Terminal and performed a feasibility analysis based on a set of criteria to select the optimum option.

2. SECONDARY CONTAINMENT SELECTION

2.1 Liner Options

Three main groups of liner options were considered for use at the Terminal:

- **Flexible Geomembranes.** These include resin-based geomembranes (HDPE, LLDPE, PVC, etc.), Bituminous Geomembrane, and Geosynthetic Clay Liner (GCL). Resin-based geomembranes are manufactured in a plant and brought to site for deployment and installation. They tend to be relatively thin (40-100 mil) sensitive to ultraviolet and cannot handle direct equipment traffic. Therefore they need to be protected with a soil cover. Bituminous geomembrane also manufactured in plant are very sturdy and resistant to ultraviolet and offer high penetration resistance. Consequently they do not need to be protected with a soil cover. GCL manufactured offsite and need to remain hydrated to be an effective barrier to petroleum product. They also need to be protected with a soil cover.
- **Structural Liners.** These include concrete, shotcrete, and asphalt concrete. These liners are constructed on site using mixes manufactured off-site. They are resistant and sturdy liner systems that do not require soil cover protection.
- **Soil based liner or soil treated liner.** These liners are all manufactured on site. The amendments (bentonite, cement, etc.) are brought to the Terminal and worked into the existing soil to create the liner system. The concept is to reduce the permeability of the soil in the secondary containment. They do not need a protective soil cover if thick enough and can fit the constraints of the site topography thereby not affecting drainage patterns.

Each liner present advantages and disadvantages and cost from few cents per square foot to few dollars per square foot. Therefore, to assess the benefit of each one and select the optimum liner for the Terminal, an evaluation process was established based on a set of selection criteria developed through review of available lining technologies and discussion with Chevron personnel.

2.2 Selection Criteria

A series of criteria were established for the Terminal and the project under consideration.

Three groups of criteria were established:

- Constructions and operational
- Performance
- Economic and regulatory

2.2.1 Construction and Operational Criteria

The Terminal is an operating facility and the new tanks will be constructed in an area previously developed and in the middle of existing ASTs. Therefore, the design and the construction must account for site conditions such as:

- Limited space to work and spread materials and equipment.
- Different activities ongoing at the same time: concrete, metal work, piping layout, electrical work, and liner installation.
- Presence of existing pipes, electrical conduct, and their supports.
- Numerous penetrations into the ground (conduits, pipes) that will need to be made water tight.
- Presence of appurtenances on the floor of the secondary containment system such as electrical control boxes, pumps, catwalks, concrete supports for pipes, etc.
- A topography almost "flat" which does not allow for easy regrading to facilitate drainage.
- Location of the drainage inlet at the ground surface.

The Terminal is a functioning revenue generating facility and this function should not be affected by the secondary containment system installed around the two new AST's. Therefore, operational flexibility and needs are a serious concern for the operator and must to be considered.

Some of those needs include:

- Possibility to get close to the tanks using standard equipment such as pick-up trucks and forklifts.
- Ability to easily and quickly repair any damage to the lining system, ideally using Chevron personnel or a local contractor.
- Improve or modify other portions of the Terminal and extend the new liner easily.
- Easy cleanup of any accidental spill.

Other criteria related to construction and operations include:

- Scheduling. The option selected must provide the contractor with flexibility so it can be installed in phases if needed and when possible based on weather, schedule of specialty subcontractors, and other factors. Ideally the liner should to require a specialty installer and could be installed by the general contractor.
- Ease of installation. To fit under the piping system, around penetration, around the tank foundation, and generally fit the complicated geometry the liner should be easy to cut and piece together.
- Stormwater management. Considering the weather conditions in Portland, a liner that can be installed in humid air or light rain conditions and that will facilitate drainage is preferred. Liners that need to be protected with a protective layer of soil will remain soggy and muddy and may even freeze during the winter. By contrast an exposed liner allows easy flow of water towards the drain system leaving the Terminal dry.
- Post spill clean-up. Following an accidental spill the operator needs to be able to clean-up the spill as quickly as possible and restore the functionality of the Terminal. Exposed liners are preferable over soil-protected liners since the product can be pumped rapidly and the area affected contained easily.

2.3 Performance Criteria

It is assumed herein that all the options will provide the degree of hydraulic control required by the regulation (i.e., "an impervious secondary containment"). However, other performance criteria are important to the operator namely trafficability, resistance to chemical and physical attacks, resistance to ultraviolet rays, and weather.

2.3.1 Financial and Regulatory Criteria

Financial considerations include capital costs and operations and maintenance costs. Capital costs are all the costs related to the design and installation of the liner system. Operations and maintenance cost include the anticipated cost related to maintaining the liner but also the extra cost associated with operating in a terminal with a liner system installed. For instance size and weight limitations for equipment that can circulate over a geomembrane may result in an increase in cost.

Regulatory approval is a critical element in designing a liner system. Some liner options are usually easier to get approved than other because of personal biases and experiences of the regulators.

2.4 Selection Matrix

The liner options and criteria were organized in a matrix where each column represents a liner option and each row is a criterion. Each criteria was assigned a number ranging from 1 (very good) to 4 (poor) and each option was 'graded' per each criterion. These grades were assigned based on both a qualitative and quantitative basis. For example, "construction costs" are quantifiable and the cheapest liner to purchase and install was given a '1' whereas the most expensive was given a '4'. By contrast "operational flexibility" is a subjective criterion and the grade assigned to each liner option was done using subjective and qualitative data based on personal experience and discussion with the operator. Therefore some criterion may vary from terminal to terminal and from operator to operator. To identify the optimum liner option the grade assigned to each criterion were summed and the optimum option was the option with the lowest grade.

Table 1 shows that the Bituminous Geomembrane was the optimum option for the project and was therefore selected.

3. DESIGN

As shown on Figure 3, Tanks 163 and 164 were constructed over the footprints of older smaller tanks that were decommissioned and demolished. Secondary containment of the Terminal is provided by a concrete wall that surrounds

it. However, this secondary containment provides for lateral containment per Federal and State regulations, as well as local regulations up to 2004. To provide for 2004 local regulations, a secondary containment had to be provided for Tanks 163 and 164. The areas corresponding to these volumes were lined with the Bituminous Geomembrane to provide the required “impervious floor”. A berm was laid out to provide for containment around the tank as shown on Figure 4 for Tank 163.

The areas within the berms were regraded to provide for drainage towards the existing drain inlets. Because of the overall flatness of the site, there was little latitude and the final slopes are on the order of ½ to 1 percent. However, because the subgrade is a firm gravelly sand (as seen on Figure 1) settlement is not expected and the slopes are expected to remain over time. Furthermore, the very low Manning coefficient of the Bituminous Geomembrane facilitates flow of stormwater toward the drain inlet. To address construction needs and the nature of the subgrade (gravelly sand) a 160 mil thick Bituminous Geomembrane was specified for the site.

A set of continuation documents, a Technical Specification, and a Construction Quality Assurance Plan was issued for grading and installation of the 160 mil thick Bituminous Geomembrane at the Terminal.

Table 1: Matrix of liner options and selection criteria

Liner Type	Flexible Membranes				Structural Liners					
	LLDPE or HDPE Geomembrane with cover	Geosynthetic Clay Liner with soil cover	Bituminous Geomembrane	Spray-On Liners	Asphalt	Shotcrete Concrete	Soil Bentonite	Soil Cement	Chemical Grouting	Compacted Clay Liner

4. INSTALLATION

Chevron had retained a specialty industrial facilities contractor to construct Tanks 163 and 164. The work involved demolishing the old tanks and associated pipes and equipment, constructing the ring foundations for the new tanks (to install the standard "Chevron double bottom"), building the tanks, installing the new pipes, valves and other systems. Because of space limitations and time constraints, the work proceeded from one tank to the next with different activities performed depending upon availability, Terminal operations, and weather conditions.

The construction schedule was complex and installing the liner was not identified as a single task for each tank to be performed in one continuous period at a given time. Rather, lining was considered a "catch-up" task that would be started and stopped when time and other activities allowed. Because the 160 mil Bituminous Geomembrane is easy to cut and seam, is very sturdy, and has great resistance to puncture, its installation does not require specialty installer, it can remain exposed, and can be driven on it was the ideal geomembrane for this project. Relatively heavy weight vehicle traffic was permitted on the installed Bituminous Geomembrane as shown on Figure 5. This allowed the contractor to keep working in and around the tanks following placement of the Bituminous Geomembrane and gave him scheduling flexibility.

Workers from the contractor personnel were trained by the manufacturer to lay and seam the Bituminous Geomembrane. Because seaming Bituminous Geomembrane is similar to seaming roofing material, special equipment is not required. A roofing torch, trowels, and a weighted roller to press the seam are all that is required. A crew was trained and was very effective but they could also perform other activities when liner was not being installed and they were needed elsewhere.

During installation the same standards of quality assurances used for other geomembranes (HDPE, LLDDP, PVC, etc.) were followed. Panels were numbered and their location recorded. The seam consists of an 8 inch overlap welded together by melting together the bitumen over the overlap and pressing the two edges together and therefore does not have the air channel seen in HDPE or LLDPE seams. Integrity testing is different from other geomembranes. Continuity of the seam is monitored by CQA personnel. The integrity and water tightness are spot checked with either the vacuum box or an ultrasound sensor. The ultrasound sensor monitors the thickness and continuity of the weld across the 8 inch wide seam. The ultrasound monitor was used for this project and a one foot segment was tested every 50 ft. of seam. Every seam was tested at least once regardless of its length.

The Bituminous Geomembrane is easily connected to concrete or steel using a bitumen-sealant mix that is applied to the concrete or steel. The Bituminous Geomembrane is then attached by heating the asphalt as shown on Figure 6. An advantage of all geomembranes is their flexibility and the ease with which they can be laid under pipes and around penetrations. As shown in Figure 7, some areas of the Terminal were congested with pipe, concrete walls and supports.

The installation was performed in late 2009 and early 2010 during the rainy season but proceeded without problems. Figure 8 shows portions of the secondary containment at Tank 164 in July 2012.

5. CONCLUSIONS

To satisfy the requirement of the City of Portland for secondary containment around new petroleum product ASTs, Chevron evaluated different liner options when replacing a series of smaller tanks new with larger capacity tanks. An evaluation of options with respect to a set of criteria led to the choice of a Bituminous Geomembrane as the optimum solution. The 160 mil thick Bituminous Geomembrane selected and installed in 2009-2010 in the secondary containment has performed to the satisfaction of the operators since. Chevron is planning to retrofit another area of the Terminal this fall (2012) and will use the same Bituminous Geomembrane.

ABSTRACT

Hybrid reinforced soil structures combine geogrids and steel meshes together to build high MSE walls or slopes, considering the geogrids as “primary reinforcement” and the wire mesh units (produced with an “integrated tail” of wire mesh) as a “secondary reinforcement” and “facing units”. In situ and laboratory results indicate that hybrid MSE structures afford high flexibility, strength and energy absorption capacity, making them ideal for the construction of structures with relevant heights in highly seismic areas. A case history is presented of a reinforced soil hybrid structure, over 80 m high, in Sikkim, India, which has recently withstood an earthquake with a 6.9 magnitude with no visible damage. The seismic resistance of the structures is analyzed while the design method in seismic conditions is compared with the actual acceleration withstood during the earthquake. Results indicate that hybrid reinforced soil structures afford very high factor of safety against seismic induced failure.

1. INTRODUCTION

Reinforced soil walls offer economic advantages over conventional mass gravity wall systems as the height of the wall increases. The cost of reinforcement constitutes an important part of the total cost of a reinforced soil retaining wall and can be as great as about 25% of the cost of the wall, depending on the wall height, backfill type, and design loading conditions. The present paper addresses the possibility of reducing the total cost of a reinforced soil wall by optimizing the vertical spacing of reinforcing geosynthetics elements, while ensuring the required Factor of Safety for the whole structure.

The reinforcement load in reinforced soil walls is commonly calculated from classic active earth pressure theory using the so-called contributory area approach. In this approach, the lateral earth pressure distribution from Rankine or Coulomb earth pressure theory is integrated over a distance equal to the spacing between reinforcement layers and the resultant load is assigned to the target reinforcement layer. In a tall retaining wall, the reinforcement load can vary with depth over a wide range of values. In such a case, more than one reinforcement type or spacing pattern along the wall height may be desirable.

Generally speaking a reinforcing geosynthetics elements with 200 kN/m ultimate tensile strength costs less than twice of a reinforcing geosynthetic with 100 kN/m ultimate tensile strength: hence a solution with half number of double strength reinforcing layers will cost less than a solution with a double number of half strength reinforcing layers.

International research and state-of-the-art practice have demonstrated that the former solution, if properly designed, ensures the same or even higher Factors of safety than the latter solution. In particular, very tall geogrid reinforced soil walls have been built with 2 – 3 m vertical spacing between the primary reinforcing layers, even in very highly seismic areas, with excellent results both in terms of total costs and structural safety.

2. HYBRID REINFORCED SOIL STRUCTURES

There is a long history of designing and providing reinforcement materials for mechanically stabilized earth (MSE) structures, through the use of double twisted wire mesh units able to provide “stone facings” or vegetated external facing.

Gabions are used since more than 100 years for the construction of gravity type retaining structures in all environments and climates. They are rectangular cages made of hexagonal woven steel wire mesh laced together and filled with stone. Gabions have been used for a variety of application in sectors of housing and commercial projects, roads and railways, bank stabilization, erosion control, architectural cladding and noise barriers, etc.

However when the height of the wall increases, gravity type retaining structures become soon impracticable, and there is the need to shift to MSE structures.

For building MSE structures it is possible to combine gabion units and wrap-around facing units (made up of double twisted wire mesh) with geogrids, considering in this case the geogrids as “primary reinforcement” and the “integrated tail” of the facing units as a secondary reinforcement (see Figure 1). In these “hybrid” structures the primary reinforcement is used to provide the tensile forces required to ensure global stability with the desired Factor of Safety; while the facing units, which are produced with a “integrated tail” of double twisted wire mesh as a secondary reinforcement, provide the local stability at the face, ensuring that no local mechanism of direct sliding, pullout or rotational failure can occur.

Figure 2 (from Hatami et Al, 2001) shows a typical tiered hybrid reinforced soil structure, with vertical gabion facing units at bottom and steep wrap-around facing units at top; it is possible to note that the primary reinforcing geogrids are always vertically spaced as a multiple of the height of the facing units.

Very tall hybrid structures have been built all over the world according to this approach; the reinforced soil hybrid structure under construction in Sikkim (India), later presented in this paper, is over 80 m high and it has recently withstood an earthquake with a 6.9 magnitude with no visible damage.

Hybrid structures usually include a vertical spacing of reinforcement that is typically multiple of 0.74 m (29 inches) - 1.00 meter (40 inches), i.e., multiple of the height of a wrap-around unit or of a gabion unit.

However, in USA, the FHWA and AASHTO limit the vertical spacing of the reinforcement to 0.80 m (32 inches). Such requirements have also affected international MSE practice as many countries follow the USA guidance. Research and state-of-the-art practice presented in this paper suggest that these limits have no real meanings and should be removed, at least for the hybrid reinforced soil structures described in this paper.

Fig. 1. Scheme of hybrid reinforced soil structures

Fig. 2. Example of tiered wrap-around / gabion faced hybrid reinforced soil structure (from Hatami et Al, 2001)

Hybrid MSE structures are versatile modular system used for soil reinforcement applications such as mechanically stabilized earth (MSE) walls and reinforced slope systems (RSS). They are used for commercial and industrial projects, road works, erosion control and bank stabilization.

Hybrid MSE structures are the most detailed and complete reinforced soil system present on the market, with the possibility of using either just the double twist wire mesh reinforcement or of combining it with facing elements of high-strength polyester geogrids in the case of very high works which are subject to large loads. The numerous possibilities for construction of the outer face enables the best choices to be made in every situation both from a technical-environmental point of view and in consideration of the landscaping requirements.

For the selection of the most suitable solution, the fundamental aspects for the correct design of MSE hybrid structures with geogrid primary reinforcement shall be carefully considered: in order to carry out a structural analysis of such structures it is required to check a large number of load conditions and geometries in accordance with the most typical and frequent situations which occur in walls and slope stability analyses.

Hybrid structures rely upon the steel mesh and the geogrids placed horizontally within the slope or wall, with backfill compacted upon them. The gabion or wrap-around facing is fully integrated with the steel mesh reinforcement, which works based on the friction acting along the surface of the wire and, more importantly, on the mechanical interlocking properties of the backfill. Some proprietary hybrid MSE systems have been evaluated and approved by HITEC (with the collaboration of AASHTO and FHWA) for 75 years design.

Figure 3 shows in details the facing units used in MSE hybrid structures:

- the gabion unit comprises a continuous horizontal panel of woven wire steel mesh, faced at one end with a gabion box, formed from hexagonal, PVC-U coated, galvanized, double twist woven steel mesh; the front and top of the gabion box are folded during manufacture; the back and sides of the gabion box are formed from a separate piece of the mesh, which is folded and fixed to the horizontal panel during manufacture; additional, separate, diaphragm (partition) mesh panels can be fixed on site to the gabion box facing as required by the design; this creates rectangular shaped cells used for stone confinement; the gabion element is filled with hard durable rockfill, while the tail is then sandwiched between layers of compacted backfill material, thereby reinforcing it; having the tail as an integral part of the gabion box removes the need for any on-site connection or pinning, where errors during installation could occur due to incomplete connection, or reduced pinning frequency; hence the gabion facing unit is rapid to construct, and can even reuse site won materials when suitable; consecutive layers of gabion units are then constructed to form reinforced soil retaining structures of almost any height when used in conjunction with high strength geogrids.

- the wrap-around unit comprises a single length of double twist mesh that forms the base, the sloping face and the top part (that is the wrap-around length) of the unit; a bio-degradable or synthetic blanket is installed immediately behind the sloping faces of the unit to control erosion and to promote rapid vegetation establishment; a wedge of topsoil is placed behind and in contact with the blanket to provide a moisture and nutrient reservoir, essential for successful vegetation; no external support or shuttering is required when installing the wrap-around units, thus increasing considerably the speed of the installation; a steel reinforcement mesh is factory assembled to provide rigidity to the face; bioengineering techniques like live staking and brush layering can be used to create a more natural look to the structure.

Hybrid MSE structures afford important advantages:

- permeability of the front face, guaranteeing drainage of the backfill;
- flexibility, enabling the structure to tolerate differential ground settlement without compromising structural integrity;
- versatility, which allows the formation of a structure with vertical, battered or stepped front face as required and minimization of environmental impact.
- durability: testimonials of existing gabion structures built since 1894 and still in operation prove that such structures can be safely designed for 120 years design life;
- economy and simplicity: the ease of construction does not require specialist labour force or special equipment; gabions are filled with natural or quarried stones obtained locally, and minimum foundation preparation is needed;
- significant sound proofing characteristics (18-28 decibel);
- structural safety in case of fire near the front face;
- reduction of environmental impact through the use of vegetation incorporated into the front face of the structure.

Fig. 3. Details of gabion facing units and wrap-around facing units used for MSE hybrid structures

3. BACKGROUND RESEARCH

The influence of a single reinforcement type with a given stiffness and length on wall response has been the subject of previous investigations.

Ho and Rowe (1996) and Ho et. al. (1996 and 1997) found that the reinforcement stiffness, vertical spacing and length to wall height ratio, L/H, are important parameters that influence the wall displacement response. Rowe and Ho (1996 and 1997) found little variation in the magnitudes of reinforcement load and soil stress for L/H values larger than 0.7. It is worth noting that the ratio L/H = 0.7 is the minimum reinforcement length ratio recommended by FHWA (1997)] and AASHTO (1998)] design guidelines for static stability of reinforced soil walls. A design chart to predict wall deformations as a function of L/H and reinforcement type (i. e., extensible geosynthetic or inextensible metallic) appears in the current FHWA (1997) and AASHTO (1998) guidelines.

Ho and Rowe (1996) concluded that placing equally spaced reinforcement layers with L/H = 0.7 is an efficient reinforcement distribution and recommended over other distribution patterns of reinforcement in reinforced soil walls. Rowe and Ho [13] showed that the magnitude of wall lateral displacement is influenced by the soil friction angle and a reinforcement stiffness factor, Λ , defined as

$$\Lambda = J / (K_a \gamma H S_v) \quad [1]$$

where:

J = reinforcement stiffness,

K_a = Rankine active earth pressure coefficient,

γ = soil unit weight,

H = wall height,

S_v = vertical spacing between reinforcement layers.

Helwany et al. (1999)] used a calibrated finite element model to investigate the effects of wall height, backfill type, and reinforcement stiffness on the response of reinforced soil walls with a hard facing. They found that the stiffness of geosynthetic reinforcement has an important influence on wall displacement response when the backfill shear strength and stiffness values are low.

Hatami et al. (2000) and Hatami et al. (2001), by using numerical simulations carried out with the assumption of plane-strain conditions, show that an alternating reinforcement scheme appears to be a more effective reinforcement arrangement, than grouped schemes with different stiffness combined together. The mixed reinforcement configurations with reduced stiffness toward the wall top did not result in significantly larger lateral wall displacements compared with walls with uniform reinforcement using the stiffest reinforcement type. Another interesting aspect for economic reinforced soil wall design is to reduce the length of every secondary reinforcement layer by 50% while maintaining the same stiffness value. This approach was found to be the best method to reduce the reinforcement supply requirement while maintaining wall serviceability and performance.

The authors demonstrated that the static and deformation behavior of hybrid MSE structures is depending on the following parameters:

1) Reinforcement stiffness and arrangement: the stiffness J of planar reinforcement materials (including geosynthetic products) is normally expressed in terms of the tensile force per unit width of reinforcement, T, for unit strain (i. e., units of kN/m) as (Figure 4):

$$J = T / \epsilon \quad [2]$$

where ϵ is the tensile strain in the reinforcement. The reinforcement is modeled as plane-strain sheets with the same cross-sectional area, perimeter and stiffness values as those of an equivalent number of cable elements per unit length of the wall (i. e., perpendicular to the wall plane). The reference reinforcement stiffness values are chosen from properties reported for woven wire mesh and polyester geogrid reinforcement products.

Figure 4. Mechanical response parameter definition for reinforcement.

2) Reinforcement quantity: the amount of reinforcement in each wall is quantified using the reinforcement stiffness J , length L , and vertical spacing S_v . The amount of reinforcement supply for a wall of given height, H , is proportional to the ratio $(J L / S_v)$. The demand from lateral earth pressure behind the wall is proportional to $(K_{ah} \gamma H^2)$, where γ is the backfill unit weight and K_{ah} is the horizontal component of the active Coulomb earth pressure coefficient given by:

$$K_{ah} = K_a \cos \left[\delta + \left(\alpha - \frac{\pi}{2} \right) \right] \quad [3]$$

Where

$$K_a = \frac{\sin^2(\alpha + \varphi)}{\sin^2 \alpha \sin(\alpha - \delta) \left[1 + \sqrt{\frac{\sin(\varphi + \delta) \sin(\varphi - \theta)}{\sin(\alpha - \delta) \sin(\alpha + \theta)}} \right]^2} \quad [4]$$

In equations (3) and (4), φ is the backfill soil friction angle, δ is the friction angle between the backfill and a hard facing, α is the wall batter angle from horizontal (i. e., $\alpha = \pi/2 + \beta$) and θ is the backfill surcharge slope. The active earth pressure coefficient is considered in the lateral earth pressure demand formulation because a plastic, active zone typically develops in reinforced zones with geosynthetic reinforcement materials due to their relatively low stiffness values (i. e., compared with metallic reinforcement stiffness).

The reinforcement ratio, R_λ , is introduced as a non-dimensional, single-valued parameter to quantify the reinforcement supply-to-demand ratio for a wall of given height H and backfill material as:

$$R_\lambda = \frac{\sum_{i=1}^n \frac{J_i l_{fi}(\lambda) L_i}{S_{vi}}}{K_{ah} \gamma H^2} \quad [5]$$

where J_i , L_i , and S_{vi} are the stiffness, length and vertical spacing (contributory height) of reinforcement layer i , respectively, and, n denotes the total number of reinforcement layers.

The length factor, l_{fi} , of the reinforcement layer i is defined as:

$$l_{fi}(\lambda) = 1 + \frac{L_i/H - \lambda}{L_i/H + \lambda} \quad [6]$$

where λ is a reference reinforcement length-to-wall height ratio that corresponds to an optimum L/H ratio value for the stability of reinforced soil walls. The value for λ is taken as 0.7 in accordance with the results of previous numerical and experimental studies, as above reported. However, a lower value for λ (i. e., optimum L/H ratio for wall stability) may be considered for higher backfill friction angles. The mathematical expression of equation (6) represents the direct influence of reinforcement length on wall stability for the range $L_i / H \leq \lambda$ and its reduced effect for $L_i / H > \lambda$.

The parameter R_λ defined in equation (5) includes both reinforcement supply and backfill friction angle which are the two most important parameters influencing the horizontal displacement of reinforced soil walls. Specifically, a higher

magnitude for the parameter R_x indicates a stronger backfill and/or greater reinforcement supply in the wall, both of which would result in lower wall lateral displacement. Equation (5) can be understood to be an indicator of the reinforcement cost.

Hatami et Al (2000) and Hatami et Al (2001) discuss the effect of the above listed parameters, coming to the following conclusions:

1) Effect of reinforcement stiffness arrangement:

uniformly stiff reinforcement over the entire height shows the smallest amount of lateral displacement, while replacing half of the reinforcement layers with a less stiff reinforcement material increases the wall lateral displacement.

However, the maximum displacement value and the displacement distribution pattern depend on the reinforcement arrangement: placing the less stiff reinforcement in the upper half of the wall results in local bulging of the facing in the upper half of the wall height; while the wall lateral displacement within the lower half does not increase noticeably; placing the less stiff reinforcement in the lower half of the wall height results in a considerable increase in wall lateral displacement in the lower half of the wall height.

Distributing the less stiff reinforcement material evenly between stiff reinforcement layers results in a wall displacement profile similar to the displacement response of uniformly reinforced wall but with larger lateral displacement magnitude at all reinforcement elevations; however the amount of displacement increase is uniform over the wall height and about half the maximum value observed in grouped reinforcement arrangements.

Therefore, an alternating reinforcement scheme appears to be a more effective reinforcement arrangement than grouped schemes with the same reinforcement ratio value to limit wall lateral displacement.

A comparison of displacement results shows the influence of using an alternating reinforcement arrangement with the same average reinforcement stiffness as an otherwise, identical configuration with uniform reinforcement: the alternating reinforcement configurations show only a slightly larger amount of deformation at end of construction compared with uniformly reinforced walls; accordingly, the deformation response of walls with alternating reinforcement stiffness arrangement can be considered to be practically the same as the response of uniformly reinforced walls with identical reinforcement ratio values.

For a wrapped-face wall the intuitive scheme of reducing reinforcement stiffness with height appears to be a cost-effective configuration that would not result in a significantly larger wall displacement compared to the alternating scheme. However, the reduction of reinforcement stiffness with elevation using an alternating reinforcement arrangement is more desirable (i. e., compared with grouped schemes) to avoid local, excessive deformation of the facing along the wall height.

2) Gabion facing vs. battered wrapped-face wall:

It is intuitive that an inclined wrapped face at 20° to the vertical usually generates less lateral displacement at the end of construction than a wall constructed with a vertical gabion facing. However the pattern of displacement profiles between wrapped-face and gabion facing walls is quite different: the maximum end-of-construction displacement occurs much higher up the face of the gabion wall (approx. at $0.75 H$) compared to the wrapped-face wall (approx at $0.35 H$). The displacement of the wrapped-face wall is considered to be due to lateral spreading of the backfill under soil self-weight, while the pattern of displacement for the vertical gabion wall is mainly due to rotation of the facing column about the toe.

3) Effect of reinforcement arrangement and vertical spacing:

the displacement response of a uniformly reinforced wall is practically indistinguishable from the response of a corresponding wall with grouped reinforcement configuration where the stiffness values of the two reinforcement groups are not substantially different (e.g. with a variation of J within 10% and difference in $R_{0.7}$ within 5%).

The combined influence of reduced reinforcement length and tiered wall construction results in greater facing displacements; however, the combined influence of tiered wall construction and reduced reinforcement length is more effective in controlling wall deformation than a battered wrapped-face structure constructed with a wider reinforcement spacing.

The above results suggest that reducing reinforcement stiffness with height while maintaining constant vertical spacing is recommended over increasing the spacing with height (as reported for a number of reinforced soil walls constructed in the past) to limit the facing lateral displacement and ensure the stability of the structure.

4) Effect of reinforcement length:

Different reinforcement schemes have been investigated, considering walls including primary reinforcement with $J = 8000 \text{ kN/m}$ and a less stiff secondary reinforcement with $J = 2000 \text{ kN/m}$:

- only primary reinforcement with uniform reinforcement length
- the secondary reinforcement is placed in an alternating scheme with the primary reinforcement; the length of every secondary reinforcement layer is equal to that of the primary reinforcement;
- the secondary reinforcement is to half length of the primary reinforcement and is placed alternating with the full-length, stiff primary reinforcement.

Results show that the magnitude and profile shape of lateral displacements of walls with the above reinforcement configurations are only marginally different.

It can be concluded that reducing the length of reinforcement for every secondary reinforcement layer is a viable strategy to reduce the required amount of reinforcement with little impact on the displacement response of the wall. The reduction in wall lateral displacement will be greater by adopting a long-stiff, short-secondary reinforcement scheme for the same total length of reinforcement material.

5) Effect of reinforcement ratio on wall displacement:

the maximum wall lateral displacement $(X_d)_{\max}$, normalized to reinforcement vertical spacing S_v , shows a consistent trend of reduction in magnitude with reinforcement ratio value (see Figure 5). The presence of S_v in the normalized parameter $(X_d)_{\max} / S_v$ emphasizes the significance of reinforcement spacing in the magnitude of wall lateral displacement compared with the influence of reinforcement length and stiffness. The alternating reinforcement length schemes provide the lowest wall displacement response magnitude for a given reinforcement ratio value. The magnitude of wall lateral displacement is less sensitive to reinforcement configuration for greater reinforcement ratio values.

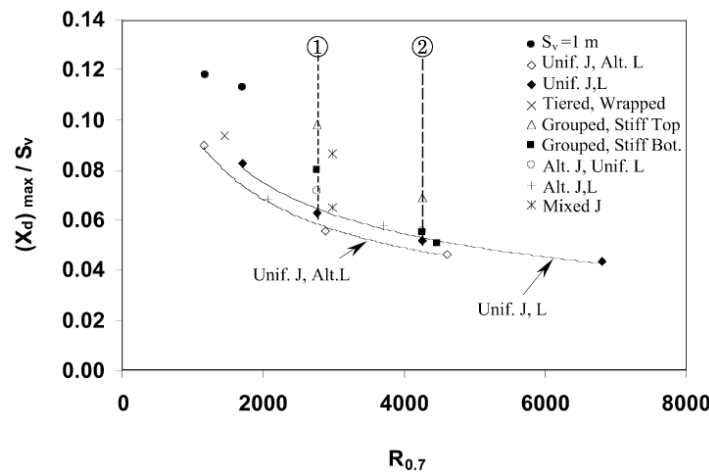

Figure 5. Variation of normalized wall lateral displacement with reinforcement ratio (from Hatami et Al, 2001)

From the above listed research it is evident that the design layout with long and stiff primary reinforcement alternated with short and less stiff secondary reinforcement (as shown in Figures 1 and 2) is the most effective option for hybrid MSE structures. The vertical spacing of the primary reinforcement equal to 2 – 3 times the height of the facing units (either gabion units or wrap-around units), with the secondary reinforcement spaced at each facing unit, affords an optimal distribution of reinforcement which minimizes the deformations of the structure, provided that the stiffness of primary reinforcement, the reinforcement ratio and length factor are properly designed.

This concept was extensively used in the design of two recent projects of high walls constructed in Sikkim and in Albania, where the use of combined reinforcement geometries provided an interesting cost saving benefit compared to the more conventional uniform reinforcement solution. They were designed using mixed reinforcement configurations with high strength geogrids as primary reinforcement and steel mesh as secondary reinforcement and facing unit.

Hence the FHWA and AASHTO limit of 32 inches (800 mm) for the vertical spacing of reinforcement layers should be revised and the vertical spacing should be limited only by design optimization, at least for the hybrid reinforced soil structures described in this paper.

4. CASE HISTORY: SIKKIM AIRPORT (INDIA)

Sikkim came into existence as a state of India in 1975. Due to its land locked scenario the state of Sikkim can only be approached by road. Sikkim is accessible via nearest airport at Bagdogra, which is 120 km from the capital city of Gangtok. Although Sikkim has ample scope of tourism development, due to non availability of an airport; the direct accessibility does not exist. Due to this reason, a new airport is now under construction at Pakyong, which is situated approximately 33 km from Gangtok. The work involves massive cutting and filling earth work. The site of the airport at Pakyong is on a hilly terrain having valleys and spurs with an acquired area of around 200 acres. When fully developed the project will have a 1700 x 30 m runway with turning pads at both ends, suitable for ATR type aircrafts.

The runway strip is planned along N-S direction and the hill is having a natural slope from West (uphill cutting portion) to East (downhill filling portion) as shown in the typical cross section in Figure 6. Since a plane surface is required for the construction of the runway, cutting of uphill portion was done and the same material was filled at downhill portion to get the required level of runway. The constraint that material from cutting should be used in filling was mandatory. As such the entire project was designed in such a way that total volume of cutting shall be equal to total volume of filling. The terrain at site is mainly a mixture of soil and rocks. In upper strata, rock is fragmented and highly weathered. But with depth weathering decreases and soft to hard rock is encountered. Therefore, uphill portion is cut and used for the filling operation. This filling was retained by providing a suitable retaining structure high enough to support and stabilize the filling. Sikkim receives a very high annual rainfall; hence proper drainage system has to be provided along with the conveying structures of the existing creeks. This has been achieved by providing series of catchwater drains and stepped intercepting drains along with gabion cascades. Water from these cascades is finally conveyed outside the site boundary by RCC box culverts, which follows the natural course.

4.1 Technical Considerations and Solution Adopted

Different types of solutions like PCC wall, Masonry wall, Soil Nailing, Gabion Walls, Hybrid MSE walls, were considered for toe walls. Following were the most important parameters specific to this project, based on which final selection of toe wall solution was chosen:

- a) Permeability: the region of Sikkim Airport Project witnesses high amount of rainfall through the year. Hence there will be lot of runoff generated and also the soil will be saturated most of the time; hence the permeability of the structure is very important to reduce the hydrostatic pressure behind the wall in the retained soil. The gabions of hybrid MSE structures are filled with cobbles or quarry stones to porosity in the range of 30% to 40%. This permeability of the front face ensures drainage of the backfill, resulting in less hydrostatic pressure and is thus a suitable option for this project.
- b) Environmental friendliness: one of the most specific requirements is to have an eco-friendly solution for the toe walls, as this area will have direct visibility from runway and terminal building. Hybrid MSE structures are very eco-friendly since they are made up of natural materials filled inside a wire mesh and can be easily vegetated.
- c) Flexibility: the Sikkim Airport Project area is in high seismic activity region. Any structure built will require inherent flexibility to absorb the shocks during seismic activity. Hybrid MSE structures are highly suitable as they are flexible structures which can take large amount of strain and settlements before failure. Flexibility of Hybrid MSE structures helps to accommodate ground settlement without any compromise in structural integrity.
- d) Speed of construction: the project needs to be completed within short duration of time and hence speed of construction is one of the major factors. Hybrid MSE structures can be assembled on site quickly and easily and, since locally available stone boulders are used, the speed of construction is very high.
- e) Cost of construction: use of locally available materials is highly important since it reduces the overall cost of the project by reducing the cost of transportation and delay; hybrid MSE structures are a cost effective solution as the installation is easy and do not require specialized labour and form works.
- f) Foundation considerations: hybrid MSE structures require lesser excavation effort as foundation depth requirement is smaller compared to RCC walls.

Based on all the above criteria, hybrid MSE structures have been selected as the best possible solution as retaining walls in the filling side.

4.2 Design and Construction

The design of hybrid MSE structures has been carried out according to BS: 8006 code, for the static load case, while the seismic load case has been designed as per FHWA code. Load combinations for static load case and seismic load case have been adopted with the appropriate material and loading factors, according to BS 8006 and FHWA, and corresponding loads for various load combinations. External checks like sliding and bearing capacity were performed, and internal checks like reinforcement rupture and pullout; internal stability have been checked according to the “slices method for slip circle analysis” (as per section 7.4.4.3 of BS 8006). Sliding stability at steel mesh and geogrid interface and bulging check at nearly vertical gabion blocks have been calculated for all sections: 3 m length of secondary reinforcement have been considered and all the specified factor of safety requirements were achieved.

Design of primary reinforcement has been based on the properties of bonded geogrids, manufactured with high strength polyester fibers encased in polyethylene coating, selected for the excellent creep characteristics and resistance to

Figure 6. Typical cross section showing cutting and filling operations for Pakyong airport and the hybrid MSE structures for filling support at downstream edge

Figure 7. Design output and typical cross section for the highest hybrid MSE structure at chainage 1640

construction damages; geogrids with tensile strength from 200 kN/m to 800 kN/m have been designed, with vertical spacing up to 2.4 m. Totally 1.7 km length of hybrid MSE structures has been designed and built for supporting the airport runway. The most impressive structure is at Chainage 1640: the hybrid MSE structure consists of a 29 m high

wall with gabion facing at bottom and a 51.35 m wrap-around slope above; an embankment of 6.61m height is present above the structure; thus the total height of the structure, including the embankment, is 86.96m. Design output and typical cross section for the highest hybrid MSE structure are shown in Figure 7. To Authors' knowledge this is presently the highest reinforced soil structure in the world. Pictures of geogrids installation and of two finished hybrid MSE structures are shown in Figures 8 and 9.

5. SEISMIC DESIGN AND BEHAVIOUR

The good performance of MSE structures during earthquake has been documented by Koseki, et.al. (2006). In Japan; nowadays MSE walls are often the preferred construction technique compared to conventional retaining wall structures due to their good resistance to earthquake loading. Even MSE walls have been used to replace conventional structures damaged in earthquakes. Koseki et. al. (2006) presented case histories of different earthquakes from different parts of the world. From the case histories it can be noted that a flexible MSE structures performs better, and that MSE structure perform equally better with rigid structure with deep foundation. MSE structures fail progressively with warning displacements. The soil reinforcement immediately distributes stresses avoiding local concentration leading to ductile-like behavior of MSE structures.

India has been divided in four seismic zones viz. II, III, IV & V as per IS1893-1. Sikkim airport project lies in seismic zone

Figure 8. Geogrids installation at Sikkim airport project

Figure 9. Two finished hybrid MSE structures at Sikkim airport project

IV, classified as severe seismic intensity zone. For 70+m high structures located in seismic zone IV, the use of hybrid MSE structure is highly necessitated. Seismic design has been carried out as per pseudo static method described in FHWA manual. Reduction factors have been considered in calculating the long term design strength of primary geogrid reinforcement from its short term ultimate tensile strength. Seismic design has been carried out for considering load factors = 1.0 for all the loads. For seismic condition the target factor of safety for respective mode of failure is 75 % of static condition as per the guide lines of FHWA. In-house software was used for slip analysis and design. It is a software

developed to perform slope stability analysis using different types of reinforcement and complex design scenarios. The software uses conventional limit equilibrium approach (Bishop, Janbu, and Displacement Method). Internal stability checks like reinforcement rupture and pullout have been checked according to the slices method for slip circle analysis. Additionally hand calculations were performed to check the design. The structure was designed for horizontal seismic coefficient of 0.12.

September 18, 2011, earthquake of magnitude 6.9 was felt across northeastern India (Sikkim), Nepal, Bhutan, Bangladesh and southern Tibet. The earthquake centered within the Kanchenjunga Conservation Area, near the border of Nepal and the Indian state of Sikkim. At least 111 people were killed in the earthquake and most of the deaths occurred in Sikkim. The peak ground acceleration for the earthquake of 6.9 on Richter scale would be 0.354 g. Horizontal seismic coefficient can be worked out as half of ground acceleration (Kramer, 1996). Seismic analyses of full height structure with horizontal seismic coefficient of 0.175 shows that factor of safeties are just more than 1.0. Figure 10 presents the seismic analysis of typical cross section with horizontal seismic coefficient of 0.175, that is 45 % higher than the design seismic coefficient.

This means that hybrid MSE structures afford an inherent Factor of Safety which can be estimated to be approx. 50 % higher than the one resulting from design calculations with the present design Codes.

During earthquake major part of the structure attained more than 60% of height. Structure 1 from chainage 280 to 680 had attained height of 50m by September 2011. A rainfall was received at site before earthquake. It is worth to note that the hybrid MSE structure have withstood an earthquake of 6.9 magnitude with no visible damage. This clearly demonstrates the resilience of hybrid MSE structure in seismic loading condition with higher vertical spacing of primary reinforcement.

Hence it is the Authors' opinion that the limit of 32 inches (800 mm) for the vertical spacing of reinforcement layers, reported in the present AASHTO regulations, should be relooked and the vertical spacing should be limited only by design optimization, at least for the hybrid reinforced soil structures described in this paper.

Figure 10. Seismic analysis of typical cross section with horizontal seismic coefficient of 0.175

6. SUMMARY AND CONCLUSIONS

Hybrid MES structures composed of gabion and wrap around facia with integrated tail can be used for construction of tall structures. The combination of facia made up of double twisted mesh and high strength geogrid are cost effective compared to other solutions. Locally available materials can be used for construction of hybrid MSE structure which reduces the overall cost of the project and delay. The integrated tail serves purpose of secondary reinforcement enabling use of vertical spacing of primary reinforcement up to 3m which is more than mentioned / recommended by FHWA with

due consideration of local stability of facia. Hybrid MSE structures are flexible structures which can bear seismic acceleration without any compromise in structural integrity.

Seismic Performance of Mechanically Stabilized Earth Wall with Lightweight Aggregate (LWA) Backfill

M. Xiao, Department of Civil and Geomatics Engineering, USA, mxiao@csufresno.edu
D. Hartman, and M. Ledezma; Department of Civil and Geomatics Engineering, USA

ABSTRACT

The paper reports a shake table test on the seismic responses of mechanically stabilized earth (MSE) wall with lightweight aggregates (LWA) backfill. A section of a reduced-scale MSE wall was built in a box that was anchored on the shake table. The MSE wall dimensions were 1.5m high, 1.2m deep, and 1.5m long. Five layers of geogrid were used as the reinforcement. The LWA were compacted at 95% of the maximum dry unit weight at the optimum water content. Scaled 1989 Loma Prieta earthquake excitations were replicated by the shake table. The wrap-around MSE wall was instrumented with accelerometers, linear variable differential transformers (LVDT), linear potentiometers, and dynamic soil stress gauges to respectively record the accelerations, wall vertical settlements, horizontal deflections of wall face, and transient effective stresses during the shaking. The results revealed satisfactory seismic performance of the MSE wall with LWA backfill.

1. INTRODUCTION

Mechanically stabilized earth (MSE) walls are widely used in retaining embankments in highway systems. The MSE walls are easier to construct and more economical than the conventional reinforced concrete retaining walls. They have shown the advantage of safety, environmental friendliness, and savings in labor costs, equipment, and time. By and large, they performed well with no evidence of visual damage or with only minor damages during some of the past major earthquakes such as the 1989 Loma Prieta earthquake (M=7.1) (Collin et al. 1992), the 1994 Northridge earthquake (M=6.7) (Sandri 1994), and the 1995 Kobe earthquake (M=6.9) (Tatsuoka et al. 1996). However, major repairs or complete collapse were also reported for some MSE walls in the 1999 Chi-Chi earthquake (M=7.6) (Huang and Tatsuoka 2001), and in the 1995 Kobe earthquake (Tatsuoka et al. 1997).

Lightweight expanded clay and shale aggregates, also known as lightweight aggregates (LWA), are a type of alternative backfill for embankments and retaining walls. Their dry unit weight ranges from 7.1 to 11.0kN/m³ (45 to 70lb/ft³). They are produced in rotary kilns at temperatures over 1200°C. LWA provide excellent permeability and satisfactory internal friction as backfill materials. The durability and chemical neutrality of LWA can reduce corrosion of steel anchors and bars in MSE walls. Holm and Valsangkar(1993) reported the mechanical properties of LWA as backfill materials and discussed various case studies of such applications. Replacing conventional sand fills with the alternative LWA can reduce settlement on weak and compressible soils, reduce lateral loads on the MSE wall, and facilitate construction through the reduction of compaction needs. For example, the optimum water content of the LWA used in this research is 5%, much less than that of sand, and the compaction effort to reach 95% of the maximum dry unit weight is less than the sand as well. Therefore, the LWA may contribute to the mission of accelerated bridge construction (ABC) promoted by the Department of Transportation.

Shake table tests on MSE retaining walls have been conducted to study their seismic behaviors and to provide earthquake design recommendations for the past 35 years since Richardson and Lee (1975) pioneered the tests on metallic-reinforced earth walls. The recent studies included the large-scale shake table tests on 2.5m tall modular-blocks and geocell-reinforced soil retaining walls (Ling et al. 2005, 2008) and the centrifuge tests on bar mat MSE walls (Siddharthan et al. 2004). Ling et al. (2004) found through parametric study on the behavior of MSE retaining walls that the backfill soil properties, seismic motions, and reinforcement layouts are the three major design parameters (in the order of significance) under earthquake loading. Helwany et al. (2012) conducted a full-scale shake table test on geotextile-reinforced-soil bridge abutment, using a staged sinusoidal horizontal motion with increasing amplitude up to 1.0g. The abutment was 3.2 m tall and concrete masonry unit (CMU) blocks were used as the facing. Thorough data analyses of the tests indicated that the model safely withstood the bridge loads while being subject to ground accelerations up to 1.0 g at 3 Hz.

With the alternative backfill, however, the performances of MSE walls have yet to be fully tested and understood under seismic conditions. Specifically, the horizontal deflections of wall face, the dynamic vertical settlement of the MSE wall, the transient vertical effective stress within the wall, and the acceleration responses are unknown and therefore the focus of this research. The objective of this research is to quantify the seismic responses of an MSE wall with the LWA as backfill using reduced-scale shake table test.

2. MATERIALS CHARACTERISTICS, EXPERIMENTAL SETUP, AND INSTRUMENTATION

The lightweight aggregates were obtained from Utelite Corp (Coalville, UT). The grain size distribution curve of the lightweight aggregates is shown in Figure 1, and their properties are listed in Table 1.

Table 1. Properties of LWA

Optimum water content	5%
Maximum dry unit weight	10.8 kN/m ³ (68.9 lb/ft ³)
Cohesion	0
Internal friction angle	36.5°
Specific gravity	1.74
Coarse aggregate duability index (based on ASTM D3744)	93

Figure 1. Size distribution of the lightweight aggregates

Figure 2. Shake table facility

Figure 3. Completed MSE wall with surcharge

A section of reduced-scale MSE wall was built in a 1.5 m (wide) × 1.87 m (long) × 1.8 m (tall) rigid steel box that was anchored on a 2.4 m × 2.1 m one-dimensional shake table. The load capacity of the shake table is 177.9 kN (20.0 tons); the actuator provides 244.6 kN (55 kips) hydraulic fluid driving force; and the maximum travel distance of the table is ±12.7 cm (± 5 inch). The shake table is capable of replicating recorded historical earthquake motions that are within its allowable displacement range. Figure 2 is a photo of the shake table and the box with a retaining wall built inside. Figure 3 shows the constructed model MSE wall.

Figure 4. MSE wall configuration and instrumentation

The model MSE wall configuration is shown in Figure 4. The wall was 1.5 m high, 1.2 m deep, and 1.5 m long. The model MSE wall simulated an MSE wall of 4.5 m tall in the field. So the dimensional scale was chosen to be 1:3 (model:prototype). Five wrap-around layers of lightweight aggregates were used. Uniaxial geogrid was used as both reinforcement and containment of the lightweight aggregates. The geogrid installation followed the field practice recommended by Tensar International, Inc. The spacing and length of each reinforcement layer were determined according to the “Geosynthetic Design & Construction Guidelines Reference Manual” (FHWA 2008) and “Designing with Geosynthetics” (Koerner, 2005). The design parameters for geogrid reinforcement are listed as follows:

- Ultimate tensile strength, $T_{ult} = 54 \text{ kN/m}$, provided by Tensar International, Inc.
- Allowable tensile strength, $T_{all} = \frac{T_{ult}}{RF_{ID} \times RF_{CR} \times RF_{CBD}} = \frac{54}{1.2 \times 2.5 \times 1.2} = 15 \text{ kN/m}$
- Factor of safety for pullout failure: $FS = 1.5$
- Height of wall (prototype): $H = 4.5 \text{ m}$
- Effective external friction angle between geogrid and LWA, $\delta' = \phi'_{LWA} = 36.5^\circ$
- Effective adhesion between geogrid and LWA: $c_a = 0$.

It was determined from the design that five layers were needed, with minimum spacing as 0.9 m and the maximum reinforcement length as 3.0 m. In the model test, the dimensions were reduced by 3 times based on the 1:3 (model:prototype) ratio. To simplify the construction of the MSE wall in the lab, uniform spacing of 0.3 m and uniform length of 1.0 m were used, as shown in Figure 4. To prevent the LWA from seeping out of the geogrid, non-woven, needle-punched geotextile was used at the facing to contain the LWA. The geotextile covered the face of the wall and did not provide reinforcement. Beneath the first layer of LWA, a 10 cm sand layer was compacted to simulate the base soil. Formwork was used to hold the wall face in place as each layer was constructed. The LWA were premixed at the optimum moisture content of 5% using a concrete mixer and were transported by a crane into the box. A 15kg hand hammer with a long handle and 30 cm × 30 cm steel base was used to compact the LWA to reach the target dry unit weight of 10.3 kN/m³ (65.5 lb/ft³), or 95% of the maximum dry unit weight. The dry unit weight and water content relationship was derived using the modified Proctor test (ASTM D 1557). A concrete slab was placed at the top of the wall and anchored to the top layer with ten steel rebar, so that the slab did not move freely during the shaking. The concrete slab simulated a surcharge of 3.38 kN/m² in the model test.

Figure 4 also depicts the instrumentations used in the model test. Figures 5 and 6 show the accelerometer, dynamic stress cell, and the materials used in the model MSE wall. Three linear potentiometers were used to measure the horizontal deflections of the wall face at the bottom, middle, and the top layers. The potentiometers were fixed to an inertial frame outside of the shake table, and an inelastic wire connected each potentiometer to the geogrid at the three

designated levels. The fourth potentiometer was connected to the shake table in order to measure the actual seismic motions generated by the actuator. The potentiometers were spring-loaded, but the spring force was significantly smaller than the seismic force. Therefore, the spring stiffness did not affect the responses of the walls. The vertical settlements of the MSE wall during the shaking were measured by LVDT transducers that were anchored on the box above the concrete slab. The transient vertical effective stresses in the backfill were measured using dynamic soil stress cells, which were placed flat at the bottom of layers 1, 2, 4, and 5. The potentiometers, the LVDTs, and the dynamic stress cells were connected to the National Instrument data acquisition system, which automatically recorded the readings during the shaking. Wire-free accelerometers were embedded in each of the five layers and were close to the wall face in order to measure the acceleration responses of the backfill. One accelerometer was attached to the shake table and one to the box to measure their acceleration responses as well. A delayed-start timer was set in each accelerometer, and the data recording (100 data points per second) started automatically at a predetermined time when the shake table test was run.

3. TEST PROGRAM

In this research, the 1989 Loma Prieta earthquake ($M = 7.1$) was simulated. The duration of the displacement-time history was 40 seconds. The earthquake's displacement-time history and acceleration-time history data were obtained from the Pacific Earthquake Engineering Research (PEER) Center Library of UC Berkeley and were implemented into the input file to the MTS® control system of the shake table. Trial shake table tests were run on the empty box, the input and measured displacements and accelerations matched well, respectively. In this research, the dynamic stress was scaled based on the dynamic scaling law for the "adequate model" that was presented by Moncarz and Krawinkler(1981). Equation (1) shows the principle of the dynamic scaling law:

$$a_r = \frac{a_{model}}{a_{field}} = L_r^{-1} = \left(\frac{L_{model}}{L_{field}} \right)^{-1} \quad [1]$$

Where a_r is the acceleration scaling factor between the model and the prototype (field), and L_r is the dimensional scaling factor and is 1/3 in this study. The dynamic stress provided by the shake table was represented by accelerations. Equation [1] shows that the acceleration scaling factor is the inverse of the dimensional scaling factor. So the input accelerations to the model test should be three times of the actually recorded accelerations in the field.

Figure 7. Displacement-time history of the shake table

Figure 8. Acceleration-time history of the shake table

Figure 7 shows the match of the displacement-time histories of the input file and the measured displacements (output) of the shake table during the 40 seconds shaking. Figure 8 shows the match of the acceleration-time histories of the input file and the measured accelerations of the shake table during the 40 seconds shaking. The input files for both the displacements and accelerations were already scaled up based on the dynamic scaling law. For example, the maximum horizontal acceleration in the field was measured to be 0.54g, so the maximum horizontal acceleration in the model test was 1.62g (three times of the prototype value).

4. RESULTS AND DISCUSSION

During the simulated 40-second intense shaking, the MSE wall with LWA backfill did not show noticeable damage and failure. The MSE wall's seismic performances in terms of the lateral deflections of the wall face, vertical settlements of the wall, accelerations of the backfill, and the transient dynamic vertical soil stresses in the backfill are presented as follows.

The maximum accelerations and their time of occurrence are listed in Table 2. The maximum input acceleration was 1.62 g. But the measured maximum accelerations of the shake table and the box were slightly off the target value due to the following two reasons. (1) The actuator is controlled by the displacement-time history through the MTS® control system. The actuator that drives the shake table may not be able to move exactly as the input displacement-time history due to various software and hardware issues. But the input and the actual shake table movements were very close, as shown by Figure 7. (2) The weight of the MSE wall on the shake table affects the acceleration response. The weight of the MSE all was already taken into account during the shake table calibration, but tolerable errors may still occur in the calibration. From Figures 7 and 8 and Table 2, we conclude that the shake table was able to simulate the scaled Loma Prieta earthquake excitations. Table 2 also showed that the bottom layer had the least acceleration. But the maximum acceleration occurred in the middle layer (layer 3). The underlying mechanism is yet to be understood by the authors.

Table 2. Maximum input and measured accelerations of the table and the backfill

Location	Input	Shake table	Box	Layer 1 (bottom)	Layer 2	Layer 3	Layer 4	Layer 5 (top)
Max Acceleration (g)	1.62	1.8	1.55	1.37	1.85	2.74	2.22	2.03
Occurring time (sec)	8.07	9.57	8.28	9.45	8.84	9.44	6.15	6.12

Figure 9 shows the lateral deflections of the wall face measured by the linear potentiometers at the top, middle, and bottom layers. The deflections were relative to the table movements, i.e., the absolute movements of the layers minus the table movements at each time stamp. The lateral deflections showed an expected increasing trend from the bottom to the top layers. The bottom layer moved less than 0.5 cm relative to the underlying ground, and the top layer moved about 10 cm relative to the ground, or 6.7% of the wall height. The maximum deflections of the three locations occurred at approximately 10 seconds into the shaking when the maximum acceleration of the table occurred (refer to Figure 8

and Table 2). After that, the MSE wall maintained the maximum lateral deflections and moved together with the shake table.

Figure 9. Lateral deflections of wall faces, relative to table movement Figure 10. Seismic settlements of MSE wall

Two LVDT transducers were positioned at the top of the concrete slab to record the dynamic settlements of the wall during the shaking. The two LVDT transducers recorded closely matched readings, showing good accuracy and reproducibility of the instrumentation. Figure 10 shows seismic settlements that were recorded by one of the LVDT transducers. The maximum settlement was approximately 4.7 cm, or 3.1% of the wall height. The settlements generally increased during the shaking with occasional upward bouncing. The occurrence of the maximum settlement also matched the time when the maximum horizontal acceleration occurred, at approximately 10 seconds. After 15 seconds into the shaking, no more settlement occurred.

As shown in Figure 4, four dynamic soil stress cells were embedded in layers 1, 2, 4, 5. The static stresses due to the weight of LWA and the concrete slab before shaking were determined to compare and verify the readings by the four stress cells. During the data analyses after shaking, we found erroneous readings by the stress cells in the very bottom and top layers (layer 1 and layer 5). The stress cell in layer 1 did not record continuous readings, and the stress cell in layer 5 recorded the initial readings that were more than three times of the static reading. We were unsure of the reason, and readings of these two stress cells are not included in the paper. Figures 11 and 12 show the dynamic vertical stresses at the bottom of layer 2 (lower layer) and layer 4 (upper layer). The initial readings are very close to the static stresses, as can be seen in the figures. The graphs showed three noticeable findings: (1) the maximum dynamic vertical stress in each layer occurred at approximately 8 to 10 seconds, the time when the maximum acceleration occurred; (2) the maximum dynamic vertical stresses doubled the initial static stresses; (3) toward the end of the shaking, the dynamic stresses stabilized and maintained at a higher level than the initial static readings, possibly due to the dynamic compaction effect. In this model test, horizontal stress was not measured.

Figure 11. Dynamic vertical stresses in layer 2
(static stress = 9.9 kN/m²;
max dynamic vertical stress = 20.5 kN/m²)

Figure 12. Dynamic vertical stress in layer 4
(static stress = 16.4 kN/m²;
max dynamic vertical stress = 31.8 kN/m²)

5. CONCLUSIONS AND LIMITATIONS OF THIS RESEARCH

This paper presented an experimental research on responses of a mechanically stabilized earth wall with lightweight aggregates backfill under simulated earthquake excitations. The research was conducted using scaled shake table test. Under the scaled earthquake excitations, the MSE wall showed no noticeable damage. This preliminary research showed promising potential of using lightweight aggregates as accelerated backfill for soil retaining walls in seismic regions.

This experimental study has several limitations. (1) The geogrid's tensile strength was not scaled and high reduction factors were used, this could result in an over-reinforced wall. (2) The reinforcement was based on static design. Seismic design using the methodologies presented by Helwany et al. (2012) and by National Concrete Masonry Association (NCMA 2010) may change the internal configuration of the MSE wall and consequently the seismic behavior. (3) The scaling law used in the model test should be improved to consider the scaling of the material properties. (4) External (global) stability, such as deep-seated rotational failure that can be caused by earthquakes, cannot be simulated in this test due to shallow soil depth. Because of these limitation, extrapolation of the model results to the field is premature at this stage. This research work is continued to address the limitations in (1), (2), and (3). Numerical model using Plaxis is being developed to simulate the laboratory conditions (including the boundary conditions, material properties, and seismic excitations). Using the same conditions, the numerical model can be calibrated using the model test results; then the numerical model can be used to predict the seismic performance in the field.

ACKNOWLEDGEMENTS

This project is funded by the California Department of Transportation (agreement number: 65A0449). Steve Scherer, research technician in the Department of Civil and Geomatics Engineering at CSU Fresno, helped the experimental setup. Mr. Darren Medeiros of Utelite Corp (Coalville, UT) provided the lightweight aggregate; Mr. Willie Liew of Tensar International provided the geogrid, and Dr. Mengjia Li of GSE World provided the geotextile. We appreciate these supports.

Separation/Stabilization Geotextiles – The Underlying Solution that We Have Had All Along for More Resilient Roads

M. Grace, Propex Operating Company, LLC, United States

ABSTRACT

Far and away the largest geosynthetic application, the use of geotextiles in separation/ stabilization, is also one of the most cost effective. The proven performance of this technology has been widely published and implemented for decades. However, geotextiles remain under-utilized. This paper is not intended to present technical guidance for specific road design, but rather to review the technology comparing its low cost to that of traditional unpaved and paved roadway building technologies. Common mythical subject matters will be addressed, and barriers to implementation will be reviewed. An update will be given on recent U.S. government activity advocating change to achieve a sustainable transportation infrastructure by using separation/ stabilization geotextiles. Readers will be presented a clear message regarding the economic and technical reasons behind the application, and will be offered confidence to support a decision to employ geotextile policies. The intent is to provide stakeholders a tool to justify increased implementation of separation/ stabilization geotextiles, lower construction and maintenance costs, while confirming what is already known about geotextile use in roads is still relevant, and even more applicable today given the challenges at hand.

1. INTRODUCTION

1.1 The Challenge for a More Resilient National Infrastructure

“Do more with less” is a common theme amongst businesses and government agencies across the United States. Furthermore, extreme weather conditions, a declining economy, an increase in raw material costs, and the need to support a growing population with limited resources has made it painfully evident that our nation’s infrastructure needs improvement, and future infrastructure projects must follow the most cost effective and sustainable policies. These adaptation efforts are currently taking place nationwide and will continue, but immediate attention to roadway infrastructure must be undertaken to further economic development in the U.S. The challenge exists to make this critical infrastructure component stronger, longer lasting, and more durable than ever before to meet current demands, while holding costs down to enable a generation of economic growth.

Currently, there are 4.05 million miles of road in the 50 United States, according to the Federal Highway Administration (FHWA). At the core of the nation’s highway system lies 46,720 miles of Interstate Highways (comprising just over one percent of highway mileage) along with 116,948 miles of major roads that make up the National Highway System. This system carries a majority of the highway freight and traffic through the United States.

Of the remaining 3.9 million miles of roadway, about 2.6 million miles are paved, which includes most roads in urban areas. However, 1.3 million miles, or more than one-third of all road miles in the U.S. are still unpaved gravel or dirt roads. The majority of our nation’s roads are, surprisingly, low volume rural roads operated and maintained on a local level. Fortunately, this is also the type of roadway category that holds the largest opportunity for improved sustainability.

The trend for the future? Transportation use is outpacing population growth. Now is the time for policy makers and engineers to work together to implement new processes and procedures for overall reductions in initial construction and in maintenance costs. Fortunately, a proven technology to solve these challenges already exists; we just need to better understand and communicate the financial saving aspects. Although a non-traditional solution, but hardly an experimental technology, incorporation of a geotextile for separation and stabilization of a roadway section is a basic value proposition. Yet, for many reasons it is a surprisingly under-utilized solution. Geotextiles have been used in separation/ stabilization applications for decades, and must be embraced by transportation agencies as pressure to further implement life-cycle economics and pavement preservation practices continues to mount. Too much effort is expended on advanced, mechanistic-empirical pavement design methodologies while some of the basic shortcomings and failure mechanisms of roads are seemingly ignored. Increased forensic evaluations of failed paved and unpaved roads would give a better appreciation of how the road support structure loses its strength and bearing capacity due to subgrade soil contamination, aggregate loss, and adverse drainage conditions. Simple solutions to the most common pavement maladies are addressed herewith, and should become a fundamental basic for all pavement design methodologies. Getting back to the basics and understanding the use of geotextiles in separation/ stabilization will enable an engineer to implement impactful technology on infrastructure improvements, while avoiding the risks of unproven methodologies. Future sustainable infrastructure

improvements will undoubtedly incorporate geotextiles, and engineers and policy makers must be imparted with confidence to lead our nation in developing smarter, more cost-effective roadways into the future.

1.2 Roadway Geotextile Application Fundamentals

Before further discussion about roads with geotextiles and their most basic functionality, a review of the two most common mechanisms that contribute to premature road failure is offered. In every road without a geotextile, contamination and intermixing of the aggregate base at the subgrade soil/ aggregate interface occurs for the following reasons:

- Soil fines migrate into the stone aggregate voids
- Aggregate punches into the subgrade soil

These two failure mechanisms are major concerns for any roadway design engineer, and are thus compensated for in one way or another. It is how these failure mechanisms are most commonly addressed today that presents the greatest opportunity for improvement. Typically, traditional approaches are chosen to override these failure mechanisms, and introduce further design flaws, often unintended consequences, when trying to achieve sustainable future standards. Therefore, the greatest opportunity for improvement involves a positive shift in design methodology to incorporate more geotextiles. First, traditional methods will be reviewed in order to fully develop the separation/ stabilization geotextile value proposition.

The most common, traditional approaches to preventing contamination and intermixing at the aggregate/subgrade soil interface are:

- Designing a tight, well-graded base which, in theory, minimizes the migration of fines upward into the aggregate layer
- Increasing the design thickness of the aggregate base to account for “sacrificial aggregate” layer that will knowingly intermix into the subgrade soils in an attempt to still maintain a design structural thickness of a road support layer

Currently, agencies such as FHWA support design methodology where contamination of a road base aggregate is addressed by requiring an additional two (2) inches of aggregate atop the design thickness needed to achieve the desired structural performance of a road. Even though there is room to improve, these “safety factors” are not questioned or critiqued, and have become commonplace in the engineering community. However, in the effort to identify more sustainable roadway design and construction, the adverse effects of this methodology should be further examined. Implementation of a well-graded aggregate base decreases a road’s ability to drain water and results in a weaker base layer, thus increasing road costs. Holistically, the net result with either inadequate approach does not satisfy the nation’s need for more resilient roads, and requires the design engineer to choose between outdated and costly conventional technologies.

A third “alternative” approach is to use a geotextile to keep the intermixing and contamination from occurring at the subgrade soil/ aggregate interface for the life of the road. Simply put, geotextile separation is defined as the introduction of a flexible, porous textile placed between dissimilar materials so that the integrity and functioning of both materials can remain intact or be improved (Koerner,1994). Geotextiles are used for a broad array of applications, but for roadway construction, geotextiles primarily enhance unpaved and paved roads when placed in between the subgrade soil and the structural aggregate base. At this location within a road’s cross section, geotextiles serve two functions:

- To act as a long-term separator of the subgrade soil from the structural aggregate, permanently keeping the aggregate uncontaminated from the likely intrusion of subgrade soil particles over time
- To act as a stabilizer, contributing to the overall structural integrity of the road.

These two functions work concurrently; hence the application becomes known as “separation/ stabilization”.

A roadway system which includes a geotextile merely for separation keeps an aggregate base material under load from being forced into the subgrade at the soil/ aggregate interface, and keeps the subgrade soils from penetrating the clean aggregate layer. The migration of subgrade soil upward into the base aggregate is dramatically increased in the presence of moisture. While more investigative work to understand the mechanisms of premature road failure is warranted in hopes of being able to utilize new forensic technologies, it is intuitive to believe that preventing the aggregate layer from subgrade soil infiltration for the design life of a road will result in a more sustainable roadway. Typical base section loss beneath a pavement is four (4) inches sometimes even in the early stages of the design life. (Jorenby & Hicks, 1985) Aggregate loss can be even more significant in an unpaved road, and more rapid when above weak soils. Analyzing geotextiles providing separation in paved and unpaved roads is very non-technical and basic, while attempts to over engineer the application has limited its implementation. A geotextile providing separation in a roadway can be seen below in Figure 1:

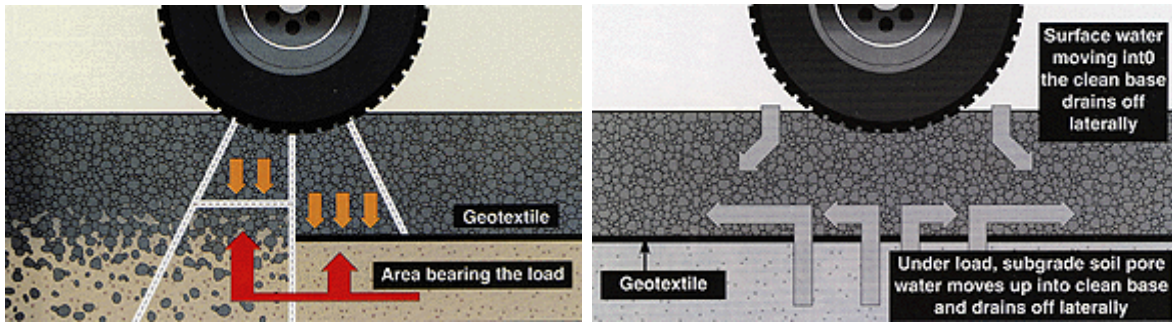

Figure 1: Geotextile placement in a roadway to provide separation and stabilization (Cyber North, 2012)

Geotextiles have functioned as separators for more than 30 years, but their implementation and acceptance is far less than the traditional approaches discussed above. A simplistic way to evaluate the cost benefit offered by a geotextile separator can be done because the cost of an installed geotextile equates to about one (1) inch of placed aggregate. Apply this rule to determine how much the traditional solutions used to prevent intermingling at the soil/aggregate interface cost and a geotextile results in at least a 50% cost savings. Another alternative view to consider is a geotextile that prevents at a minimum one (1) inch of aggregate base from being contaminated is a “break even” investment. These simple, conservative analyses do not capture all the benefits of using a geotextile, but alone justify the use of a geotextile beneath every road. Notable cost savings are also experienced after construction, specifically of unpaved roads since frequent and significant amounts of replacement aggregate are no longer needed for the duration of the road service.

An additional value-add proposition offered by geotextile separators is the potential to use a better, free draining aggregate for the structural layer of a road without fear of subgrade contamination. A more open aggregate drains faster, and is rewarded technically by often achieving twice the structural contribution per inch according to AASHTO design (AASHTO 1986 and 1993). As an aggregate base drains rapidly, there is less lingering free water to weaken the subgrade or cause freeze/ thaw cycles in extreme climates as depicted in Figure 1, right hand side.

In addition to separation, stabilization is the other significant value proposition offered by a geotextile used between the subgrade soil and the aggregate layer. Stabilization takes on more of an engineered evaluation when compared to the separation function since a composite road support system results. First, when the aggregate is compacted over the top of a geotextile for the first time, the individual stones directly above the geotextile become “seated” making impressions in the geotextile and the subgrade. This interaction locks the bottom of the aggregate into a fixed position, thus stabilizing the aggregate layer indefinitely. Secondly, the geotextile under load provides vertical confinement of the subgrade soil, making it more resistant to shear failures. It is widely proven that the incorporation of a geotextile changes the soil failure mode from local shear to general shear allowing 80% additional load before the soil’s strength is exceeded. This mechanism allows for a reduced structural section of between 15-25% over a subgrade stabilized with a geotextile, directly reducing the initial project cost of building both paved and unpaved roads. (Marienfeld, 2011) The membrane reinforcing affect makes it possible to reduce the thickness of the base course required for initial construction and is most significant when subgrade CBR values are less than 3%. (Barkdsdale,1989)

Whether evaluating the benefits provided by separation, stabilization or both, geotextiles are proven and recognized for reducing the need for several inches of aggregate required in the design of a conventional road section. Even if the decision is made to implement the traditional approach structural layer thicknesses, the incorporation of a separation/ stabilization geotextile will extend the life of a road by increasing allowable loadings, Equivalent Single Axle Loads (ESALs), by 50 to 75% (Al-Qadi, 1997) The decision should not be focused on whether or not to use a geotextile, but rather every road should incorporate a geotextile, and policy makers and engineers have to decide based on cost models, budgets, and goals when and how to reap the greatest cost benefit offered by a separation/stabilization geotextile—all savings up front to minimize construction cost, all savings through extended road life, or the commonly used method of saving just enough up front to pay for the geotextile and gaining extended road life.

To summarize, the separation/ stabilization geotextiles impact the overall approach to road design and when incorporated, they become no risk, high reward propositions because they:

- Reduce initial construction costs
- Reduce operation and maintenance costs
- Increase the lifecycle of a road by allowing additional traffic loading
- Separate aggregate from the subgrade soils

- Allow the use of free draining aggregate, for more strength and less freeze/thaw damage
- Reduce the aggregate thickness in a road by subgrade and base aggregate stabilization
- Increase subgrade soil bearing capacity; preventing vertical deformation of the road
- Distribute stress across a wider area limiting local failures which propagate to larger failures

2. FACT OR FICTION: THE TRUTH BEHIND THE SEPARATION/ STABILIZATION GEOTEXTILE

2.1 Using Geotextiles in a Road's Cross Section is a New Concept and a New Technology.

FICTION. The truth of the matter is that geotextiles used in separation/ stabilization applications started in the 1920s in the United States, and significant advancements have been made since. Nevertheless, even with advancement and now a better understanding as to the cost benefits that the technology provides, geotextile usage still has significant upside potential for increased usage. Geotextiles have been repeatedly proven to work, and numerous laboratory and field tests have been conducted and have documented positive results. Below is a list of just a few notable studies available:

Table 1. A list of references and a short summary of their contribution to the discussion of the benefits of incorporating a separation/stabilization geotextile (Narejo, 2005).

Reference	Type of Study	Results of Study
Jorenby & Hicks, 1985	Field Tests	Review of several pavements showed an average base aggregate loss of four inches due to subgrade soil upward migration.
US Army Corps, 1999	Field Tests	Separation geotextiles were found to be necessary to prevent oozing of fine subgrade soil into coarse base course.
Tsai, et. al., 1993	Field Tests	Control sections using no geotextiles were found to have significant fines in base course, whereas the sections with geotextiles were found to have significantly less fines.
Metcalf, et. al., 1995	Full scale projects	Twenty two pavements with geotextile separators were evaluated. Geotextiles were found to be successful in providing separation function at all of the sites.
Baldwin & Long, 1987	Full scale projects	A three year study found that free draining base courses obtained with geotextiles are effective in preventing water build up in pavements.
DeBerardino & Baldwin, 1996	Full scale project	Borings drilled through pavements with geotextiles, after thirteen years found no migration of fines.
Leu & Tasa, 2001	Full scale projects	Geotextiles were found to be successful in preventing contamination of the base course. At the end of ten year period, sections with geotextiles were found to have fifty percent less cracking than those without.
Guram, et. al., 1994	Field tests	Nine years later, separation geotextile and six inches of base aggregate were found to provide performance equivalent to 24 inches of lime treated subgrade, with the same pavement section at a much lower cost.
Faure & El Amir, 1982	Laboratory tests	Geotextiles were found to be successful in preventing fouling of aggregate by fines.
AL-Qadi, et. al, 1997	Laboratory tests	Geotextiles were found to be successful in preventing fouling of aggregate by fines.
Glynn & Cochrane, 1987	Laboratory tests	Geotextiles were found to be successful in preventing fouling of aggregate by fines.
DeBerardino & Hawkins, 1994	Full scale projects	After a period of twenty years, geotextile samples were dug. Geotextiles were found to adequately perform the separation function.
Bonaparte, et. al., 1988	Full scale projects	Geotextile excavated from seven sites after 1 to 12 years of burial proved that geotextiles provide adequate separation.

The studies cited above demonstrate the proven performance of separation/ stabilization geotextiles in actual applications. Additional information will be presented later in this paper when focus is on the separation/ stabilization application to lower initial construction costs and/or the lifecycle cost of a roadway.

2.2 Separation/ Stabilization Geotextiles Can Cause a Problem in a Road.

FICTION. Consider a road without a geotextile. It only takes about 20% by weight of subgrade soil mixed into the aggregate base to reduce the bearing capacity of the aggregate base to that of the subgrade soil.(Yoder, 1959) Thus, a road without a geotextile is at high risk to the mixing of aggregate and subgrade compromising the structural integrity of the road. There is no downside risk to using a geotextile, which makes it easy to implement in a road versus choosing not to use one. Even if the geotextile selected is not optimal for installation survivability or drainage, the geotextile will still function

as a separator maintaining the integrity of the initial road design, automatically extending the service life of a road. Plus, using geotextiles during construction promotes short-term separation allowing subgrade soils to consolidate. Studies by Austin and Coleman have shown that this short-term gain offered by a geotextile is more critical to unpaved roads rather than their long-term performance because of the subsequent strength gain of subgrade soils when a geotextile provides separation. (Austin and Coleman, 1993)

2.3 Understanding Which Geotextiles to Use for a Roadway Application is Simple and Geotextiles are Easy to Specify.

FACT. Specifying geotextiles in transportation projects is as simple as understanding their function, how they will be installed, and understanding the environment into which they will be installed. There are several methodologies and guidelines available for a designer to follow in order to include geotextiles in design, but the two specifications available from reputable major organizations, AASHTO M288-06 and FHWA FP-03, are invaluable resources and a design engineer needs to look no further. The performance properties needed from the geotextile, for most applications, are not complicated, and the user of the AASHTO M288-06 specification will make excellent geotextile choices based on knowledge of site-specific installation stresses and soil hydraulic properties for the project application.

AASHTO M288-06 categorizes the survivability of the geotextile into one of three different classes based on the intensity of installation conditions: Class 1 being the most severe and Class 3 being the least severe. The potential survivability of the geotextile within each class is determined by a standard set of properties generated from ASTM test methods. These properties are Grab Tensile Strength, Trapezoidal Tear Strength, CBR Puncture Strength, and Ultraviolet Stability. Why is there so much focus on the installation stresses of a geotextile? Installation is the point in a geotextile's design life that it will be subjected to the greatest stress, and maintaining the integrity of the geotextile through the installation process will ensure it performs as designed. In addition to evaluating the survivability of the geotextile, hydraulic properties are included based on the site soil conditions or percent fines. The properties associated with soil conditions are Permittivity and Apparent Opening Size. From a cost standpoint, there is actually very little difference between the lowest and the highest survivability class AASHTO recommended geotextile, so a default to Class 1 is often a reasonable approach.

To become an expert on the subject matter, understand the surface friction required and the CBR values of the soils present in the application. For example, the higher the surface friction desired, the more appropriate a nonwoven geotextile becomes. If lower CBR value soils are present, then a woven geotextile is more likely to provide the strength needed at lower strains to bridge over softer soils. But again, you cannot go wrong using AASHTO M288-06 and remember, even if the most optimal geotextile is not selected, there are no downside risks.

2.4 Geotextiles are Sensible Solutions to Lower Initial Project Costs and Maintenance.

FACT. From a cost-savings perspective, geotextiles make more sense now than they historically ever have, but still remain under-utilized. Their intrinsic value to supporting a more resilient national infrastructure is priceless. Diminishing transportation operational budgets and rising raw material costs have prompted owners and DOT officials to find other means and methods of roadway construction. Geotextiles provide solutions through short term and long term benefits.

The following is a hypothetical scenario to analyze the use of geotextiles in new road construction to reduce initial costs. For example, a high-level exploration of a state's DOT budget examines how geotextiles could be implemented to come in under budget while still improving the roadway system. Figure 2 below depicts two theoretical road cross sections equivalent in performance a) without a geotextile and b) with a geotextile. For comparison ease, the traditional method represents the average road cross section of all new roads that this state's DOT has budgeted to construct in 2012.

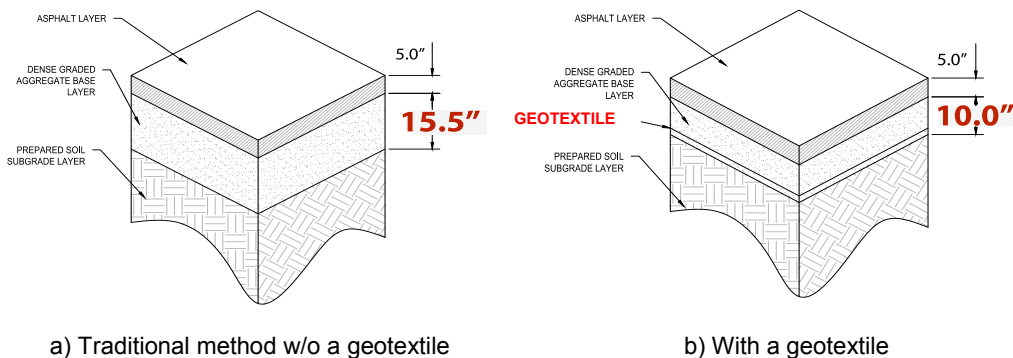

Figure 2: The differences in road cross sections w/o and with a separation/ stabilization geotextile

Comparing the construction costs associated with each, the traditional method utilizes 15.5" of a dense aggregate base which historically costs the DOT per 1" thickness \$1.64/ square yard. The geotextile costs on average about \$1.00/ square yard. Using this information, the state's DOT 2012 road budget can now be analyzed.

Table 2: Theoretical State Department of Transportation 2012 Road Budget and Volume

Budget Information	
Total Road Budget	\$1.817B
Spend Allocated to New Roads	\$732M
Estimated Total Lane Miles Built Annually	1600
Relate Lane Miles to Square Yards	
Lane Width (ft)	12
Surface Area per Lane Mile (ft ²)	63360
Total Square Yards/ Lane Mile	7040
Total Square Yards in the Budget	11.26MM
Savings Using a Geotextile (Figure 3)	
Amount of aggregate the geotextile displaces	5.5 inches
Cost for 1" thickness of dense aggregate	\$1.64/ square yard
Cost for 5.5" thickness of dense aggregate	\$9.02/ square yard
Cost for a geotextile	\$1.00/ square yard
Savings (per square yard)	\$8.02/ square yard
POTENTIAL BUDGET SAVINGS WITH A GEOTEXTILE	\$90.31MM

In this particular example, the geotextile displaces 5.5" of aggregate in the new road section, saving the DOT a minimum of \$90.31MM, or 12% of the total dollars allocated towards new road construction. Since geotextiles can reduce a minimum of 20 to 35 percent of the original required thickness of structural layers in a road and local raw material costs can fluctuate, the overall savings may vary. Yet, this example generally shows the potential for upfront cost savings provided by incorporating geotextiles and reducing other materials needed to build new roads.

Recall from earlier discussion that approximately one (1) inch of aggregate is equal to the cost of a geotextile covering the same surface area and that conventional FHWA design methodologies suggest a minimum of an additional two (2) inches of sacrificial aggregate be used to design the appropriate aggregate base thickness. We are seeing developing nations build their first real infrastructure and doing it correctly using geotextiles as part of state-of-the-art design. So, without being jaded by traditional, outdated design thinking, their infrastructure will be better built and require less maintenance than ours. The following chart demonstrates the geotextile value proposition compared to aggregate resources that are typically wasted.

Figure 3: Comparison of cost of geotextile to the cost of contaminated, wasted base aggregate

The use of separation/ stabilization geotextiles in construction greatly reduces the need for future maintenance, especially for the municipalities with unpaved roads losing aggregate to subgrade soils every year. If all roads were built over geotextiles, maintenance budget spend today would be re-allocated and more tax dollars could go towards new or improved roads.

2.5 Geotextiles are Difficult to Install.

FICTION. Proper installation of a separation/ stabilization geotextile can be perceived as intimidating. Yet in reality, the installation is quite simple and may easily be explained to inexperienced laborers on the jobsite. The chief concerns surrounding installation include potential abuse of the fabric during deployment, and proper repair of the material if damaged. These concerns can be mitigated through proper training and common sense. Installation considerations and guidelines that address items such as overlap widths, direction of overlap, direction of application, and others are well established and easily obtained for any project. Detailed installation guidelines are available from product manufacturers for any geotextile application.

3. BARRIERS TO USE

If geotextiles are time proven, result in less expensive road construction when compared to traditional construction methodologies, contribute to longer lasting roads, are easy to design and are easy to install then why doesn't every road constructed in the United States utilize a geotextile for separation/ stabilization? One possibility is the lack of understanding of the economic benefit gained through such a simple technology. Another is that the technology is forgotten, undervalued, or overlooked by the engineering design community. Since the mid-1990's, manufacturers of geotextiles have focused promotional efforts towards other products, believing that there is little room for differentiation in this specific application. Conversely, the challenge(s) an engineer faces when designing a sustainable road are widespread, understood, easily defined, and must be compensated for in every road built today (yet still, they are not using a geotextile as a separator). Several barriers to use (explored below) were discussion points presented at GeoAmericas 2008. (Marienfeld, 2008) Since then, these barriers have compounded with deterioration of global economic conditions.

3.1 Lack of Understanding of the Root Causes of Road Failures

Agencies and owners generally fail to pursue the root causes of failure, such as; base aggregate contamination by subgrade soil intrusion, damage caused by the presence of water, and the loss of structural layer strengths and effective thicknesses. These discoveries are easily obtained by quick forensic analyses of failed roads before they are reconstructed. Unfortunately, the designer rarely sees the failure of their designs due to the loss of integrity of the originally

designed and installed structural layers. If they simply communicated with the people responsible for the maintenance and reconstruction of their roads, they would learn the root causes of why their designs failed and then simple inclusion of an inexpensive separation/stabilization would then seem absolutely necessary.

3.2 Comfort and Tendencies in Using the Traditional Technologies Outweigh the Rewards for Thinking Outside the Box.

The roadway design and construction industry of today does not readily reward those professionals that employ creative methodologies or push to implement innovative and cost-effective technologies. The litigious nature of the industry also makes the reduction of personal liability and risk a significant objective in the practice of engineering. Although using geotextiles in the design of roadways is proven and risk-averse, any deviation from conventional approaches is often met with hesitation. It is therefore critical to provide more education and promote the use of geotextile technology as a true solution to the crisis facing our national transportation infrastructure system. Focusing on lifecycle cost reduction and sustainable construction techniques must be a part of the next generation of engineering education.

3.3 There is a Mixed Message in the Industry about the Performance of Geotextiles.

Engineers that embrace innovation are unfortunately faced with the daunting task of deciphering mixed messages from the industry about geotextile performance. Manufacturers of geotextiles, contractors, owners, end users, and other design engineers all offer independent and often conflicting views of successes and failures when using geotextiles in road construction. In particular, a great deal of promotional effort is put into the marketing of the higher profit margin geogrids as superior products to geotextiles. Manufacturers often recommend geogrids for use in stabilization applications without an underlying geotextile, in an effort to minimize overall system costs. Geogrid market literature suggests separation and filtration is not generally needed, but the filter criteria they reference is not applicable to the dynamic pumping of subgrade soil fines into an aggregate base. Without an underlying geotextile, the geogrid cannot provide any separation function, and will lead to eventual contamination and intermixing of subgrade soils into the aggregate base above. (Al-Qadi, 2007). Testimonies of geotextile performance by entities that support competing technologies (e.g., manufacturers with incentives to promote alternative products, contractors that operate quarries that supply aggregate) can be inaccurate and misleading if the product was not installed properly. Many times owners of roadways and governing agencies don't understand the true performance of a road or the life cycle cost comparison with and without a geotextile, and therefore do not mandate the use of geotextile technology, even when there was a desire to implement change at the design level. Finally, engineers typically seek guidance from engineers with knowledge and experience in specific technologies. Equipping the engineering community with factual information and results of laboratory and field performance is critical to propagating the value-add message of geotextile technology success. All the competing product clutter can be bypassed simply by using the AASHTO M 288 national guideline specifications.

3.4 Lack of Supportive Policies Exists for Using Geotextiles.

While some agencies do provide guidance for using geotextiles to enhance road design, to the engineer who wishes to implement the technology, there are extremely few policies in existence that mandate the use of the technology in a road. The lack of supportive policies can be directly linked to the lack of data available that clearly defines the cost effectiveness of geotextiles in road construction for the entire life cycle of a road. Without this type of cost justification, agencies find it difficult to put policies in place that mandate or support geotextile usage. The development of a model to substantiate geotextile life cycle cost benefits for use as separators and stabilizers under roadways is greatly needed. Performance testing is not needed, since the technical merits of the system are widely proven. Existing studies and data are very good, just somewhat dated and not fresh in the mind of designers.

3.5 Geotextiles Don't Find Their Way from Design to Construction.

Contractors today find themselves fiercely competing for fewer projects, with more jobs having selection criteria based on low-bid proposals. Thus, many contractors find themselves struggling to obtain work and submit bids at break-even costs to preserve their businesses. In an effort to cut costs after winning a bid, contractors will often attempt to identify removal of items that are easier to justify than others. Unfortunately, geotextiles have become targeted items for removal due to the lack of understanding of its function and purpose. This bidding strategy for a contractor is high risk, but owners and agencies find themselves also limited on funds and are also often motivated to negotiate work after a bid that results in shared upfront cost reductions with the contractor.

Unfortunately, in this circumstance both parties are only thinking about short term gains, and many times the original intent of the design is lost. The owner or agency may not fully understand the value proposition of a geotextile, nor the intent of the design due to lack of education or exposure to the technology. Better communication with all stakeholders must be achieved at multiple levels, which results in knowledgeable agencies letting contracts to informed contractors. This is a key element in furthering sustainable infrastructure improvement.

3.6 Taxpayers Are Not Informed Enough to Demand Technologies that Result in Better, More Cost-Effective Roadways.

The responsibility for education about geotextiles and their use in roads to enhance road performance falls to the leading manufacturers within the industry. In recent years, manufacturers have placed too much focus on promoting specific product characteristics. Less emphasis should have been placed on the nuances of specific geotextile performance property discrepancies. More time should have been spent making the general public aware of the basics that the technology can do to make our nation’s infrastructure more sustainable. Geotextile education should be available through all channels within our society, with focus on college level education so the generic technology implementation becomes faster and easier into the future. Manufacturers have always directed marketing efforts at engineers, but frustration is moving them to approach transportation budget administrators.

4. RECENT GOVERNMENT DEVELOPMENTS AND TRENDS TO USE MORE GEOTEXTILES IN ROADWAYS

Below in Figure 4 is an excerpt of a letter to members of the Geosynthetics Materials Association (GMA) from Andrew Aho, managing director, explaining recent actions that our nation has taken towards making our roads more resilient. By suggesting geotextile usage is mandatory the net result will be responsible transportation spending and enhanced road performance:

Dear GMA Member,

Transportation Bill

On Friday, July 6, 2012, President Barack Obama signed into law H.R. 4348, the “Moving Ahead for Progress in the 21st Century Act” (MAP-21), a two-year, \$105 billion surface transportation bill that reauthorizes taxes that support the Highway Trust Fund through Sept. 30, 2016, and the authority to make expenditures from that Fund through Sept. 30, 2014. This law will provide states and the construction industry the needed funding certainty to continue work on existing projects and appropriately plan for future projects. States and the construction industry have been operating on nine short-term extensions of the surface transportation authorization since September 2009.

Fiscal Year 2013 Transportation, Housing and Urban Development Appropriations/Funding Bill (THUD).

On June 29, 2012, the U.S. House passed the THUD appropriations bill that provides funding to the U.S. Department of Transportation. From our perspective, the good news is that U.S. Rep. Jack Kingston (R-Ga.) and his staff worked with GMA to craft report language for the this bill that highlights the cost saving and environmental benefits of geosynthetics as well as the upcoming Government Accountability Office (GAO) study on innovative materials (see “GAO Study” below). The full Senate now needs to pass its THUD funding bill to move the appropriations process along. Directive language to the Federal Highway Administration (FHWA) in the bill reads:

Geosynthetics—The Committee directs the FHWA to continue assessing the use of geosynthetics in highway and civil infrastructure applications, especially potential cost savings and environmental benefits. The Committee also encourages FHWA to review and consider the recommendations in GAO’s upcoming report on geosynthetics and the associated life-cycle costs of incorporating innovative materials in pavement.

Figure 4: Letter excerpts from Andrew Aho of GMA to its members summarizing government interest in geotextile implementation (GMA, 2012).

These actions taken by the GMA advocating a higher degree of incorporation of geotextiles into roadways proves that the government is ready to listen. As discussed earlier, there is a defined need and high level of concern across the country when it comes to our aging infrastructure. In October 2011, GMA announced that two members of Congress sent a letter to the U.S. Government Accountability Office (GAO), requesting a study of geosynthetic materials in roadway systems. The coauthors of the letter were Rep. John Duncan (R-Tenn.) and Rep. Frank LoBiondo (R-N.J.), both members of the House Transportation and Infrastructure Committee. Rep. Duncan also serves as chairman of the Subcommittee on Highways and Transit, and Rep. LoBiondo serves as chairman of the Subcommittee on Coast Guard and Maritime Transportation. GMA has worked with GAO and Transportation Committee staff members to provide access to technical data and studies on the use of geosynthetics in transportation applications. The GAO was expected to complete the study by September 21, 2012 however the report back to Congress has been delayed. Preliminary speculation is positive; however more details will be available in 2013.

5. JUSTIFICATION TO USE SEPARATION/ STABILIZATION GEOTEXTILES IN ROADWAYS

The objective of this paper is to provide a reference tool for engineers, owners, and other stakeholders that desire the support for justifying the need to advocate geotextiles use in roadway applications. The material herein is not intended to provide in-depth technical analysis or design methodology, but rather to present a clear and precise message regarding the benefit of geotextile separation/ stabilization. Fundamental advantages exist when incorporating geotextiles into road design, and have become even more critical given the current climate and condition of the nation's economy and infrastructure, coupled with the rising cost of conventional roadway construction materials. A renewed emphasis must be placed on understanding geotextiles for use in roadway separation/ stabilization.

Looking ahead, the United States must find innovative ways to build roadways better, more durable, and at less cost. Geotextiles are tested and proven solutions that design engineers can rely on for better roads. In our search to develop more sound and sustainable infrastructure for the next generation, we must re-evaluate engineering practices and embrace change. Although the value proposition of a geotextile functioning as a separator and stabilizer in paved and unpaved roads is not new, reinforcement of the basic principles included herein provides a compelling reason to transition from outdated conventional approaches to sensible ones.

It is expected that the use of geotextiles will become increasingly routine, and that geotextiles will be the standard technology of choice for building better roads of the future. The wiser, most cost-conscious transportation agencies are already incorporating geotextiles under all roads as standard practice. Forward-thinking local agencies are also mandating the use of geotextiles under roads installed by private developers, so that eventual public operation and maintenance will require reduced costs. Yet more support in educating and highlighting the cost justification for separation/stabilization geotextiles is greatly needed, and will only result in a better spend of resources and money for a sustainable future.

ABSTRACT

This paper presents the development and design of a settlement-compensating geomembrane connection between a non-settling fixed structure built on a landfill and the surrounding landfill cap geomembrane placed on the settling landfill surface. This paper addresses the design concept, design development process, full size prototype testing, field testing, final design and specifications, fabrication and installation quality assurance plans, and fabrication and installation experience.

1. INTRODUCTION

The former Cal Compact Landfill occupies 64 hectares in the City of Carson, California, of which approximately 55 hectares were used mainly for disposal of municipal solid waste and some hazardous waste from 1959 through 1964, with waste thickness up to 20 m. The site is being developed into a commercial/residential mixed use complex known as "The Boulevards at South Bay." All buildings will be on pile-supported structural slabs to eliminate the effect of settlement. When completed, there will likely be over 8,000 piles supporting over 140,000 m² of structural slab.

As part of the remedial systems at the site, a landfill cap will cover all waste areas, including under the pile-supported structural slabs consisting of, in most areas, a 1.5 mm linear low density polyethylene (LLDPE) geomembrane with 405 g/m² geotextile above and below. The approved remediation plan (DTSC 1995 and Brown & Root 1995) includes a requirement that the landfill cap be sealed to the piles and that a settlement-compensating connection be provided between the non-settling pile-supported structure and the landfill cap. A system was developed that includes a mechanical connection of the landfill cap geomembrane to the pile caps with an unfolding "boot" that allows slack for settlement compensation without relying solely on the elongation properties of the geomembrane material. The system is comprised of two parts: (a) an embedment "ring" that is installed into the pile cap at the time the pile cap concrete is placed, and (b) a boot made of LLDPE geomembrane that is connected to the pile cap at the ring and connected to the surrounding landfill cap geomembrane. Figure 1 shows how the landfill cap system transitions from the open area outside the buildings to under the building slab where the connection to the pile caps is made. Figure 2 shows a plan view of the boot final design.

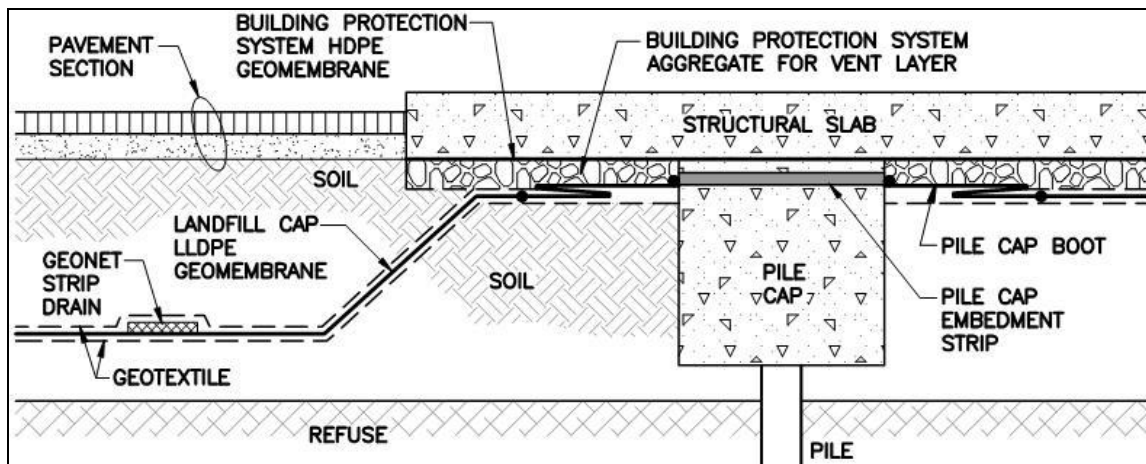

Figure 1: Boot-Ring settlement compensation system for a landfill cap under pile-supported structures

Figure 2: Final design of the single flap pile cap boot

2. DESIGN DEVELOPMENT

2.1 Design Goals

The design goals for the boot-ring system (Tetra Tech 2008) were:

- Develop a boot configuration that provided slack upon deployment to avoid excessive tension in the material and the welds and to avoid relying solely on the elongation properties of LLDPE.
- Develop a method (i.e., the embedment ring) by which the boot could be securely attached to the pile cap and form a reliable seal of the landfill cap geomembrane to the pile cap.
- Demonstrate that the boot-ring system would function reliably under building slabs to meet the design settlement.
- Develop rigorous specifications and quality assurance plans for fabrication and installation of the boot-ring system.
- Develop the boot and ring designs so that they could be fabricated offsite in a controlled and documented manner and be installed in the field as easily possible.

2.2 Design Settlement

Potential remaining settlement of the landfill was estimated (KFM Geoscience 2007) using the method proposed by Huitric (1981), and mapped to the site to illustrate the estimated settlement at all site locations, reflecting that the waste thickness varies around the site. The waste has been consolidating at the site since 1959. The maximum remaining settlement at the site was estimated to be 17 cm at the location of deepest waste (20 m). In the same location, the project Geotechnical Engineer of Record (Leighton Consulting 2008) specified a design settlement of 53 cm, thus incorporating a factor of safety of >3.

2.3 Early Concepts – Basic Geometry of the Boot

Early in the design process, a series of small models were constructed by The Barber-Webb Company to qualitatively explore the three-dimensional nature of how a boot of various shapes would function relative to square and round pile caps, and to explore relative dimensions, such as how large must the boot be relative to the pile cap to deliver satisfactory performance for the needed amount of settlement compensation. These models were constructed of wood, paper, and compressible foam. Settlement action was simulated by pressing down on a wood base, compressing the underlying foam, relative to the non-settling wood “pile cap.” Three configurations were investigated:

- a) Round boot on round pile cap
- b) Square boot on square pile cap

c) Round boot on square pile cap

The round boot on a round pile cap behaved as expected, with the boot opening in pure “accordion” fashion with no three-dimensional buckling of the boot geomembrane. However, the extra cost and complication of constructing 8000 round pile caps in the field, along with the greater difficulty and expense of a round embedment ring was judged to be countering factors to selecting this configuration.

The square boot on a square pile cap also opened in an accordion-like manner, but only to the an extent limited by the widths of the flaps of the boot, after which it was clear that the corners of square boots would experience high stresses on the welds. The square boot would also be difficult to fabricate and would need to be much larger than a round boot to achieve the same settlement compensation.

The round boot on a square pile cap allowed the use of standard square pile caps, square embedment rings, and provided satisfactory boot performance. As the boot opened with settlement, some three-dimensional distortion was induced, warping the boot surface, but the round shape served to allow for the distortion to be easily distributed and not concentrated. Thus, our fundamental concept was defined.

2.4 Full Size Boot Prototype Model and Testing

Going forward from the results of the small scale model that defined the general geometry of the pile cap boot, a series of full-scale prototype model tests were performed by GSE Lining Technology:

- Round boots were fabricated with 1.5 mm LLDPE geomembrane with an outer diameter of 2.3 m.
- A “single flap” boot and a “double flap” boot were fabricated and tested to be certain that the full range of the design settlement would be accommodated in the testing. The double flap boot incorporates more slack for settlement compensation.
- The top of the boot was secured to a simulated 0.9 m square pile cap (made of plywood).
- The pile cap and boot were centered in a 4.3 m square wooden box that would allow up to 30 cm of gravel to be placed over the boot (see Figures 3 and 4). Gravel was 1 cm rounded pea gravel.
- An electric jack was placed under the pile cap, allowing it to be raised in a controlled manner up to 71 cm.
- The box was lined with 1.5 mm LLDPE and the base of the boot was welded to the underlying geomembrane.
- The displacement of the pile cap relative to the base of the box (the settlement) was measured by a board calibrated in inches that was placed through the pile cap and visible in photographs and videos of the test.

Many tests of a variety of conditions were performed (Tetra Tech 2008), including redundancy tests, generally as follows:

- The functionality of the boots upon settlement was tested without the layer of gravel to see if the behavior of the boot at full size is the same as predicted in the small models. The full size boots were observed to behave in the same manner as in the small model.
- The functionality of the boots upon settlement was tested with the layer of gravel to see if the boots opened and provided slack for settlement by displacing the gravel. Upon settlement, the boot displaced the gravel to the side, leaving the gravel piled near in a circle surrounding the pile cap (Figures 5 and 6).
- The integrity of the boot extrusion welds was tested for leaks after deployment through the gravel layer. This was done with a blower and smoke generator to provide pressurized smoke into the boot through a sealed pile cap. In all cases, no leaks in the boots were observed. In all cases, the smoke exited the model from under the bottom geomembrane and was observed at the bottom and outside edge of the box.
- The boots were subjected to endurance tests without the gravel layer through 100 cycles of opening and closing, followed by a smoke test to confirm seam integrity. No boot failure occurred.
- Seam strength tests – upon completion of the tests, coupons were cut through the seams of the boots and tested for peel strength per ASTM D-6392. The extrusion welds used to fabricate the boot are subject to peel action upon deployment. The average peel seal strength after boot testing was 402 N/25mm, which exceeds the minimum of 290 N/25mm recommended by GRI-GM19 (2011) for extrusion welds in 1.5 mm LLDPE.
- Material tensile strength and elongation to break – upon completion of the tests, coupons were cut through the boot away from the seams and tested for tensile strength per ASTM D-6693. This was done to confirm that the material used for the boot met standard manufacturing specifications and had not been affected by the testing. As the boot deploys, it was observed that the material is subject to tensile forces as the boot pulls out from the gravel layer and displaces the gravel to the side.

Figure 3 – Prototype boot in test box without gravel layer

Figure 4 – Prototype boot in test box with 30 cm gravel layer

Figure 5 – Typical behavior of boot displacing 30 cm gravel layer upon differential settlement of 15 cm (approximately the maximum estimated remaining settlement of 17 cm). Dashed line added to show approximate location of base of cone of displaced gravel.

Figure 6 – Typical behavior of boot displacing 30 cm gravel layer upon differential settlement of 66 cm (exceeding the Design Settlement of 53 cm, which includes a factor of safety >3) Dashed line added to show approximate location of base of cone of displaced gravel.

2.5 Embedment Ring Development and Testing

The criteria for the development of the embedment ring in the pile cap to which the boot is welded were:

- The weld between the boot and the ring must provide a leak-proof seal.

- The extruded shape/profile of the ring material must provide a high pullout strength.
- The dimensions of the extruded shape/profile must be compatible with the structural design of the pile cap and anticipated location of attachment in the pile cap. Clearance from the reinforcing steel in the pile cap and distance from the edges of pile cap to the embedment ring were coordinated with the structural engineer.
- The extruded shape must be able to be reliably welded with a high production fabrication method into a square shape with strong welds to form a square ring.
- The ring must be easily installed into the pile cap forms by a concrete contractor.

Several manufactured embedment strips were evaluated and T-Lock material provided by EnviroCon Systems was selected (Tetra Tech 2010a). Pullout tests were conducted (TRI/Environmental 2009) to failure with forces applied to the embedment strip both perpendicular to the face of the pile cap (direct pull out) and parallel to the face of the pile cap (shear). 27.6 MPa concrete was used. In all tests, the failure occurred through the concrete around the embedment strip and not through the embedment strip itself.

2.6 Field Tests

Four test piles that were installed for geotechnical evaluation were also used to test and refine all steps needed from the time a pile is placed through the installation of the boot on the pile cap (Tetra Tech 2010b), including:

- Excavation around the pile for the pile cap, which may involve excavation and relocation of waste.
- Forming the pile cap, some below grade in a neat-cut excavation and some above grade with lumber. The height of the above-grade form corresponds to the thickness of the BPS aggregate vent layer shown in Figure 1. The required thickness of the aggregate layer was determined by the membrane protection needed to accommodate the method and equipment used to place and spread the aggregate in a thin layer over the membrane.
- Location of the embedment ring in the form (Figure 7), as previously coordinated with the structural engineer.
- Embedment rings of slightly varying size were tested to determine best fit and ease of installation.
- Methods of securing the embedment ring into the form that would provide a tight and unmovable connection to the pile cap form during concrete pouring and vibration without damage to the ring, and for ease of installation. Also of interest was minimizing the amount of concrete cream that worked into the space between the form and the embedment ring. That material must be removed in preparation for the installation of the boot.
- Placing concrete into the form and vibrating around the reinforcing steel and embedment strip.
- Stripping the forms without damage to the embedment strip, and cleaning and preparing the embedment strip for boot installation. Figure 8 shows the embedment strip in the finished pile cap.
- Placement of the prefabricated boots over the pile cap and protruding rebar, as previously coordinated with the structural engineer. Different neck designs of the boot were tested to determine best fit and ease of installation.
- Welding the boot neck to the embedment ring per the specifications. These field tests were done on test piles, so no surrounding landfill cap geomembrane was installed, and therefore the boots were not welded at the bottom for this test.

Figure 7: Embedment ring installed in pile Cap form

Figure 8: Finished pile cap with embedment ring for attachment of boot

2.7 Final Design

Based on all testing, field experience, and fabrication experience, the final design of the system was established:

- Thickness of BPS aggregate layer and above-grade portion of the pile cap form was selected at 18 cm (using 2x8 lumber for forms).

- Finalized the location of the embedment ring in the form (top edge of ring to be 5 cm from the top of form).
- The outside dimensions of the embedment ring were finalized at 91.1 cm square, which allowed easy insertion into a 91.4 cm square pile cap form, accommodating a certain amount of thermal expansion of the ring.
- The method of securing the ring into the form was finalized. Embedment ring would be secured with screws from the outside of the form, both above and below the midline of the embedment ring. This screw pattern held the ring close to the form, minimizing the concrete cream that worked between the ring and the form caused by vibrating the concrete around the reinforcing bar and embedment ring. This minimizes the effort needed to clean up the embedment ring for the attachment of the boot.
- Boot neck design was finalized to correspond to the final height of the above-grade form and final embedment strip location within the form.
- Specified that the boot neck would be welded to the embedment ring above the highest holes left in the embedment ring by the screws used to place it in the form.
- Boot dimensions were revised slightly to optimize the use of material based on best-fit layout of the boot pieces on 6.9 m wide geomembrane rolls. The final dimensions of the single flap boot are shown in Figure 2.
- Figure 9 shows the final single flap boot free-hanging by securing it at the neck and to a wooded pallet at the bottom, with the boot neck raised until the wood pallet lifted off the ground. Certainly more boot extension could be obtained by adding more weight hanging from the bottom of the boot, but it was judged that this boot extension would represent a settlement condition where the boot was not over-stressed. The extension of the single flap boot shown in Figure 9 is 76 cm, exceeding the maximum design settlement of 53 cm. This 76 cm extension yields a factor of safety of 4.5 relative to the estimated maximum remaining settlement of 17 cm. It should be noted that by using the same boot (with a 76 cm settlement compensation rating) in site areas where remaining settlement is less than 17 cm (i.e., where the waste prism is thinner) will result in a factor of safety even higher than 4.5.

Figure 9: Single flap boot on display at the site since April 2010; extended to compensate for 76 cm of settlement.

3. SPECIFICATIONS AND FQA AND CQA PLANS

The specifications for the fabrication and installation of the boots and rings, and the associated Fabrication Quality Assurance (FQA) Plan and Construction Quality Assurance (CQA) Plan were incorporated into the overall landfill cap Specifications and CQA Plan (Tetra Tech 2009a, 2009b), with appropriate adaptations pertinent to the boots and rings, as follows:

- All of the extrusion welds to fabricate the boots must have an embedded copper wire to allow spark testing of all seams for seam integrity.

- In field installation, the extrusion weld to fasten the boot to the embedment strip must have an embedded copper wire for spark testing. Either spark testing or vacuum box testing is approved for the extrusion weld of the base of the boot to the underlying landfill cap geomembrane.
- Trial welds are required for boot fabrication, with on-site seam strength testing. Trial weld seams are also sent out for lab destructive testing because cutting destructive seam samples from the boot can not be patched and the boot is destroyed. The trial weld logs and laboratory test logs allow any bad seam tests to be traced back to the specific boots represented by the failed seam test.
- A special boot fabrication QA form was developed that documented the provenance of the geomembrane used for each boot. The form records the roll number from which each panel of each boot is cut so that, with the geomembrane manufacturing and conformance test documentation, a complete paper trail for each boot is maintained. Each boot is uniquely numbered so that it's location of installation can be documented.
- The boot fabrication QA form also documents the seaming record of each seam on each boot, exactly like it is done in a field installation of geomembrane, providing a paper trail for any required follow up.
- Because boots and rings are fabricated off site, quality inspections are conducted prior to acceptance, which includes: (a) review and approval of all QA forms produced by the fabricator, and (b) complete inspection of a percentage of the boots and rings in the batch being inspected for acceptance and shipment to the site. In the boots inspected so far, this varied from 10% of the batch to 100% of the batch at the discretion of the inspector. The inspection includes complete spark-testing of every inch of every weld in any boot selected for inspection. The FQA plan also provides for unannounced inspection of the fabrication if deemed necessary.
- The acceptance inspection of the rings includes: (a) confirming integrity and sufficient squeeze-out of material at the welded corners, (b) confirming dimensions, (c) confirming squareness, and (d) manual strength test...can you pull it apart?

4. PRODUCTION FABRICATION

The fabricator implemented a boot and ring production process that resulted in a high degree of confidence that all of the boots and rings would be fabricated consistently and with detailed and complete documentation of quality control (Tetra Tech 2012). The production process included using cutting dies and jigs, fabrication forms, automated processes, color coding, unique numbering, forms, and full-time quality inspection. As of the publication of this paper, 2008 single flap boots and 1832 pile cap embedment rings have been fabricated.

5. INSTALLATION

Boots and rings have been installed on 68 pile caps for the first building developed at the site, as shown in Figure 10. Installation was routine, in accordance with the Specifications, and without problems, indicating that the design development process was effective.

ACKNOWLEDGEMENTS

The authors wish to thank Carson Marketplace, LLC, for permission to publish this paper. The authors also wish to acknowledge the contributions and valuable input provided by Thomas Cota, Ning-Wu Chang, Ph.D., P.E., Daniel Zogaib, and S. Steven Hariri, M.S., P.E., of the Department of Toxic Substances Control (DTSC) of the California Environmental Protection Agency. The Barber-Webb Company contributed to the conceptual design and the final design and fabricated and installed the boots and rings. GSE Lining Technology contributed to the conceptual design and designed and tested the prototype boot.

ABSTRACT

Soil erosion is a natural phenomenon enhanced by human activity which occurs in all landscapes under different land uses with climate and geology as the most important factors influencing them. Universal Soil Loss Equation (USLE) is widely accepted and designed for predicting long-term average annual soil losses. Slope stabilization using Coir Geotextile which is biodegradable can aid in vegetative turfing along the slopes and thereby reduce soil erosion. The objective of this paper is to develop and evaluate a Fuzzy Logic Model based on USLE empirical equation and thereby simulating the effects of Coir Geotextile on soil erosion during rainfall events. The Fuzzy model can be used for predicting soil erosion intensity in Kerala for different types of soil in various combinations of slope angle, crop cover, rainfall intensity etc., and also can be used to select the appropriate variety of coir geotextile for soil erosion control.

1. INTRODUCTION

Soil erosion is a complex dynamic process and is of great concern to humanity as it effects land degradation, limits the supply of hydropower, causes catastrophic floods damaging huge areas of low-lying fields, etc. Besides the influence of human activities, it can also be caused by morphometric characteristics of the land surface, the erosive forces of rainfall and the erodibility of soils (Lal, 2004). Conventional methods such as bench terracing, dry rubble packed bunds etc. have proven to be unsuitable in many of the steep slopes which are highly susceptible to erosion. A permanent and self-propagating vegetative cover is found to be an ideal solution to most of the erosion problems. Stabilization of soil along the hill slopes using natural and biodegradable materials such as Coir Geotextile is found to be a recent technique (Lekha, 2004).

Scientific planning for soil erosion reduction requires knowledge of the relations between those factors that causes soil erosion and those factors helps to reduce such losses. The Universal Soil Loss Equation (USLE) was designed to predict long-term average annual soil losses from sheet and rill erosion on given field slopes under specified land use and management (Wischmeier et al.1978). Soil loss calculations can also be made more reliable with the Revised Universal Soil Loss Equation (RUSLE) for some conditions that are not included in the USLE, if the fundamental information is available. This study is based on USLE, as the available data is more readily cope up with this equation.

Field surveys are however expensive, time consuming and difficult due to the complex interplay of many factors, such as climate, land cover, soil, topography, and human activities. There is a need in many emerging nations to develop simple methods for predicting areas of extensive soil erosion using imprecise, but real-world input data at low cost with considerable accuracy (Mitra et al.1998). This paper reports the application of Fuzzy logic modeling (Cohen et al. 2008) for predicting soil erosion intensity in Kerala for different types of soil in various combinations of slope angle, crop cover, rainfall intensity etc. Fuzzy logic model proved to be more realistic in the soil loss prediction and thereby used to select the appropriate variety of Coir geotextile for soil erosion control.

2. OBJECTIVES

- 1) To develop and evaluate Fuzzy Logic Model based on Universal Soil Loss Equation, thereby predicting soil erosion intensity in Kerala for different types of soil in various combinations of slope angle, crop cover, rainfall intensity etc.
- 2) To simulate the effects of Coir Geotextile on soil erosion by rainfall and runoff, and thereby select an appropriate variety of coir geotextile for soil erosion control.

3. DATA COLLECTION

3.1. For the Development of Fuzzy Logic Model

The Kerala state lies between 8° 18' and 12° 48' N and 74° 52' and 77° 22' E and covers an area of 38864 Sq.km. A major part of Kerala is in a very high rainfall and lower altitude zone with undulating topography and is highly susceptible to erosion. The average annual rainfall over the State is about 3000 mm (Lekha, 2004). Demographically, this state has three rain seasons, viz. pre-monsoon from February to May, monsoon from June to September and post-monsoon from October to January. Laterite soil, forest loams and coastal loams are the major soil types of the State. The land slope ranges from 5 % to over 40 %. Field bunding and terracing are the commonly adopted soil conservation practices in Kerala. (Balan, 1995)

The data set used in this study was obtained from existing study results in Kerala (Table1).

Table1.Description of data used in the study

Source	Project	Duration	Plot size	Data Collected
1. KAU ¹ , Thrissur, Kerala	Agrotechniques for soil conservation systems in Taungya systems	1984-1985 (2 years)	24 X 4 Sq.m	Rainfall intensity (EI values), Soil type, Slope details, Calculated C factor, Measured Soil loss.
2. KCAET ² , Malappuram, Kerala	a) Erodibility and Runoff potential of laterite soils under simulated rainfall conditions	1998-1999 (2 years)	20 x 5 Sq.m (each zone)	Rainfall intensity, 3 series of laterite soil, LS details, Calculated C factor, Measured Soil loss.
	b) Estimation of erosion and runoff project report	2003 (10 years)	40.25 hectares	Rainfall intensity, soil type, LS details, Calculated Soil loss as per USLE of 39 subdivided plots.

¹KAU : Kerala Agricultural University .Vellanikara, Thrissur, Kerala

²KCAET : Kelappaji College of Agricultural Engineering & Technology, Tavanur, Malappuram, Kerala

As per the data source (1) mentioned in table 1, the experiment was conducted in the College of Horticulture campus where the soil type is Sandy Clay Loam as per textural classification. They adopted seven types of treatments (T1 to T7) with different cultivations, of which the value of C factor ranges between 0.10 – 0.60. For the measurement of eroded soil, a multi-slot device with 47 slots of size 2.5 x 10 sq.cm each was fixed on the outer edge of the settling tank of dimension 3.4x0.75x0.35 cu.m.

As per the data source (2.a) mentioned in table 1, the experiment was conducted in three zones of laterite soils with different permeability, water holding capacity and drainage properties which are named as Mannamkulam series, Naduvattom series and Vellanikara series. The experiment was conducted in bare soils without any vegetation. Multi slot devices were used for the measurement of soil loss.

As per the data source (2.b) mentioned in table 1, the experiment was conducted in the college campus itself. The Plot size is about 40.25 ha. and the entire area is subdivided into 39 subareas which are mentioned in the report as L1 to L39. They adopted different types of vegetations for each plot for the estimation of soil loss through erosion and runoff. The value for cover management factor obtained from the report ranges between 0.2 to 0.7

3.2. For Simulating the Effects of Coir Geotextile

Coir geotextile is a natural geotextile made of coir applicable for erosion control which is more preferred to synthetic fibres on account of the fact that the material is environmental friendly and ecologically compatible as it gets degraded with the soil. It serves the purpose of protecting the seeds and surface soil from being washed away in the initial stage and the final stability of the slope is attained by the roots of vegetation and soil consolidation. This method is more appropriate in places where vegetation is considered to be the long-term answer to the slope stabilization (Lekha, 2004).

Table 2: Description of data used in the study

Source	Project	Duration	Plot size	Data Collected
1. NCRMI ¹ , Trivandrum, Kerala	Coir geotextiles as an effective erosion control measure in varying slopes of tropical humid condition	2000-2003 (3 years)	25 x 5 Sq.m	Rainfall intensity, Forest loam soil details, LS details (20%, 30%, 40% and 50% slope), Coir geotextile – 3types (1", 1/2", 1/4"), Measured annual soil loss.

¹NCRMI : National Coir Research and management Institute, Kudappanakkunnu

As per the data source (1) from NCRMI mentioned in table 2, the study was conducted at the Soil Conservation Research Station, Konni which is located at 9°51'20" and 9°51'44" North latitude and 76°13'54" East longitude, where the soil type is typical forest loam. The 11 slot multi-slot divisors known as Geib divisor were used to measure the runoff from the plot. The Coir geotextiles considered in this study (table 2) are woven types of three mesh sizes namely Less opening (1/4 inch), Medium Opening (1/2 inch) and High opening (1 inch). As the coir geotextiles has its role only up to the stage where vegetation starts sprouting, the data obtained were considered only up to the action of Geotextiles alone. The slope percentage considered ranges from 20% to 50%.

4. METHODOLOGY

4.1 Universal Soil Loss Equation (USLE)

USLE is a set of mathematical equations that estimate average annual soil loss and sediment yield resulting from interrill and rill erosion. It is derived from the theory of erosion processes, more than 10,000 plot-years of data from natural rainfall plots, and numerous rainfall-simulation plots. The Universal Soil Loss Equation (Wischmeier and Smith, 1978) is:

$$A = R * K * LS * C * P \quad [1]$$

- A - Annual soil loss (t/ha/yr)
- R - Rainfall erosivity factor (mm/yr)
- K - Soil erodibility (t/ha/mm)
- LS - Slope length and steepness
- C - Cover management
- P - Support practice factor

4.1.1. Rainfall Erosivity (R):

R factor represents the driving force for sheet/rill erosion. It is sum of individual storm erosivity values for qualifying storms over a time period. Storms of less than 0.5 inch and by more than 6 hours are not included in the computations. The R factor corresponds to USLE is found more appropriate as per the collected data (table 1). The R factor as per USLE (Wischmeier and Smith, 1978) is given by:

$$R = \sum_{i=1}^n \frac{EI}{100} \quad [2]$$

The variable EI is the product of the total energy for a storm and the storm's maximum 30-minute intensity and n represents the number of storms in the series.

4.1.2. Soil Erodibility (K):

K factor indicates a soil's inherent susceptibility to erosion. It is the rate of soil loss per unit of R for a specified soil as measured on a unit plot. The K values were usually estimated using the soil-erodibility nomograph (Das, 2009) method and is found more appropriate as per collected data (table 1). The K factor (Wischmeier and Smith, 1978) is given by:

$$K = 2.8 \times 10^{-7} M^{1.14} (12 - a) + 4.3 \times 10^{-3} (b - 2) + 3.3 \times 10^{-3} (c - 3) \quad [3]$$

- M - Particle size parameter
- a - Percent organic matter
- b - Soil structure code
- c - Profile permeability class

4.1.3. Topographical Factors (LS):

Two factors considered here are Slope length and Steepness. Slope length (L) represents the distance from the point of origin of overland flow to the point where the slope decreases sufficiently for deposition to occur. Slope steepness (S) is the field segment slope, expressed as percentage. The combined LS factor is given by (Wischmeier and Smith, 1978):

$$LS = (L_s/22.13)^m (65.41 \sin^2\theta + 4.56 \sin\theta + 0.065) \quad [4]$$

- L_s - Slope length in meters
- m - Exponent that depends on slope steepness ($m = 0.5$ for slope exceeding 5%)
- θ - Slope angle

4.1.4. Crop Management Factor(C):

The C cover-management factor is used to express the effect of plants and soil cover. The C-factor is defined as the ratio of soil loss from land cropped under specified conditions to the corresponding loss from clean-tilled, continuous, fallow land. To calculate the value of the C factor, the ratio of soil loss under a given crop stage period is given a weightage in accordance with the rainfall factor of that particular period (Das, 2009).

$$C = EI (\%) \times \text{Soil Loss Ratio} (\%) \quad [5]$$

4.1.5. Support Practice Factor (P):

It is the rate of soil loss caused by a specific support practice divided by the soil loss caused by row farming up and down the slope. It is used in USLE calculations only for row cropped land uses, and for all other land uses it is always taken as 1.00 (Das 2009). In this study, since no soil conservation practices were considered, a constant value of 1.00 is assigned

4.2. MATLAB – Fuzzy Logic Toolbox

MATLAB (short for MATrix LABoratory) is a computer program optimized to perform engineering and scientific calculations where problems and solutions are expressed in familiar mathematical notation (Overman, 2012). The design of the fuzzy system must include all of the four blocks in the block diagram (Fig 1). The singleton fuzzyfier will involve the smallest volume of calculations. The centroid defuzzyfier gives the best accuracy with the system output compared to other defuzzifiers (Wang, 1997). The Fuzzy Logic toolbox in MATLAB helps to model complex system behaviors using simple logic rules, and then implement these rules in a fuzzy inference system (Pazhouhesh et al. 2011).

Fig 1- Block Diagram of the Fuzzy system

4.3. Results and Discussion

4.3.1. Development of Fuzzy Logic Model

Determination of Annual soil loss parameter (A) in the USLE model depends on five factors such as: Rainfall erosivity factor (R), soil erodibility factor (K), Length-Slope-gradient factor (LS), Cover management factor (C) and Support practice factor (P). The equations (Eq. 1 to 5) for each factor were developed in MATLAB programming through M-files, which can execute a series of statements. The collected data (table 1) such as Rainfall intensity, Soil type, Slope angle etc. is then substituted accordingly in M-files and obtained the range of values for R, K, LS, C and A factors.

The value obtained for R factor (Eq.2) is in the range between 0-4000. The values above 3000 are not considered in this study. The K factor (Eq.3) was based on Wischmeier's Nomograph (Das, 2009). The types of soil considered in this study are sandy loam, fine sand and Lateritic soil, of which the value for K factors ranges between 0.02 and 0.13. The value for slope length gradient (Eq.4) varies between 0.04-15 according to the slope angles of collected data. The C factor (Eq.5) value ranges between 0-2. The value greater than 1 is considered as severely high. The value for annual soil loss (Eq.1) ranges between 0-50. The range above 50 is considered as Very Severely High (VSH).

The range of values thus obtained are then sub categorized from very low (VL) to extremely high (EH) as shown in table 3 for creating Membership functions in Fuzzy logic.

Table 3: Range of values for each factors (VL= Very Low, ML = Moderately Low, L= Low, LM= Least Moderate, MM= Moderately Moderate, VM= Very Moderate, M= Moderate, LH= Least High, MH= Moderately High, H= High, VH= Very High, SH= Severely High, EH= Extremely High)

R		K		LS		C		A	
0-250	- VL	0-0.025	- VL	0-0.07	- VL	0-0.03	- VL	0-0.10	- VL
250-500	- ML	0.025-0.04	- ML	0.07-0.08	- ML	0.03-0.075	- ML	0.10-0.75	- ML
500-750	- L	0.04-0.06	- L	0.08-0.10	- L	0.075-0.20	- L	0.75-1.50	- L
750-1000	- LM	0.06-0.08	- LM	0.10-0.80	- LM	0.20-0.25	- LM	1.50-2.50	- LM
1000-1250	- MM	0.08-0.10	- M	0.80-1	- VM	0.25-0.30	- MM	2.50-3.50	- MM
1250-1500	- VM	0.10-0.115	- H	1-3	- M	0.30-0.40	- VM	3.50-5	- VM
1500-1750	- M	0.115-0.13	- VH	3-4	- LH	0.40-0.45	- M	5-7	- M
1750-2000	- LH			4-5	- H	0.45-0.50	- LH	7-9	- LH
2000-2250	- MH			5-8	- VH	0.50-0.70	- H	9-12	- MH
2250-2500	- H			8-13	- SH	0.70-0.80	- VH	12-16	- H
2500-2750	- VH					0.80-2	- SH	16-20	- VH
2750-3000	- SH							20-25	- SH
								25-40	- EH

Fuzzification plays a greater role for fuzzifying data, which is based on certain membership functions. Large number of membership functions with overlapping will increase the system accuracy (Pazhouhesh et al. 2011). Figures 2a to 2e show the trapezoidal membership functions with overlapping of all the five factors and annual soil loss in the Fuzzy system as per the range of values mentioned in table 3.

Fig 2a- Membership functions of 'R factor' (input 1)

Fig 2b- Membership functions of 'K factor' (input 2)

Fig 2c- Membership functions of 'LS factor' (input 3)

Fig 2d- Membership functions of 'C factor' (input 4)

Fig 2e- Membership functions of 'Annual Soil loss' (output)

Fig 2- Membership functions of R, K, LS, C factors and Annual Soil Loss (A) as per table-3

After deriving the membership functions for the inputs and output, the rule base should be developed. So, many configurations using USLE empirical equation have been extracted to develop the rules in Fuzzy system. Three examples are shown in table 4a. Around 650 such configurations were obtained to get more refined output.

Table 4a: Rules extracted using USLE empirical equation

No	R	K	LS	C	A-USLE
1	317 - ML	0.026 - ML	3.43 - LH	0.097 - VL	2.74 - VM
2	213 - VL	0.043 - L	2.50 - M	0.04 - ML	0.916 - L
3	1520 - M	0.015 - VL	8.10 - SH	0.76 - H	140 - VSH

The most important step in the fuzzy system is the expression of the process in the IF-THEN logic. It is quite important to be able to determine which entry would produce the largest output with the smallest incremental change (Burrough et al. 1992). The example of three fuzzy rules relating to annual soil loss is summarized and shown in Table 4b.

Table 4b: Fuzzy rules relating to Annual Soil Loss

Rules	IF	R	IF	K	IF	LS	IF	C	THEN	A
1	IF	ML	IF	ML	IF	LH	IF	VL	THEN	VM
2	IF	VL	IF	L	IF	M	IF	ML	THEN	L
3	IF	M	IF	VL	IF	SH	IF	H	THEN	VSH

4.3.2. Evaluation of Fuzzy Logic Model

For evaluating the model, the fuzzy predicted annual soil loss values (A-Fuzzy) must be compared with actual field measured values (A-Field). The results from the fuzzy model (A-Fuzzy) were obtained from the “Rule Viewer” as shown in figure 3. The input and output tab is marked as ‘a’ and ‘b’ respectively in figure 3, which illustrates the example 1 in table 5. For verifying the performance of the designed fuzzy system, five experimental data sets have been chosen and applied to the model. Table 5 shows a summary of the results.

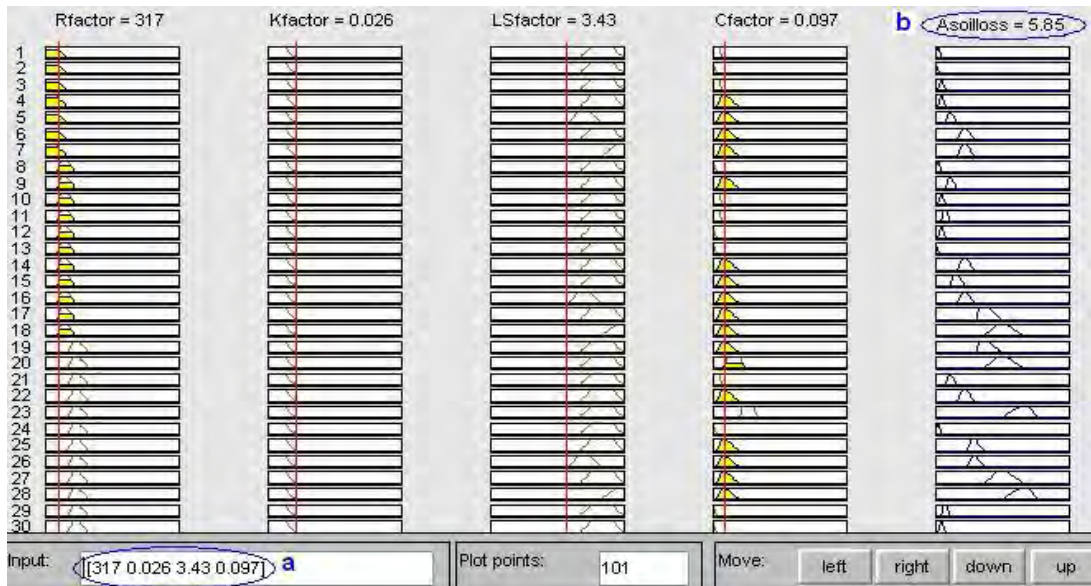

Fig 3- Rule Viewer in Fuzzy Logic

The comparison in Table 5 indicates that the values of the Annual Soil loss calculated by the fuzzy system are quite closer to the actual values obtained in the field (A-Field). Results showed that the fuzzy model performed better than USLE. Hence it can be presumed that the efficiency of the fuzzy model will be higher than USLE.

Table 5: The results of Annual Soil Loss obtained with the fuzzy system and with the USLE model

No	R	K	LS	C	A-Field	A-USLE	A-Fuzzy
1	317	0.026	3.43	0.097	5.10	2.74	5.85
2	213	0.043	2.50	0.04	1.20	0.916	1.49
3	697	0.030	7.10	0.20	25.30	21.92	26.70
4	689	0.065	0.22	0.70	2.60	5.90	2.10
5	742	0.065	0.22	0.70	4.30	7.50	3.80

4.3.3. Selection of Coir Geotextile Type

The collected data (table 2) such as rainfall intensity, soil type, slope angle etc. is substituted accordingly in the M-files of MATLAB programming and obtained the values of corresponding R, K and LS factors. Three types of Coir geotextiles were considered in this field study namely Less opening (LO), Medium opening (MO) and High opening (HO). The C factor of Coir Geotextile is thus obtained using the equation:

$$C = (\text{Measured Annual soil loss}) / (R * K * LS) \quad [6]$$

For various slope percentages, the range of values of C factor for coir geotextile is summarized in table 6.

Table 6: Range of C values depends on Slope percentage

Types	Mesh size	20%	30%	40%	50%
LO	0.25"	0.04-0.10	0.02-0.11	0.20-0.60	0.30-0.60
MO	0.50"	0.06-0.20	0.05-0.15	0.30-1.00	0.40-1.20
HO	1.00"	0.08-0.30	0.07-0.30	0.50-1.10	0.50-1.30

For predicting the type of geotextile for various combinations, soil type according to textural classification (Das, 2009) is considered which ranges from sandy soils (less erosive) to fine textured clayey and silty soils (highly erosive). The annual soil loss less than 5 (t/ha/yr) is considered as low erosion potential (Lal, 2004). Table 7 shows the range of values for each factor.

Table 7 – Range of values for each factors (EL=Extremely Low, VVL= Very Very Low, VL= Very Low, ML = Moderately Low, L= Low, LM= Least Moderate, VM= Very Moderate, M= Moderate, H= High, VH= Very High, SH= Severely High)

R	K	LS	A	C
0-250 – VL	0.01-0.03 – S (Sand)	0-1 – VL	0-1.5 – EL	0.03-0.2 – LO
250-400 – L	0.04-0.05 – LS (Loamy Sand)	1-5 – L	1.5-2.5 – VVL	0.2-0.6 – MO
400-600 – VM	0.06-0.09 – FS (Fine Sand)	5-10 – M	2.5-4 – VL	0.6-1 – HO
600-800 – M	0.12-0.14 – SL (Sandy Loam)	10-15 – H	4-5 – L	
800-1000 – H	0.15-0.2 – SCL(Sandy Clay Loam)	15-20 – VH		
1000-1500 – VH	0.16-0.23 – SC (Sandy Clay)			
1500-2000 – SH	0.2-0.25 – C (Clay)			
	0.25-0.27 – SiC (Silty Clay)			
	0.26-0.34 – L (Loam)			
	0.3-0.4 – SiCL (Silty Clay Loam)			
	0.35-0.45 – SiL (Silty Loam)			
	0.41-0.5 – Si (Silt)			

Accordingly membership functions for each factor were developed as per the values in table 7. Figures 4a to 4e shows the trapezoidal membership functions with overlapping of all the four factors (R, K, LS and A) for the prediction of C factor in the Fuzzy system.

Fig 4a- Membership functions of 'R factor' (input 1)

Fig 4b- Membership functions of 'K factor' (input 2)

Fig 4c- Membership functions of 'LS factor' (input 3)

Fig 4d- Membership functions of 'Annual Soil Loss' (input 4)

Fig 4e- Membership functions of 'C factor' (output)

Fig 4- Membership functions of R, K, LS factors and Annual Soil Loss (A) for the prediction of C factor as per table 7

After deriving the membership functions for the inputs and output, the next step is the development of rules using USLE empirical equation. First set of rules were created by considering the typical forest loam soil type ($K = 0.026$) for different slope percentages as per the collected data mentioned in table 2. The subsequent sets of rules were then created by considering all the soil types as per textural classification. Around 300 set of rules were developed for the prediction of

coir geotextile for various combinations. The example of three such fuzzy rules relating to the selection of the type of coir geotextile is summarized in Table 8.

For example, the first example shows that for a particular site where the soil type is Sandy (K factor = S) having very low (VL) R factor and LS factor, in order to reduce the annual soil loss to extremely low condition (A = 0 to 0.15), adopt High opening (HO) type of coir geotextile.

Table 8: Fuzzy rules relating to Coir geotextile selection

Rules	IF	R	IF	K	IF	LS	IF	A	THEN	C
1	IF	VL	IF	S	IF	VL	IF	EL	THEN	HO
2	IF	M	IF	SCL	IF	M	IF	VL	THEN	MO
3	IF	SH	IF	SiL	IF	H	IF	L	THEN	LO

Therefore for a particular combination of rainfall intensity, soil type and slope gradient, it become possible to select the appropriate type of coir geotextile for the minimum soil erosion potential.

5. CONCLUSIONS

Fuzzy logic method is shown to be a relatively easy way for determining soil erosion potential. Comparing the A values calculated using the designed fuzzy model with those obtained from the USLE model showed that the fuzzy logic modeling for determination of the Soil loss factor is more flexible and realistic procedure for describing the relationship with the five factors. Thus the evaluated model can then be used for the prediction of the type of coir geotextile for a particular combination of rainfall, soil type and slope gradient for the minimal soil loss. Due to changing weather conditions year by year, the dataset for minimum twenty years is required for different soil type, slope angle, cover factor etc. to have accurate prediction. One major advantage of fuzzy logic model is that they can be used in developing countries where digital data are not readily available and where simple and inexpensive techniques are useful for a preliminary reconnaissance survey of soil erosion potential.

Specifying Allowable Geomembrane Leakage Rates Based on Available Technology

Glenn T. Darilek, P.E., Leak Location Services, Inc., San Antonio, Texas, USA, glenn@llsi.com
Daren L. Laine, Leak Location Services, Inc., San Antonio, Texas, USA

ABSTRACT

Engineering and regulatory specifications for allowable leakage through geomembranes should be consistent with state-of-the-art technologies for locating leaks. In many actual cases, surface impoundments are allowed to leak an order of magnitude more than what could be easily attained by locating leaks using currently available leak detection technologies. In some cases for landfills, if an allowable leakage rate is exceeded, there is no technology that can be used to locate the small leak or leaks for repair.

ASTM D7007, the established standard for geomembrane leak location with water or earth materials on the geomembrane, and a mathematical equation for leakage rate versus size of the leak are used to examine what is achievable and what is unrealistic for the specification of allowable leakage rates.

Specification writers and design engineers should specify low, but realistic allowable leakage rates that can be attained using geomembrane leak location surveys.

1. ALLOWABLE LEAKAGE RATES

Allowable Leakage Rates or Action Leakage Rates (ALRs) are specified for installed geomembranes to quantify the maximum allowable liquid leakage. If the ALR is exceeded, then corrective action must be taken to reduce the leakage rate below the set limit. To lower the leakage, the holes in the geomembrane must be located and repaired. In some cases, the allowable leakage rate can be set so low that if it is exceeded, there is no technology that can be used to locate the very small leak or leaks for repair. In other actual cases, surface impoundments are allowed to leak an order of magnitude more than what could be easily attained by locating and repairing leaks using currently available leak detection technologies.

When the U.S. Environmental Protection Agency promulgated the final rule for Action Leakage Rates (1992), it considered what was usually attainable with good construction quality assurance. They may not have considered what could be attained with the available leak location technologies, nor the consequences if it was not technologically possible to detect leaks that would cause the ALRs to be exceeded particularly for landfills. Paradoxically, the usual technical guidelines that geomembranes covered with water are allowed to leak 10 times more than geomembranes covered with earth materials is opposite than what is attainable with the technologies available today. The result is that some surface impoundments are allowed to leak 10 times more than necessary, and some landfills that may never meet their allowable leakage specification by a factor of about 10. So today, the capabilities of currently available technologies should be considered when specifying allowable leakage rates.

2. MEASURING LEAKAGE RATES

2.1 Rudimentary Leak Detection Systems

The concept of allowable leakage rates depends on being able to measure the leakage over time. In some instances, a relatively permeable earth drainage material layer with an underlying relatively impermeable clay layer are used to collect leakage and drain the leakage to a leak collection sump. Because of wide variations in the construction and performance of the layers, the quantity of leakage measured is less than the actual leakage. Actual leakages may be much more, so the measured leakages are more qualitative than quantitative.

2.2 Water Balance Testing

Water balance testing is another way to measure leakage in single-geomembrane liners. The methodology is to measure the water level over a period of time and compensate for evaporation, rainfall, geometry, and runoff.

The accuracy of water balance testing is questionable. Even using the best protocols, it is problematic to accurately read the water levels to the accuracy needed and make the corrections accurately. Compensating for rainfall must account for the rain that falls on the unflooded side slopes that drain into the pond. Any rainfall drainage that flows into the impoundment from the surrounding berms or road surfaces will cause error. The evaporation rate for a large body of water is not the same as that for the smaller control container used to measure the evaporation. If the evaporation pan used for measuring the evaporation and rainfall is disrupted unintentionally or by animals during the long period of measurement, the results will be invalidated.

The leak detection sensitivity for water balance testing is poor, and the method only detects the presence of leakage, and not the location of the leaks. Because of meniscus and wave effects, the water level usually cannot be read to an accuracy greater than about 2 mm. This allows an error in the measurement of 20 cubic meters per hectare (2,140 gallons per acre).

A significant amount of time and cost are needed to fill the impoundment, then empty the impoundment and dispose of the water. For sensitive leak detection, the water level monitoring must occur over a period of weeks. During that time, the test can be subject to disruption, vandalism, and tampering.

Most of the errors in the water balance test act in the favor of passing the test. The results of some water balance tests falsely indicate that water is created during the test! Some specifications for water balance testing allow evaporation ponds to leak more than they evaporate. Water balance testing results in questionable results, costs a lot, and takes a long time.

2.3 Double Geomembranes

The most accurate and common leakage detection system is to use double geomembranes with a drainage layer between the geomembranes. The drainage layer incorporates a geonet, earthen drainage material, or structured geomembrane. The drainage layer is sloped to a sump between the geomembranes, which is pumped out to determine the leakage. The cost of the secondary geomembrane and the drainage layer is significant, but often required by regulatory agencies.

Assuming proper design and construction, that the secondary geomembrane is intact, this method is very accurate for determining leakage rates. Leakages of a few liters per month can be gauged. Leakages can be measured as frequently as needed.

2.4 Geomembrane Leak Location Technologies

Geoelectric leak location technologies do not measure the leakage rates as such, but they are used to detect the leaks so once the leaks are found and repaired, the leakage rates can be expected to be very low. The various implementations are described in ASTM Standard D6747. Various methods are used to locate leaks in bare geomembranes, geomembranes covered with water, and geomembranes covered with earth materials. Various implementations are used to locate leaks in bare geomembranes, geomembranes covered with water, and geomembranes covered with earth materials. Other leak location methods include visual inspection, vacuum box testing, and pressure testing of seams, but these methods are usually limited to pre-service testing, and are not applicable after earth materials are installed on the geomembrane.

3. LOGICAL CRITERIA FOR SPECIFYING ALLOWABLE LEAKAGE RATES

Allowable leakage rates should be specified at a low level that is consistent with being able to detect leaks that would contribute significantly to the ALR. The best available technologies for locating leaks in geomembranes are geoelectric leak location methods. The practical approach is to specify allowable leakage rates that are achievable in all reasonable cases when currently available leak detection technologies are applied.

By this criteria, it does not make sense to specify a high allowable leakage rate if the leakage rate can be easily met using the available geomembrane leak location technology. Allowing a higher leakage rate allows inferior construction standards and possible future environmental damage.

It is usually possible to construct a facility with very low leakage rates, and that is certainly the goal. But specifying a leakage rate that can be exceeded by a leak that cannot be located using any technology is unrealistic and untenable. The logical criteria for specifying an allowable leakage rate is not whether a certain low leakage rate is achievable with good construction and quality assurance practices, but whether there is a practical solution if the low leakage rate is not achieved for some reason.

3.1 Approach

ASTM Standard D7007 for geomembrane leak location with water or earth materials on the geomembrane requires determining the distance from which an actual or artificial test leak of specified sizes can be found. Then the leak location surveys are conducted so that the leak detection probe passes within that distance of every point on the geomembrane. Leaks smaller than the actual or artificial leak are routinely found when the measurement probe passes closer to the leak, but one can expect to locate all leaks larger than the actual or artificial test leak. So one can assume the worst-case condition of free-flow through the leak of that size. The free-flow leakage rate can be calculated using an equation derived from Bernoulli's equation for free flow through an orifice (Giroud and Bonaparte, 1989).

$$Q = 0.6 a \sqrt{2 g h} \quad [1]$$

Where Q = leakage rate (m^3/s)
 a = area of the leak (m^2)
 g = acceleration of gravity (m/s^2)
 h = hydraulic head (m)

Then if one assumes one leak of this size for an assumed area, an allowable leakage rate can be assigned on this basis. For this paper, one leak is assumed for every 4,050 square meters (1 leak per acre).

3.2 Water-Filled Impoundments

Geoelectric leak location surveys with only water covering the geomembrane can very easily locate leaks that would contribute to a sometimes-suggested allowable leakage rate of 9,350 liters per hectare per day (1,000 gallons per acre per day). Figure 1 is a graph of the free flow leakage rate versus the leak size for surveys with water on the geomembrane using Equation 1. ASTM D7007 specifies a 1.4 mm (0.055 in.) test leak. The equipment and survey parameters are set up to be able to detect leaks this size under near worst case conditions. This diameter and the corresponding leakage rates are also indicated in Figure 1 for two depths of water above the leak. Assuming free flow, which is the case with a properly designed leak detection system, the graph shows that the leakage rate from such a leak is about 790 and 353 liters per day (80 and 180 gallons per day) for water depths of 1m (3.3ft) and 5m (16ft), respectively. Such a leak is very practical to detect, and those leakage rates are typically a fraction of the usual allowable leakage rates for water-filled impoundments.

This illustration is for only one leak. For large impoundments, it is reasonable to assume there would be multiple leaks. If one would expect maybe 2.5 leaks per hectare (1 leak per acre), the illustration can be extrapolated to larger impoundments. However, it is unsound to interpolate for smaller impoundments, because that would result in a leakage rate and leak size that may not be located using leak location methods.

In general, this analysis suggests that typical allowable leakage rates could be made more stringent for ponds larger than about one acre. Using the analysis and assumptions above, a more suitable allowable leakage rate of approximately 940 liters per hectare per day (100 gallons per acre per day) would be more suitable.

Figure 1. Free Flow Rate versus Leak Diameter with Water on the Geomembrane

3.2 Impoundments and Landfills with Earth Materials on the Geomembrane

The analysis for geomembranes with earth materials covering the geomembrane shows that increases in the allowable leakage rates may be warranted in some situations. Figure 2 shows a graph of the free flow leakage rate vs. leak size for surveys with earth materials on the geomembrane. ASTM D7007 specifies a 6.4 mm (0.25 in.) test leak. Again, as part of the leak location procedure, the equipment and survey parameters are set up to be able to detect leaks this size under near worst case conditions. This diameter and the corresponding leakage rates for water heads of 0.3 m (1 ft) and 1.0 m (3.3 ft) are also shown in Figure 2.

Assuming free flow, which would be essentially the case with granular drainage materials or geosynthetic drainage materials above and below the geomembrane; the graph shows the leakage rate from such a leak is about 4,045 and 7,385 liters per day (1,070 and 1,950 gallons per day) for typical hydrostatic heads of 0.3m (1ft) and 1m (3.3ft), respectively. A leak with this diameter is practical to detect, but these leakage rates are more than an order of magnitude higher than some allowable leakage rates for landfills.

This illustration shows that if an allowable leakage rate is set very low, then detection of the small leaks in the geomembrane that cause the leakage may not be possible. This unrealistic requirement can result in disastrous consequences that may prevent the permitting of the landfill cell.

Fortunately in some cases, when a very low allowable leakage rate is specified, a low-permeability layer such as a geosynthetic clay liner (GCL) is placed under the geomembrane to help meet the leakage criteria. A low-permeability layer greatly decreases the leakage rate if the geomembrane makes good contact with the layer. Therefore, larger holes can be located or tolerated. However, if the geomembrane is not in intimate contact with the low-permeability layer, such as on wrinkles or bridging, the unsolvable problem remains if there are leaks in these areas.

A common geoelectric leak location specification for landfills calls for detecting all leaks that could contribute to an allowable leakage rate of 187 liters per hectare per day (20 gallons per acre per day). This leakage will flow through a 0.86 mm (0.034 in.) diameter leak assuming free flow with only 0.3 m (1 ft.) of head. Meeting this low ALR depends almost entirely on the GCL or other leak-sealing layer having intimate contact with the geomembrane and not on the detection capabilities of the geoelectric leak location method. The analysis above shows that meeting that geoelectric leak location specification may be in conflict with the ASTM standard and the available technology.

4. SENSIBLE APPROACHES

4.1 Surveys of Bare Geomembranes

It may not be possible to detect smaller leaks, after the overlying earth layer is installed. To meet a low allowable leakage rate, and certainly if there is no low-permeability layer in contact with the geomembrane, a sensible approach is to test the bare geomembrane for leaks before the earth materials are placed. This can be easily accomplished using the water puddle method specified in ASTM Standard D 7002. This will detect the smaller geomembrane installation

Figure 2. Free Flow Rate versus Leak Diameter with Earth Materials on the Geomembrane

leaks. Leaks that are caused by machinery placing the earth materials on the geomembrane are generally larger, and may be detected after the earth materials are being placed on the geomembrane.

4.2 The Misconception of Specifying Zero Leakage

Some engineers and owners are still specifying zero leakage or no leaks. Specifying zero leakage for a geomembrane is even more unreasonable than specifying an allowable leakage rate that is too low. A reasonable person could interpret zero leakage as never a drop. Although one strives to obtain the best attainable results with a specification, it is naive to specify something that cannot be remedied if the specification is not met. That is the case when specifying zero leakage in a geomembrane of any practical size. There have been several instances of this faulty specification, most notably in water storage reservoirs with many pipe penetrations and roof support columns with battens and other details. Sometimes, one is fortunate and the leakage is zero or ignorable. But specifying zero leakage or specifying that a liner has no leaks almost always results in disputes and sometimes unsolvable problems.

4.3 The Dilemma

The industry has been fortunate for the most part in installing geomembranes to meet low allowable leakage rates. However, that does not justify flirting with disaster by continuing to specify allowable leakage rates that are too low. Despite best efforts, for whatever reason, the primary geomembrane may have a leakage that is slightly above a specified low allowable leakage rate. A geoelectric leak location survey can be conducted in the hope that any leaks detected and repaired will lower the leakage rate. However, if the leaks are too small to be detected, the only alternative is to remove the cover material and geosynthetics from the geomembrane, remove and replace the geomembrane, and hope that the problem does not reoccur. All of this added expense and possible lost revenues and liquidated damages over a small amount of leakage through the primary geomembrane, and probably very negligible leakage through the secondary geomembrane! This can be avoided if a proper and reasonable allowable leakage rate is specified from the beginning.

4.4 Easily Attainable Better Performance

The prospect for water-filled impoundments is much more promising. In fact, in most cases, the allowable leakage rates can be made much lower. It does not make sense to install a geomembrane as an impermeable layer and tolerate easily detectable leaks. The technology is widely available to locate leaks that would contribute an order of magnitude less than some allowable leakage rates. If a lower allowable leakage rate is exceeded, there are easy ways to solve the problem.

5. CONCLUSIONS

Allowable leakage rates should be set according to what is easily attainable using existing technologies. Many ALRs for impoundments can be easily decreased by using geomembrane leak location technologies. But, particularly for geomembranes covered with earth materials, an important part of engineering and specification writing is to balance the desire for perfection with what is suitable for the purpose, at a reasonable cost, and attainable with existing technology.

Although perfection may be the goal, specifying perfection or the unattainable without regard to the technology and cost and consequences is not good engineering. The logical criteria for specifying low allowable leakage rates is not whether a certain low leakage rate is achievable with good construction practices, but whether there is a practical solution if the low leakage rate is not achieved. Specification writers and design engineers should consider what is attainable using the available technologies and understand the implications for their project if the ALR cannot be met.

Storage of Coal Combustion Residuals with a Geosynthetic Liner – A 30 Year Forensic Study

B. Ramsey, GSE Environmental LLC, Houston, Texas, USA, bramsey@gseworld.com

B Betke, GSE Environmental LLC, Houston, Texas, USA

I. Peggs, I-CORP INTERNATIONAL, Inc., Ocean Ridge, FL, USA

ABSTRACT:

The storage of coal ash has become an increasing concern in recent years. The December 2008 failure at the power facility in Kingston, Tennessee, USA along with the October 2011 failure in Oak Creek, Wisconsin in addition to over 50 documented cases of groundwater contamination at or nearby coal ash storage facilities and consideration of the US EPA's issuance of new regulations for the storage of coal ash will require the use of geosynthetic materials as a critical part of the containment system.

This paper will present pertinent facts on a long term success story in the use of geomembranes as containment for coal combustion residuals. Recently material that has been in use in this exact application was exhumed from a power company site in Florida where the geomembrane had been used to successfully contain coal ash for over thirty years.

1. INTRODUCTION

1.1 Introduction and History

The geosynthetics market as a whole, and the geomembrane industry in particular, received its first large growth spurt with the 1976 U.S. congressional bill that is known as RCRA [The Resource Conservation and Recovery Act]. These regulations were issued in two sections, the first specific to material deemed as hazardous waste, the second addressing the long-term fate of solid waste. Hazardous waste has since become known as "subtitle C" type waste and solid or most commonly household waste has become known by that specific section of the regulations "subtitle D." There is an additional waste stream known as construction and demolition waste or "C& D material" that is not regulated under RCRA but is instead addressed on a state-by-state or local regulatory basis. The second significant regulatory impact occurred in 1980 with passage of the Comprehensive Environmental Response, Compensation and Liability Act more commonly known as "Superfund." This regulation not only increased demand for geosynthetic materials but helped to spur large growth in the capping applications, using geosynthetics as surface or near surface barriers to prevent rainwater infiltration.

The proper place to begin a review of coal ash and its regulation, and lack thereof, within the United States is in calendar year 1980 with the passage by the U.S. Congress of what is known as the "Bevill Amendment," named for former Representative Tom Bevill (D-AL). In passing the law, RCRA was amended by adding section 3001(b)(3)(A)(ii), known as the Bevill exclusion, to exclude "solid waste from the extraction, beneficiation, and processing of ores and minerals" from regulation as hazardous waste under Subtitle C of RCRA. Further, an EPA study of the impact of coal ash on the environment was mandated. This study was completed and published in the Federal Register on May 22, 2000. The report states "The Agency has concluded these wastes do not warrant regulation under subtitle C of RCRA and is retaining the hazardous waste exemption under RCRA section 3001(b) (3) (C). However, EPA has also determined national regulations under subtitle D of RCRA are warranted for coal combustion wastes when they are disposed in landfills or surface impoundments,..." However, the EPA determination for subtitle "D" regulation was not heeded and the absence of regulations of coal ash storage continued. Just before 1 a.m. on Monday, December 22, 2008, a dike containing coal fly ash slurry ruptured at an 84-acre (0.34 km²) solid waste containment area at the TVA Kingston Fossil Plant in Roane County, Tennessee, USA. An estimated 1.1 billion U.S. gallons (4,200,000 m³) of coal fly ash slurry was released. Subsequent direct clean-up and remediation costs have been estimated at greater than 1.3 billion dollars.

On October 31, 2011 a failure occurred at a power generation facility owned by a WE Energies located on the shore of Lake Michigan in Oak Creek Wisconsin, south of Milwaukee. This event resulted in a significant quantity of coal ash being released into Lake Michigan. According to a report published by the State of Wisconsin Department of Natural Resources, the spill was the result of construction of a sediment retaining basin over old coal ash deposits. "...the FGD sediment basin would potentially be constructed in coal ash deposits (see figure 5). During construction, ash deposits were found in the western portion of the FGD sediment basin. These deposits were removed and replaced with suitable soil in accordance with the contaminated materials management plan. However, a liner plan was not submitted to the Department when ash deposits were discovered..." "A significant component of the bluff collapse material appears to be the coal ash deposited in a ravine in the 1950s – 1960s."

This incident and other issues with groundwater contamination at or near coal combustion residual storage facilities has resulted in the US EPA considering new regulation of coal ash storage and significant companion actions on the legal, federal congressional and multiple governmental fronts.

In the absence of regulations, some coal burning power generation facilities and companies have voluntarily chosen, over the years, to apply the use of geosynthetic materials to the issues of coal ash storage. This paper addresses one such facility that was constructed in Hillsborough County near the city of Tampa, Florida. The facility was constructed in 1981/1982 and the barrier system consisted of a 2.0 mm (80 mil) High Density Polyethylene Liner (HDPE) which was manufactured by SLT (Schlegel Lining Technology) in Conroe, Texas. This facility of ~ 5.25 hectares, has operated successfully since the installation and has stored approximately 5.7×10^8 kilograms (~ 650,000 tons) of coal combustion residuals. Recently the decision was made, based on the age of the lining system, the appearance of a few stress cracks along extrusion welds at the tops of the slopes and the current legal and economic environment and significant costs associated with a leak or other containment failure, to replace the geomembrane with current, more advanced materials. This decision has offered a rare opportunity to obtain forensic samples for testing and evaluation and to document the performance of these materials subjected to real world aging and exposure conditions. Samples were obtained from multiple locations within the containment structure; at the bottom of the structure, along the side walls/slopes and at the freeboard level(s), from the upper sections of the side slopes which have seen a near continuous exposure and from the upper anchor trenches where the materials have only been exposed to soil and have neither had UV exposure, nor exposure to the stored ash materials.

Figure 1. Site overview during sample collection

1.2 Sample collection and Identification

Multiple samples were obtained for testing and evaluation. The samples are identified in the table below, which includes references to the sources of the sample and the existence or absence of field welds ("FW") within the sample.

Table 1. Sample Identification		
Sample Name	Field weld	Location
IC-2	N	South facing slope
IC-3-FW	Y	West slope at freeboard/waterline
IC-3	N	West slope at freeboard/waterline
IC-4-FW	Y	Floor sample
IC-4	N	Floor sample
IC-5	N	Toe of SE corner
AT	N	Anchor Trench

Data is presented on samples from 5 locations within the site. Descriptions are as follows: IC-2 is a sample from the southern facing (North) slope; this sample was above the evidence of waterline, near the anchor trench. IC-3 was taken from the western slope at the visible waterline deposits. It is presumed to have been exposed to the largest quantity of wet dry cycling. IC-4 was taken from the site floor and is assumed to have little UV exposure, but maximum chemical exposure. AT designates materials that were taken from the anchor trench on the upper perimeter of the site. These samples are presumed to have seen no UV, chemical exposure or highly variable moisture levels during the sites operation.

2. GEOMEMBRANE CONSTRUCTION AND HISTORICALLY COMPARABLE MATERIALS

Placing this material into proper context is important. In 1982, President Regan was still fighting the cold war, the Bell System provided telephone service, England and Argentina were at war over the Falkland islands, the Dow Jones Industrial Average was just over 800, and the USA Today newspaper premiered. A cell phone (the Nokia Senator model) and a computer (the Kaypro II) looked like this:

Figure 2.circa 1982 cell phone and computer

..and geomembranes were several generations earlier than current practice in performance and durability. Multiple advances have been made in machinery, process controls, and importantly, polymer characterization, dramatically reducing the residual catalyst levels within the polymer. New stabilizers that are more effective and more difficult to extract from the polymer matrix and other advances have rendered the exhumed geomembranes “ancient” in their overall composition and quality. Nevertheless the exhumed materials have done an excellent job of providing containment and protecting the environment.

The passage of three decades has also made it difficult to obtain comparative technical data for evaluation of the existing samples. The manufacturer does not have retained samples that are from the time period when the original materials were created and there is very limited data available. Three data sets are used in this paper for baseline comparison. Within a few years after the manufacture of this material, the National Sanitation Foundation (NSF) published NSF 54, a standard for minimum properties of geomembrane used to store potable water. NSF-54 has since been discontinued, however, during that general time period was the “standard” by which these materials could be expected to perform. Additionally, very limited test data from that time period has been found and can be used as a comparison. Also, the samples properties are (on a very unfair basis) compared with the existing materials standards (GM-13, Revision 10, date April 11, 2011). Again, in

historical context this would be similar to comparing the output of a secretary using an IBM Selectric Typewriter to the output from the Dell laptop that I used to write this paper.

Further, and perhaps most important, there was a major structural difference between the geomembrane that was exhumed and today's materials. This is the result of significant differences in the manufacturing equipment that was used to make the exhumed geomembrane and that which is used today. In the early 1980's equipment did not exist to manufacture geomembrane in the necessary widths in one continuous and uniform piece. In order to produce the needed widths, a geomembrane strip about 450 mm wide was extruded onto and across a large rotating drum about 6 m wide. This process was repeated and continued to produce a geomembrane ~ 6 meters in width and ~ 100 meters in length. The geomembrane thus contained hundreds of linear feet of "factory welds". These welds were, of course, present in the exhumed samples and are tested and compared with both the field welds and the un-welded "normal" sections of the geomembrane. In the following data, the sheet itself is given the designation from table one, where factory welds or field welds are tested, they are designated as such and peel and shear strength values are reported.

3. TESTING RESULTS

In the tables below, test results are reported and comparisons can be made between the four site locations that have been described above, where the geomembranes were exposed to the contained materials and the elements. Also included in the test results is geomembrane taken from the anchor trench which has the same age as the other four samples, but was not exposed to the contained materials or the elements. These results are compared with two industry standards of practice. The first is the National Sanitation Foundation (NSF) Standard 54 for materials in contact with potable water. The second the current version of the Geosynthetic Research Institute GM-13 "Standard Specification for Test Methods, Test Properties and Testing Frequency for High Density Polyethylene (HDPE) Smooth and Textured Geomembranes" and GM-19 "Standard Specification for Seam Strength and Related Properties of Thermally Bonded Polyolefin Geomembranes". Note the weld testing data is presented in English units as such units are representative of the methodology used when it was tested and in the opinion of this author, does not convert "cleanly" to SI units.

Additionally, samples of the materials were subjected to infrared analysis. The goal of this testing was to attempt to quantify the chemical degradation and oxidation of the geomembranes by observing the size of the peak(s) in the range of 1700-1750 cm^{-1} . The peaks in this range correspond to the quantity of carbonyl entities which are generated during the degradation of the geomembrane. The figure (2) below indicates some of the difficulty associated with that process. This figure presents results from three different scans from the same geomembrane sample (IC-4). The lowest (blue) line, labeled "smooth side" was taken from the underside of the sample and was in contact with the subgrade soils. The middle (green) line, labeled "rough side..." was taken from the top of the geomembrane in contact with the contained materials. The top (red) line labeled "below the exposed outside surface" was taken from the top of the geomembrane in contact with the contained materials after cleaning the surface of the geomembrane.

Figure 2. Infrared Spectrum of Sample IC-4 (floor)

The figure (3) below indicates the potential of this technique of investigation. This figure compares results from the same geomembrane sample (IC-4) with a sample taken from the anchor trench (AT). The now top (green) line, labeled “floor” was another scan of IC-4 taken from the top of the geomembrane in contact with the contained materials. The bottom (red) line labeled “anchor trench” was taken from the anchor trench and does shown qualitatively a lower degree of degradation and oxidation as compared to the other sample.

Figure 3. Infrared Spectrum of Sample IC-4 (floor) and AT (anchor trench)

The difficulty with the application of this technology is twofold. One issue is that the reading are taken on a very small portion of the sample and the selection of the specific area for testing can dramatically affect the results obtained, particularly if the degradation is not uniform in distribution as is often the case. Secondly, the deposition of foreign materials on the samples

and amount of cleaning that is done to the samples prior to testing can also strongly influence the test results. On the other hand degradation will first occur on the surface so it is important that surface changes be monitored.

4. CONCLUSION and ACKNOWLEDGEMENTS

Data has been presented on a 30 year old geomembrane that was used, successfully to contain coal ash. This data can be compared among the samples taken and evaluations and estimation of the further utility of the materials made. Clearly the geomembrane has 'aged" and suffered chemical oxidation and degradation. However the material's physical properties are still quite good even when compared to current standards. There are still stabilizers present in the aged materials as illustrated by the oxidative induction time (OIT) results. The performance of the geomembrane would appear to be in agreement with the scheme described in GRI report #16: "Long Term Durability of HDPE Geomembranes" and thus could be expected to supply containment service for several more decades. Admittedly the stress crack properties of the aged geomembrane being a legitimate concern; the "notched constant tensile load" (NCTL) properties are lower than current standards, but are consistent with the performance of geomembranes from that time period. As technology has advanced, the performance of this geomembrane clearly must be judged as inferior to current product. However, if one assumes that only the stress crack resistance was improved to current standards, the expected lifespan of currently produced materials would be in agreement or potentially exceed expected lifespan predictions. In short, even old geomembrane has done a good job of coal ash containment, there is every reason to expect current improved materials to offer improved performance.

In addition to recognizing the contributions of my co-authors, without whom this paper would have not come to realization, I should also offer thanks to Mr. David Barnett, Project Manager for COMANCO Environmental Corporation. Comanco was a key supporter of this effort; further inquiries regarding the installation can be addressed to David or to Mr. Mark Topp, President, COMANCO Environmental Corporation. Additionally Dr. Lili Cui, Plastics/Polymer Engineer for Chevron Phillips Chemical Company LP should be recognized for her and CP Chem's support of the IR/analytical portion of this work; their support is greatly appreciated.

ABSTRACT

This paper studies the effects of prestressing the reinforcement in granular bed on the load carrying capacity and settlement response of a geogrid reinforced granular bed (RGB) overlying weak soil. A series of laboratory scale bearing capacity tests are conducted to study the behaviour of unreinforced (GB), reinforced (RGB) and prestressed geogrid reinforced (PRGB) granular bed overlying weak soil. The parameters varied are strength of the underlying weak soil, thickness of the GB, magnitude of prestressing force applied and direction of prestressing forces. It is found that there is a significant improvement in bearing capacity and reduction in settlements, by addition of prestress to the geogrid reinforcement. Biaxial Prestressing is found to be better than uniaxial prestressing. A punching shear failure (numerical) model is envisaged. The BCR (Bearing Capacity Ratio) values predicted from the model are found to be in good agreement with the experimentally obtained BCR values.

1 INTRODUCTION

Over the past three decades, the beneficial use of various types of geosynthetics to increase the bearing capacity of soil has been clearly established. Extensive research has been carried out by several researchers to understand the role of reinforcement materials in improving the bearing capacity of foundation soils. The use of geosynthetic reinforced foundation bed over weak soil effectively reduces settlement and increases the bearing capacity of weak soil. Many experimental and analytical studies have been performed to investigate the behaviour of reinforced foundation beds for different soil types (eg. Binquet and Lee (1975), Shivashankar et al. (1993)). Several experimental and analytical studies were conducted to evaluate the bearing capacity of footings on reinforced soil (eg. Shivashankar et al. (1993); Shivashankar and Reddy (1998); Madhavilatha and Somwanshi (2009); Alamshahi and Hataf (2009); Vinod et al. (2009) etc).

Earlier studies have shown that geosynthetics demonstrate their beneficial effects only after considerable settlements, since the strains occurring during initial settlements are insufficient to mobilize significant tensile load in the geosynthetic. This is not a desirable feature since for foundations of certain structures; the values of permissible settlements are low. Thus there is a need for a technique which will allow the geosynthetic to increase the load bearing capacity of soil without the occurrence of large settlements. Lovisa et al. (2010) conducted laboratory model studies and finite element analyses on a circular footing resting on sand reinforced with prestressed geotextile. The improvement in bearing capacity due to prestressing the reinforcement was particularly studied. It was found that the addition of prestress to reinforcement resulted in significant improvement in the load bearing capacity and reduction in settlement of foundation.

The purpose of this paper is to study the effects of prestressing the reinforcement in granular bed on the load-bearing capacity and settlement response of a reinforced granular bed overlying weak soil. The study involved laboratory model tests on a square footing of size 100mm x 100mm x 20 mm thick. Numerical analysis is conducted using the improvised model of Shivashankar et al. (1993) and the results are compared with those obtained from the model tests. The parameters studied are the strength of the underlying weak soil, thickness of granular bed, magnitude of prestress, direction of prestress. The settlements at the interface between weak soil and GB are also measured.

2 EXPERIMENTAL PROGRAMME

The experimental programme mainly involved a series of laboratory scale bearing capacity tests (typically one-tenth scaled model tests) conducted on a model footing resting on a prestressed reinforced granular bed overlying weak soil. Details of the experimental programme, test procedures and analysis of test results are presented in the following paragraphs.

2.1 Materials

The material used for granular bed is well graded medium sand and its properties are given in Table 1 and particle size distribution is shown in Figure 1. Locally available soil termed as 'Shedi soil' is used as weak soil and its properties are also given in Table 1 and particle size distribution is shown in Figure 1. The Shedi soil is used in two conditions namely moist condition (termed as moist soil or weak soil 1) and also used in submerged condition (termed as submerged soil or weak soil 2). The reinforcement used is geogrid and its properties are given in Table 2. The geogrid used is a somewhat weak geogrid with a tensile strength of only 7.68 kN/m, for purpose of laboratory scale model tests.

Table 1. Properties of sand and weak soils used in the model tests

Property	Sand	Value	
		Weak soil 1 (Moist soil)	Weak soil 2 (Submerged soil)
Specific gravity	2.61	2.32	2.32
Average dry unit weight during model test (kN/m ³)	16.60	16.00	16.00
Void ratio during model test	0.54	0.42	0.42
Water content during model test (%)	0	10	31.5
Effective grain size D ₁₀ (mm)	0.50	0.11	0.11
D ₆₀ (mm)	1.30	0.155	0.155
D ₃₀ (mm)	0.80	0.125	0.125
Coefficient of uniformity C _u	2.60	1.41	1.41
Coefficient of curvature C _c	1.00	0.92	0.92
Friction angle Φ (degrees)	31.0	12	6
Cohesion (kPa)	0	10	5.5

Figure 1. Particle size distribution of sand and weak soil used

Shedi soils are predominantly found in the west coast (Konkan coast) of southern peninsular India and most of the foundations are placed on this soil layer. These soils are problematic in the sense that their strength reduces drastically under saturation condition, which is the typical behaviour of dispersive type of soils. It has resulted in many foundation problems wherever it is met with in this area.

2.2 Test Setup

Laboratory scale bearing capacity tests are carried out on a square rigid footing made of mild steel. The dimensions of the model footing are 100mm x 100mm x 20 mm thick. The model footing is kept on the surface of soil during all the tests. The test tank is made of ferrocement having internal dimensions 0.75 m x 0.75m in plan (7.5 times size of footing and sufficient to nullify any edge effects) and 0.75m high (Figure 4). A single layer of reinforcement is used. The prestress applied is equal to 1%, 2% and 3% of the tensile strength of the geogrid and is distributed over three pulleys. In uniaxial prestressing the prestress is applied only in the X-direction whereas in biaxial prestressing it is applied in both X and Y directions as shown in Figures 2 & 3 respectively. The figure of the test setup is shown in Figure 4 and photograph of the same is shown in Figure 5.

The load is applied using a hydraulic Jack of 10 kN capacity. The load is measured using a proving ring and deformation using two dial gauges placed diametrically opposite to each other. Preparation of underlying soil in all the tests involved compaction

of soil using a rammer. In the preparation of foundation (granular) bed, the sand was compacted using a small plate vibrator. The densities to which the soils were compacted are indicated in Table 1.

Table 2. Properties of geogrid used in the model tests

Property	Value
Mass per unit area (gm/m^2)	730.00
Aperture size (mm)	8 x 6
Thickness (mm)	3.30
Tensile strength (kN/m)	7.68
Extension at maximum load (%)	20.20
Color	Black
Polymer	HD-Polyethylene

Figure 2. Uniaxial prestressing

Figure 3. Biaxial prestressing

In the literature, it is reported that optimum depth of placement of the first layer of reinforcement is 0.2B to 0.5B (B is the width of footing) (Sharma et al. 2009). The depth of reinforcement from the base of footing is adopted as 0.5B for all the tests. Same procedure and same compactive effort are used in all the tests to maintain consistency and for sake of comparison.

Figure 4. Test set up

Figure 5. View of test set up

2.3 Test Details

At first the weak soil is filled in the ferrocement tank to the required level with compaction done in layers, to achieve the pre-determined density. Then sand is filled up to the bottom level of reinforcement and compacted. The reinforcement is then placed with its centre exactly beneath the jack, and the prestress is applied. Then sand above the reinforcement is placed and compacted to the pre-determined density. Thus prestressing is applied before the top layer of granular fill is placed and compacted. In all the tests, reinforcement is kept at a depth of 50 mm (0.5 B) from the base of model footing. The compactive effort required to achieve the required density of both the soils is determined by trial and error. The settlement is measured using two dial gauges and their average value is adopted. The settlement at the interface between two soils is determined by measuring the levels at specified points at regular intervals on the surface of weak soil before and after each test. The test

tank is emptied and refilled for each test to ensure that controlled conditions are maintained throughout the investigation. The details of testing programme are given in Table 3.

Table 3. Testing programme

Series	Type	Thickness	Prestress
A	Weak soil 1 (Moist soil) (Unreinforced) Granular bed (GB) on weak soil 1	B & 2B	
B	Reinforced granular bed (RGB) on weak soil 1	B & 2B	
C	Prestressed reinforced granular bed (PRGB) on weak soil 1	B & 2B	Uniaxial 1%,2%&3%
D	Prestressed reinforced granular bed on weak soil 1	B & 2B	Biaxial 1%,2%&3%
E	Weak soil 2 (Submerged soil) (Unreinforced) Granular bed on weak soil 2	B & 2B	
F	Reinforced granular bed on weak soil 2	B & 2B	
G	Prestressed reinforced granular bed on weak soil 2	B & 2B	Uniaxial 1%,2%&3%
H	Prestressed reinforced granular bed on weak soil 2	B & 2B	Biaxial 1%,2%&3%

Under series A, tests are conducted on weak soil 1 (moist soil) and on weak soil 1 overlain with unreinforced granular bed of thickness B or 2B. Under series B, tests are conducted on weak soil 1 overlain with reinforced granular bed of thickness B or 2B. Under series C, tests are conducted on weak soil 1 overlain with prestressed reinforced granular bed. The prestress applied is uniaxial. The parameters varied are magnitude of prestress and thickness of granular bed. Series D is similar to series C except that prestress applied is biaxial. Series E, F, G and H are similar to series A, B, C and D respectively, except that the underlying soft soil is kept submerged (termed as weak soil 2). The level of water table in the test tank is monitored by installing four peizometers.

3 NUMERICAL ANALYSIS

In the present study, loading tests on unreinforced and reinforced granular beds are simulated numerically by improving the model proposed by Shivashankar et al. (1993). They proposed a punching shear failure mechanism in which both the footing and the portion of the reinforced granular bed directly beneath the footing are envisaged to act in unison to punch through the soft soil underneath. The improvement in bearing capacity of a reinforced granular bed is considered to comprise of three components namely Shear layer effect, Confinement effect and Surcharge effect. These effects are represented in Figures 6, 7 & 8(a), respectively. They proposed the following equations for computing Bearing Capacity Ratio (BCR).

$$BCR = 1 + \Delta BCR_{SL} + \Delta BCR_{CE} + \Delta BCR_{SE} \quad [1]$$

Where

ΔBCR_{SL} , ΔBCR_{CE} , ΔBCR_{SE} = Improvement in bearing capacity ratio due to Shear layer, Confinement and Surcharge effects respectively

Figure 6. Shear layer effect for GB, RGB and PRGB (Shivashankar et al. 1993)

Figure 7. Confinement effect for GB, RGB and PRGB (Shivashankar et al. 1993)

3.1 Shear Layer Effect

In shear layer effect, the shear stress mobilized along the failure surface due to the passive pressure developed in soil is considered (Figure 6). The equation proposed for strip footings is

$$\Delta BCR_{SL} = 2 \tau_1 / Q \quad [2]$$

$$\tau_1 = P_p \tan \phi_s \quad [3]$$

$$\Delta q_{SL} = 2 \tau_1 / B \quad [4]$$

Where

Q = Bearing capacity of underlying weak soil

τ_1 = Total vertical force along the punching shear failure plane due to shear layer effect

P_p = Force due to passive pressure developed on the sides of failure surface, acting normally, per unit length

ϕ_s = Angle of shearing resistance.

The above equation was developed for a strip footing. In the present study, since a square footing is used, the equation is modified as given below

$$\tau_1 = P_p' \tan \phi_s \quad [5]$$

$$\Delta BCR_{SL} = 4 \tau_1 / Q \quad [6]$$

$$\Delta q_{SL} = 4 \tau_1 / B^2 \quad [7]$$

Where

P_p' = The passive pressure developed on each of four sides of square column of granular soil beneath the square footing of width 'B'

3.2 Confinement Effect

The tensile stress mobilized in the reinforcement will provide a confinement effect to the soil beneath the footing. The shear stress developed along the failure surface due to this confining stress is considered here (Figure 7). The equation proposed for strip footing was

$$\Delta BCR_{CE} = 2 \tau_2 / Q \quad [8]$$

$$\tau_2 = T_R \tan \phi_s \quad [9]$$

$$\Delta q_{CE} = 2 \tau_2 / B \quad [10]$$

Where

τ_2 = Total vertical force along the punching shear failure plane due to confinement effect of reinforcement

T_R = Tensile stress mobilized in the reinforcement = $2L\sigma_v \tan \delta$

L = Length of reinforcement beyond the failure surface

σ_v = Vertical stress at the level of reinforcement

δ = angle of friction between reinforcement and soil = ϕ_s for geogrid

The above equation was developed for a strip footing. In the present study, since a square footing is used, the equation is modified as given below

$$\tau_2 = T_R' \tan \phi_s \quad [11]$$

$$\Delta BCR_{CE} = 4 \tau_2 / Q \quad [12]$$

$$\Delta q_{CE} = 4 \tau_2 / B^2 \quad [13]$$

Where

T_R' = Tensile stress mobilized in reinforcement beyond each of the four sides of square column of granular soil beneath the square footing

B = Width of the square footing

In the case of PRGB, if the friction on reinforcement (on one side of the square prism, along plane of reinforcement) is less than the applied prestress, value of T_R' is taken as equal to the value of applied prestress. If the friction in reinforcement is more than applied prestress, the value of T_R' is taken as equal to value of frictional resistance over the reinforcement. The same principle applies also in the case of field application of PRGB. However the optimal value of prestress to be applied to the reinforcement in field will have to be investigated and is expected to be larger than laboratory optimal value due to larger vertical stress on reinforcement. Stronger geogrid will have to be used in field and strength of geogrid is not likely to influence the confinement effect.

3.3 Additional Surcharge Effect

The vertical stresses along the punching shear failure surface due to shear layer effect and confinement effect are envisaged to act as a surcharge stress on the underlying soft soil. There will be an improvement in bearing capacity due to this surcharge stress. The distribution of this surcharge stress was assumed to be exponential as shown in Figure 8(a) for a strip footing (Shivashankar et al. 1993). The improvement in bearing capacity due to this surcharge stress is given by

$$q_o = 0.84(\Delta BCR_{SL} + \Delta BCR_{CE}) \quad [14]$$

Where q_o = Intensity of surcharge stress at the edge of the failure plane due to shear layer and confinement effects

Surcharge stress was envisaged to decrease exponentially from q_o at edge of footing to $0.01q_o$ at end of reinforcement. In the present study, in case of PRGB, the additional surcharge stress is envisaged to be uniform over the reinforcement in the direction of prestressing (Figure 8(b)). This is also justified from the measured settlements. In case of Uniaxial prestressing, the surcharge stress is considered to decrease exponentially in the cross direction. Average surcharge stress is considered around the square footing and accordingly ΔBCR_{SE} is estimated.

$$\Delta BCR_{SE} = q_{avg} \times N_q \quad [15]$$

Figure 8(a). Surcharge effect for GB and RGB (Shivashankar et al. 1993)

Figure 8(b). Surcharge effect for PRGB proposed in the present study

4 RESULTS AND DISCUSSION

4.1 Improvement in Bearing Capacity

Vertical stress (load per unit area) vs normalized settlement curves are shown in Figures 9 to 18. The footing settlement 'S' is expressed in non-dimensional form as 'S/B' (%). It is clearly observed that the addition of prestress significantly improved the settlement behaviour of soil. The load carrying capacity of footing is also significantly improved.

Figure 9. Stress vs normalized settlement curves for granular bed of thickness B with uniaxial prestressing overlying (moist) weak soil 1

Figure 10. Stress vs normalized settlement curves for granular bed of thickness B with biaxial prestressing overlying (moist) weak soil 1

4.1.1 Effect of Magnitude of Prestress and Type of Weak Soil

4.1.1.1 Granular Beds Overlying (Moist) Weak Soil 1

From Figure 9 which represents the variation of bearing pressure with footing settlement of uniaxially prestressed granular bed of thickness B overlying (moist) weak soil 1, it can be seen that maximum improvement is observed when the magnitude of prestress is equal to 2% of the tensile strength of reinforcement. Further addition of prestress is not beneficial. However for a granular bed of thickness B with biaxial prestressing overlying (moist) weak soil 1, it is observed that the maximum improvement in settlement behaviour occurred when the magnitude of prestress is equal to 1% of the tensile strength of reinforcement. Further increase in prestress is not beneficial (Figure 10).

The results obtained from a granular bed of thickness 2B with uniaxial prestressing overlying (moist) weak soil 1 are shown in Figure 11. It is observed that the maximum improvement is when the magnitude of prestress is equal to 3% of the tensile strength of reinforcement. The results obtained from a granular bed of thickness 2B with biaxial prestressing overlying (moist) weak soil 1 (Figure 12) indicates that maximum improvement is also got when the magnitude of prestress is equal to 3% of the tensile strength of reinforcement.

Figure 11. Stress vs normalized settlement curves for granular bed of thickness 2B with uniaxial prestressing overlying (moist) weak soil 1

Figure 12. Stress vs normalized settlement curves for granular bed of thickness 2B with biaxial prestressing overlying (moist) weak soil 1

4.1.1.2 Granular Beds Overlying (Submerged) Weak Soil 2.

Figure 13 presents the variation of bearing pressure with footing settlement of uniaxially prestressed granular bed of thickness B overlying (submerged) weak soil 2. It can be seen that maximum improvement is observed when the magnitude of prestress is equal to 2% of the tensile strength of reinforcement. Further addition of prestress did not show any improvement. This is same as in case of weak soil 1. In case of granular bed of thickness B with biaxial prestressing overlying submerged weak soil2, from Figure 14, it is observed that the maximum improvement in settlement behaviour occurs when the magnitude of prestress is equal to 2% of the tensile strength of reinforcement. Further increase in prestress showed no gain.

This is unlike in case of weak soil 1, which peaked at 1% itself. With increased thickness of granular bed to 2B and with uniaxial prestressing overlying (submerged) weak soil 2, it is observed (Figure15) that the maximum improvement is observed when the magnitude of prestress is again equal to 2% of the tensile strength of reinforcement. Further increase in prestress caused a reduction in the improvement in bearing capacity.

Figure 13. Stress vs normalized settlement curves for granular bed of thickness B with uniaxial prestressing overlying (submerged) weak soil 2

Figure 14. Stress vs normalized settlement curves for granular bed of thickness B with biaxial prestressing overlying (submerged) weak soil 2

It is also observed that the improvement in bearing capacity when the prestress was increased from 1% to 2% was only marginal. The results obtained from a granular bed of thickness 2B with biaxial prestressing overlying (submerged) weak soil 2, it is observed that the improvement in settlement behaviour with 3% prestress is less than that with 1% and 2% (Figure 16).

4.1.2 Effect of Thickness of Granular Bed

For moist soil (weak soil 1) experimental results indicate that greater prestress (of 3%) is optimal for thicker granular bed (Figure 17). However from Figures 13 to 16, for submerged soil (weak soil 2), 2% prestressing is found to be optimal for both B and 2B thickness of granular bed, for both uniaxial and biaxial prestressing.

Figure 15. Stress vs normalized settlement curves for granular bed of thickness 2B with uniaxial prestressing overlying (submerged) weak soil 2

Figure 16. Stress vs normalized settlement curves for granular bed of thickness 2B with biaxial prestressing overlying (submerged) weak soil 2

4.1.3 Effect of Direction of Prestress

A comparison between the experimentally observed improvements in settlement behaviour of a granular bed of thickness B, overlying (moist) weak soil 1, due to uniaxial and biaxial prestressing is shown in Figure 18. Therein and from other figures it is observed that improvement in settlement behaviour is generally better when prestress is biaxial.

Figure 17. Comparison between stress vs normalized settlement curves for GB of thickness 2B overlying (moist) weak soil 1 and (submerged) weak soil 2 with uniaxial prestressing

Figure 18. Comparison between stress vs normalized settlement curves for GB of thickness B overlying (moist) weak soil 1 with uniaxial and biaxial prestressing

4.1.4 Initial Stiffness Modulus

The initial stiffness modulus is defined as slope of initial part of the stress – strain curve, ie at origin. Strain is calculated as 'S/B' when the granular bed thickness is 'B' and as 'S/2B' when the granular bed thickness is '2B'. The variation of initial stiffness modulus with prestress for granular bed of thickness B is shown in Figure 19. It is observed from the figure that for weak soil 1 with uniaxial prestress, the initial stiffness modulus is maximum when the prestress is 2%, and for biaxial prestress, 1% prestress is found to be optimum. In weak soil 2, for both uniaxial and biaxial prestress, maximum initial stiffness modulus is at 2% prestress.

Fig 19. Prestress vs initial stiffness modulus curves for granular bed of thickness B

Fig 20. Prestress vs initial stiffness modulus curves for granular bed of thickness 2B

The maximum value of initial stiffness modulus for weak soil 1 with granular bed of thickness 2B for both uniaxial and biaxial prestressing is when the prestress is equal to 3%, whereas for weak soil 2, prestress of 2% is found to be most optimal (Fig 20).

4.2 Numerical Analysis

All the above various cases are analysed numerically using the 'improvised model' of Shivashankar et al. (1993) proposed in this paper. The Bearing Capacity Ratios (BCRs) obtained experimentally and those predicted by the model are shown graphically in Figure 21. It is observed that the model predicts the bearing capacity ratio with fairly good accuracy, especially for the moist soil (weak soil 1).

Figure 21. Comparison between observed and predicted values of bearing capacity ratios (BCRs) for GB, RGB and PRGB overlying (moist) weak soil 1 and (submerged) weak soil 2

5 CONCLUSIONS

Based on the results obtained from experimental and numerical studies, the following conclusions can be made on the behaviour of prestressed reinforced granular beds overlying weak soils.

1. The addition of prestress to geogrid reinforcement significantly improves the bearing capacity and settlement behaviour of the soil. Prestressing the geosynthetic reinforcement results in increased load bearing capacity of soil without the occurrence of large settlements, as compared to geosynthetics without any prestress. Improvement is more significant in case of submerged soil (weak soil 2) when compared to moist soil (weak soil 1).
2. The improvement in bearing capacity depends upon the thickness of granular bed, magnitude of prestress and the direction of prestress. The improvement in bearing capacity is found to be more with biaxial prestressing than uniaxial prestressing. The improvement in bearing capacity increases with the thickness of granular bed.
3. The proposed numerical model predicts the bearing capacity ratios for granular beds overlying weak soil with reasonably good accuracy.
4. Experimental results indicate that greater prestress of about 3% is optimal for thicker granular beds on moist soil (thickness of 2B).

ABSTRACT

The State of Kerala, which is named after coconut tree, has the first place in the production of coir, in India. The waste generated during the process includes coir pith along with some baby fibers. For every 1 kg of coir fiber production 2 kg of coir pith is generated. The disposal of this coir waste becoming a major issue nowadays. Soil reinforcement using randomly distributed fibers has been proved fruitful. The use of natural fibers in soil stabilization is often advantageous as they are cost effective and locally available. No major studies are conducted on the influence of the coir waste in the engineering behavior of soil. The present study investigates the compaction characteristics of two types of soils mixed with different percentages of coir waste. The main objective of the present investigation is to assess the usefulness of coir waste as a soil admixture, especially for pavement construction.

1. INTRODUCTION

Coconut (*Cocos nucifera* Lignin) is one of the most useful palms to mankind amongst the various tropical palms. Coir pith is a biomass residue generated during the extraction of coir fiber from coconut husk and is a byproduct of the coir manufacturing industry. Normally, they are dumped as agricultural waste and become accumulated as a waste product in the form of heaps of coarse and fine particles with lots of baby fibre and short fibre. It is estimated that at present there is an accumulated stock of 10×10^6 metric tons of coir pith in Kerala. This waste has traditionally been disposed off by burning, which results in various environmental problems, including carbon deposits as well as the warming of the atmosphere. During the rainy season, the tannins and phenols of the coir pith are leached out into the soil and into the irrigation canals, thereby making agricultural lands unproductive. Moreover, the water pollution caused by such leaching is harmful to the aquatic and soil biological life. Therefore, finding out an alternate way to dispose the coir pith is of critical importance.

The concept of soil reinforcing with tensile elements has been widely accepted in engineering practice. It is the combination of soil and reinforcement, suitably placed, to withstand tensile stresses and also to improve the resistance of soil in the direction of greatest tensile strain. The basic principles of reinforced soil are demonstrated abundantly in nature by the action of tree roots. Reinforcement of soil is practiced to improve the mechanical properties of the soil by the inclusion of structural elements such as granular piles, lime or cement mixed soil, metallic or plastic strips, synthetic or natural fiber etc. The presence of reinforcement modifies the stress field giving a restraint mostly in the form of friction or adhesion so that less strain is induced and tension is avoided. Conventional methods of reinforcement include continuous inclusions of strips, fabrics, and grids into an earth mass. But as a modification technique, various types of fibers are also considered for reinforcing soil. Soil reinforcement using discrete randomly distributed fibers has been widely investigated over the last thirty years. The use of fibers, such as jute, coir, bamboo, polypropylene, nylon etc. as soil reinforcement materials, is prevalent for a long time and they are abundantly used.

The main advantage of using fibers as reinforcing material is that they are locally available and are very cost effective. Processing of these materials into usable form is an employment generation activity in rural areas of countries in which they are prevalent. Effective use of these materials uplifts the rural economy and its use in engineering construction reduces the construction cost.

Coir manufacturing units are mainly concentrated on the banks of back water in Kerala, near to the coastal areas, where the major portions of soil are lateritic soil or soft clay. The use of coir waste as soil admixture in these soils has been investigated in this paper. This paper presents the influence of coir waste on compaction and compressive strength of two types of soil viz., lateritic soil and soft Kuttanad clay.

2. LITERATURE REVIEW

The process of randomly mixing discrete fibres into the soil has become a proven technology to improve the strength of the soil as pointed out by various researchers. The fibers increase the cohesion among the soil particles. In addition

the interaction of the fibers among themselves and the flexibility of the fibers makes them behave as a structural mesh that holds the soil together increasing the soil structural integrity. Advantages of this method are: (i) there are several different materials that can be used to reinforce the soil, (ii) the machinery required is minimal, and (iii) the fibers are inexpensive and environmentally friendly. Disadvantages of this method are that, some of the fibers have less durability and can only be implemented in shallow depths. However, this characteristic of the reinforcement method allows it to be easily implemented in large areas (Babu & Vasudevan, 2008).

Several studies have been conducted to study the influence of natural fibres on different strength aspects of soft soils. Aggarwal and Sharma (2010) have proved that addition of natural fibres to expansive soils improves the California Bearing Ratio value. This is mainly because of the fact that the randomly distributed natural fibres prevent the development of weak failure planes in soil. But, Aggarwal and Sharma (2010), Ramesh et al. (2010), Prabakar and Sridhar (2002) and Jamellodin et al. (2010) are of the opinion that addition of randomly distributed natural fibres increases optimum moisture content and decreases maximum dry density. This is due to the fact that inclusion of materials with low specific gravity and unit weight replaces the soil mass and also due to the rearrangement of soil particles with reinforcing particles.

However, all other strength parameters are seen to improve as explained below. Ghavami et al. (1999), Ramesh et al. (2010), Bouhicha et al. (2005) and Marandi et al. (2008) showed that addition of randomly distributed natural fibres to expansive soils increases strain after reaching peak strength showing the ductile behaviour of the sample. Ghavami et al. (1999), Bouhicha et al. (2005) also reported that compressive strength of the soil also increases slightly. Chauhan et al. (2008) showed that the unconfined compressive strength value of poor soils increases with addition of natural fibres. Prabhakar and Sridhar (2002), Bouhicha et al. (2005), Huat et al. (2005), Babu et al. (2008) and Jamellodin et al. (2010) showed that the value of cohesion and shear stress of fibre reinforced soil improves due to the addition of natural fibres. Although, Babu et al. (2008) reported that friction angle also increases with increase in fibre content, this aspect is not highlighted in other works related to shear strength parameters on fibre reinforced soils.

The influence of natural fibres on the stress strain parameters of fibre reinforced soils were also studied with much significance. Nagrale et al. (2006) reported that inclusion of fibres in expansive soils improves the modulus of elasticity of soil and reduces the compressive strain. This reduction can be exploited either to reduce the thickness of intermediate layers of pavement sections or to increase the life of pavements. Marandi et al. (2008) showed that the secant modulus also increases with increase in fibre content. Babu and Vasudevan (2008), Babu et al. (2008) showed that stress – strain behaviour, deviator stress, stiffness and energy absorption capacity (hence toughness) increase with the inclusion of fibres. Chauhan et al. (2008) proved that the fibre reinforcement enhances the resilient response for soils, but the amount of enhancement depends on the type of soil. The author also concluded that resilient strain is less in soils reinforced with coir fibre than with synthetic fibre, indicating that coir fibre can help in delaying the failure of subgrade in pavement systems. It is also reported that fibres can reduce rut formations in the pavement structures depending on the fibre used as reinforcement. Coir fibre exhibits better responses than synthetic fibre. Also, coir fibre exhibits greater enhancements in resilient modulus or strength of the soil than the synthetic fibre.

Along with strength parameters, the swell / shrink behaviour of soils is also reported to improve. Ghavami et al. (1999) and Bouhicha et al. (2005) showed that inclusion of natural fibres in the soil matrix prevents the development of shrinkage cracks due to the drying process in expansive soils while Babu et al. (2008) reported that inclusion of fibres reduces the swell potential. Babu et al. (2008) reported that compression index also reduces due to fibre inclusion.

Among the natural fibres, coir is having the highest lignin content (46%) which provides the highest durability for coir fibre (Rao and Balan, 2000). Balan (1995) conducted accelerated durability studies on coir yarn and reported that the life of coir yarn is controlled by the type of embedded soil, climatic conditions, water content, organic content and the type of coir used. Coir degrades at a faster rate in sand with high organic content followed by clay with high organic content or burial, sand and finally clay where the degradation is least.

As seen from the literature review, fiber inclusion normally increases the strength of soils. In the coir fiber producing centres, coir baby fiber and coir pith become the industry waste which mixes up with the natural soil surrounding the production centres. In Kerala, the southernmost state of India, coir production units are all concentrated along the coastal belt and also near to the backwaters. The soil in these production centres are either of clay or of lateritic in nature. The main coir industry in Kerala is situated in the District of Alleppey, where in the highly soft clay commonly called as Kuttanad Clay is abundantly available. Hence based on the literature, it was decided to have a detailed study on the influence of coir pith on the engineering behaviour of Kuttanad Clay and lateritic soil. The study basically concentrated on the compaction and California Bearing Ratio behaviour of both the soils when coir pith was added as admixture.

3. EXPERIMENTAL WORK

Two different types of soil was used in this study, Lateritic soil and Kuttanad Clay. Indian Coir Industry is concentrated in Alleppey district of Kerala in India. Kuttanad in Alleppey district is a water logged area, which is below mean sea level and the predominant highly soft soil in this region is known as Kuttanad Clay. The physical properties of both the soils are given in Table 1. The coir waste used in this study was in a soaked state and it was then sun dried to reduce the water content to 0%. The saturated clay was also sundried to bring down the moisture content to 0% and it was then powdered (to a size less than 4.75 mm) using mallet, in order to mix the coir pith in a uniform manner. The coir pith was obtained by sieving the coir waste through 4.75 mm sieve, by this process medium to large fibres along with gravel sized coir waste are all removed. The sieved pith consisted of baby fibres which were difficult to separate manually. The coir pith was brown in colour and was light in weight (specific gravity was determined as 0.12). It has a property of imbibing water and swells 600 times more than its weight. This property of coir pith is advantageously being used in agriculture to replace peat moss.

The soil samples were prepared by mixing coir pith with soil in 0%, 0.5%, 1%, 1.5%, 2%, 2.5% and 3% by weight of soil. Standard Proctor Compaction test was conducted for each mix to find out maximum dry density and optimum moisture content. California Bearing Ratio tests, both soaked and unsoaked were also conducted in the above mix at their respective maximum dry density. The mix was filled in the CBR mould with a moisture content that was obtained in the compaction test conducted for corresponding mix.

Table 1. Characteristics of tested soils

PROPERTY OF SOIL	LATERITIC SOIL	KUTTANAD CLAY
Specific gravity	2.4	2.3
Liquid limit (%)	43	93
Plastic limit (%)	22	31
Plasticity index (%)	21	62
Maximum dry density (g/cc)	1.7	1.4
Optimum moisture content (%)	17.5	28
Unconfined compressive strength (kN/m ²)	49	24
Cohesion (kN/m ²)	11	12
Angle of internal friction (degrees)	24	0

4. RESULTS AND DISCUSSIONS

4.1 Effect of Coir Waste Content on Dry Density and Optimum Moisture Content (OMC)

4.1.1. Dry Density – OMC of Lateritic Soil Mixed with Coir Waste

The effect of coir waste addition on compaction shows that the shapes of the compaction curves are similar to that of unreinforced sample. For all samples, the dry density increases with increase in water content up to the point of optimum moisture content beyond which increase in water content reduces the dry density. The compaction curves of lateritic soil with and without coir waste addition are shown in Figure 1.

It was observed that dry density decreases and OMC increases with increase in coir waste content. The variation of dry density and OMC with coir waste content is shown in Figures 2 and 3 respectively. A sudden decrease in dry density and increase in OMC was found beyond 1.5% of coir waste content.

Figure 1. Compaction curves for lateritic soil with different percentages of coir pith

Figure 2. Variation of maximum dry density with coir pith content for lateritic soil and Kuttanad clay

Figure 3. Variation of OMC with coir pith content for lateritic soil and Kuttanad clay

Figure 4. Compaction curves for Kuttanad clay with different percentages of coir pith

4.1.2 Dry Density – OMC of Kuttanad Clay Mixed with Coir Waste

The compaction curves for Kuttanad clay with and without coir waste are shown in Figure 4. The shape of the compaction curves for coir pith mixed soil is similar to that of raw sample without pith. Dry density decreases and the optimum moisture content increases with increase in coir waste content. The variation of dry density and OMC of Kuttanad clay with increase in coir waste content is shown in Figures 2 and 3 respectively.

Optimum moisture content of both types of soil increases with increase in percentage of pith content because of the absorption of water by coir pith. The decrease in dry density can be attributed to the low density of coir pith.

Figure 5. Variation of CBR value with coir pith content for lateritic soil

Figure 6. Variation of CBR value with coir pith content for Kuttanad clay

5.2. Effect of Coir Pith Content on California Bearing Ratio (CBR)

The variation of unsoaked and soaked CBR value with increase in coir pith content for lateritic soil and Kuttanad clay is shown in Figures 5 and 6 respectively. It is seen that the CBR value decreases at low coir pith content and then increases for both soaked and un-soaked conditions. Maximum CBR value is obtained at 1.5% of pith content for lateritic soil while for Kuttanad clay; it is obtained at 2% pith content. The variation of soaked and unsoaked CBR values shows the same trend.

In both the soil types, the unsoaked and soaked CBR value suddenly decreases with an inclusion of 0.5% of pith, there after an increase in the inclusion of pith to both types of soil increases the CBR value upto 1.5% and 2% respectively for lateritic soil and Kuttanad clay respectively. After that point, further increase in pith content decreases the CBR value. The initial decrease in the CBR Value may be due to insufficient adhesion between the soil and the pith. With an increase in the pith content there are sufficient pith particles to attain cohesive attraction between the pith particles and also the presence of baby fibers (the amount of which is higher in higher grams of pith) provides reinforcement effect. This is why the CBR value increases after 0.5% of pith content. Pith content of more than 1.5% and 2% respectively in lateritic soil and Kuttanad clay, decreases the CBR value. This may be due to the cushioning effect of pith and the higher replacement of soil by pith. The optimum value of pith content in lateritic soil is found to be 1.5% and the corresponding un-soaked and soaked CBR values are 1.764% and 1.144% respectively. For Kuttanad clay the optimum value of pith content is 2% and the corresponding un-soaked and soaked CBR values are found to be 2.044% and 1.499% respectively.

6. CONCLUSIONS

The results show that the addition of coir waste with baby fibres improved the engineering behavior of both lateritic soil and Kuttanad clay. The addition of coir waste increases optimum moisture content and decreases maximum dry density because of its water absorption capacity and low unit weight. In the case of lateritic soil, beyond 1.5% an abrupt increase in OMC and decrease in dry density is observed. For lateritic soil, a CBR value higher than plain soil is observed at 1.5% coir pith content and for Kuttanad clay at 2%. Kuttanad clay with 2% coir pith can be used for rural road subgrades since it gives a CBR value higher than 2.

In the coir waste in addition to baby fibres, medium to short fibres will also be present. The effect of these fibres at optimum coir waste content arrived from above has to be evaluated further.

Study on Geogrids for Improving Safety in Underground Mining

Martins, P.M., Pimenta de Ávila Consultoria Ltda, Brazil, paula.mello@pimentadeavila.com.br
Gontijo, A.A., DSI Fosminas Mining & Tunneling, Brazil, alexandre.gontijo@dsifosminas.com.br

ABSTRACT

To protect against the fall of small blocks between the mesh of anchors in the openings, meshes that are used today has been replaced by geogrids, due to its flexibility, resistance to oxidation, high strength, lightweight and due to decreased risks during the installation. This work will present technical considerations about this new geosynthetic application regarding the advantages presented, as well as a discussion of the actual requests these materials in various possibilities of application, executive considerations and test results in underground mining from Brazil.

1 INTRODUCTION

Among the methods of mining, underground mining is growing every day around the world due to high mineral commercialization that occurs today. The work in underground mines have essentially two major aspects of security: security structural of underground openings involving roofs, floors, walls and pillars; environmental safety, which refers to creating and maintaining a working environment and proper conditioning to perform the tasks relevant the enterprise. The environmental concern has a broad sense and includes this concern about safety.

Knowing that the mines is done by observing three fundamental principles, safety, economy and the best use of reserves, no one doubts that the first of these principles overlap to the other and has been extended beyond the great concern about loss of life. High investments in equipment and structures that have to be created to provide access to sites where the minerals are removed, they cannot be at the mercy of accidents, mainly caused by falls of small blocks.

So, to protect against the fall of small blocks between the mesh of anchors in the openings, meshes that are used today has been replaced by geogrids, due to its flexibility, resistance to oxidation, high strength, lightweight and due to decreased risks during the installation. This work will present technical considerations about this new geosynthetic application regarding the advantages presented, as well as a discussion of the actual requests these materials in various possibilities of application, executive considerations and test results in underground mining from Brazil.

2 CRITICAL AREAS RELATED TO FALLS OF SMALL BLOCKS

In underground mining, the redistribution of stresses can generate large deformation and ruptures of the rock mass, such as peeling, falling blocks, lateral movements and even subsidence as a result of the performance of tensions.

Generally the performance of tensions behaves according the Figures 1a and 2b, below.

Figure 1: Performance of tensions.a) Stress induced an excavation simple.b) Stress concentration on the pillar.

The measure of tensions in the scale of engineering (m, km) is performed by tests performed on the same job site, with test methods and use of equipment that enables the data register of stresses acting on site, thereby defining the direction and intensity of the principal stress (σ_1), and secondary stresses (σ_2) e (σ_3).

These measures can be obtained from boreholes or surface areas exposed rock mass. For each type of measurement are, today, different techniques.

Stress concentrations in the excavation walls can be of great intensity, reaching mobilize resistance of the rock mass locally or at larger scales, often leading to rupture of the rock.

The major ruptures of larger scale are contained by anchors or systems appropriately designed to reach the safety of the work. But between these anchors still becomes necessary to use a system which protects the fall of small blocks.

In places where the redistribution of stresses resulting in an horizontal principal stress, we observe the occurrence of ruptures predominantly in the roof of the underground excavation, as shown in Figure 2.

Figure 2: Higher horizontal stress, UHE – ITA, Brazil (Barton & Infanti, 2006, Quadros, 2010)

In places where the redistribution of stresses resulting in a vertical principal stress, we observe the occurrence of ruptures predominantly in the walls of the underground excavation, as shown in Figure 3.

Figure 3: Higher vertical stress, UHE – Jinping II, Sichuan - China (Hudson, 2009).

The pillars in room and pillar mining method (Figure 4) are subjected to vertical stress due to overburden rock mass and horizontal stress relieve due to entries excavation around them.

Figure 4: Partially benched pillar failing under elevated stress at the edge of bench mining (Esterhuizen, G.S. et al. 2011).

In Brazilian underground mining (coal and metals) that work with room and pillar mining method usually pillars design by the Salamon-Munro formulation (Salamon and Munro, 1967).

3 TRADITIONAL METHODS OF PROTECTION AGAINST FALLS OF SMALL BLOCKS

3.1 Introduction

In recent years, the meshes began to use more frequently in conjunction with roof bolts to prevent skin falls in weak roofs such as weathering-sensitive shale. Its function is to cover the roof area, and support and hold in place the broken roof between bolts, preventing injuries (Robertson and Hinshaw, 2002).

Some Mines are applying rock bolts and steel straps to improve the pillar strength and consequently to reducing the pillar size. The Figure 5, shown some examples the type of protection.

Figure 5: Examples of the traditional meshes to cover roofs and pillars.

3.2 Types of Meshes

The wire meshes and straps are usually used in underground mines to prevent the fall of small blocks of rock from the roof and pillars between roof bolts (Figure 6).

There are two types of wire meshes used in this application, chainlink mesh and weldmesh. Chainlink consists of an array of woven wire. The wire can be galvanized for corrosion protection, is flexible and strong. The weldmesh are used to strengthen the application of concrete and consist of a square mesh of steel wires, welded at their intersection points. They are more rigid and easier to install.

Another options are the straps, this system is used where the bolts cannot support alone roofs immediate formed by layers of small thickness.

Figure 6: Wire mesh and straps application.

4 THE GEOGRID APPLICATION

4.1 Introduction

Since 1994, longwall coal mines have used polymer geogrids during longwall recovery to control intrusion of gob material into shield/pan line area (Bailey, 2006).

Grids of different strengths and materials have been used in concert to answer the challenges of differing mine. Nowadays, it possible found geogrids from an average of ultimate strength of 55 kN/m to over 500 kN/m.

4.2 Geogrids

The main geogrids applies in underground mine are biaxial polypropylene an polyester geogrids.

The polypropylene geogrids (Figure 7) are manufactured by extrusion of a polypropylene sheet. Drawing is done under controlled temperatures and strain rates, so as to avoid fracture while allowing ductile flow of the molecules into an elongated condition. Besides, significant increases in modulus and strength, the creep sensitivity of the elongated ribs is greatly reduced by the drawing process. The resulting geogrids are referred to as homogeneous, utilized, or relatively stiff geogrids (Koerner, 1998).

The polyester geogrids (Figure 8) are made from high-tenacity polyester yarns, woven into an open structure with the junctions being knitted together or physically intertwined to link the transverse and longitudinal ribs, and coated with PVC (Koerner, 1998). This type of geogrid presents greater ultimate tensile strength and high-modulus than the polypropylene geogrids, therefore today should be the most applied.

Figure 7: Polypropylene geogrids extruded.

Figure 8: Polyester geogrids.

4.3 Case Studies

4.3.1 Dolinar (2006)

Dolinar (2006) presents a results of tests comparing same types of wire meshes and a geogrid. The author discusses in his paper a series of tests were conducted to evaluate the effects of various parameters such as bolt tension, the type of load bearing surface and the size of bearing plates.

The Figure 9 shown same results of these tests.

Figure 9: Dolinar (2006) results.

A very important note is, in the tests presented the geogrid used was polypropylene extruded geogrid with low ultimate tensile strength.

4.3.2 Applications in a Gold Mining from Brazil.

In July 2011, one gold mine from Brazil did a pilot test with polyester geogrids. Usually they used wire meshes to protect the underground excavation against fall of small blocks.

The geogrid was placed in the roof and attached by plates spaced at 1.5 to 1.5 m, as shown in Figure 10.

a) Area for geogrid application.

b) Manual installation.

c) Detail of anchor installation through the geogrid.

d) Geogrid installed and details of plates and its spacing.

Figure 10: Details of geogrid installation in a gold mining from Brazil in 2011.

These geogrids are working until today. During the application some considerations were shown by the worker:

- the geogrid rolls are lighter than wire meshes rolls, is easier to carry;
- easier installation;
- its minimum aperture size was enough to apply the anchor bolt;
- the geogrids has no sharp edges that compromise the safety of the worker.

5 INSTALLATION NOTES COMPARING GEOGRIDS AND WIRE MESH

Geogrids and wire meshes can be installed by manual or mechanized processes and there aren't a lot of differences between their installation processes, as shown in Figure 11.

a)

b)

Figure 11: a) Manual installation of wire mesh using rock bolts to fix in roof. b) Manual installation of geogrid using rock bolts to fix in roof.

During manual installation Geogrid or wire mesh has to be unrolled and pinned to anchors; the anchors are often installed first and the mesh is attached to the anchors afterwards using scissor lifts or baskets on tool carriers. When use the wire mesh the operation will be slow and labour intensive. Geogrid is easier to install them wire mesh

The mechanical system to installation of wire mesh was development to hard rock Mines seeking to reduces manual handling and personal exposure during the installation process reduces support cycle time, enables the mesh to follow the rock surface contours more closely, as shown in Figure 12.

Figure 12: Automatic component installation of wire mesh adapted to standard jumbo.

The same system was developed to geogrids and has been used frequently, mainly in mining that use the longwall method, as shown in Figure 13.

Figure 13: USA and Australian Coal Mines working with Longwall method mining are using geogrid how surface control in underground mines .

6 DISCUSSION

As all geosynthetic products that start your application on the market, at first they are done empirically. Most considerations and comments are made on the field and people learn directly at the time of product application.

What this paper has as main objective is to highlight the need to develop requirements for design, specification and installation correct for these types of products in underground mining, from the survey of the state of the art current application.

Designing methods should be further elaborated, taking into consideration the size and weight of the blocks, average distance between the anchors and fixing points of geogrids.

Another issue to be significant also in relief is the chemical compatibility of geogrids to the environment of each type of underground mining. This guarantees the durability and effectiveness of the product.

In addition to, the development of methods and equipment adapted for underground installation also put to use in ideal operating conditions.

7 CONCLUSION

According to the previously presented, it was possible to conclude that the application of geogrids for protection with falling blocks in underground mining is an application more and more feasible.

Observations in the field show the following advantages of the product compared to traditional application of metallic screens, such as:

Advantages:

- It is light - reduces costs and operating time.
- No tip-sharp, these reduce the risk of injuries.
- Easily accommodates in the surface of underground excavation.
- Chemicals and Mechanicals properties anti-corrosive.

In relation to the minimum aperture size is important to note that this should remain larger than 60 x 60 mm, to enable the implementation of the anchors through the geogrid.

In relation to the spacing of the attachment plates, a general rule which can be used for deciding the spacing between support bolts is that the distance between the plates should be about equal to 3 times the average spacing of the planes of weakness of the rock mass. Therefore, if a set of planes layering together and create wedges or blocks with an average length of 0.5 m, the ideal spacing between screws should be about 1.5 m length of the bolt should be two times the spacing, i.e., 3 m.

In relation to the ultimate tensile strength of geogrids, further study should be done, considering biaxial geogrids with ultimate tensile strength greater than 200 KN / m and checking the influence of the high-modulus.

Geogrids with higher stiffness also facilitates product application.

ABSTRACT

At a large development site in Malvern, Pennsylvania, twelve segmental retaining walls were required to achieve the proposed grades. The subgrade investigation in the karst geology underlying the site revealed a pinnacled bedrock surface underlying partially saturated overburden varying from low plasticity silts to silty sands. Blow counts within the overburden were generally less than 10, and many were observed to be weight-of-hammer. As part of the subsurface investigation a substantial laboratory testing was performed on recovered samples. Subsequent design analyses that subgrade improvement was required beneath six of the twelve retaining walls. Subgrade improvements selected included staged construction, subgrade surcharging, and surcharging with vertical strip drains.

For staged construction analyses, the maximum height of retaining wall that could be constructed with the initial undrained cohesion value and comply with required total stress safety factors were determined. The undrained shear strength required to adequately support the total height of the retaining wall under total stress conditions was then calculated where needed. The amount of strength gain and duration needed to develop the strength gain is a function of the distribution of the applied stress, the stress history, and consolidation parameters of the supporting soils. Considering the laboratory data, the anticipated anisotropic stress distribution and strength gain theory, a relationship was developed for undrained strength gain for the saturated fine-grained soils at the site. Finally, the duration to develop the required strength gain was calculated.

Monitoring of construction was performed using pore pressure transducers and settlement plates. This paper will discuss the subgrade investigation, laboratory testing and design analyses necessary to provide the necessary subgrade improvement beneath the segmental retaining walls.

1. INTRODUCTION

At a 42hectare brownfields site in Malvern Pennsylvania, a prominent developer envisioned revitalizing the former steel mill into a thriving town center featuring retail shops, restaurants, a bowling alley, a movie theatre, offices and residential units. The initial phase of the redevelopment involved demolition of the steel mill buildings and storage buildings and related structures. Figure 1 is an aerial photograph taken prior to redevelopment. Twenty four buildings were proposed to be constructed for the town center, along with three bridges to cross a stream that flows from the west to the east across the property. Twelve retaining walls were proposed at the property, with eight located along the stream to provide providing building geometries averaging 7m above the stream elevation.

An extensive subsurface investigation was performed at the site for each of the major structures proposed, followed by laboratory testing and development of geotechnical recommendations for each structure. The subgrade investigation revealed a pinnacled bedrock surface underlying partially saturated overburden varying from low plasticity silts to silty sands. The overburden soils were found to have a consistency ranging from very soft to firm. Subsequent laboratory testing and design analyses showed that subgrade improvement would be required beneath six of the twelve retaining walls.

Construction of site works began in 2007 and continued until 2009 when construction temporarily ceased due to funding issues. Additional funding for the project was obtained, however the project was reconfigured to accommodate economic criteria and different tenants from those who were identified for the initial planning for the project. A total of ten segmental retaining walls and one reinforced earth slope were constructed during the initial phase of construction. Currently, two retaining walls are being redesigned to accommodate the current reconfigured development.

Figure 1- Aerial view of the site prior to redevelopment, with north towards the top of the photograph. The building at the lower right is approximately 285m long (Google Earth, 2012).

2. SUBSURFACE INVESTIGATION

The site is primarily located above a karst geologic formation, known as the Conestoga Formation, which is particularly prone to the development of sinkholes. Along the southern end of the property there is a geologic contact with schist of the Octororo Formation. Over 285 borings were performed across the site during the subsurface investigation of the proposed buildings, bridges and retaining walls. Cone penetrometer testing (CPT) was initially performed at 25 locations across the site to provide estimates of average shear wave velocities of the overburden for seismic site classification. Figure 2 shows the overall site development and locations of completed borings and CPT locations.

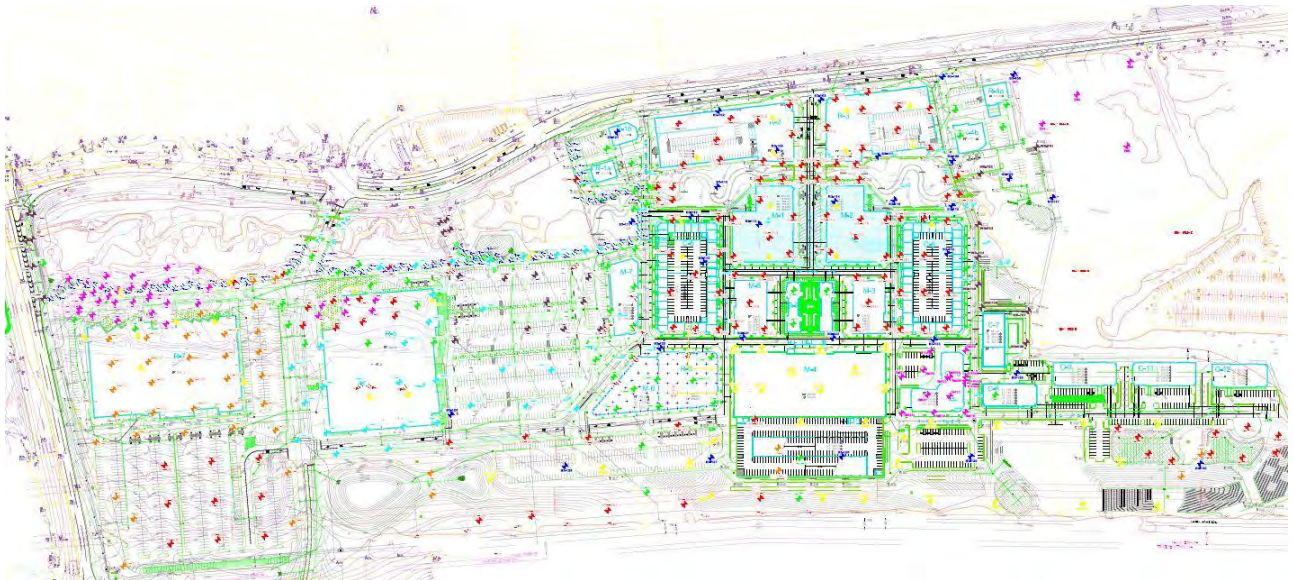

Figure 2- Plan view of 2006 development.

2.1 Field Investigation

The subgrade investigation in the karst geology underlying the northern portion of the site revealed a pinnacled bedrock surface underlying partially saturated overburden was relatively consistent, varying from low plasticity silts to silty sands. The consistency of the overburden overlying the karst was found to be very soft to firm, with blow counts observed to be generally less than 10, and many were observed to be weight-of-hammer. The CPT tip resistances observed correlated well with blow counts, with most observed below 2,394kPa. Numerous thin-walled tube samples were recovered during the subsurface investigation for subsequently laboratory testing. Along the southern portion of the site, the overburden was found to be much more competent, consisting of dense weathered schist. Groundwater was observed to be 6m to 8m within the overburden, generally coinciding with the elevation of the stream. The depth to bedrock was highly sporadic across the site, ranging from 1m to over 35m below the existing grades.

2.2 Laboratory Testing

Index testing of split-spoon samples was performed in the laboratory included classification, moisture content and organic content. Moisture content profiles were developed on continuous samples recovered in the field at many of the boring locations. Laboratory testing performed on recovered thin-walled soil samples included consolidation, unconsolidated-undrained (UU) triaxial shear and consolidated undrained (CU) triaxial shear. Direct shear tests and compaction testing were performed on bulk samples recovered from the site.

Considering the blow counts and CPT results observed in the field investigation, the results of the consolidation testing showed overconsolidation ratios (OCRs) ranging from 1.0 to 3.5 for the seven consolidation tests performed. The higher OCRs were noted in portions of the site previously supporting the steel mill buildings. The vertical coefficient of consolidation (c_v) ranged from 0.23cm²/min to 2.01cm²/min, averaging 0.83cm²/min. The compression index (C_c) of the overburden soil was very well behaved, varying only between 0.10 and 0.14. The average recompression index (C_r) was 0.014.

The peak undrained shear strengths observed in the UU tests were variable, with shear strengths ranging from 37kPa to 131kPa, depending on the applied normal stress. Strains to the peak stress generally exceeded 15%, introducing uncertainty to actual behavior in the field. To develop a high degree of certainty to field performance, the undrained shear strength at 5% strain was considered appropriate. Considering the erratic behavior of undrained shear strength observed in the laboratory, preference was given to the lowest value of undrained shear strength observed, 26kPa.

The consolidated undrained tests performed on recovered samples also had variable results. The effective stress internal angles of friction observed in the CU tests were 33° and 38°. The higher value is inconsistent with typical values associated with low plasticity silts and silty sands. The lower value showed reasonable agreement with the results of direct shear testing performed on remolded samples obtained from the site.

3. DESIGN ANALYSES AND RECOMMENDATIONS

Foundation design for the buildings varied substantially given the vast difference in building types and bearing pressures. Many of the buildings and the bridge abutments were recommended to be supported on mini-piles. Where possible, shallow foundations were recommended, however subgrade improvement would be required. As segmental retaining walls were envisioned to be constructed along the stream corridor and elsewhere on the site, the developer elected to have the design of the retaining walls designed by the contractor under a design-build contract. However, due to exclusions in the wall designer's contract, geotechnical support was required for the wall design.

3.1 Consolidation Analyses for North Town Center

One of the primary initiatives of the developer was to construct the entrance of the town center to attract tenants for the development. Specifically, the four buildings identified as M-1, M-2, R-2 and R-3 in Figure 3 would be the first buildings constructed. Along the stream, approximately 7m of fill would be required to achieve the building pad elevations. As these four buildings would be constructed largely on engineered fill, shallow foundations were recommended, provided consolidation of the underlying overburden soils could occur prior to building construction. The entire area was to have a 3m surcharge placed above the fill, which would remain for 9 months, which conformed to the initial development schedule. The stream had been previously diverted away from this area. Vertical deformation associated with consolidation of the overburden was estimated to be 155mm in response to the embankment and fill loading.

As with many projects, the developer's willingness to wait 9 months for the required consolidation to occur diminished as the onset of construction neared. Using wick drains spaced 1.5m apart in a triangular pattern and a 7m surcharge, the consolidation period was reduced to 30 days. This satisfied the revised schedule, however the expected costs for wick

drain installation was twice what the developer wanted to pay. The developer decided to accelerate the consolidation beneath the M-1 and M-2 buildings and wait 9 months for surcharge without wick drains consolidation. Figure 3 shows the limits of wick drains hatched in light blue. The surcharge would also benefit the subgrade beneath the retaining walls adjacent to the creek, driving out excess pore pressures prior to wall construction.

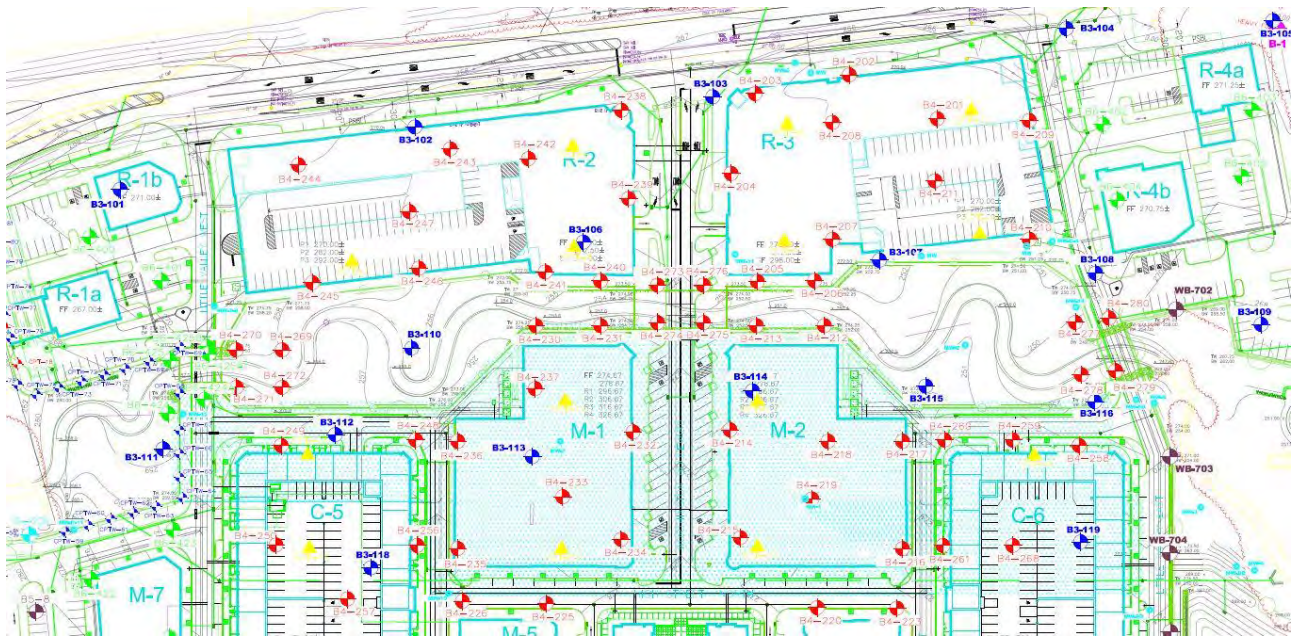

Figure 3- First buildings to be constructed at the north end of the town center.

3.2 Geotechnical Engineering for Segmental Retaining Walls

As typical in many design-build contracts for segmental retaining walls, the wall designer initially stipulated that the design of the segmental retaining walls only evaluated internal stability and that bearing capacity, settlement, and overall stability was the responsibility of the developer's geotechnical engineer. This stipulation was initially rejected, particularly for retaining walls along the stream outside the aforementioned surcharge area. It was later agreed that the geotechnical engineer would provide any additional data needed by the wall designer to evaluate all aspects of stability and vertical deformation.

As differential settlement beneath the retaining walls along the stream was anticipated to be problematic, the wall designer decided to incorporate joints in the retaining wall fascia every 8m. To provide wall designer the geotechnical information needed to support the design concept to address differential settlement, an additional subsurface investigation was performed gain a clear understanding of anticipated vertical deformation beneath the retaining walls adjacent to the stream. Cone penetrometer testing (CPT) was performed in 80 locations at approximate 8m on center locations along the alignment of the retaining walls. The results of the previously performed consolidation testing were used in subsequent analyses.

The bearing pressures beneath the wall fascia were then attenuated to the mid-point of the saturated fine-grained soils subject to consolidation in accordance with Newmark's attenuation relationship for rectangular flexible footings. No attenuation was considered at the rear of the reinforced zone of the retaining walls as the bearing soils would be subject to embankment loading at these locations. A 122 consolidation analyses performed in this study. Elastic settlement of the vadose zone soils was been neglected in these analyses as this vertical deformation would not be time dependent, and therefore assumed to occur during construction of the walls. Consolidation was calculated for the fascia and the reinforced zone of the retaining walls at each analysis point, as well as the anticipated duration for consolidation to occur. Results of these analyses showed that deformations in excess of 200mm and consolidation periods greater than 90days are anticipated in many locations along the proposed retaining walls along the stream. The retaining walls in the area of the surcharge area were excluded from this study.

The initial total stress global stability analyses suggested that in order to have adequate safety factors against instability, phasing of retaining wall construction would be required. It was identified that the fine-grained soils supporting the retaining wall would need to experience a gain in shear strength as consolidation to applied stress occurred. The amount of strength gain and duration needed to develop the strength gain is a function of the distribution of the applied stress,

the stress history, and consolidation parameters of the supporting soils. Considering the laboratory data, the anticipated anisotropic stress distribution and SHANSHEP theory (Ladd, 1986), a relationship was developed for undrained strength gain for the saturated fine-grained soils at the site.

To account for the varying thickness of overburden beneath the retaining walls, the largest drainage path beneath the retaining walls was considered in estimating the average degree of consolidation that would occur over a given period. Once the drainage paths were established, a time factor relationship was developed for each evaluation. The progress of construction the wall installer hoped to achieve was 600mm vertical over a 180m distance per day. The average degree of consolidation, excess pore water pressure and strength gain over this period was then determined. The maximum height of retaining wall that could be constructed with the initial undrained cohesion value and comply with the total stress safety factor against instability discussed above was determined. Safety factors considered appropriate in these analyses were in agreement with suggested values in the literature (Collin, et.al, 2007). Results of these analyses suggested that phased construction would be required in some areas of the proposed retaining walls. The undrained shear strength required to adequately support the total height of the retaining wall under total stress conditions was then calculated where needed. Finally, the duration to develop the required strength gain was calculated, which was estimated to be as much as 3 months. The maximum height of construction of the retaining walls and subsequent periods required for the strength gain were provided to the wall installer.

4. CONSTRUCTION OF INITIAL PHASE OF DEVELOPMENT

Demolition of the former steel mill began in the fall of 2006, followed by land development beginning in the spring of 2007. Grading necessary and installation of wick drains occurred first, followed by placement of the embankment and surcharge in the northern portion of the town center. Site grading and construction of retaining walls in other areas of the site began after construction of the surcharge.

4.1 Wick Drains and Surcharges

Once grading was completed for the wick drain field in the northern portion of the town center, 6,160 wick drains were installed at a spacing of 1.5m apart over the 1.43hectare area. Each wick drain was advanced to refusal at the bedrock surface, ranging in depth between 9m to 13.5m. Figure 4 is a photograph of the wick drain installation.

Figure 4- Installation of wick drains in the northern portion of the town center.

Once the wick drains were installed, a 305mm thick layer of free draining gravel was installed over the area to permit drainage of the wick drains. Twelve settlement places and pore pressure transducers were then installed in discrete locations across the entire area to be surcharged. Each pore pressure transducer was installed at the approximate mid-point of the fine grained strata subject to consolidation. Figure 5 shows construction of a settlement marker after a pore pressure transducer was installed. The 7m embankment and 3m surcharge was then constructed over the area.

Monitoring of the settlement markers and pore pressures was then performed daily for 38 days. The period required for dissipation of excess pore pressures within the saturated fine grained overburden was approximately 25% longer than that predicted during design analyses. Vertical deformation recorded in the settlement markers varied from 96mm to 150mm, compared to the 150mm predicted.

Figure 5- Settlement plate and pore pressure transducer cable.

4.2 Retaining Wall Construction

Once the surcharge and embankment were removed from the northern town center, construction of the segmental retaining walls along the stream began. Preparation of subgrade for the three bridges also began at this time. Construction of the retaining walls went rapidly, and the retaining walls soon reached either their full height or the height required for staged construction. As with the surcharge area, settlement plates and pore pressure transducers were installed where staged construction of the retaining walls was required.

Construction of the mini-pile foundations for the three bridges began after the subgrade was prepared, but due to the nature of the work, advanced at much slower rate in comparison to the retaining wall construction. The pile contractor elected to install the mini-piles by jetting them through the overburden. The jetting led to a localized issue where the surface soils liquefied, creating a 1m depression as shown in Figure 6. The surface depression created a loss of subgrade support for one of the retaining walls, as can also be seen in Figure 6. The wall yielded at this location, creating differential settlement, cracking the wall fascia approximately 5m from the surface depression. To remediate, the retaining wall was locally dismantled after completion of the mini-piles. The subgrade restored, and then the wall was rebuilt.

5. SUMMARY

Construction of the initial phase of development concluded in the fall of 2008, when funding for the project was interrupted. Two of the building pads on the western portion of the site were completed, allowing for construction of buildings by the two tenants who would occupy this portion of the site. Infrastructure and building pads were also completed for most of the town center. The retaining walls along the stream and the three bridges were completed. Figure 7 and Figure 8 show the completed retaining walls, bridges and completion of the stream bed.

Other than the opening of the two buildings at the western portion of the site, the project remained idle for three years while the developer secured alternative funding. In the fall of 2011, funding for the project became available. Unfortunately, many of the previously secured tenants had lost interest in the development. Furthermore, the project was required to be downsized from the initial development plan, which prompted redesign of the town center area. Two of the proposed retaining walls were not constructed, and are currently under design due to the reconfiguration. One of the retaining walls is over 300m long, and will have a maximum height approaching 15m. Construction of the

reconfigured town center is anticipated to begin in the spring of 2013, and should be completed in time to prepare a follow up paper for the next geosynthetics conference.

Surface Analysis of Weathered HDPE Geomembrane Studied by LSCM and FTIR Spectroscopy

Wu, P., Yang, H.H., Luo, S.H., Zhu, T.G., Zhe, D.M., China Petroleum & Chemical Corporation Beijing Research Institute of Chemical Industry, China, wupeng.bjhy@sinopec.com

ABSTRACT

Surface of three high density polyethylene (HDPE) geomembrane (GM) samples was examined using laser scanning confocal microscope (LSCM) after artificial weathering test. Although no significant changes were observed on the surface of the GM samples, it was found that the variation of roughness value was different among the three samples due to differences in weathering resistance. Changes of surface chemistry were studied using Fourier transform infrared (ATR-FTIR) spectroscopy to monitor the development of photodegradation of GM samples. To estimate weathering resistance, tensile properties and oxidation induction time (OIT) of GM samples were also determined after artificial weathering. The results showed that surface roughness have correlation with weathering resistance, although the correlation is not strong. And it still needs to be further investigated.

1. INTRODUCTION

HDPE geomembranes are commonly used in geotechnical and civil engineering systems to provide barrier to advective and diffusive migration of contaminants (Rowe, 2005). Membranes can perform one or more functions such as liquid and gas barrier and stress crack resistance during long period (50 to >100 years). Many researches show that the properties of GM change with time due to ageing (Rowe et al. 2004; Rowe, 2005; Müller, 2007). Ageing of exposed geomembranes is mainly initiated by ultraviolet (UV) light, combined with heat, oxygen and other factors such as rain, oxides of nitrogen and sulphur. Generally, geomembranes are exposed to UV light for only a limited time. While for some special cases, geomembranes are used in exposed applications, without clay or vegetative covering layers. Thus, it is important that HDPE GM remain chemically and mechanically stable over its design life.

LSCM Confocal laser scanning microscopy (CLSM or LSCM) is a technique widely-used in numerous biological science disciplines, such as cell biology, microbiology, genetics and so on (Samuel et al. 2007). The main advantage of confocal microscopy is its ability to acquire high-resolution optical images with depth selectivity.

As the laser scans over the plane of interest, a single image is obtained pixel-by-pixel and line-by-line. Images of different focal planes can be collected by raising or lowering the microscope stage or objective lens. Finally, a three-dimensional picture of a specimen can be obtained by assembling a stack of these two-dimensional images using computer (Mathia, 2011).

Unlike atomic force microscopy (AFM) or scanning tunneling microscope (STM), LSCM doesn't need a probe scanning on the surface. The distance from the objective lens to the sample surface can be hundreds of micrometres to several millimeters.

In this paper, laser scanning confocal microscope (LSCM) and ATR-FTIR spectroscopy are mainly used to analyze surface changes of some exposed GM samples during ageing.

2. MATERIALS AND PROCEDURE

Three HDPE geomembranes were studied in this article: sample 1 for 1.5mm smooth geomembrane, sample 2 for 2.0mm single textured geomembrane and sample 3 for 2.0 mm smooth geomembrane.

The artificially simulated weathering was carried out using an Atlas UVTest, equipped with eight low-pressure Hg fluorescent lamps, with a maximum emission at 343 nm (type 1A UVA-340). Tests were performed for up to 1680 h in accordance with GRI Standard GM 11, tests consisted of 20h UV cycle at 75±3°C black panel temperature, followed by 4h condensation at 60°C. The intensity of the UV radiation sources was frequently verified with calibrated 340 nm radiometers. Black panel thermometer was checked to assure the accuracy during the test periods. The test pieces were placed in a similar position relative to the radiation source and any differences in the distribution of the weathering parameters were compensated by periodic change of position of the lamps. The samples were randomly distributed after each periodic LSCM analysis.

3. RESULTS AND DISCUSSION

3.1 Surface Roughness

Surface roughness is a measurement of the texture of a surface. There are many different roughness parameters in use. By convention 2D roughness parameter is a capital R followed by additional characters in the subscript. Ra is the arithmetic average of the roughness profile. In this paper, Ra (2D surface roughness) was calculated based on DIN EN ISO 4287, using LSCM.

LSCM is useful for acquiring surface morphology of polymer materials. A Carl Zeiss LSM 700 laser scanning confocal microscope is used to examine surface morphology of three HDPE GM samples for roughness analysis. LSCM images showed in this paper are in 2D maximum intensity projection and 3D. They are representative of a series of overlapping optical slices (a stack of z-scan images) with a z-step of 0.05 μm . The laser wavelength used is 405nm.

LSCM analysis was conducted on the three GM samples after every 168 hours' UV exposure. The LSCM images (Fig.1, Fig.3), in the form of 2D maximum intensity projection and 3D, show the topography of original GM samples and GM samples after 1680 hours' UV exposure respectively. From the LSCM images it can be seen that there are significant differences among these samples, but no obvious changes on the surfaces of aged GM compared with the original sample. Height information of the sample's surface could be obtained at the same time using LSCM, from which the roughness of the surface can be calculated. In the analysis of LSCM, the roughness of several dispersed positions of each sample was measured, and same trend of each sample was found. So in this paper, a fixed position of each geomembrane was chosen for the LSCM analysis to observe the changing of surface roughness under different exposure time. Roughness was calculated based on the same scan area marked out by the white rectangle, as shown in Fig. 1. Each scan area was chosen by some special points which could be easily recognized in the LSCM images.

(a) sample 1

(b) sample 2

(c) sample 3

Fig. 1 LSCM micrographs of the surface of the three samples before (left) and after 1680 hours' UV exposure (right)

Fig. 2 Surface roughness change as a function of exposure time

The variation in roughness of three GM samples with respect to age time is shown in Fig. 2. The roughness of three GM samples was different from each other, which is consistent with the LSCM images. As shown in Fig. 2, three GM samples show different variation in roughness.

Sample 1 had the biggest original roughness. Roughness remained unchanged up to 800h and increased from 4.469 to 4.947 at 840h. Then the roughness subsequently decreased and the final value was 4.188, lower than the initial value 4.452.

During the initial aging period there was a sharp decrease in roughness of sample 2 from the original value 2.033 to 1.313. Then it kept decreasing slowly until 800h. After that the roughness values gradually increased until 1176h. During the whole ageing period, the roughness value was lower than the initial value. The roughness value after ageing for 1680h was 1.441, about 71% of its original value.

For sample 3, the roughness values were basically at a steady state. There was only a slight increase during the whole ageing period from the initial value of 2.254 to 2.316.

Based on the analysis of LSCM results, it could be deduced that the different changes of surface roughness among the three samples were caused by their different UV resistance. UV resistance of sample 2 was weaker compared with the other two samples, and sample 3 had the best UV resistance. In order to see if there is correlation between the surface roughness and UV resistance, GM samples were also tested for ATR-FTIR intensity changes, tensile properties and OIT after artificial weathering to estimate their UV resistance.

Fig. 3 LSCM images of three samples in the form of 3D

3.2 ATR-FTIR

ATR-FTIR is a well-established, nondestructive method implemented in various different studies for determining the chemical composition of materials based on their chemical bonding. In order to obtain a better identification of the functional groups present in the exposed samples, ATR-FTIR spectra were recorded with a Varian 1000 Fourier Transform IR spectrometer conducted in the ATR mode. Spectra were made up to 32 co-added scans and resolution was set to 4 cm^{-1} . Samples were analyzed as a function of exposure time. In this paper, the ATR-FTIR band selected for chemical degradation analyses was from strong absorption band and ATR-FTIR results will be used just to check weathering resistance of the three different samples.

Fig. 4 show ATR-FTIR intensity changes of a band at 1730cm^{-1} (due to C=O stretching of a ketone) for the 3 samples respectively. Each data point shown in Fig. 4 was obtained from approximately the same location. Intensities were obtained from the ATR-FTIR spectra at a specific exposure time after adjusting for the base line shift.

For sample 2, it can be seen that the intensity of band at 1730cm^{-1} increased with exposure time and it had the most significant changes due to photo oxidation. The intensity value increased from 0.004 to 0.025 after 1680h exposure. The rising of the value was rapid in the first 168h and appeared to be stable in the next 1344h. Compared with the results of LSCM, it can also be seen that the roughness of sample 2 had a sharp decrease in the first 168h, and then the value slowly went down until 840h. This means the variation of surface roughness have correlation with the ATR-FTIR intensity change. The intensity value of sample 1 and sample 3 had only slight changes. The trends were also in good agreement with the changes of surface roughness of sample 1 and sample 3.

From the ATR-FTIR results we can see that UV resistance of sample 2 was weaker than the other two samples, which also can be inferred from the analysis of LSCM results.

Fig. 4 Intensity change of 1730cm^{-1} as a function of exposure time

3.3 Tensile Properties

The tensile properties of a GM provide an index as to how it will respond to physical stress and are a useful means to assess the durability of the GM (Rowe and Sangam,2002). Generally, polymer degradation due to ageing leads to decreases in strength and strain at break while increases in tensile modulus and yield stress, which signifies the transition from a ductile material to a brittle one as a result of degradation. The tensile properties of the GM were obtained in accordance with ASTM D6693 using a Zwick Roell test machine equipped with load cell, crosshead measurements, and self-aligning wedge grips. The dumbbell shaped GM specimens were stretched at a speed of 50 mm/min until rupture. Tensile properties at yield and break were recorded.

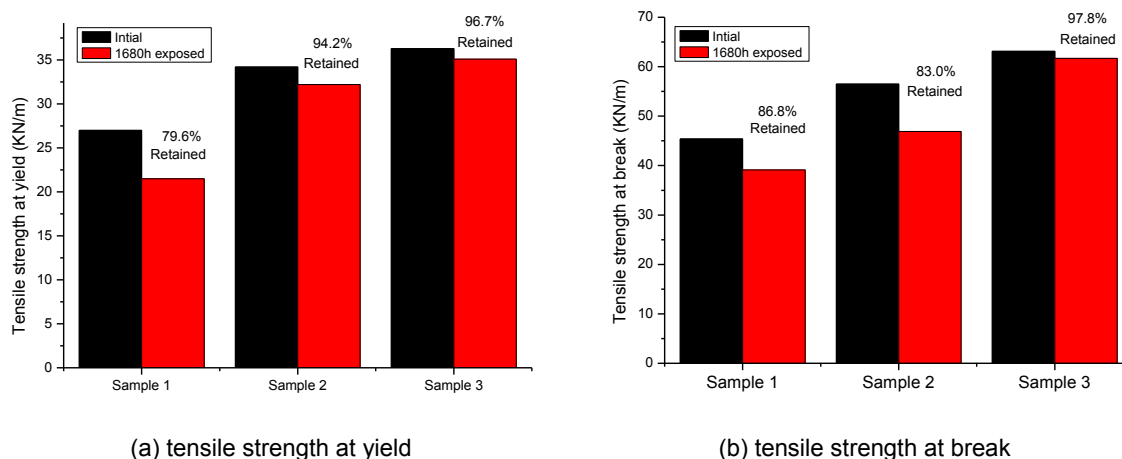

Fig. 5 Tensile properties change of three samples before and after 1680 hours' UV exposure

Fig. 5 respectively shows the tensile strength at yield and tensile strength at break of the three GM samples before and after UV radiation. From the histogram, it can be seen that the yield strength of sample 1 had dropped by 20% and tensile strength at break decreased by up to 13% of its original value during 1680 hours of testing. The tensile strength at break of sample 2 decreased by up to 17% while the yield strength only changed a little. Sample 3 was the most stable one compared with sample 1 and sample 2. There were only slight changes in tensile properties observed after the artificially simulated weathering (could be due to a small variability in tensile properties at different locations along the GM roll), which showed that sample 3 had the best weathering resistance.

3.4 Oxidation Induction Time (OIT)

Studies show that service life of HDPE GM can be divided into three stages (Hsuan and Koerner, 1998; Sangam and Rowe, 2002; Müller and Jakob, 2003). Stage I: Antioxidant depletion, Stage II: Induction time to the onset of polymer degradation, and Stage III: Polymer degradation. The sum of the three stages is regarded as the service life of GM. According to test method GM 13, the UV resistance of GM is based on percent retained value regardless of the original OIT value, which is initially controlled by the rate of antioxidant depletion in Stage I. Hindered amine light stabilizers (HALS) are not present in the GM samples. We use standard OIT tests to estimate UV resistance of three samples. Standard OIT tests were carried out following ASTM D3895 with differential scanning calorimeters (DSC) PE Diamond. The GM samples were heated to 200 °C in nitrogen, and then held isothermally at 200 °C and 35 kPa in an oxygen environment until the exothermic peak was detected. The time to the onset of exothermic peak resulting from oxidation was taken as the OIT value.

During UV exposure, antioxidants are lost by evaporation and chemical reactions with oxygen, free radicals and alkylperoxides at the polymer surface. Thus OIT value of the GM decreases as antioxidants are depleted with time.

Fig. 6 OIT change as a function of exposure time

Fig. 7 Variation of OIT with ageing time using linear regression (from 504h to 1680h)

Fig. 6 presents typical plots of OIT with ageing time for three GM samples respectively. It can be seen from the figure that OIT value of the three samples decreased in varying degrees during the ageing test. For sample 1 and sample 3, the Std-OIT retained 52.4% and 53.3% of the original value respectively, both greater than 50%. There was most significant difference between the std-OIT value of the virgin GM and sample 2 being aged after 1680h with the Std-OIT retained being only 43.1% of the original value. It was also observed that the std-OIT value of three GM samples remained steady for a period of time during the ageing test. Then the OIT value began to decrease at a relatively higher rate.

By using linear regression through the data points (from 504h to 1680h for sample 1, from 1008h to 1680h for sample 2 and sample 3), it can be calculated that if the OIT value dropped down to zero, 3261 hours of ageing test would be needed for sample 1, 2721 hours for sample 2 and 3032 hours for sample 3. The coefficient of determination R^2 of the regression line ranged from 0.976 to 0.998. The results of OIT test showed that UV resistance of sample 2 was weaker than the other two samples, which also can be concluded from the result of ATR-FTIR and LSCM.

4. CONCLUSIONS

Surface roughness of a series of HDPE GM samples were analyzed using laser scanning confocal microscope (LSCM) after UV exposure. The exposed samples were also tested for OIT, ART-FTIR spectra and tensile properties. Due to the difference in UV resistance, sample 2 showed the most significant change in surface roughness, decline in tensile strength and OIT, while sample 3 remained stable in surface roughness, tensile properties, and had the highest retention of OIT. Based on the test results, the following conclusions were reached.

- (1) During the period of UV exposure, the change of surface roughness was consistent with the variation in tensile properties, OIT and ATR-FTIR results. So surface roughness can be used to evaluate the UV resistance of HDPE GM.
- (2) The value of surface roughness changed significantly with decreased UV resistance. The surface roughness remained stable for HDPE GM with better UV resistance.

It is proposed that surface roughness has correlation with weathering resistance when the geomembrane is still in the stage of antioxidant depletion (Stage 1). Maybe the roughness is not uniquely related to a single parameter but influenced by many factors, such as loss of antioxidants (by evaporation and chemical reactions) on the surface of GM, outward migration of antioxidants from the core to the surface, formation of low molecular weight polymers due to photo-oxidation. The correlation between surface roughness and weathering resistance, and the trends of roughness change during its entire service life cycle need to be further studied.

Ten Years of Innovation in the Application of Piled Embankments in the Netherlands

A.E.C. van der Stoel, PhD., University of Twente / CRUX Engineering Netherlands, vanderstoel@cruxbv.nl

ABSTRACT

This paper describes the construction and some general aspects of the design and execution of several Load Transfer Platforms (LTPs) or piled embankments in the Netherlands over the past 10 years. In this period extensive innovations were carried out in both design and execution, resulting in a new design guideline and innovative applications. Because of the particularly poor soil circumstances, many specific challenges were encountered during construction of piles and geogrids.

The paper first briefly outlines the major design rules in Dutch Guideline CUR226 after which an extensive overview is given of the major characteristics of various executed projects for road and rail constructions. The paper concludes with two completely new and innovative applications: one for a cemetery (currently being realized) and one for the crane platforms of the biggest on-shore wind farm in the Netherlands (>7,5MW, >198m tip).

1. INTRODUCTION

Because of an emphasis on reducing construction time, lateral movements near existing structures (bridges, aqueducts) and reducing the disturbance to the surrounding area during the construction of embankments, several Load Transfer Platforms (LTPs) on piles or Piled Embankments (PEs) have been constructed in the Netherlands in the past 10 years. Piled embankments generally consist of a large number of piles, installed at a small spacing, overlain by geogrids in a platform of material with a high friction, the Load Transfer Platform (LTP). The general principle is illustrated in Figure 1: after applying a working platform of sand (1), the piles (2) and steel pile reinforcement (3) are installed, on which a pile cap (4) is placed (prefab) or casted. On top a mattress (5) consisting of geogrids and granular material is constructed. Finally, on top of this the embankment and (rail)road can be constructed without (piles in bearing layer) or with limited settlements (friction piles, *not* shown in Figure 1) any settlements occurring.

Figure 1: Principle of piled embankment installation

2. SOIL CONDITIONS IN THE NETHERLANDS

To sketch the typical circumstance in which piled embankments are applied in the Netherlands, two typical soil profiles are outlined. Most typical for the soil conditions is that the top meters consist of soft soils with a high groundwater table. In Figure 2 (left, Amsterdam) a soil profile, that is typical for the ground conditions in the western part of the Netherlands is shown. The top layer of the first meters below surface level consists of Anthropogenic sand. Below this top layer the

Holocene deposits are found until a depth of about 10-15 m below surface level. The Holocene formation can be divided (from top to bottom) into peat (Hollandveen), clay (Oude Zeeklei), silty sand (Wadzand), clay (Hydrobiaklei) and peat (Basisveen). The soft Holocene has been deposited on top of the stiff Pleistocene sands which are sometimes divided by an intermediate silty, clayey sand layer (Allerod). The phreatic water level is found about 0.4 m to 1.5m below surface level. The artesian water level in the Pleistocene sand layers usually lie 2 m below the phreatic water level.

Figure 2: Characteristic soil profile for western part (left) and northern part (right) of the Netherlands

For the northern part of the Netherlands, the soil conditions are comparable with the western part of the Netherlands, only the Holocene layers are generally much more loamy, see Figure 2 (right, Leeuwarden). The phreatic water level is found about 1.0 m to 2.5m below surface level.

For the central and eastern part of the Netherlands, the soil consists of mainly medium dense to dense Pleistocene sand layers, locally overtopped by some Holocene clay or silt layers. The application of piled embankments for these profiles is generally less interesting compared to convention settlement reducing solutions.

3. MODELING PILED EMBANKMENTS

3.1 Introduction to CUR226

In 2010, the Dutch Design Guideline for the design of piled embankments CUR 226 (2010), has been introduced. The outlines of this Design Guideline are given by Van Eekelen et al (2010). The choices made within the Dutch Design Guideline are based on comparisons with and analyses of several field tests, finite element calculations, parameter studies, and work of several authors. The BS8006 (1995 and 2010) and the EBGEO (2010) have been discussed in great detail and the decision was made to adopt the design method of Zaeske (2010) / EBGEO.

The safety philosophy and the constraints of the EBGEO for the applicability of the design rules have been adapted for the Dutch situation.

In the first stage of the design of a piled embankment, the efforts can usually be limited to calculations for the grids and the bearing capacity of the piles. Lateral loads can however cause relatively large bending moments in the piles, and because the steel pile-reinforcement significantly contributes to the total costs, the determination of displacements, lateral forces and bending moments plays an important role in the design process. In the next paragraphs the design stages of the CUR 226 will be explained.

3.2 Analytical Grid Calculation

In the design of the geosynthetic reinforcement, several calculation steps are distinguished. After the material properties on load- and material factors are determined, all loads are converted to an uniformly distributed load and the force distribution within the piled embankment (piles, reinforcement & subsoil) is determined. The line loads that result from this are translated into a strain and membrane tensile force and the spreading perpendicular to the (rail)road axis is included. Because the tensile force depends on the tensile stiffness of the grid, this calculation is an iterative process.

In the past years much research has been performed by Van Eekelen et al. (2012a, 2012b, 2012c), which will probably be incorporated in a revised version of the CUR226 guideline.

3.3 Pile Calculation

The vertical bearing capacity of the piles is determined analytically using the Dutch design guidelines Eurocode 7 - NEN 9997-1 (2012). The LTP can be either considered as a Settlement Free Construction (SFC+ settlements < 3cm), where the end-bearing piles transfer the full load to the bearing layers, or as Settlement Reduction Construction (SRC), where a limited settlement of the LTP is accepted and part of the load is transferred to the subsoil between the pile(cap)s and the rest is transferred to (friction) piles.

3.4 Bending Moments in Piles

A major part of the design of the LTP is formed by the determination of the bending moments in the piles, caused by for example vehicle loads or asymmetry of the embankment. Because of the complicated deformation behavior of the LTP, this can generally not be done analytically. Therefore, Finite Element Method (FEM) calculations are used to calculate pile moments and deformations. The FEM computer program PLAXIS is very suitable for modeling LTPs (Slaats & Van der Stoel, 2009 & Van der Stoel et al 2007b).

Based on the SI the soil profile for the model geometry is determined. For modeling the soil layers the Hardening Soil or Soft Soil Creep model are most appropriate, because they are capable to describe reduction of stiffness as well as irreversible deviator strains due to deviatoric stress. In order to get appropriate parameters for the model, samples have to be taken from the (soft soil) layers that are considered to be most important regarding deformations. Besides determining the volumetric weight (γ), triaxial tests and oedometer tests should be performed for determining stiffness parameters (E_{50} , E_{oed}) and strength parameters (c' , ϕ'). Although complex geometries justify a 3D approach, 2D FEM is still preferred because of lower model complexity and limited calculation time.

The validity of the CUR226 approach has been verified Houten case (Table 1, #22), using Plaxis 3D Tunnel and Plaxis 2D v9 respectively, see also Figure 3. The bending moments in the piles have been compared for various cases with different traffic loads and soil support, from which the conclusion could be drawn that the bending moments generally occur at the same locations and the extreme bending moments per pile do not differ significantly. Therefore it was concluded that 2D calculations assess the maximum occurring bending moment quite accurately and some reserve should be made when using a 2D model to determine the exact location of the extreme bending moments.

Figure 3: Example of 3D (left) and 2D model (right) based on CUR 226

Recently the calculations of the pile reinforcement and grids of the piled embankment of the highway A12 in Woerden (Table 1, #23), designed using PLAXIS 2D v9, was compared with PLAXIS 3DTunnel (2.4) and PLAXIS 3D 2011 calculations by Oskam (2012). The results, see Figure 4, confirm the CUR 226 findings.

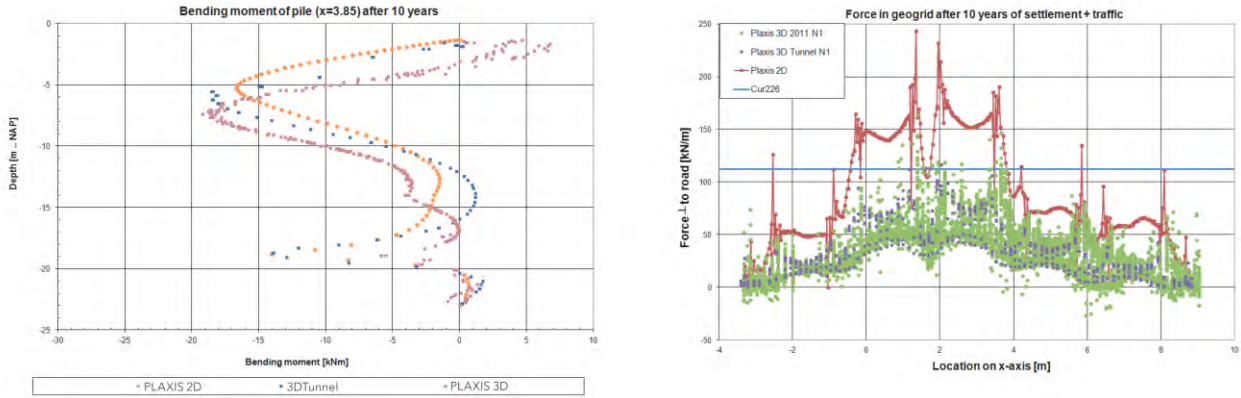

Figure 4: Bending moments and grid forces 2D vs. 3D after Oskam (2012)

4. OVERVIEW OF DUTCH PILED EMBANKMENTS

4.1 Realized Projects

In Table 1 an overview is given of the piled embankments that have been realized in the Netherlands over the past decennium; the numbers (#) of these projects are used as a reference in the next paragraphs. In the first years most designs were based on the British Standard 8006. From 2010 this formally (regulation) changed to the German Standard (EBGEO) and after since about 2010 the Dutch Standard CUR226. The embankment at Carnisselande (#5) was the first LTP for a light rail system (Van der Stoel et al, 2006) and the application with the highest embankment so far. Because of great variety in embankment height, width and pile center to center distances combined with little experience at that time, measurements were conducted, but also many problems were encountered that have led to many improvements in later projects. In the next paragraphs some characteristic and innovative features of these projects are outlined.

4.2 Almere, First LTP-Gabion Intergraded System (#10)

In Almere a noise barrier consisting of an integrated system of a LTP and a gabions wall was constructed on very soft and very heterogeneous soil, demanding specific execution measures for the High Speed Piles (HSP) and geotextile grids used for the system. The gabions consist of boxes made of twisted or welded steel wire filled with stones, and are anchored by geotextiles to ensure stability. The architectural demands require the gabions to appear nearly (visually) horizontal for a period of over 30 years, thus limiting the allowed settlements of the LTP significantly. Design and execution are outlined in Van der Stoel et al (2007a) and the main principle is shown in Figure 5.

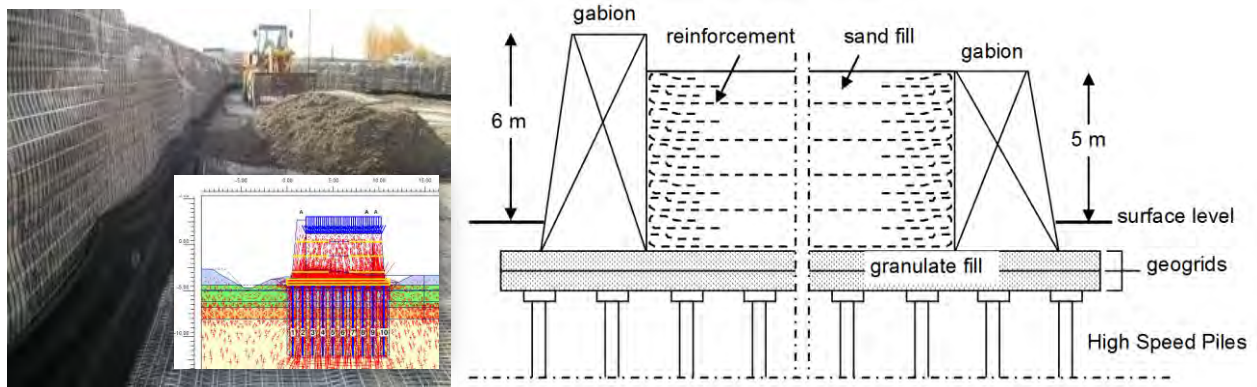

Figure 5: Execution, PLAXIS output stresses model gabions and LTP (left) and cross section LTP and gabions (right)

4.3 A2 Beesd 2x2 Abutments KW9 (#21)

In Figure 6 the first application for a major highway is shown. Special feature in the piled embankment was that it was constructed next to a very old bridge that had to stay in function during the construction of phase 1. Therefore lateral

displacements were a big issue and no consolidation time was available. Thus, the high abutment foundation was constructed before construction of the LTP. When the embankment and new bridge were completed, the old bridge was demolished and at this location also a piled embankment was constructed.

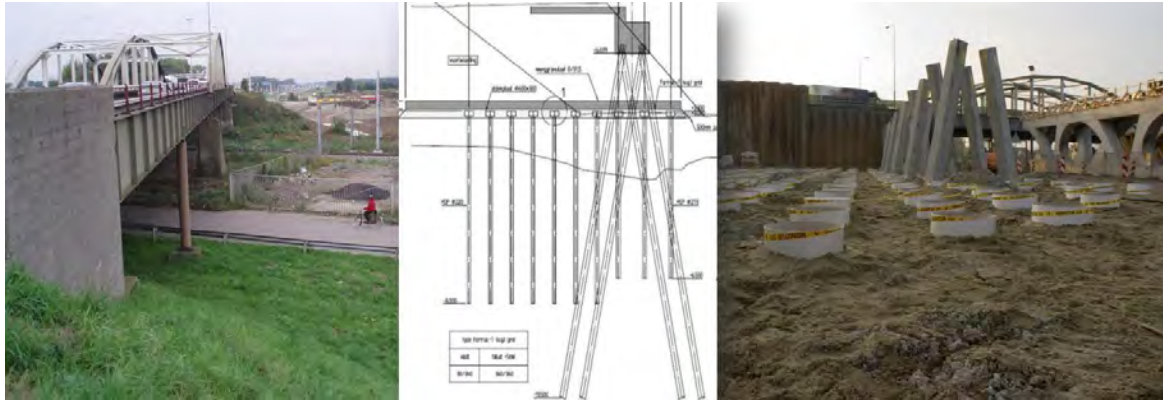

Figure 6: Existing bridge (old situation, left), LTP, sheet pile and abutment foundation (right)

* please note that this table only shows the main properties of the piles, main center to center distances, pile lengths and types of reinforcements applied. Each construction has had special geometrical challenges in which tailor-made solutions were applied, mainly having to do with the overlap of the grids and the depth and center to center distance of the piles. In general more / deeper piles and heavier grids are applied for situations where the piles could not be applied in the general grid. In the transition zones between the regular LTP and conventional solutions (vertical drains, excess loads etc.) piles spacing is generally increased / depth is decreased and/or no piles (just grids) are applied.

** the author has been involved in / responsible for the design of the *italicized* projects

4.4 Houten, First Railway Application and Special Transition Zone (#22)

In Houten, the first LTP for a main railway system was applied (Van Duijnen et al, 2010 and Van der Stoel et al 2010). Because of the specific requirements that had to be met for the transition between a (rigid bridge) foundation on one side and a regular embankment on the other side, a LTP transition zone was applied, see Figure 7. After the regular LTP in zone 2, in zone 3A first the pile spacing was increased, after which in zone 3B this spacing was increased further and the length of the piles was reduced. Finally in zone 4 no piles were applied, thus creating a smooth transition.

4.5 Zwolle Hanzelijn, Rail Crossing and Integrated System (#25)

Near Zwolle, the Hanzelijn, the new rail link between the central Randstad urbanization and the north of the Netherlands is constructed. Prior to constructing a railtunnel trough (see Figure 8), the surrounding area was partially preloaded with sand to limit the settlement caused by the fill alongside the tunnel. The need for a piled embankment for the railway lines around the intersection arises from the local geotechnical impact of connecting to the existing tunnel trough (Van der Stoel et al, 2012). The tunnel comprises a closed part with an open part at each end. The two lines cross at the closed part. The lateral loads on the walls of the open parts are relieved through the use of a reinforced soil construction for the fill (see Figure 9). The piled embankment at the intersection will help to reduce the horizontal soil pressure against the open trough and duct, and prevent excessive moments in the piles underneath the structure. This method also guarantees the stability of the reinforced soil construction. This solution, with high demands on differential settlements between the piled embankment and the rigid tunnel foundation, was the first application for a railway / tunnel crossing.

Figure 9: Hanzelijn pile installation (left), bottom grid (middle) and layered soil reinforcement (right)

4.6 Gouda, Very Low Embankment, Road and Parking (#29 & #30)

In Gouda, both a road and a large parking were constructed on very soft soil. Special circumstances were the possible presence of WWII explosives, so for the first time, vibration free screwed piles were used. To reduce the risk of hitting explosives during pile installation, high center to center distances were demanded. Combined with the very low embankment due to the necessary connection to existing roads, this led to the most 'slender' piled embankment system so far, see Figure 10. To be able to transfer the loads to the piles, relatively large pile caps had to be applied combined with a small excavation below water level before pile installation / construction.

Figure 10: Gouda very slender LTP, pile grid and construction (upper) and cross section (lower)

4.7 Ablasterdam, Cemetery (#31; Still Under Construction)

In Ablasterdam the capacity of an existing cemetery had to be significantly increased. Because of the fact that the location for this expansion is positioned approximately 4m lower than the existing cemetery, the very soft soil and the high groundwater table, a solution was designed in which both 'sand graves' as well as 'concrete basement graves' are positioned on top of a piled embankment, see Figure 11. Because of the very low embankment this leads to a situation in which the arch of the LTP either goes through the sand grave or through the concrete shaft. In the case of the concrete basement graves, the center to center distance of the piles was therefore increased to fit the dimensions of the concrete U-shaped boxes (2,56mx2,15m). Because of the structural properties of the boxes, the grid forces could also be reduced. For the sand graves an uniform 2,15mx1,15m grid was applied.

This very innovative application of a piled embankment has the main advantage that the expansion could be realized without having to take into account long consolidation times that normally apply for these kind of locations in order to meet the strict settlement requirements. Also, the maintenance costs of the cemetery will be drastically reduced because of the settlement free solution and the flexibility of the application. Construction will be finished by the end of 2012.

4.8 Noordoostpolder, Wind Park (to Be Constructed Fall 2012/Spring 2013)

A partnership of more than 100 agricultural entrepreneurs from the North East Polder and energy company RWE/Essent are about to construct the largest wind farm in the Netherlands (website). It will be located on-shore and near-shore along the dikes of the IJsselmeer. The estimated total investment comprises about 1 billion euros. The 86 wind turbines (>7,5MW, >198m tip) of Windpark Noordoostpolder will generate 1.4 billion kWh of clean sustainable electricity per year in 2015, enough to power more than 400,000 households every day. This makes the North East Polder one of the leading European regions in modern wind energy.

In order to build the first 12 on-land wind turbines, a huge mobile crane is needed to place the generator on the tower. In order to build this crane, smaller (but still large) mobile cranes are needed. To position these cranes on the very soft soil and to be able to reach the needed positioning accuracy at hub height, settlement is not allowed at the platform. Therefore, piled embankments will be applied at each location, as shown in Figure 12. Because of the high load on the crane platform (260 kN/m²) and the surrounding platform (185 kN/m²), a HSP pile grid of 1,10x1,10m and 1,30x1,30m respectively will be used. The area of the platforms is 5000 m² each, adding up to about 60.000m² total, making it the largest application of a LTP in the Netherlands so far.

Special attention is required for the interface between the foundation of the turbines themselves and the crane platform. For this, special FEM interaction calculations have been made, which will be published in near future.

Figure 12: Two cross sections and plan view of wind mill construction LTP (and interaction with mill foundation)

5. CONCLUSION

The application of piled embankments has taken a huge flight in the Netherlands in the past ten years. Because of the work conducted by the CUR committee, the publication of the CUR226 guidelines, the many research projects and the fast experience that has been gained in multiple applications, design and execution have been brought to a next level, in which innovative applications, as for the cemetery and wind turbines, are made possible.

Tensile Behavior of Triaxial Geogrid: Application of the Theoretical Method

Robert H. Swan, Jr., University of North Carolina at Charlotte, USA, rswan1@uncc.edu
Zehong Yuan, Ph.D., P.E., SGI Testing Services, LLC, USA, zyuan@sgilab.com

ABSTRACT

Questions have been raised as to the proper determination of the wide width tensile strength as well as strength versus strain behavior characteristics for triaxial geogrids. This paper details how single-rib tension tests can be used to determine the tensile properties of triaxial geogrids. Laboratory testing of single-ribs are used in conjunction with a theoretical analysis developed by the authors using a technical approach based in structural mechanics. Using this approach, the wide width tensile strength behavior of two triaxial geogrids are presented. This analysis will be based on the classical approach for a two dimensional truss due to the slenderness ratio of the geogrid ribs. An analysis of the tensile behavior for a number of geogrid orientations ranging in rotation from MD to TD using both force equilibrium and deformation compatibility will allow for the determination of the wide width tensile strength of the two triaxial geogrids.

1. INTRODUCTION

Over the past thirty plus years, geosynthetic materials have been used in both bound and unbound layers of pavement structures for a wide range of applications. In unbound layers, geosynthetics have been used within the subbase and/or base material or at the interface between the unbound base or subbase layer and subgrade for separation, stabilization, drainage, reinforcement and as moisture barrier, as discussed by Koerner (1984) and Holtz et al. (1998). In bound wearing courses such as hot-mix asphalt (HMA), geosynthetics have been utilized for tensile reinforcement and as stress absorption membrane interlayers to reduce the potential of reflective cracking (Koerner, 1984). When designing and specifying pavement structures incorporating geosynthetics an understanding of the geosynthetic products' wide width tensile behavior in particular the tensile modulus is useful. Traditionally these applications have used geogrids, which have had orthogonal tensile elements in the machine and transverse directions (i.e., geogrids with square or rectangular apertures). Therefore, the wide width tensile strength and strength vs. strain behavior have been determined using either ISO 10319 or ASTM D 6637 standard test methods. Both of these test methods are conventional uni-directional tensile tests. ISO 10319 is solely a wide width test having a test specimen with a minimum width of 200 mm and a width to length ratio 2:1. ASTM D 6637 allows for three types of test specimens, which include: a) minimum 200 mm wide width multi-rib specimen b) single-rib specimens or c) multi-layer specimens. As written, both of these test methods only use test specimens, which are orthogonal in the machine and transverse directions of a geogrid.

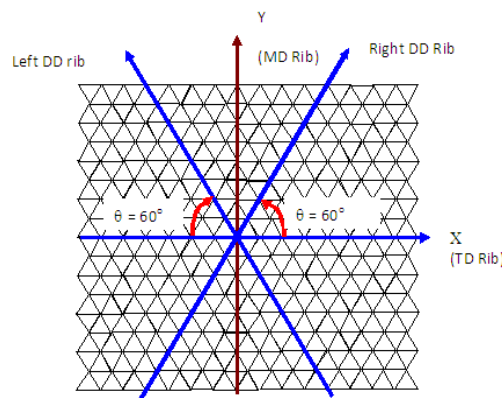

Figure 1. A schematic diagram of a triaxial geogrid where MD is the machine direction, TD is the cross-machine direction, DD is the diagonal direction, and θ is the angle of equilateral triangle.

With the recent introduction of triaxial geogrids, questions have been raised by design professionals and testing agencies as to the proper determination of the appropriate ultimate wide width tensile strength as well as strength versus strain behavior characteristics (tensile modulus) for these products. For definition purposes, a triaxial geogrid is a geogrid consisting of three sets of tensile elements (ribs) to form a grid-like structure with equilateral triangular apertures as schematically shown in Figure 1.

For a given triaxial geogrid consisting of three sets of ribs forming junctions with equilateral triangular apertures, there are a couple basic questions, which need to be addressed before these new types of geogrids can be used in any soil or base reinforcement application. They are: 1) what is the tensile force–strain relationship in the MD, TD and DD directions and 2) what is the tensile strength of the triaxial geogrid in MD, TD, and DD? Naturally one would attempt to answer the above two questions simply by running a wide width (multi-rib) tensile test in accordance with ASTM D 6637 as schematically shown Figure 2. However, due to the unique geometric construction of triaxial geogrids, there exists a boundary effect in testing the triaxial geogrid by the multi-rib method. This boundary effect defined as the effect of those ribs with one end clamped and other end free are herein referred to as exposed ribs. Figure 2, shows these exposed ribs as the “green” DD ribs. These exposed ribs cannot mobilize their full strengths in this type of wide width tensile test; therefore, a multi-rib triaxial geogrid specimen with exposed ribs may significantly underestimate the tensile strength of the triaxial geogrid in the direction it is tested. Therefore, requiring a complex structural analysis to precisely quantify the exposed rib effect on the tensile behavior of the triaxial geogrid.

Swan et al. (2013) developed a theoretical approach to determine the wide width tensile strength of a triaxial geogrid based on the single-rib tensile properties of a triaxial geogrid. This theoretical approach was based on structural mechanics using both force equilibrium and deformation compatibility based on small deformation theory. In this analysis for a triaxial geogrid, the slenderness ratio was defined as the distance between the two adjacent nodes divided by the rib width. For a typical triaxial geogrid, the slenderness ratio is in the range of 35 to 40. Based on structural mechanics, the bending stress in a tensile element (rib) having a slenderness ratio of that magnitude is negligible. Therefore, they made a reasonable assumption that DD and TD ribs were simple tensile elements, which could only carry tensile force. Based on this assumption a classical approach for analyzing a 2-D truss was adopted for the theoretical analysis of the triaxial geogrid using both force equilibrium and deformation compatibility. This paper will detail how the single-rib tension method of ASTM D 6637, can be utilized in conjunction with the theoretical analysis to determine the tensile properties of triaxial geogrids in MD, TD, and DD directions as well as the strength versus strain behavior characteristics of these types of geogrids.

2. DETERMINATION OF ULTIMATE WIDE WIDTH STRENGTH

Based on the work of Swan et al. (2013) the wide width tensile force–strain relationships have been fully defined for: (i) the MD direction by Equations 1 and 2, (ii) the TD by Equations 3 and 4; (iii) the 60-degree direction by Equations 5 and 6; and (iv) the 30-degree direction by Equations 7 and 8. Where T_{WMD} is the wide width tensile force (kN/m) in the MD direction, T_{D-RIB} is the tensile force (kN) in the two DD ribs, h is the rib pitch (m), θ is equal to 60° , ε_{MD} is the wide width tensile strain in the MD direction, ε_{RIB} is the tensile strain in the DD ribs, T_{WTD} is the wide width tensile force (kN/m) in the TD direction, T_{T-RIB} is the tensile force (kN) in the TD rib, ε_{D-RIB} is the tensile strain in the DD rib, ε_{T-RIB} is the tensile strain in the TD rib, T_{W60} is the wide width tensile force (kN/m) in the 60-degree direction, T_{D-60} and T_{D-120} are the tensile forces (kN) in the two DD ribs, ε_{D-60} and ε_{D-120} are the tensile strains in the DD ribs, T_{W30} is the wide width tensile force (kN/m) in the 30-degree direction, $T_{DRIB-60}$ is the tensile force (kN) in the DD rib in the 60-degree direction, and ε_{30} is the wide width tensile strain in the 30-degree direction.

$$T_{WMD} = 2T_{D-RIB} \frac{1}{h} \sin^2 \theta \quad [1]$$

$$\varepsilon_{RIB} = \varepsilon_{MD} \sin^2 \theta \quad [2]$$

$$T_{WTD} = T_{T-RIB} \frac{1}{h} + 2T_{D-RIB} \frac{\cos \theta}{2h} \quad [3]$$

$$\varepsilon_{D-RIB} = \frac{\cos\theta}{2} \varepsilon_{T-RIB} \quad [4]$$

$$T_{W60} = T_{D-60} \frac{1}{h} + (T_{D-120} + T_{T-RIB}) \frac{\cos\theta}{2h} \quad [5]$$

$$\varepsilon_{T-RIB} = \varepsilon_{D-120} = \frac{\cos\theta}{2} \varepsilon_{D-60} \quad [6]$$

$$T_{W30} = (T_{DRib-60} + T_{T-RIB}) \frac{1}{h} \sin^2 \theta \quad [7]$$

$$\varepsilon_{RIB} = \varepsilon_{30} \sin^2 \theta \quad [8]$$

It should be noted that the wide width tensile properties of the triaxial geogrid in the 120-degree direction (i.e., parallel to the left DD rib) are the same as those in the 60-degree direction if the left and right DD ribs have approximately the same tensile properties. Therefore, Equations 5 and 6 can also be used to determine the wide width tensile force-strain relationships in the 120-degree direction. Similarly, the wide width tensile properties of the triaxial geogrid in the 150-degree direction are the same as those in the 30-degree direction if the left and right DD ribs have approximately the same tensile properties. Therefore, the wide width tensile force-strain relationship in the direction of 150 degree can also be determined by Equations 7 and 8. Also for a given direction (MD, TD, or DD, etc), establishing the wide width tensile force-strain curve requires calculating a large number of force-strain data points. However, it becomes a single data point calculation if the focus is to define a characteristic strength, for example, the ultimate tensile strength of a triaxial geogrid in MD.

For this study single-rib tensile tests were conducted in accordance with ASTM D 6637 on two styles of integrally formed (punched and drawn) Polypropylene (PP) triaxial geogrids with equilateral triangular apertures which are referred to as Triaxial A and Triaxial B geogrids. Testing was conducted in both the TD and DD for each geogrid. A total of five (5) single-rib tensile tests were conducted in each direction for each geogrid under a strain rate of 10% per minute using mechanical face grips. A summary of the average tensile strength test results are presented in Table 1. The tensions vs. strain plots for each geogrid are presented in Figures 3 and 4. This data will be used to complete the various calculations throughout the remainder of this paper.

Table 1. Average Single-rib tensile test results for triaxial A and B geogrids in both the TD and DD.

Geogrid Style	Test Direction	Rib Pitch (ft)	Angle of Equilateral Triangle (°)	Tension at 0.5% (lb)	Tension at 2% (lb)	Tension at 5% (lb)	Ultimate Rib Strength (lb)	Strain at Ultimate Strength (%)
Triaxial A	DD	0.1275	60	16.5	50.6	99.0	132.4	8.5
Triaxial A	TD	0.1275	60	9.3	43.4	95.5	137.6	9.9
Triaxial B	DD	0.1283	60	17.5	53.1	102.8	135.8	8.5
Triaxial B	TD	0.1283	60	20.6	60.1	115.0	150.2	8.9

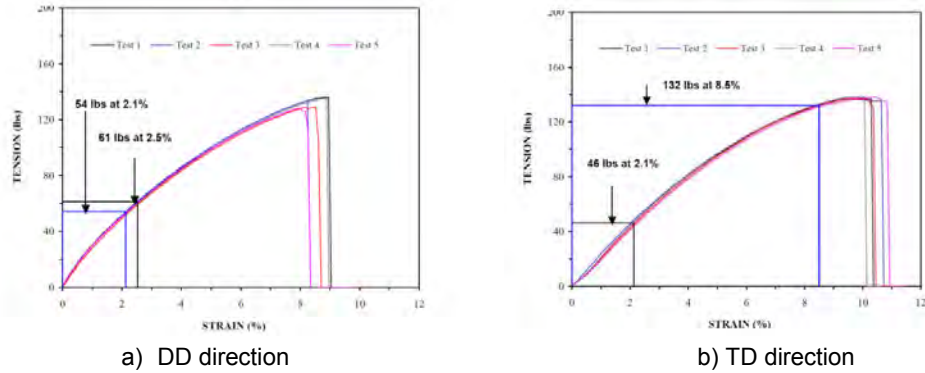

Figure 3. Single-rib tensile test results for Triaxial A geogrid in both the TD and DD directions.

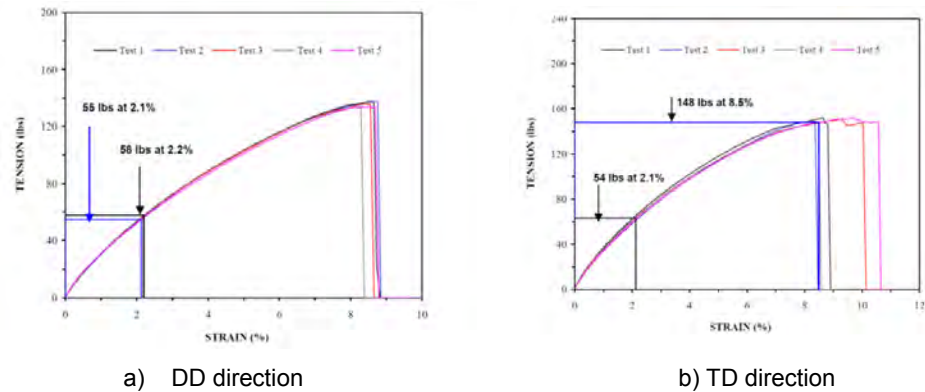

Figure 4. Single-rib tensile test results for Triaxial B geogrid in both the TD and DD directions.

2.1 Tensile Strength In The Machine Direction

The procedures to calculate the ultimate wide width tensile strength of a triaxial geogrid in the machine direction (T_{WMD}) are as follows:

- Conduct single-rib tensile testing on both the left and right DD ribs in accordance with ASTM D 6637 and determine the average ultimate strength of the right and left DD ribs;
- Measure the rib pitch; and
- Calculate the ultimate wide width tensile strength in the MD direction using Equation 1.

Therefore the ultimate wide width tensile strength of the Triaxial A geogrid in the MD direction was calculated to be 1558 lb/ft using the values of $T_{D-RIB} = 132.4$ lb, $h = 0.1275$ ft, and $\theta = 60^\circ$ from the DD single-rib test results presented in Table 1. For the Triaxial B geogrid in the MD direction the ultimate wide width tensile strength was calculated to be 1588 lb/ft using the values of $T_{D-RIB} = 135.8$ lb, $h = 0.1283$ ft, and $\theta = 60^\circ$ from the DD single-rib test results presented in Table 1. The sample calculations are presented in Equations 9 and 10.

$$T_{WMD} \text{ (for Triaxial A geogrid)} = 2(132.4 \text{ lb}) \frac{1}{0.1275 \text{ ft}} \sin^2(60^\circ) = 1558 \text{ lb/ft} \quad [9]$$

$$T_{WMD} \text{ (for Triaxial B geogrid)} = 2(135.8 \text{ lb}) \frac{1}{0.1283 \text{ ft}} \sin^2(60^\circ) = 1588 \text{ lb/ft} \quad [10]$$

2.2 Tensile Strength In The Transverse Direction

The procedures to calculate the ultimate wide width tensile strength of a triaxial geogrid in the transverse direction (T_{WTD}) are as follows:

- Conduct single-rib tensile testing on both the left and right DD ribs in accordance with ASTM D 6637 and determine the average ultimate strength of the right and left DD ribs;
- Conduct single-rib tensile testing on TD ribs in accordance with ASTM D 6637 and determine the average ultimate strength of the TD ribs;
- Measure the rib pitch;
- Determine the rupture (ultimate) strain of TD ribs;
- Calculate the mobilized strain in DD ribs using Equation 4;
- From the measured DD rib force-strain curve, determine the mobilized strength in DD ribs using the mobilized strain; and
- Calculate the ultimate wide width tensile strength in the TD using Equation 3.

Therefore, for the Triaxial A geogrid, when the TD ribs reach their ultimate strain of 9.9% (see Table 1), the mobilized strain in the DD ribs in the TD orientation were calculated to be 2.5%. From the DD rib tensile-strain curves (Figure 3a) the value of T_{D-RIB} was determined to be 61.0 lb at the mobilized strain of 2.5%. The ultimate wide width tensile strength of the Triaxial A geogrid in the TD was then calculated to be 1318 lb/ft using the values of $T_{T-RIB} = 137.6$ lb, $h = 0.1275$ ft, and $\theta = 60^\circ$ from the TD single-rib test results presented in Table 1. The sample calculations are presented in Equations 11 and 12.

$$\varepsilon_{D-RIB} \text{ (for Triaxial A geogrid)} = \frac{\cos 60^\circ}{2} (9.9\%) = 2.5\% \quad [11]$$

$$T_{WTD} \text{ (for Triaxial A geogrid)} = 137.6 \text{ lb} \frac{1}{0.1275 \text{ ft}} + 2(61.0 \text{ lb}) \frac{\cos 60^\circ}{2(0.1275 \text{ ft})} = 1318 \text{ lb/ft} \quad [12]$$

For the Triaxial B geogrid, when the TD ribs reach their ultimate strain of 8.9% (see Table 1), the mobilized strain in the DD ribs in the TD direction were calculated to be 2.2%. From the DD rib tensile-strain curves (Figure 4a) the value of T_{D-RIB} was determined to be 58.0 lb at the mobilized strain of 2.2%. The ultimate wide width tensile strength of the Triaxial B geogrid in the TD direction was then calculated to be 1397 lb/ft using the values of $T_{T-RIB} = 150.2$ lb, $h = 0.1283$ ft, and $\theta = 60^\circ$ from the TD single-rib test results presented in Table 1. The sample calculations are presented in Equations 13 and 14.

$$\varepsilon_{D-RIB} \text{ (for Triaxial B geogrid)} = \frac{\cos 60^\circ}{2} (8.9\%) = 2.2\% \quad [13]$$

$$T_{WTD} \text{ (for Triaxial B geogrid)} = 150.2 \text{ lb} \frac{1}{0.1283 \text{ ft}} + 2(58.0 \text{ kN}) \frac{\cos 60^\circ}{2(0.1283 \text{ ft})} = 1397 \text{ lb/ft} \quad [14]$$

2.3 Tensile Strength At 60-Degree

The procedures to calculate the ultimate wide width tensile strength of a triaxial geogrid in the 60-degree direction (T_{W60}) are as follows:

- Conduct single-rib tensile testing on both the left and right DD ribs in accordance with ASTM D 6637 and determine the average ultimate strength of the right and left DD ribs;
- Conduct single-rib tensile testing on TD ribs in accordance with ASTM D 6637 and determine the average ultimate strength of the TD ribs;
- Measure the rib pitch;
- Determine the rupture (ultimate) strain of the DD ribs;
- Calculate the mobilized strain in the left DD and TD ribs using Equation 6;
- From the measured DD rib force-strain curve, determine the mobilized strength in the left DD ribs using the mobilized strain;
- From the measured TD rib force-strain curve, determine the mobilized strength in TD ribs using the mobilized strain;
- Calculate the ultimate wide-width tensile strength in 60 degree using Equation 5.

Therefore, for the Triaxial A geogrid, when the DD ribs reach their ultimate strain of 8.5% (see Table 1), the mobilized strain in the left DD and TD ribs in the 60-degree direction were calculated to be 2.1%. From the DD and TD rib tensile-strain curves (Figures 3a and 3b) the value of T_{D-120} and T_{T-RIB} were determined to be 54.0 lb and 46.0 lb respectively at the mobilized strain of 2.1%. The ultimate wide width tensile strength of the Triaxial A geogrid in the 60-degree direction was then calculated to be 1235 lb/ft using the values of $T_{D-60} = 132.4$ lb, $h = 0.1275$ ft, and $\theta = 60^\circ$ from the DD and TD single-rib test results presented in Table 1. The sample calculations are presented in Equations 15 and 16.

$$\varepsilon_{T-RIB} \text{ (for Triaxial A geogrid)} = \varepsilon_{D-120} = \frac{\cos 60^\circ}{2} (8.5\%) = 2.1\% \quad [15]$$

$$T_{w60} \text{ (for Triaxial A geogrid)} = 132.4 \text{ lb} \frac{1}{0.1275 \text{ ft}} + (54.0 \text{ lb} + 46.0 \text{ lb}) \frac{\cos 60^\circ}{2(0.1275 \text{ ft})} = 1235 \text{ lb/ft} \quad [16]$$

For the Triaxial B geogrid, when the DD ribs reach their ultimate strain of 8.5% (see Table 1), the mobilized strain in the left DD and TD ribs in the 60-degree direction were calculated to be 2.1%. From the DD and TD rib tensile-strain curves (Figures 4a and 4b) the value of T_{D-120} and T_{T-RIB} were determined to be 55.0 lb and 54.0 lb respectively at the mobilized strain of 2.1%. The ultimate wide width tensile strength of the Triaxial B geogrid in the 60-degree direction was then calculated to be 1271 lb/ft using the values of $T_{D-60} = 135.8$ lb, $h = 0.1283$ ft, and $\theta = 60^\circ$ from the DD and TD single-rib test results presented in Table 1. The sample calculations are presented in Equations 17 and 18.

$$\varepsilon_{T-RIB} \text{ (for Triaxial B geogrid)} = \varepsilon_{D-120} = \frac{\cos 60^\circ}{2} (8.5\%) = 2.1\% \quad [17]$$

$$T_{w60} \text{ (for Triaxial B geogrid)} = 135.8 \text{ lb} \frac{1}{0.1283 \text{ m}} + (55.0 \text{ lb} + 54.0 \text{ lb}) \frac{\cos 60^\circ}{2(0.1283 \text{ ft})} = 1271 \text{ lb/ft} \quad [18]$$

2.4 Tensile Strength At 30-Degree

The procedures to calculate the ultimate wide width tensile strength of a triaxial geogrid in the 30-degree direction (T_{w30}) are as follows:

- Conduct single-rib tensile testing on both the left and right DD ribs in accordance with ASTM D 6637 and determine the average ultimate strength of the right and left DD ribs;
- Conduct single-rib tensile testing on TD ribs in accordance with ASTM D 6637 and determine the average ultimate strength of the TD ribs;
- Measure the rib pitch;
- Determine the rupture (ultimate) strains of the DD and TD ribs from the single-rib test results;
- Determine the mobilized ultimate strain in the right DD and TD ribs based on the fact that the mobilized ultimate strain is equal to the ultimate strain of the DD or TD rib, whichever is smaller;
- From the measured DD and TD rib force-strain curves, determine the mobilized tensile forces in the right DD and TD ribs using the mobilized ultimate strain; and
- Calculate the ultimate wide-width tensile strength in 30 degree using Equation 7.

Therefore, for the Triaxial A geogrid, when the DD and TD ribs mobilize their ultimate strain of 8.5% and 9.9% (see Table 1), the mobilized strain in the left DD and TD ribs in the 30-direction will be limited to 8.5% due to the DD ribs. From the DD and TD rib tensile-strain curves (Figures 3a and 3b) the value of $T_{DRib-60}$ and T_{T-RIB} were determined to be 132.4 lb and 132.0 lb respectively at the mobilized strain of 8.5%. The ultimate wide width tensile strength of the Triaxial A geogrid in the 30-degree direction was then calculated to be 1555 lb/ft using the values of $h = 0.1275$ ft, and $\theta = 60^\circ$ from the DD and TD single-rib test results presented in Table 1. The sample calculations are presented in Equation 19.

$$T_{w30} \text{ (for Triaxial A geogrid)} = (132.4 \text{ lb} + 132.0 \text{ lb}) \frac{1}{0.1275 \text{ m}} \sin^2(60^\circ) = 1555 \text{ lb/ft} \quad [19]$$

For the Triaxial B geogrid, when the DD and TD ribs mobilize their ultimate strain of 8.5% and 8.9% (see Table 1), the mobilized strain in the left DD and TD ribs in the 30-direction will be limited to 8.5% due to the DD ribs. From the DD and TD rib tensile-strain curves (Figures 4a and 4b) the value of $T_{DRib-60}$ and T_{T-RIB} were determined to be 135.8 lb and 148.0 lb respectively at the mobilized strain of 8.5%. The ultimate wide width tensile strength of the Triaxial B geogrid in the 30-

degree direction was then calculated to be 1659 lb/ft using the values of $h = 0.1283$ ft, and $\theta = 60^\circ$ from the DD and TD single-rib test results presented in Table 1. The sample calculations are presented in Equation 20.

$$T_{W30} \text{ (for Triaxial B geogrid)} = (135.8 \text{ lb} + 148.0 \text{ lb}) \frac{1}{0.1283 \text{ ft}} \sin^2(60^\circ) = 1659 \text{ lb/ft} \quad [20]$$

2.5 Development Of A Wide Width Force vs. Strain Curve

The procedures to develop a wide width force vs. strain curve of a triaxial geogrid in the any of the calculated directions (0, 30, 60, 90, 120, 150, 180, 210, 240, 270, 300, 330-degrees) are as follows:

- Conduct single-rib tensile testing on the TD and DD ribs in accordance with ASTM D 6637 and plot force-strain curves for each set of ribs;
- Calculate average rib force and strain data to develop an average force-strain response for each set of ribs. The average curve should contain at least 15 points ranging from 0 strain to the ultimate rib strain in increments of 0.5% strain;
- Calculate the wide width tensile force using the average rib data and the specific equations related to the orientation of interest as discussed in Sections 2.1 through 2.4; and
- Plot the calculated wide width tensile force-strain data to develop the average wide width force vs. strain curve.

For example to develop a wide width force vs. strain curve in the MD orientation for a triaxial geogrid one would need to first run the single-rib tensile tests on both the left and right DD ribs. Then develop the average force-strain response for each set of ribs as shown in Figure 5a. Rearrange Equation 2 to determine the strain in the MD direction (ϵ_{md}) for each of the 0.5% increments of rib strain (ϵ_{rib}). Then use Equation 1 to calculate the wide width strength T_{WMD} for each increment of rib strain (ϵ_{rib}). Finally plot the results of T_{WMD} vs. ϵ_{rib} to develop the average wide width force vs. strain curve as shown in Figure 5b.

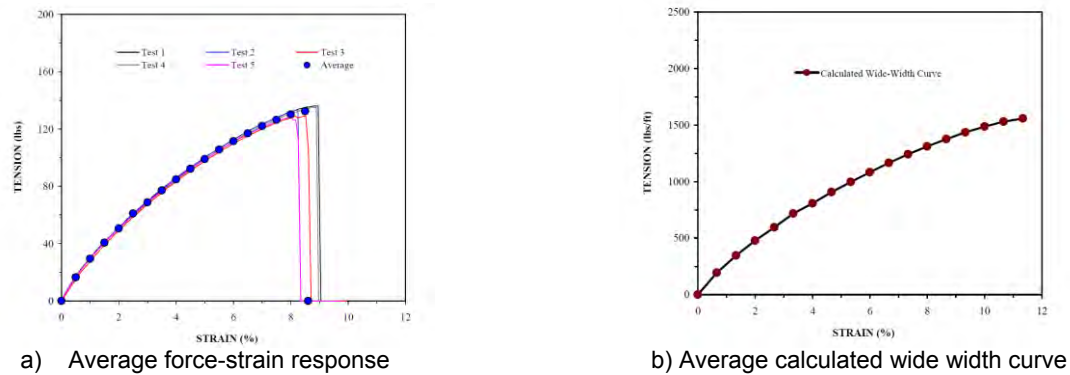

Figure 5. Examples of average single-rib and wide width strength curves in MD direction.

3. DISTRIBUTION OF ULTIMATE WIDE WIDTH TENSILE STRENGTH

The calculated ultimate wide width tensile strengths in directions of 0, 30, 60, 90, 120, 150, 180, 210, 240, 270, 300, 330-degrees are summarized in Table 2 for the Triaxial A geogrid and Table 3 for the Triaxial B geogrid. The distributions of the calculated ultimate wide width strengths along the z-axis with the direction of θ are graphically presented in Figure 6 for the Triaxial A geogrid and Figure 7 for the Triaxial B geogrid.

Table 2. Summary of calculated ultimate width tensile strengths for triaxial A geogrid.

Direction Θ (°)	Ultimate Strength $T_{W\Theta}$ (lb/ft)	X $T_{W\Theta} \cos \Theta$ (lb/ft)	Y $T_{W\Theta} \sin \Theta$ (lb/ft)	R $\text{Sqrt}(x^2 + y^2)$ (lb/ft)

300	1271	636	-1100	1271
330	1659	1437	-829	1659

4. CONCLUSIONS

Based on the application of the theoretical method, developed by Swan et al. (2013), presented in this paper, one can clearly see that the ultimate wide width strength of triaxial geogrids can be established through the use of single-rib tensile testing in accordance with ASTM 6637. From the distribution plots of the calculated ultimate wide width strengths presented in Figures 5 and 6 for each triaxial geogrids, the actual ultimate wide width strength can be established for each geogrid based on the minimum calculated wide width strength measured in the 60, 120, 240, and 300-degree directions. Therefore, the actual ultimate wide width strength for the triaxial A geogrid would be 1235 lb/ft and for the triaxial B geogrid would be 1271 lb/ft. Though higher strengths can be calculated for each geogrid, the geogrid must act as a system of connected ribs and nodes (junctions) whose strength is limited by the weakest rib or junction. Using this analogy, triaxial geogrids can be considered to have homogeneous and isotropic behavior when they are constructed of equilateral triangular apertures. In order to establish the wide width tensile force-strain curves for any given direction (MD, TD, or DD, etc), requires calculating a large number of force-strain data points. However, it becomes a single data point calculation if the focus is to define a characteristic strength for a specific direction.

ABSTRACT

Questions have been raised as to the proper determination of the wide width tensile strength and strength versus strain behavior characteristics for triaxial geogrids. For traditional type (uniaxial and biaxial) geogrids, this can be determined using ASTM International (ASTM) D 6637. The single-rib method within ASTM D 6637 is applicable to triaxial geogrids; however there is a boundary effect that occurs due to the unique geometric construction of the triaxial geogrid when the multi-rib method is performed. Therefore, the multi-rib method may significantly underestimate the tensile stiffness and strength of the triaxial geogrid. Using a technical approach based in structural mechanics for a two-dimensional truss, the wide width tensile response of triaxial geogrids in varying orientations is analyzed. The results of the analysis show that the wide width tensile strength of the triaxial geogrid in a specific orientation can be determined based on single-rib tensile properties of the triaxial geogrid.

1. INTRODUCTION

Over the past thirty plus years, geosynthetic materials have been used in both bound and unbound layers of pavement structures for a wide range of applications. In unbound layers, geosynthetics have been used within the subbase and/or base material or at the interface between the unbound base or subbase layer and subgrade for separation, stabilization, drainage, reinforcement and as moisture barrier, as discussed by Koerner (1984) and Holtz et al. (1998). In bound wearing courses such as hot-mix asphalt (HMA), geosynthetics have been utilized for tensile reinforcement and as stress absorption membrane interlayers to reduce the potential of reflective cracking (Koerner, 1984). When designing and specifying pavement structures incorporating geosynthetics an understanding of the geosynthetic products' wide width tensile behavior in particular the tensile modulus is useful. Traditionally these applications have used geogrids, which have had orthogonal tensile elements in the machine and transverse orientations (i.e., geogrids with square or rectangular apertures). Therefore, the wide width tensile strength and strength vs. strain behavior have been determined using either ISO 10319 or ASTM D 6637 standard test methods. Both of these test methods are conventional uni-directional tensile tests. ISO 10319 is solely a wide width test having a test specimen with a minimum width of 200 mm and a width to length ratio 2:1. ASTM D 6637 allows for three types of test specimens, which include: a) minimum 200 mm wide width multi-rib specimen b) single-rib specimens or c) multi-layer specimens. As written, both of these test methods only use test specimens, which are orthogonal in the machine and transverse directions of a geogrid.

Figure 1. A schematic diagram of a triaxial geogrid where MD is the machine orientation, TD is the cross-machine orientation, DD is the diagonal orientation, and θ is the angle of equilateral triangle.

With the recent introduction of triaxial geogrids, questions have been raised by design professionals and testing agencies as to the proper determination of an appropriate ultimate wide width tensile strength as well as strength versus strain (tensile modulus) behavior characteristics for these products for acceptance and design purposes. For definition purposes, a

triaxial geogrid is a geogrid consisting of three sets of tensile elements (ribs) to form a grid-like structure with equilateral triangular apertures as schematically shown in Figure 1. In the following analysis, the triaxial geogrid is considered structurally symmetric in three principal orientations (0, 60, and 120 degree) in the coordinate system as shown in Figure 1.

For a given triaxial geogrid consisting of three sets of ribs forming junctions with equilateral triangular apertures, there are a couple basic questions, which need to be addressed before these new types of geogrids can be used in any soil or base reinforcement application. They are: 1) what is the tensile force–strain relationship in the MD, TD and DD orientations and 2) what is the tensile strength of the triaxial geogrid in MD, TD, and DD? Naturally one would attempt to answer the above two questions simply by running a wide width (multi-rib) tensile test in accordance with ASTM D 6637 as schematically shown Figure 2. However, due to the unique geometric construction of triaxial geogrids, there exists a boundary effect in testing the triaxial geogrid by the multi-rib method. This boundary effect defined as the effect of those ribs with one end clamped and other end free are herein referred to as exposed ribs. Figure 2, shows these exposed ribs as the “green” DD ribs. These exposed ribs cannot mobilize their full strengths in this type of wide width tensile test; therefore, a multi-rib triaxial geogrid specimen with exposed ribs may significantly underestimate the tensile strength of the triaxial geogrid in the orientation it is tested. It is difficult, if not impossible, to precisely quantify the exposed rib effect on the tensile behavior of the triaxial geogrid, and correct the directly measured test data in the test (Figure 2) to define the true tensile response of the triaxial geogrid.

Figure 2. A uniform tensile load applied to a wide specimen in MD.

It should be obvious to those familiar with testing uniaxial and biaxial geogrids that if any active tensile element (rib) parallel to the orientation of the applied tensile force is precut prior to testing then the tensile properties obtained from the test will not characterize the actual tensile behavior of the geogrid. Figure 3 describes such a condition.

Figure 3. An orthogonal (biaxial) geogrid tensile test with an active rib precut.

Similarly when testing a triaxial geogrid, the same principle of “no active tensile element should be precut” should be applied to the testing procedures. Practically speaking, can one maintain that all the active tensile elements are intact in the wide width tensile test on the triaxial geogrid? In order to answer this question, consider a wide width test on a triaxial geogrid similar to that shown in Figure 2. For a given test specimen length, the number of exposed ribs is fixed. In Figure 2, the test specimen length is $8h$ (with h being the height of an equilateral triangle), therefore there are six (6) exposed “green” DD ribs on each side of the test specimen. One would expect that the impact of these six exposed DD ribs on the measured tensile strength will decrease as the specimen width increases, and will increase as the specimen width decreases. Theoretically, one would need to test a specimen with an infinite width in order not to have the exposed rib effect. In practice, we can only test a specimen with a limited width. It would be difficult and probably cost prohibitive to

conduct tensile testing on a very wide triaxial geogrid specimen. Therefore, there is a need to develop a theoretical approach to determine the wide width tensile strength of a triaxial geogrid based on the single-rib tensile properties of the triaxial geogrid. This paper will present such an analysis based in structural mechanics using both force equilibrium and deformation compatibility.

2. TECHNICAL APPROACH

2.1 Basis of Theory

In structural mechanics, there are two major types of structural components (members) within a structure. These members are classified as beams and trusses based on their slenderness ratios. The slenderness ratio is defined as the length of a structural member divided by the dimension of its cross-section (width or diameter). When this ratio is sufficiently large, the structural member is considered as a truss member. By definition, a truss member can only carry axial force (tension or compression). When the ratio is sufficient small, the structural member is considered as a beam. By definition, a beam can carry axial forces and moments. Further, a truss is simply a very long beam, which carries little or no moment. (Laursen (1978) and Timoshenko and Gere (1972)). In this analysis for a triaxial geogrid, the slenderness ratio is defined as the distance between the two adjacent nodes divided by the rib width. For a typical triaxial geogrid, the slenderness ratio is approximately in the range of 35 to 40. Based on structural mechanics, the bending stress in a tensile element (rib) having a slenderness ratio of that magnitude is negligible. Therefore, it is reasonable to assume that DD and TD ribs are simple tensile elements that can only carry tensile force. Based on the above assumption a classical approach for analyzing a 2-D truss has been adopted for the theoretical analysis of the triaxial geogrid using both force equilibrium and deformation compatibility.

2.2 Relationship of Axial And System Deformation

In order to define the deformation compatibility for this analysis, small strain theory was used in order to develop a relationship between the axial strain and system deformation, as is discussed in this section. Let us assume a 2-rib system is subjected to a vertical load at node C as shown in Figure 4 and the two ribs (i.e., AC and BC) have the same tensile properties and the same length (i.e., structurally symmetric in the orientation of applied tensile force).

Figure 4. Deformation in a 2-rib system.

Under the action of the vertical load, node C displaces vertically to point D. From the Pythagorean Theorem, the axial deformation (i.e., change in the length) in the two ribs is presented in Equation 1. In Equation 1, δ_{RIB} is the axial deformation (i.e., net stretch) of the rib AB or rib AC, a is the initial distance between nodes A and B, h is the height of equilateral triangle, and L is the initial length of the rib AB or rib AC. Further L can be expressed in terms of “ a ” and “ h ” as shown in Equation 2.

$$\delta_{RIB} = \sqrt{0.25a^2 + (h + \delta)^2} - L \quad [1]$$

$$L = \sqrt{0.25a^2 + h^2} \quad [2]$$

Equation 1 can then be rewritten as Equation 3.

$$\delta_{RIB} = \frac{2h\delta + \delta^2 - \delta_{RIB}^2}{2L} \quad [3]$$

If the displacements of δ and δ_{RIB} are small in magnitude then they can be defined as small deformations, and terms involving the square of the displacements can be neglected. Equation 3 can then be reduced to Equation 4 and by further substituting $\sin \theta$ for h/L yields the final relationship between axial strain and system deformation as shown in Equation 5.

$$\delta_{RIB} = \frac{h}{L} \delta \quad [4]$$

$$\delta_{RIB} = \delta \sin \theta \quad [5]$$

The general conclusion from the above analysis is that, for small displacements, each deformed rib can be considered parallel to its original position, and the axial displacement of the deformed rib can be calculated using Equation 5.

3. TENSILE BEHAVIOR

The tensile behavior of a triaxial geogrid will be theoretically analyzed using both force equilibrium and deformation compatibility based on the technical approach discussed previously. Analyses will be discussed with respect to the MD and TD orientation as well as 60° and 30° parallel to the orientation of loading of the diagonal orientation (DD) ribs.

3.1 With Respect to the Machine Direction

3.1.1 Force Equilibrium

Assume a representative area from a triaxial geogrid is subjected to a uniform tensile load in the MD orientation as shown in Figure 5. For the analysis, the uniform load, is applied along the top and bottom rows of nodes and is distributed to each of the nodes evenly.

Figure 5. A uniform tensile load applied in MD orientation.

Further, assume the tensile properties of the left and right DD ribs are the same. Therefore, at an arbitrary node i , the force equilibrium in the MD orientation can be expressed in Equation 6. Where N_{MD} is the tensile force (kN) in the MD orientation at the arbitrary node i , T_{D-RIB} is the tensile force (kN) in the two DD ribs, and θ is equal to 60°.

$$N_{MD} = 2T_{D-RIB} \sin \theta \quad [6]$$

The corresponding wide width tensile force in the MD orientation is expressed in Equation 7. Where T_{WMD} is the wide width tensile force (kN/m) in the MD orientation and a is the center to center distance (m) between two adjacent nodes. Furthermore, a is the related the distance between two adjacent ribs (i.e., rib pitch) where h equals $a \sin \theta$. Therefore, Equation 7 can be further reduced to Equation 8.

$$T_{WMD} = 2T_{D-RIB} \frac{1}{a} \sin \theta \quad [7]$$

$$T_{WMD} = 2T_{D-RIB} \frac{1}{h} \sin^2 \theta \quad [8]$$

Equation 8 is strictly derived from the force equilibrium in the MD orientation at an arbitrary node i . Whether or not the DD rib has a linear or nonlinear force-strain relationship, Equation 8 is valid for determining the wide width tensile force in the MD orientation from a given DD rib force. Since the triaxial geogrid described in this analysis is symmetric along the y -axis (MD), it is expected that the triaxial geogrid will reach its ultimate wide width strength in the MD when both the right and left DD ribs reach their ultimate single-rib strengths simultaneously.

3.1.2 Deformation Compatibility

Assuming uniform tensile load acting on the upper and lower boundary, a $2h$ long triaxial geogrid deforms to a final length of $2h + 2\delta_{MD}$ as shown in Figure 5. If δ_{MD} is $\ll h$, then the above geogrid structure can be analyzed in the frame of small deformation theory, as discussed previously. Following the principle of small deformation analysis, a deformed rib can be considered parallel to its original position for determining the relationship between the nodal and axial displacement. At node i , the MD displacement is related to the DD displacement as shown in Equation 9.

$$\delta_{DD} = \delta_{MD} \sin(\theta) \quad [9]$$

The wide width tensile strain (ϵ_{MD}) of the triaxial geogrid in the MD orientation can then defined in Equation 10.

$$\epsilon_{MD} = \frac{\delta_{MD}}{h} \quad [10]$$

The tensile strain in the DD ribs (ϵ_{RIB}) can then be defined in Equation 11.

$$\epsilon_{RIB} = \frac{\delta_{RIB}}{a} \quad [11]$$

Further substituting Equation 9 into Equation 11 results Equation 12:

$$\epsilon_{RIB} = \frac{\delta_{MD} \sin \theta}{a} \quad [12]$$

Substituting Equation 10 and $h = a \sin \theta$ into Equation 12 results in Equation 13 that relates the tensile strain in DD ribs to the wide-width tensile strain in the MD:

$$\epsilon_{RIB} = \epsilon_{MD} \sin^2 \theta \quad [13]$$

Equation 13 shows that the mobilized tensile strain in the DD ribs is 75% of the wide width tensile strain in the machine direction. For the analysis, the two sets of DD ribs (i.e., left and right DD ribs) of the triaxial geogrid were considered to be the same strength and symmetrical along machine direction. Further, it was assumed that the left and right DD ribs would

reach their ultimate strain and/or strength simultaneously. Therefore, the triaxial geogrid would reach its ultimate wide width strength in MD when both DD ribs reach their ultimate strengths simultaneously.

3.2 With Respect to the Transverse Orientation

3.2.1 Force Equilibrium

Assume a representative area from a triaxial geogrid is subjected to a uniform tensile load in the traverse (TD) orientation as shown in Figure 6. For the analysis, the uniform load, is applied along left and right rows of nodes and is distributed to each of the nodes evenly. Therefore, at an arbitrary node j , the force equilibrium in the TD can be expressed in Equation 14. Where N_{TD} is the tensile force (kN) in the TD at the arbitrary node j , T_{D-RIB} is the tensile force (kN) in the two DD ribs, T_{T-RIB} is the tensile force (kN) in the TD rib, and θ is the equal to 60° .

$$N_{TD} = T_{T-RIB} + 2T_{D-RIB} \cos\theta \quad [14]$$

The corresponding wide width tensile force in the TD is expressed in Equation 15. Where T_{WTD} is the wide width tensile force (kN/m) in the traverse orientation and h is the rib pitch (m).

$$T_{WTD} = T_{T-RIB} \frac{1}{h} + 2T_{D-RIB} \frac{\cos\theta}{2h} \quad [15]$$

Figure 6. A uniform tensile load applied in TD.

Equation 15 is strictly derived from the force equilibrium in the TD at an arbitrary node j . Whether or not the TD and DD ribs have the linear or nonlinear force-strain relationships, Equation 15 is valid for determining the wide width tensile force in the traverse direction from given single-rib forces in the DD and TD ribs.

3.2.2 Deformation Compatibility

Using Figure 6, at node j , and assuming small deformation conditions, the displacement compatibility of the triangle AjB is shown in Equation 16. Where δ_{T-RIB} is the displacement of node θ in the TD orientation and δ_{D-RIB} is the change in the length of the DD rib over an initial length $2a$. It should be noted that δ_{T-RIB} is the same as the TD rib length increase over the initial length a . Therefore, Equation 17 defines the strain in the TD orientation, Equation 18 defines the strain in the diagonal direction, and Equation 19 relates the strain in the DD rib to the strain in the TD rib.

$$\delta_{D-RIB} = \delta_{T-RIB} \cos\theta \quad [16]$$

$$\varepsilon_{T-RIB} = \frac{\delta_{T-RIB}}{a} \quad [17]$$

$$\varepsilon_{D-RIB} = \frac{\delta_{D-RIB}}{2a} \quad [18]$$

$$\varepsilon_{D-RIB} = \frac{\cos\theta}{2} \varepsilon_{T-RIB} \quad [19]$$

Equation 19 shows that the mobilized strain in DD ribs is 25% of that in TD ribs when the triaxial geogrid is subjected to a uniform tensile load in the TD orientation. It should be noted that the mobilized strains in the TD orientation and DD ribs are not the same when the triaxial geogrid is subjected a uniform tensile load in the TD orientation. Under the loading conditions as shown in Figure 6, the tensile strain in TD rib will always be 4 times the strain in DD ribs. Therefore, when the TD rib reaches its ultimate strain and/or strength, the mobilized tensile strain in the DD ribs will only be 25% of that in the TD rib and the mobilized strength in DD ribs will be significantly less than its ultimate rib strength. Therefore, it is expected that the triaxial geogrid reaches its ultimate wide width strength in TD when the TD ribs reach their ultimate strengths. The contribution of the DD ribs to the wide width tensile strength in TD orientation is the mobilized tensile force in DD ribs at a strain level equal to 25% of the wide width rupture strain (i.e., rupture tensile strain in TD ribs).

3.3 With Respect to 60 Degree Orientation

3.3.1 Force Equilibrium

Knowing that the triaxial geogrid is geometrically symmetric along three principal orientations, we can use the coordinate system shown in Figure 7, to define these three principal orientations as: (i) TD (0 -180 degree); (ii) right DD (60-240 degree); and (iii) left DD (120-300 degree).

Figure 7. A uniform load applied in 60 degree.

When a uniform load is applied in the orientation parallel to the right DD rib, at an arbitrary node k , Equation 20 can be used to define the force equilibrium in the 60-degree orientation (right DD rib). Therefore, the corresponding wide width tensile force in the TD orientation is shown in Equation 21. Where T_{W60} is the wide width tensile force (kN/m) in the 60-degree orientation and h is the rib pitch (m).

$$N_{D-60} = T_{D-60} + (T_{D-120} + T_{T-RIB}) \cos\theta \quad [20]$$

$$T_{W60} = T_{D-60} \frac{1}{h} + (T_{D-120} + T_{T-RIB}) \frac{\cos\theta}{2h} \quad [21]$$

3.3.2 Deformation Compatibility

Using Figure 7, at node k , and assuming small deformation conditions, the displacement compatibility can be expressed in Equations 22 and 23. Where δ_{D-60} is the displacement of node k in the orientation of 60-degree orientation (right DD rib), δ_{D-120} is the change in the length of the left DD rib over an initial length $2a$, and δ_{T-RIB} is the change length of the TD rib over an initial length $2a$. Therefore, Equation 24 relates the strain in the left DD rib to the strain in the right DD rib and Equation 25 relates the strain in the TD rib to the strain in the right DD rib.

$$\delta_{D-120} = \delta_{D-60} \cos\theta \quad [22]$$

$$\delta_{T-RIB} = \delta_{D-60} \cos\theta \quad [23]$$

$$\varepsilon_{D-120} = \frac{\cos\theta}{2} \varepsilon_{D-60} \quad [24]$$

$$\varepsilon_{T-RIB} = \varepsilon_{D-120} = \frac{\cos\theta}{2} \varepsilon_{D-60} \quad [25]$$

Equation 25 shows that the mobilized strain in either the TD or left DD rib is 25% of that in the right DD rib. It should be noted that the mobilized strains in the TD (0 degree) and left DD (120 degree) ribs are different from that in the right (60 degree) rib when the triaxial geogrid is subjected to a uniform tensile load in the 60-degree orientation. Under the loading conditions as shown in Figure 7, the tensile strains in the TD and left DD ribs are the same. When the right DD rib reaches its ultimate strain and/or strength, the mobilized tensile strain in the TD and left DD ribs are only 25% of that in the right DD rib, and the mobilized strength in the TD and left DD ribs are significantly less than the ultimate single rib strength. Therefore, it is expected that the triaxial geogrid reaches its ultimate wide width strength in the right DD when the right DD ribs reach their ultimate strengths. The contribution of the TD and left DD ribs to the wide width tensile strength in the 60-degree orientation is the combined mobilized tensile force in the TD and left DD ribs at the strain equal to 25% of the wide width rupture strain (i.e., rupture tensile strain in the right DD ribs).

3.4 With Respect to 30 Degree Orientation

3.4.1 Force Equilibrium

In the coordinate system as shown in Figure 8, when a uniform load is applied in the 30-degree orientation and is distributed to each of the nodes evenly, at an arbitrary node m , Equation 26 defines the force equilibrium in the 30-degree orientation of a triaxial geogrid. Therefore, the corresponding wide width tensile force in the 30-degree orientation is shown in Equation 27. Where T_{W30} is the wide width tensile force (kN/m) in the 30-degree orientation and h is the rib pitch (m).

$$N_{30} = (T_{DRib-60} + T_{T-RIB}) \sin\theta \quad [26]$$

$$T_{W30} = (T_{DRib-60} + T_{T-RIB}) \frac{1}{h} \sin^2\theta \quad [27]$$

Figure 8. A uniform load applied in 30 degree.

3.4.2 Deformation Compatibility

Under a uniform tensile load acting in the 30-degree orientation, a $2h$ long triaxial geogrid deforms to a final length of $2h + 2\delta_{30}$ as shown in Figure 8. If δ_{30} is $\ll h$, then the geogrid structure can be analyzed in the frame of small deformation theory. Following the principle of small deformation analysis, a deformed rib can be considered parallel to its original position for determining the relationship between the nodal and axial displacement. At node m , the displacement in the 30-degree orientation is related to the displacement in the right DD and TD ribs as shown in Equation 28.

$$\delta_{DRib-60} = \delta_{T-Rib} = \delta_{30} \sin \theta \quad [28]$$

Equation 29 defines the wide width tensile strain (ϵ_{30}) of the triaxial geogrid in the 30-degree orientation.

$$\epsilon_{30} = \frac{\delta_{30}}{h} \quad [29]$$

The tensile strain in the right DD and TD ribs (ϵ_{RIB}) is defined in Equation 30, where δ_{RIB} is the strain in the right DD and TD ribs.

$$\epsilon_{RIB} = \frac{\delta_{RIB}}{a} \quad [30]$$

Substituting Equation 28 into 30 results in Equation 31:

$$\epsilon_{RIB} = \frac{\delta_{30} \sin \theta}{a} \quad [31]$$

Further substituting $h = a \sin \theta$ into Equation 31, The relationship between the tensile strain in the right DD or TD rib and wide width tensile strain in the 30-degree orientation is presented in Equation 32.

$$\epsilon_{RIB} = \epsilon_{30} \sin^2 \theta \quad [32]$$

Equation 32 shows that the mobilized tensile strain in the right DD or TD ribs is 75% of the wide width tensile strain in the 30-degree orientation. Theoretically, the tensile behavior of the triaxial geogrid in the 30-degree orientation should be identical to that in the MD orientation if the TD and DD ribs have the same tensile properties and $\theta = 60^\circ$.

4. CALCULATION OF ULTIMATE WIDE WIDTH STRENGTH

Based on this theoretical analysis on the triaxial geogrid, the wide width tensile force-strain relationships have been fully defined for: (i) the MD by Equations 8 and 13, (ii) the TD by Equations 15 and 19; (iii) the 60° orientation by Equations 21 and 25; and (iv) the 30° orientation by Equations 27 and 32. It should be noted that the wide width tensile properties of the triaxial geogrid in the 120-degree orientation (i.e., parallel to the left DD rib) are the same as those in the 60-degree orientation if the three sets of ribs have approximately the same tensile properties. Therefore, Equations 21 and 25 can also be used to determine the wide width tensile force-strain relationships in the 120-degree orientation. Similarly, the wide width tensile properties of the triaxial geogrid in the 150-degree orientation are the same as those in the 30-degree orientation if the three sets of ribs have approximately the same tensile properties. Therefore, the wide width tensile force-strain relationship in the orientation of 150 degree can also be determined by Equations 27 and 32.

In summary, when the tensile properties of DD and TD ribs are known, the wide width tensile force-strain relationships can be determined in 0, 30, 60, 90, 120, 150, 180, 210, 240, 270, 300, 330-degree orientations.

5. CONCLUSIONS

Based on the theoretical analysis presented in this paper, the following conclusions can be drawn:

- Due to the unique geometric construction, there exists an “exposed-rib” effect in testing a triaxial geogrid by the multi-rib method (ASTM D 6637).
- The wide width tensile test on a triaxial geogrid specimen with a limited specimen width will underestimate the ultimate tensile strength of the triaxial geogrid due to the effect of the exposed ribs.
- In traverse direction, analysis shows that the DD ribs carry a portion of applied tensile load in TD and contribute to the ultimate strength of the triaxial geogrid in traverse direction. However, in the typical wide width test in TD (ASTM D 6637), almost all of the DD ribs are exposed. Therefore, the wide width test as it exists today cannot properly measure the contribution of DD ribs to the ultimate wide width strength in the traverse direction.
- The typical triaxial geogrid as manufactured have slenderness ratios in the range of 30 to 50. The DD and TD ribs can be defined as simple tensile elements which carry tensile forces only (no moments).
- Under the small deformation conditions, the wide width tensile properties of a triaxial geogrid in 0, 30, 60, 90, 120, 150, 180, 210, 240, 270, 300, 330-degree orientations can be determined based on the tensile properties of DD and TD ribs by using this proposed theoretical method.

ABSTRACT

The development of wind farms requires heavy cranes to erect the wind turbines under very severe safety working conditions. Often the ground conditions are not meeting the safety conditions in terms of settlement, bearing capacity etc., which requires the necessity to reinforce the crane working platform with geosynthetics. The design of such working platforms is often based on practice and empirical methods; one of these methods is described in BR470. In order to be able to verify and improve the design methodology a good knowledge of the real behavior of the reinforcement geosynthetic is required. The paper presents some aspects about the platform design and the first results of a test field carried out for a geocomposite reinforced crane working platform at a wind farm project in the Dobrogea area, which is located in the South-Eastern part of Romania.

1. INTRODUCTION

1.1 Reinforced Working Platforms

The foundation ground with weak soil layers can cause severe damages upon the structures that are built on it. Working platforms are geotechnical structures that provide a stable working surface for mobile cranes and other heavy construction equipment, these structures are critical for plant stability. Many of these are built on soft, compressible subgrades with low shear strength, providing weak support for the expected loads. The incidents involving overturning of piling rigs and cranes have led to an increased awareness of the importance of providing a stable working platform and to achieve an acceptable level of safety. Conventional improving methods involve replacing part of the weak soil with a layer of granular fill. An alternative is the use of geosynthetic materials for improving the soft soils (Figure 1). The resulting reinforced soil mass provides better stress distribution on top of the underlying weak soil and reduces the settlements.

The benefits that can be realized are as follows:

- reduction of the quantity of granular material required for working platforms through the incorporation of suitable geosynthetic reinforcement;
- bearing capacity increasing, particularly important if heavy plants are used;
- smaller quantity of higher quality material resulting in cost savings both in procurement and avoidance of transport costs;
- reduced maintenance, better response of the working platform under heavy loads and improved working conditions for heavy plant;
- as the principle of sustainable construction is requiring, the excavation should be minimised and the use of waste by-product materials should be maximized; also, a considerable reduction in transport requirements can be obtained, resulting in significant avoidance of greenhouse gas emissions.

The geotechnical properties of the subgrade have a substantial effect on the design of the working platform.

For construction of a working platform the granular materials such as gravel or crushed rock are generally used. The reinforcement can be a nonwoven or woven geotextile, geogrids or geocomposites. Geofabrics are used to separate a granular platform from a cohesive subgrade, these acting as a filter. Geogrids has the function of strengthening the platform. Geosynthetics are generally placed between the subgrade and the working platform.

Figure 1 – Reinforced working platform scheme

1.2 Design Calculation Guidance

Recommendation for the design of working platforms given in BR470 “Working platforms for tracked plant” (2004) was prepared by the British Research Establishment (BRE) and provides a good practice guidance on the design, installation, maintenance and repair of ground supported working platforms. In case of cohesive subgrades BR470 is applicable only for soils with an undrained shear strength $20\text{kPa} < c_u < 80\text{kPa}$.

The design calculation given in BR470 is based on an analysis by Meyerhof (1953), Valsangkar and Meyerhof (1979), Hanna and Meyerhoff (1980) and Hanna (1981) for a footing punching through a strong platform material overlying a weak subgrade

The bearing resistance of a platform on soft soil is considered to be the sum of the shear required to punch through a vertical plane in the granular platform material and the bearing capacity of the subgrade (see Figure 2).

Figure 2 – Punching failure mechanism.

The geotechnical parameters that are used in design calculations are:

- density, γ of the natural soil and of the granular material [kN/m^3];
- angle of friction, ϕ' [$^\circ$] of the platform fill material;
- undrained shear strength, c_u [kPa];
- angle of shear resistance, ϕ' [$^\circ$].

According to BR470, the loading operations can be divided into two loading cases:

Case 1 Loading - Standing, Traveling, Handling;

Case 2 Loading - Installing casing, Drilling, Extracting an auger, bucket or casing, Traveling.

The first one may be applied when the crane operator is unable to avoid an imminent platform failure. The second one is applicable when the crane operator can control the load safely.

The first step is to determine the bearing resistance of the subgrade, if this is large enough, only a running surface would be required. If the bearing resistance is too low, a working platform is required and the bearing capacity is calculated taking into account both subgrade and working platform. If the bearing capacity is still too low, a platform material with higher shear strength (higher ϕ') needs to be used. Then the platform thickness (unreinforced) is calculated.

In order to decrease the thickness of the granular working platform and/or for a more uniform repartition of the loads, a geosynthetic reinforcement can be used. When a load is applied on the geosynthetic reinforced granular layer, the horizontal tensile stresses developed in the geogrid are transferred to the base. As stresses at the base increase, aggregate interlock becomes stronger and the base becomes more rigid. Consequently, the base spreads the loads over a larger area of the subgrade. This allows building a thinner, but stronger geogrid-reinforced granular base. The stress

on the subgrade is held constant while the base is thinned, due to the increased strength of the reinforced granular base (Figure 3).

Figure 3 - Reinforced soil foundation, stress distribution (Binquet, Lee 1975)

The aggregate is inter-locking with the geogrid and thus the tensile forces are transferred to the geosynthetic (Figure 4).

Figure 4 – Interlocking mechanism between aggregate and geogrid

When a load is applied to the subgrade, the bearing resistance can be calculated using known bearing capacity factors (N_q , N_v , N_c), while for calculation of the bearing resistance of a two-soil system (the case of the working platform which is placed on the natural soil) demands deep analysis.

The distribution of pressure under machine tracks should be calculated and the maximum track pressures can be estimated by static calculation for critical jib positions, according to Annex B of SR EN 996+A3:2009 - "Calculation of piling equipment stability and ground pressure". In order to calculate equipment stability, the following characteristics have to be estimated: angle of stability, dumping lines, barycenter, partial security factors, working load, static moment, centrifugal moment (if is applicable) etc. For the worst combinations of the operating conditions, the maximum ground pressure should be established. This pressure can be introduced in the design of the working platform.

2. TESTING PROGRAM

2.1 The Sălbatica Wind Farm, Romania

The main objective of this experimental test is to determine the real behavior of the reinforcement geocomposite within the working platform during the loading. The further objective is to determine what the benefits are of using reinforced soil foundations to improve the bearing capacity and reduce settlements of working platforms and also to improve the design methods.

The Sălbatica Wind Farm is located in Romania's Dobrogea region, near Tulcea city. From an energy generation perspective, Dobrogea is one of the best places in Europe for the construction and operation of a wind farm. Its open lands are characterized by some of the continent's most dependable, strong winds. The Sălbatica Wind Farm involved the construction of 35 turbines in the first stage, followed by another 35 in the second stage, each producing 2 MW of power. The annual production of the site is 85.5 million kWh/year. This is enough to power 29,000 households. Equally important, from an environmental standpoint, is the reduced carbon footprint. Sălbatica's turbines produce power that if

produced by traditional means would have released 48,000 metric tons of CO₂ per year. That pollution is prevented through Sălbatica's renewable energy approach.

The cranes used for lifting the wind turbines are of 750 tones and require special measures of working safety. As the natural ground on site was not meeting the geotechnical requirements, a working platform of crushed stone was provided and reinforced by one layer of laid-and-welded geocomposite (Figure 5), whose material properties are described below. With regard to the project specific requirements a working platform thickness of 60 cm would have required to distribute the crane loadings to acceptable rates for the available strength of the in-situ subgrade. An alternative design using a biaxial laid-and-welded geogrid allowed the reduction of the working platform thickness to 40cm.

2.2 Natural Soil and Platform Characteristics

The subgrade on site is mainly composed of loess – yellow silty clays and clayey silts, stiff – solid, sensitive to wetting. The soil in its natural state has an oedometric modulus of approx. 9000kPa, an undrained cohesion (c_u) of about 25kPa, an additional settlement to wetting, $i_{m3} = 1.1 - 9.74 \%$ (according to Romanian regulations, for more than 2% the soil is considered sensitive to wetting).

A working platform has been built using 40 cm of compacted crushed stone (0/63 mm) for each of the 4 pads of the crane. One of these 4 working platforms was instrumented with strain gauges and pressure cells attached to the geocomposite. All 4 pads were treated identically.

In order to determine the strength of the in-situ soil, a plate loading test according to DIN 18134 was carried out using a loading plate with 300 mm diameter. The plate tests performed on natural soil after compaction showed values of $E_{V1} = 19 - 34 \text{ MPa}$ and $E_{V2} = 35 - 62 \text{ MPa}$.

Figure 5. Cross – section through the working platform

2.3 Reinforcement Geocomposite

The reinforcement geocomposite is a laid-and-welded geocomposite made of a welded biaxial geogrid (PP) with mass of 240 g/m² and a nonwoven needle punched geotextile (PP) with mass of 150 g/m², firmly bonded between the longitudinal and transversal ribs. This material is used for stabilization, separation and filtration applications in various civil engineering fields. The tensile strength of the reinforcement in longitudinal and transverse direction is 30 kN/m; the strain level at failure is $\leq 8\%$.

Strains taken by the geocomposite reinforcement are measured by linear strain gauges (max. elongation 100,000 $\mu\text{m/m}$ ($\pm 10 \%$) and max. allowable bridge supply voltage of 8V, nominal resistance of 120 Ω) which were glued onto the geogrid reinforcement bar (Figure 6.a).

Figure 6 - Application of strain gauges (a) and pressure cells (b) on geocomposite

2.4 Field Test

The geocomposite was instrumented with 8 strain gauges attached to the geogrid and 3 pressure cells placed between the geocomposite and the granular layer to measure the applied load (Figure 6.b). The scheme of the installation is presented in Figure 8. The load is applied in the center of the platform of the crane. Only one of the 4 crane pads were instrumented.

Once the Lucas plate test was completed, the instrumented 4,75m x 10m geocomposite was installed over the test platform. The strain gauges, pressure cells and all the cables were covered with sand taken from the site to protect them from deterioration (Figure 6.b). From that moment on, the recordings of each gauge and cell data started. Finally, the geosynthetic reinforcement was carefully covered with 400 mm of crushed stone (grading: 0/63 mm) and compacted using a 7.5t drum roller.

Figure 7 - Instrumentation scheme

Settlements under the crane pad were determined using a wireless laser level.

2.5 Recording Data

The recording of the strains, stresses and settlements under the crane pad started with the installation of the 400 mm thick working platform and covered the complete construction steps to assemble the 750 t mobile crane. In total, 22 measurements were performed during the several stages of the construction, the measurement being singular or continuous recording in time. The assembly of the crane in the working platform area took a full working day. The maximum load in the area of the crane pad was expected when the full counterweight of 225t was directly positioned over the crane pad without having a lifting weight at the boom (Figure 8).

Figure 8 - Most critical load scenario over crane pad in situ (a) and scheme (b)

First measurement (single type measurement) was performed after the geocomposite was covered with the crushed stone layer. The 2nd measurement (continuous type measurement) corresponds to the static compaction of the instrumented platform. The 3rd measurement was performed during the dynamic compaction of the working platform using a 7.5 t drum roller. In Figures 9 and 10 are presented the results for the 3rd measurement in terms of strain vs. time and pressure vs. time. These results, corroborated with the 2nd stage ones prove that the gauges are working correctly.

Figure 9 - Strain versus time during the dynamic compaction of the working platform (3rd measurement).

Figure 10 - Pressure versus time during the dynamic compaction of the working platform (3rd measurement).

2.6 Monitoring Results

The results for stages 16 and 22 were chosen to be presented in this paper; the 16th measurement is corresponding to the application of the counterweights to the crane (maximum load scenario), while the 22nd measurement is corresponding to assembling of crane lattice jib.

Figure 11.a presents the recorded strains in the reinforcement geocomposite during stage 16, for each strain gauge (SG), in the crane position showed in Figure 8.b. A maximum strain of 0.42 % was recorded for strain gauge no. 4.

Figure 11.b shows the strain vs time graph for stage 22. During this stage a maximum strain of 0.45% was recorded for the same strain gauge, no. 4.

In Figure 12.a and 12.b are presented the variation of the strains (12.a) and pressures (12.b) with the distance from the center of crane pad, for stages 16 and 22 of measurement. For stage 16, the maximum value of the pressure was of 143.52kPa, while for stage 22, the maximum pressure was of 121.20kPa.

Figure 13 shows the real level of the stress and strain in the geosynthetic compared with the overall stress – strain curve of the material.

The maximum measured settlement was about 9.5mm (final loading and positioning).

3. CONCLUSIONS

Working platforms are used for offering a safe and stable support for heavy equipment. They are often built on soft soils which cannot provide the adequate bearing capacity and the required safety conditions. One of the common solutions is to reinforce the platform using geosynthetics, this resulting in increased safety and durability, lower maintenance, less thick platforms and also environmental benefits.

Figure 13. Level of stress and strain for the reinforcement geosynthetic

Working platforms are usually designed based on BR470, which uses mainly practice and empirical methods.

The paper presents a field test from a Romanian wind farm, where a working platform for a heavy crane was reinforced with an instrumented geocomposite, together with the performed measurements and the main obtained results. The geosynthetic reinforcement was monitored using 8 strain gauges and 3 pressure cells.

The objective of the field test is to assess more exactly the behavior of the geosynthetic reinforcement in order to improve the design methods. The paper presents only the results of the monitoring performed on site. These results will be used in the near future for calibrating a numerical model and to further improvement of the design methods (aspects which will be published latter).

The working platform used for this test field was made of 40 cm thick crushed stone reinforced with a geocomposite at its base. If no geosynthetic had been used for reinforcement, the overall thickness of the required working platform would have been 60cm, which allowed savings in the range of approx. 30%.

Testing and Specifying Rolled Erosion Control Products

C. J. Sprague, TRI/Environmental, Inc., United States
J. E. Sprague, TRI's Denver Downs Research Facility, United States

ABSTRACT

Sediment continues to be a major pollutant of public water resources even though erosion control best management practices, BMPs, are now commonly used. In order to help protect water quality as it relates to sediments, regulatory agencies and site designers are increasingly asking how well specific BMPs will perform quantitatively relative to alternatives. While a large amount of information on erosion control products (ECPs) has been available for quite some time, the information has too often been non-standard, out-of-date, insufficient, or unable to be compared to alternative products, making it difficult for users to create generic construction specifications or qualified product listings of comparable products.

Standardized test procedures have been recognized as the means to develop comparable product data. Thus, a two decade effort by industry professionals has produced recognized tests for measuring relevant material properties as well as performance capabilities of ECPs – with most effort focused on rolled erosion control products (RECPs).

This paper discusses the details of these now commonly used standardized index, bench-scale, and large-scale tests for RECPs, along with a review of data from hundreds of independent tests performed on a range of RECPs under the auspices of the National Transportation Product Evaluation Program (NTPEP). Along with an assessment of the relevance and correlation of the various tests, recommendations will be made on the appropriate use of these test results in specifications for RECPs.

1.0 MANUFACTURED EROSION CONTROL PRODUCTS AND ASSOCIATED TESTING

1.1 Manufactured Erosion Control Product Types

While conventional erosion control materials ranging from loose straw to rock riprap continue to be used extensively, new developments in erosion control systems are being used, including the following types of rolled erosion control products (RECPs):

- Temporary RECPs - For applications where natural vegetation alone will provide sufficient permanent erosion protection.
 - Open Weave Textile (OWT). OWTs are a degradable product composed of processed natural or polymer yarns woven into a matrix. The most common of these are comprised of jute or coir.
 - Erosion Control Blanket (ECB). ECBs are composed of processed natural or polymer fibers mechanically, structurally or chemically bound together to form a continuous matrix.
- Permanent RECPs - For applications where natural vegetation alone will not sustain expected flow conditions and/or provide sufficient long-term erosion protection.
 - A turf reinforcement mat (TRM) is a permanent RECP composed of non-degradable synthetic fibers, filaments, nets, wire mesh and/or other elements, processed into a permanent, three-dimensional matrix of sufficient thickness.

1.2 Quality Control, Quality Assurance and Performance Testing of RECPs

Basic index tests are typically needed to assure manufacturing quality control of RECPs. Not only are these tests useful for manufacturing quality control, but when used on the same materials deployed in bench-scale and large-scale performance tests, they serve to “bench-mark” the performance results to specific material properties. A variety of performance tests have been developed over the years to answer designers’ and specifiers’ questions regarding performance among different products and product categories.

Since 2003, the National Transportation Product Evaluation Program (NTPEP) has provided a program for independent testing of RECPs. The program has included both index tests and bench-scale “indexed performance” tests. The goal of the program is to minimize duplicative testing of erosion control products done by individual State Departments of Transportation (DOTs) by providing a process where manufacturers and suppliers submit their products to the NTPEP

for independent index and bench-scale testing. The results of the testing are then shared with participating DOTs. The results of the testing may be used for assessing product conformance to material specifications. Further, the testing results provide quantitative material data necessary for placing specific products on, or removing specific products from a DOT's qualified products list (QPL). The NTPEP program is intended to serve as a nationwide quality assurance (QA) program for the DOTs.

Additionally, in 2009, NTPEP began offering independently verified large-scale performance testing to complement ongoing index and bench-scale testing. NTPEP (2011) describes the purpose and rationale for exclusive use of standardized test procedures in the programs.

1.2.1 Index Testing

Index tests are standard tests that may be used for manufacturing quality control and to compare the relative material properties of several different RECPs. Quality Control tests are index tests which are performed on a production basis to evaluate product integrity, quality and continuity, and to assess the impact of changes in production methodology on product properties. Quality control test results can be reported with statistical relevance when they are run with sufficient frequency. Recently, ASTM D4354, "Standard Practice for Sampling of Geosynthetics for Testing", has been revised to include appropriate sampling frequencies to achieve a 95% confidence level for RECP quality control, quality assurance, and conformance testing. Following are the index test methods used for RECPs:

Mass per Unit Area: ASTM D 6475, "Standard Test Method for Measuring Mass per Unit Area of Erosion Control Blankets"; ASTM D 6566, "Standard Test Method for Measuring Mass per Unit Area of Turf Reinforcement Mats". The mass per unit area, also known as the "weight" per square yard of a sample, is an important quality control property. The ECB test uses ten 8"x8" specimens at ambient laboratory conditions. The TRM test uses five larger, typically 12"x14", specimens that have been dried at 50° overnight.

Thickness: ASTM D 6525, "Standard Test Method for Measuring Nominal Thickness of Permanent Rolled Erosion Control Products". Thickness is another important quality control property which is measured after application of a 6-inch diameter presser foot under a 0.029 psi pressure.

Tensile Strength: ASTM D 6818, "Standard Test Method for Ultimate Tensile Properties of Turf Reinforcement Mats". The ASTM tensile test method for RECPs uses at least 5 inch-wide grips.

Light Penetration: ASTM D 6567, "Standard Test Method for Measuring the Light Penetration of a Turf Reinforcement Mat (TRM)". Within a light box, a calibrated meter measures the amount of light that is able to pass through the specimen from a 150 watt light source on the other side of the specimen. The inverse of the percent of light passing through the specimen is termed the "% cover".

Water Absorption: ASTM D 1117 Section 5.4 and ECTC-TASC 00197, "Standard Guide for Evaluating Nonwoven Fabrics – Absorptive Capacity Test (for Larger Test Specimens)". Water absorption is a measure of a material's capacity to absorb water and is generally applicable to organic RECPs.

Specific Gravity: ASTM D 792, Method A, "Standard Test Methods for Density and Specific Gravity (Relative Density) of Plastics by Displacement". Specific gravity is the ratio of the unit weight of a material to that of water.

1.2.2 Bench-scale Testing

Bench-scale "indexed" performance tests are a class of tests that have been developed to focus on testing the RECP/soil system under carefully controlled "standard" conditions. Bench-scale tests have been developed for slope erosion, channel erosion, and vegetation enhancement for RECPs. Variations in the mass per unit area, raw materials, manufacturing processes, and other product and production components are a constant challenge to manufacturers of RECPs. Since performance of RECPs relies on the complex interaction of the RECP structure with the soil and the water impact/flow, it is helpful and beneficial to a quality assurance program to be able to examine the effects of product variability without having to rerun large-scale tests. Bench-scale testing facilitates lower costs and quicker testing for evaluating product conformance. However, it is critical to emphasize that bench-scale testing is not appropriate for use in design models unless correlated to large-scale testing. Bench-scale tests do not reflect product installation techniques or site conditions to which these materials are typically subjected. Therefore the results of these tests may not be indicative of a RECPs actual field performance.

Slope Erosion and Runoff Reduction: ASTM D 7101, "Standard Index Test Method for Determination of Unvegetated Rolled Erosion Control Product (RECP) Ability to Protect Soil from Rain Splash and Associated Runoff under Bench-Scale Conditions". This test method evaluates the ability of RECPs to protect soil from rain splash and immediate

runoff-induced erosion. The critical element of this protection is the ability of the RECP to absorb the impact force of raindrops, thereby reducing soil particle loosening through “splash” mechanisms. The test method utilizes containers of both bare and RECP-protected soil that are exposed to simulated rainfall and immediate runoff for 30 minutes in the test apparatus. It is a sloped table enclosed by a curtain. Rainfall is simulated using a laboratory drip-type simulator capable of creating uniform drops with a median diameter of 3.0 to 3.5 mm from a drop height of 2.0 ± 0.1 m and producing rainfall intensities as high as 150 mm/hr. The amount of soil that splashes or is washed out of the containers is collected and weighed. From this data, an appropriate soil loss ratio (SLR) can be calculated by comparing the RECP-protected soil loss to the control. The inverse of the SLR is comparable to the C-factor which is more commonly used to relate to performance, but should not be used as a true measure of performance without verification from large-scale testing.

Permissible Shear and Channel Erosion: ASTM D 7207, “Standard Test Method for Determination of Unvegetated Rolled Erosion Control Product (RECP) Ability to Protect Sand from Hydraulically-Induced Shear Stresses under Bench-Scale Conditions”. This test method evaluates the ability of RECPs to protect soils from flow-induced erosion. The test method utilizes containers of RECP-protected soil that are immersed in water and subjected to shear stresses caused by the rotation of a three-blade impeller for 30 minutes in the test apparatus. The shear stress test apparatus includes a tank, test well, motor, plastic lid, and impeller. The three-blade impeller is mounted in the cylindrical tank so that the lower edge of the blades is slightly above the floor of the tank. The sample test well is a recession in the floor of the tank that holds the pots of soil prepared for testing. When the pots are placed in the well, the test surface is flush with the floor of the tank. Pots holding soil and test specimens are normally 200 mm diameter plastic pipe sections with height of 100 mm. The amount of soil that erodes is found by weighing the containers under water. The results of the testing include the amount of soil lost at various shear stresses. From this data, an appropriate permissible shear can be calculated by assuming a critical amount of soil loss, typically 13 mm (1/2-inch). The index limiting shear stress value obtained is comparable to the “permissible shear stress” commonly used to relate to performance, but should not be used as a true measure of performance without verification from large-scale testing.

Germination/Vegetation Growth: ASTM D 7322, “Standard Test Method for Determination of Rolled Erosion Control Product (RECP) Ability to Encourage Seed Germination and Plant Growth under Bench-Scale Conditions”. This test method established procedures for evaluating the ability of RECPs to enhance the rate and quantity of seed germination and facilitate subsequent establishment of vegetation. Containers of soil are sown with a single indexed seed mix and then covered with an RECP. Additional containers are left uncovered as controls. Testing is conducted within a growth chamber where the light, water, and temperature are regulated and documented. The rate of germination is measured periodically throughout the test, and the weight of vegetation is calculated at the conclusion of the test. The testing results include the rate and total weight of germination after 21 days. From this data, a percent enhancement can be calculated by comparing results from the RECP-protected soil to the control.

1.2.3 Large-scale Testing

Large-scale performance tests have been developed to simulate expected field conditions to report performance properties of “as installed” RECPs. Large-scale tests have been developed for slope erosion and channel erosion. The channel erosion test may be conducted un-vegetated or vegetated. Performance of RECPs relies not only on material properties but also on the installation techniques. Products are installed on the test slope or channel per manufacturer installation recommendations. The results of these tests are more indicative of actual field performance of RECPs and are acceptable for use in design calculations.

Slope Erosion: ASTM D 6459, “Standard Test Method for Determination of Rolled Erosion Control Product (RECP) Performance in Protecting Hillslopes from Rainfall-Induced Erosion”. This large-scale test is conducted on one bare soil control and three replicate RECP-protected soil 3:1 slopes. Rainfall is simulated at target intensities of 2, 4, and 6 inches per hour which are applied in sequence for 20 minutes each. Runoff from each slope is collected and soil loss is measured. From this data, an appropriate soil loss ratio and associated C-factor can be calculated by comparing the RECP-protected soil loss to that of the control.

Channel Erosion: ASTM D 6460, “Standard Test Method for Determination of Rolled Erosion Control Product (RECP) Performance in Protecting Earthen Channels from Stormwater-Induced Erosion”. This large-scale test is conducted in a rectangular flume with at least four sequential increasing flows applied for 30 minutes each. Unvegetated RECP-protected soil is tested on a 10% slope flume. Vegetated RECP-protected soil is tested on a 20% slope flume. The limiting or permissible shear stress is defined as the shear stress necessary to cause an average of 0.5 inch of soil loss over the entire channel.

2. NTPEP TESTING TO-DATE.

As noted earlier, the NTPEP's nationwide quality assurance program for RECPs began in 2003 and uses three bench-scale "indexed performance" tests; as well as several index tests, including mass per unit area, thickness, tensile strength, percent cover (i.e. inverse of % light penetration), and water absorption (for ECBs) or specific gravity (for TRMs) to provide member DOTs with independent data on the RECPs entered into the program. Sprague and Nelson (2009) reported on the testing and how it is useful in identifying a hierarchy of product types for each performance measurement. Additionally the data can be used by the individual states to identify products that are excessively outside the expected average for a particular product class.

2.1 NTPEP Index and Bench-scale Testing To-date

As noted earlier, the NTPEP's nationwide quality assurance program for RECPs began in 2003 and uses the index and bench-scale tests discussed above to provide member DOTs with independent data on RECPs entered into the program. Table 1 shows the number and types of the most commonly tested RECPs and the average index and bench-scale test results (and associated standard deviations) for each type of RECP. All the products, except the 2NFF (double net polyfiber matting), are ECBs. The 2NFF is a TRM. None of the few tested OWTs are included.

2.2 NTPEP Large-scale Testing To-Date

Not available until recently, large-scale performance testing information has now been added to the voluminous amount of index and bench-scale data found at www.ntpep.org to better characterize and differentiate between various RECP types. Table 2 shows the results of independent large-scale slope and channel testing done under the NTPEP program and the index property results that "bench-mark" the large-scale results. Also included in Table 2 are the index and bench-scale results for testing from 2009 thru early 2012 – the same years as the large-scale testing results. These are the data that will be reviewed and compared herein.

Figure 1. Comparison of Average Index Properties Measured on Products used for Bench-scale vs. Large-scale Testing

Figure 2. Comparison of Average Bench-scale vs. Large-scale Performance Results

2.3 Review of Index, Bench-scale and Large-scale Testing

The data presented in Table 2 has been graphically presented in Figures 1 and 2 to facilitate a visual comparison of the data. Figure 1 suggests that sufficient uniformity exists in associated index test results from products used in both the bench-scale and large-scale tests to support comparing performance results as shown in Figure 2. Still, one index property – thickness – demonstrates a clear bias toward lower values when tested as part of the index/bench-scale program. This may be because the index properties for the large-scale tests are performed on samples that have been removed from the roll at the large-scale laboratory, repackaged (but not tightly re-rolled) and shipped to the index laboratory, where they are once again unpackaged and cut into specimens. This likely allows the RECPs to “rebound” or even loosen leading to greater thickness and lower % cover.

The data was further evaluated to attempt to identify any meaningful correlation(s) between index (QC) tests and associated bench-scale and large-scale performance tests. If a correlation between properties, or at least a consistent relationship between properties and product types could be found, it would be easier to develop generic specifications for the range of products studied. To this end, possible relationships between index, bench-scale, and large-scale results were explored and are summarized in Table 3.

It quickly becomes clear, based on the correlation coefficients, that no strong credible correlations exist between any of the index properties and product performance as measured by the bench-scale and large-scale tests used. Still, there are “hints” that mass/area, thickness, and % cover may be related to performance. Yet, the correlations are spotty. All correlations are shown in Table 3.

Fortunately, Figure 2 demonstrates quite convincingly that there is a hierarchy of performance among the commonly available RECPs. Additionally, Figure 1 presents the typical index properties for each of these RECPs. Used together, the index and performance data facilitates the preparation of generic specifications that include performance criteria as well as minimum property “thresholds” to assure that only proven materials are used.

Table 3. Possible Index, Bench-, and Large-scale Correlations

Index Test	vs. Bench-scale Test	vs. Large-scale Test	Best Fit Equation	Correlation Coefficient, R ²
Mass/Area, D6475	Slope Erosion, D7101		$C = -0.0021X + 0.1087$	0.0161

		Channel Erosion, D6460	$\tau = -0.0046X + 3.858$	0.6531
Tensile Strength, D6818	Slope Erosion, D7101		$C = -0.0019X + 0.1235$	0.3425
		Slope Erosion, D6459	$C = -0.0015X + 0.0422$	0.8478
	Channel Erosion, D7207		$\tau = 0.0462X + 1.4293$	0.6121
		Channel Erosion, D6460	$\tau = 0.0214X + 1.8589$	0.3819
Light Penetration, D6567 (% Cover)	Slope Erosion, D7101		$C = -0.0024X + 0.2755$	0.4776
		Slope Erosion, D6459	$C = -0.0006X + 0.0678$	0.4397
	Channel Erosion, D7207		$\tau = -0.0179X + 3.681$	0.0852
		Channel Erosion, D6460	$\tau = -0.0023X + 2.4177$	0.0069

3. SPECIFICATIONS FOR RECPs

Many different specifications for RECPs are in circulation, including proprietary specifications promoted by product suppliers, broad product “categorizations” published by industry groups, and generic specifications used by public agencies. To insure free and fair competition, there are at least three critical elements to a material specification for use on public projects – the focus of this effort. The elements include:

1. The specification must be generic. That is, it must be completely comprised of requirements that are not exclusive to a single product.
2. The specification requirements must be relevant. That is, that each requirement must be shown to relate to how the product is expected to perform or must be critical to assuring product quality.
3. Specification conformance must be verifiable. That is, it must be possible to corroborate every requirement within the specification via independent sampling and verification (a.k.a. conformance) testing. For properties requiring long-term testing, a test report from an independent, accredited laboratory may be acceptable.

3.1 Existing Specs

The most widely circulated “generic” specifications for RECPs are the categorizations presented by the ECTC (2006) and the Federal Highway Administration’s FP-03 (2003) and are reproduced in Tables 4 and 5.

Table 4. Temporary Rolled Erosion Control Product (RECP) Specifications (per FP-03, Table 713-3)

Property	1.A ⁽¹⁾	1.B	1.C	1.D	2.A ⁽¹⁾	2.B	2.C	2.D	3.A ⁽¹⁾	3.B	4	Test Method

Maximum “C” factor ⁽⁴⁾	0.10 at 1V:5H	0.10 at 1V:4H	0.15 at 1V:3H	0.20 at 1V:2H	0.10 at 1V:5H	0.10 at 1V:4H	0.15 at 1V:3H	0.20 at 1V:2H	0.10 at 1V:5H	0.25 at 1V:1½H	0.25 at 1V:1H	ASTM D6459 ⁽⁷⁾
Minimum permissible shear stress ⁽⁵⁾⁽⁶⁾ (lb/ft ²)	0.25	0.50	1.50	1.75	0.25	0.50	1.50	1.75	0.25	2.00	2.25	ASTM D6460 ⁽⁷⁾

(1) Obtain max “C” factor and allowable shear stress for mulch control nettings with the netting used in conjunction with pre-applied mulch material.

(2) Functional longevity are for guidance only. Actual functional longevity may vary based on site and climatic conditions.

(3) Minimum average roll values, machine direction.

(4) “C” factor calculated as ratio of soil loss from rolled erosion control product protected slope (tested at specified or greater gradient, v:h) to ratio of soil loss from unprotected (control) plot in large-scale testing. These performance test values should be supported by periodic bench scale testing under similar test conditions and failure criteria using ASTM D7101.

(5) Minimum shear stress the rolled erosion control product (unvegetated) can sustain without physical damage or excess erosion (> 1/2-inch soil loss) during a 30-minute flow event in large-scale testing. These performance test values should be supported by periodic bench scale testing under similar test conditions and failure criteria using ASTM D7207.

(6) The permissible shear stress levels established for each performance category are based on historical experience with products characterized by Manning’s roughness coefficients in the range of 0.01 to 0.05.

(7) Or other qualified independent large scale test method determined acceptable by the CO.

Categories of Temporary RECPs : 1.A, 2.A, 3.A = mulch control nets; 1.B, 2.B = netless ECBs; 1.C, 2.C = single net ECBs and Open Weave Textiles; 1.D, 2.D = double net ECBs; 3.B, 4 = ECBs & Open Weave Textiles

Table 5. Turf Reinforcement Mat (TRM) Specifications (per FP-03, Table 713-4)

Properties ⁽¹⁾	Rolled Erosion Control Product Type			Test Method
	5.A	5.B	5.C	
Minimum tensile strength ⁽²⁾⁽³⁾ (lb/ft)	125	150	175	ASTM D4595
UV stability (minimum % tensile retention)	80	80	80	ASTM D 4355 (500-hr exposure)
Minimum thickness ⁽²⁾ (inches)	0.25	0.25	0.25	ASTM D 6525
Minimum permissible shear stress ⁽⁴⁾ (lb/ft ²)	6.0	8.0	10.0	ASTM D6460 ⁽⁵⁾

(1) For TRMs containing degradable components, obtain all property values on the non-degradable portion of the matting alone.

(2) Minimum average roll values, machine direction only.

(3) Field conditions with high loading and high survivability requirements may warrant the use of turf reinforcement mats with tensile strengths of 3,000 pounds per foot or greater.

(4) Minimum shear stress the turf reinforcement mat (fully vegetated) can sustain without physical damage or excess erosion (>1/2-inch soil loss) during a 30-minute flow event in large-scale testing. These performance test values should be supported by periodic bench scale testing under similar test conditions and failure criteria using ASTM D7207.

(5) Or other qualified independent large scale test method determined acceptable by the CO.

3.2 Proposed Generic Specs

Table 6 is a proposed specification that includes all of the critical specification elements listed above, reflects as much as possible the generally accepted specification requirements of Tables 4 and 5, and incorporates new knowledge gained (and discussed above) from the NTPEP program. This includes using minimum “thresholds”, or lower limits, to

protect against deficiently manufactured or underperforming product being furnished to the project. Shaded values in Table 2 are used to guide the choice of minimum “thresholds” recommended in Table 6.

Table 6. Proposed Generic Specification for RECPs

RECP Classification		Type 1	Type 2	Type 3	Type 4	Type 5	Type 6	Type 7
Typical RECP Type (for guidance only)		1NS, 1NX (ECB)	2NS, 2NX (ECB)	2NSC (ECB)	2NC (ECB)	2NFF (TRM)	Other TRM	Other TRM
Durability (for guidance only)		Ultra Short-Term	Short-term	Extended Term	Long-Term	Permanent	Permanent	Permanent

4. CONCLUSIONS

Commonly used index, bench-scale, and large-scale standardized tests have been discussed along with a review of results from independent testing performed on a range of rolled erosion control products (RECPs) under the auspices of the National Transportation Product Evaluation Program (NTPEP).

Using results to-date, potential correlations have been identified between commonly measured index properties and the ability of specific product types to protect against both rainfall-induced erosion and erosion associated with concentrated flows. Based on these identified relationships a generic specification has been presented for consideration.

The Comparison and Analysis of International Tensile Test Methods and Results

K. Lin, A. Tang, B. Lai, W. Yu, ACE Geosynthetics, Taichung city, Taiwan

ABSTRACT

One of the most fundamental tests on the geosynthetics materials is tensile property. By means of tensile test, the ultimate tensile strength, elongation, initial tensile modulus, et cetera could be acquired, which are not only the good index for design works but also the fine reference for conformity checks.

Test specimen preparation, conditioning atmosphere, procedures, as well as apparatus such as types of clamps and jaw faces are specified and declared thoroughly in individual literatures. All these elements have certain influences upon the test result. By far it is inappropriate to cite values from random or unassociated tests. However, when tests are carried out by the one method, it still might explore variances in results due to dissimilar setups without violating the norms. Focusing upon the differentiation among the international tensile test methods, this article illustrates the variation of principles and analyzes reciprocal effects resulted from multiplicity test settings.

1. FOREWARD

Many geosynthetic materials, for instance geogrid, geotextile and geostrip are suitable for reinforcement. However, when properties of reinforcement materials are varied, optional testing methods are required. Among mechanical, physical and hydraulic properties, tensile strength testing which is found in numerous national standard test methods is taken as the most significant indicator to assess the quality. The obtained results of tensile strength test, an index test, are taken into consideration when it comes to design the reinforcement structure or to contract for the merchantability and goods conformity criteria. Although all test methods are designed to calculate the tensile strength, the test setups and conditions are not necessary in line with each other. At any rate, it is not allowed to grab the testing results of method A to represent or support an outcome carried out by method B. In order to read the relationship between conditions and test results, a condition-permutation project covering 3 grades of flexible geogrid examined by 5 international and national test methods – ISO, ASTM, JIS, GB, CNS (legalized in Taiwan) as well - is thus conducted.

2. ANALYSIS

Common tensile strength test methods consisting in ISO 10319 (EU and international), ASTM D6637 (America), JIS L 1096, JIS L 1908 (Japan), GB/T 15788, GB/T 17689 (China) and CNS 13330 (Taiwan) are summarized in terms of scope, apparatus, strain rate, specimen dimension, as well as pretension. Please refer to Table 1(I) and (II).

Table 1. Test method comparison (I)

Test method	ASTM D6637	ISO 10319	CNS 13300
Version	2011	2008	1993
Test specimens	Single rib & Multit-rib	Wide-width	Wide-width
Scope	Geogrid	Most Geosynthetics, including woven & nonwoven geotextiles, geocomposites, knitted geotextiles, felts, geogrids, similar open-structure geotextiles, not applicable to polymeric or bituminous geosynthetic barriers	Most geotextiles that include woven & nonwoven fabrics, layered fabrics, knit fabrics, and felt that are used for geotextile application.
Tensile testing machine	CRE	CRE	CRE
Testing clamp	Fixed & roller grip clamping system	Wedge, compressive, capstan	Wedge
Gauge length (mm)	Minimum 60	≥60	NA
Strain rate (%/min)	10±3	20±5	10±3 (10±3 mm/min)
Length between the clamps (mm)	Greater distance of 3 junctions or 200±3 mm	100±3	100±3
Number of test specimens	5 for MD & CD	5 for MD & CD	3 for MD & CD
Dimensions of test specimens	<ul style="list-style-type: none"> ●Method A: contain 3 junctions long in test direction. ●Method B: a min. 200 mm wide and contain 5 ribs by at least 3 junctions or 300 mm long in test direction. 	<ul style="list-style-type: none"> ●GT: 200 × sufficient length. ●GG: 200 × sufficient length (at least 100 mm), contain at least one row of junction, excluding the junctions held in the jaws. For products of pitch < 75 mm, at least 4 complete ribs in the width. For products of pitch 75 ~ 120mm, at least 2 complete ribs in the width. 	<ul style="list-style-type: none"> ●200×200 ●the exhibit strengths approx. 100 kN/m, 100 mm width specimens may be substituted for 200 mm width specimens.
Preload	●1.25% of max. load or 225N	1% of the max. load	NA

For products of pitch < 120mm, at least 2 complete ribs in the width.	10 for single rib, 5 for multi-rib •single rib method: contain 3 junctions long in test direction. •multi-rib method: a min. 200 mm wide and contain 5 ribs by at least 2 junctions or at least 100 mm long in test direction.
Dimensions of test specimens	•woven & nonwoven geotextile: 50 or 200 mm wide. •Geogrid & Geonet: at least 200 mm wide.	•Ordinary fabric: approx. 50 or 25 × approx. 300 •Heavy fabric : 30 × approx. 300		
Preload	1% of the max. load	test specimen of 10 m	1% of the max. load	1% of nominal strength

2.1 Scope

Test methods necessarily specify the applicable materials and fields and point out the purposes. Standard test methods ISO 10319, ASTM D6637, GB/T 15788, GB/T 17689 and JIS L 1908 all plainly identify that the geogrid is one of the applicable materials to be tested. The method JIS L 1908 states it is suitable for geogrid and geonet which are more properly categorized as one of stiff materials. Even though the method JIS L 1096 is designed for woven fabrics, the reality is that in Japan, it is definitely to be applied for geogrid. Similarly, the method CNS 13300, Method of Test for Tensile Properties of Geotextiles by the Wide-Width Strip, is actually used to test not only woven fabrics but also geogrid in Taiwan as there is not a specific method for geogrid drawn up. A series of 7 methods are brought into this discussion, thus.

2.2 Apparatus

2.2.1 Tensile Testing Machine

Doubtlessly, constant rate of extension type (CRE), constant rate of traverse type (CRT) and constant rate of loading (force) type (CRL) tensile machines have found as the most accepted equipments to conduct the index test of tensile strength. CRE type tensile machine is recommended to apply in the rest 5 methods with the exception of methods JIS L 1096 which individually establishes unlike setups per 3 different testing apparatus and GB/T 17689 which does not precisely denote a suitable machine type. There is no evidence to link test results derived from CRE and CRT type machine. Providing any disagreement is raised, it is suggested settle by arranging a test by CRE type machine as judgment.

2.2.2 Testing Clamp

It is understandable the choice of clamp is quite depending on the features and strength of materials to be tested. Wedge jaws and compressive jaws and capstan grips are employed to perform this type of testing when we narrow down to 7 tensile strength test methods discussed in this essay. The fact is that only the methods ISO 10319 and GB/T 15788 have directly indicated the use of clamp. Generally speaking, wedge jaw is appropriate to test low-grade specimen; either capstan grip or compressive jaw high-grade specimen. It is worth noting that confined to grasping strength, compressive jaw is incapable of performing very high strength testing.

2.2.3 Extensometer

Extensometer is mandatory to measure the movement of the reference points from the point of view of test methods ISO 10319, ASTM D6637 and GB/T 15788; yet this device is not mentioned in the rest methods. In the test method JIS L 1096, the elongation is counted by reading the movement of length between clamps.

2.3 Set-Up Conditions

2.3.1 Strain Rate

Strain rate of $(20\pm 5)\%$ per minute is given in the methods ISO 10319, GB/T 15788, JIS L 1908 as well. The method JIS L 1096 determines the strain rate by calculating the length between clamps. In the method GB/T 15788, the strain rate is determined in accordance with 20% per minute of Ge-ju length (隔距長度) which lacks the definition. Since the framework of GB/T 15788 was derived from the method ISO 10319:1993, the author presumes Ge-ju length means the length between clamps. Yet the strain rate in ISO 10319:2008 has clarified as $(20\pm 5)\%$ per minute in the gauge length of the specimen. The method GB/T 17689 declares 20% per minute of clamping distance for strain rate. Methods ASTM D6637 and CNS 13300 both share the same strain rate $(10\pm 3)\%$ per minute of the gauge length; however, the method JIS L 1096 states to take 50% or 100% of clamping distance per minute. Evidently, different strain rate shall bring dissimilar results. The gauge length, assert the methods ISO 10319 and ASTM D6637, is meant to compute the elongation, instead of being straight taken as strain rate. The method ISO 10319 apparently organizes the setup as thorough as possible compared with the rest that produce extra variances in the events.

2.3.2 Width of Specimen

With the exception of JIS L 1096, all methods spell the specimen with 200 mm wide. When it comes to the classification of geogrid, at least 5 nodes have to be included in the width. When the tensile strength of woven fabrics exceeds 100kN/m, 100 mm wide specimen is allowed, says the method CNS 13300, to replace 200 mm wide specimen. In a similar system, the method JIS L 1096 states either 5 cm or 2.5 cm wide specimen is for general woven fabrics and 3 cm wide specimen for high strength specimen. The tensile strength usually is expressed in kilonewtons per meter (kN/m) but it pretty much is calculated based on the strength per the width of tested specimen. The specimen coupon is on a quite small scale contrast to the sheet of reinforcing materials installed in the engineering structure. Therefore, there is a possibility to overestimate the real tensile strength through the conversion of unit measurements. ISO 10319 defines how to calculate strength based on the number of ribs in the sample and the number of ribs in a metre of product to avoid this over-estimate.

2.3.3 Length Between Clamps

Once wedge jaws are assigned, the length between clamps is set at 100 mm as the methods ISO 10319 and GB/T 15788 indicate. The method JIS L 1908 also adopts the above operation when it involves neither geogrid testing nor a capstan operation. The method ASTM D6637 requests a length of greater distance of three junctions or 200 mm. Likewise, a length of 200 mm is given by the method JIS L 1096. The method GB/T 17689 is in absence of this discussion.

2.3.4 Gauge Length

An initial distance of at least 60 mm is agreed by methods ISO 10319, ASTM D6637, GB/T 15788 as well. In ISO 10319 the gauge length must be a whole number of rib pitches with measurement from rib centre to rib centre across at least one junction

2.3.5 Pretension

A major reason to set up a preload is to eliminate the errors in the act of operation among testers and ensure the effectiveness of test results. The method CNS 13300 is missed in this section. A preload of 1% of the estimated maximum load is shared and agreed by method ISO 10319, JIS L 1908 and GB/T 15788. On the other hand, the method GB/T 17689 has the same opinion to the preload but it is on nominal strength basis. The method ASTM D6637 comes up to a strict requirement to be limited to 1.25% of the peak tensile strength or 225N (50 lbf). The method JIS L 1096 takes a preload by assessing the tensile strength of a 10 cm specimen.

2.4 Test Results and Applications

By means of a tensile test, all associated values including ultimate tensile strength, ultimate elongation, strain strength, initial tensile modulus, offset tensile modulus and secant tensile modulus are obtained to set out the practical engineering design. In the scope of the civil engineering, long term strength and stress-strain are two key factors to design reinforced structures such as retaining wall, embankment, and so on; meanwhile, they are valuable figures to evaluate the feasibility of the design. Furthermore, since tensile testing is an index test, it commercially turns a basic and important indicator for merchantability.

2.5 Comparison

A summery is made to list the scope of each test method. Please refer to Table 2. The author uses the flexible geogrid to conduct a program in accordance with several methods and is going to details in the following paragraphs.

Table 2. Test methods and products

3. DISCUSSION

3.1 Conditions

Three grades of geogrids are selected to perform tensile testing program, as schemed. The conditions of strain rate, length between grips, gauge length, width of specimens and the use of clamps are all given as per methods in Table 3. Since GB/T 15788 and JIS L 1908 have quite similar instructions on many terms, they are taken as one same method to perform in this program. In order to lessen variances, the following elements had been categorized. Distance between the clamps is set up at 30 cm from centerline to centerline of rollers when capstan is applied and 20 cm to wedge jaws. Typically, 60 mm and 100 mm gauge lengths are adapted by standards. In aspect of the setting of test speed, a trial test is required beforehand in order to calculate the test speed in accordance with requirements of the standards as the extensometer is to determine the gauge length for use in elongation calculations and not test speed. Please refer to Table 4.

Table 3. Conditions

Item(s)	ISO 10319	ASTM D6637-A	ASTM D6637-B	CNS 13300	GB/T 15788 JIS L 1908
Strain rate (%/min)	20	10	10	10 mm/min	20 ¹

GG3	19.3	200	9.6	100	10	60

¹20 %/min of the length between 2 grips

3.2 Results

Test results are tabled in Table 5 – 10. Gauge length of 60 mm or 100 mm gives negligible difference in the results when rest conditions remain. The readings of tensile strength of Type 1 and Type 2 are not very unlike whether capstan grips or compressive wedge jaws are applied. However, when it comes to Type 3 group, the tensile strength carried out by capstan grip appears higher. A better performance of strength at 2% and 5% strain is observed while compressive wedge jaws are used. Given that the strain rate is accelerate, the tensile strength and strain strength go higher without raising the elongation.

Table 5. Type 1 tensile strength result (Gauge length: 60mm)

4. CONCLUSION

- Strain rate interferes with tensile strength and elongation. High strain rate produces high strength, including strength at 2% and 5% strain, initial tensile modulus, setoff tensile modulus and secant tensile modulus, at lower elongation.
- The selection of gauge lengths influences upon the elongation quite slightly as far as remaining conditions are not changed.
- Capstan grip earns a better performance in the strain strength at lower elongation. This phenomenon seems not noticeable in tests of low-grade geogrid though it is easier to observe the efforts in tests of high-grade geogrid. Compared with capstan grips, the mechanism of wedge jaws is relevantly limited to the grasping strength so often slippage or jaw breaks are occurred.
- A flexible geogrid greater than 200 kN/m is recommended to be executed tensile tests with capstan grips.
- Without violating the normative procedure of test method, either the form of clamps or the length between clamps possibly controls the test results. Any controversy in inspection activity could be raised so long as an ambiguity is found in the explanation of procedures, testing setup and conditions.
- A requirement of strain rate appears missed or imprecise in many test methods. A strain rate is at 20% of Ge-ju length (隔距長度) as per GB/T 15788, which could be defined as length between clamps or length of gauge. According to the method ASTM D6637, the strain rate is at 10% per minute of the gauge length based on the gauge length so the dependence of strain rate and gauge length is seen. A strain rate is at 10±3%/min (10±3 mm/min) as far as the length between clamps is 10±3 mm as per CNS 13300.

The Impact of Site Conditions on the Electrical Surveying of Pond Liner Installations

Bennett, Phillip. Managing Director. Geotest Pty Ltd. Australia. pbennett@geotest.net.au

ABSTRACT

Contractors, with over six year's experience, were engaged to survey and report on the condition of a HDPE liner in Queensland, Australia. The 35,000m² pond was a clay lined, cut and fill construction with a trench anchored, 2.0mm HDPE liner with no appurtenances or perforations. All fill and discharge was undertaken over the top of the basin. The pond contained a solution of 7000ppm saline water, a by-product of coal seam gas extraction.

In the course of preparing the survey equipment (in accordance with ASTM.D7002¹, ASTM D.7007² and ASTM D7703³), it became evident that the voltage was unstable and the contractors were unable to electrically identify the calibration puck, thus making it impossible to identify the parameters for the equipment settings, or to successfully carry out the requirements of the test regime. Further extensive investigation eventually identified a set of conditions peculiar to the site, and which impacted on the surveyors' ability to undertake effective testing.

This paper intends to explore this specific incident, in which several major site related factors, including:

1. Salinity levels of contained liquid;
2. Substrate conditions;
3. Metallic properties of contained pond sediment, and
4. Ambient meteorological conditions

The above contributed directly to the detrimental effect on the electrical surveying of a pond liner. The subsequent importance of understanding site conditions and nuances when undertaking electrical survey is highlighted within.

1. INTRODUCTION

Integrity surveys are increasingly being used as a process to test the integrity of installed geomembrane throughout Australia. The success of such a process has given rise to specifiers requiring, now more often as a matter of course, that the liner be electrically tested.

The installation of geomembranes to prevent leakage from storage ponds into the environment has been in longstanding and successful use worldwide, and as the industry has developed, so have the materials and the installation techniques peculiar to their construction. These developments have not only been in the materials themselves, and their properties in resisting chemical and environmental attack, but so have the techniques relating to the installation and the subsequent verification of the installation.

Traditionally the materials have been well tested and verified, as have the techniques of installation and the construction of the liner as a completed product, but final inspection has traditionally been restricted to a visual methodology, incorporating the finished surface of the liner. This particular methodology has the potential to overlook hidden damage or holes that are not readily detectable with the naked eye.

The use of electrical integrity testing has now given the industry a tool with which it can verify the completed installation, both on the surface and deep within it. This process has not been recognised by the industry and has proven itself as an extremely valuable tool for locating voids, thus allowing repairs, and improving the overall quality of the installation.

The basic outline of the integrity test is to use the geomembrane itself as an electrical insulator; between the water within the pond and the ground beneath the pond. When an electrical potential is applied to the surface of the pond, either via a wetted surface, or the water stored in the pond, the geomembrane (if intact) acts as an electrical insulator. In this manner, if the and the overall circuit is not connected, it means that there will be no flow of current. Is however, there are holes present in the geomembrane, the circuit will not be completed, and a flow of current will therefore exist. The amount of current in existence will generally be proportionate to the resistance of the geomembrane; the higher the number and/or the size of the holes, the lower the resistance will be, and the greater the current flow. If there are holes in the liner, the electrical current passes through the hole, and this can then be measured by sensitive equipment.

The potential applied to the pond is a DC current, which has direction , thus enabling traceability of the current to as a means of locating the holes in the pond. (Refer to FIG 1-6 below)

Fig 1. Schematic of basic setup for electrical surveying and flow of the current (in one direction)

KEY

- Connection to the earth peg and energiser plate within the pond to the DC energiser
- Direction of the current with the pond
- - - ← Direction of the current through the hole and return to the energiser via the ground.

As with the testing of any engineered product, and especially those products which are containment solutions, the process of electrical testing and liner verification should be undertaken by an experienced operator. Given the risks involved with the containment of solutions and the fallout associated with possible liner integrity failure, such an operator should be totally au fait with all aspects of the equipment, including its purpose.

The process of electrical surveying has been used for many years and has been successfully applied around the world by Specialist Companies. Such companies have been on an exponential learning curve as they have developed their systems and garnered a complete understanding of the process. Such understanding is often the result of having been exposed to a wide variety of site conditions.

While Electrical Surveying is based on a process of applying a potential to the surface of a membrane, measuring the return current and using a mathematical formula to calculate the approximate area of damage to the membrane, site conditions have the propensity to significantly affect outcomes. The complexity of site conditions, which range from the geotechnical through to metallurgic and atmospheric, are much more complicated than is generally perceived.

Simple circuitry equations bear little significance in the field. The process is very effective in simple applications, particularly when the elements of the circuit are simple, but when the complexity of circuit is affected by the introduction of multiple components (some of which act differently and change resistance when a potential is applied), it is then that changes occur within the process. The test has, under such circumstances, the potential to evolve from a simple test to a complex situation which requires a greater analytical skill.

The industry now faces significant risk to its integrity. Currently, the impartation of small amounts of knowledge to a handful of people with little or no specialist experience, has resulted in such individuals promoting themselves as having the skills to understand and undertake the necessary tasks. Sadly, where results are often open to interpretation, as is the case in the electrical testing of liner integrity, small amounts of knowledge and limited experience can often count for nought when site conditions vary as constantly as they have been known to do.

As a consequence, the industry is in danger of a growing misinterpretation of testing results, and such a situation has the potential to damage the reputation of the process itself as a result, to say nothing of the possible ramifications to in situ products and the solutions contained within them.

Recently, I encountered a lining contractor who advised his client that his company had ***“bought the equipment, and the process is so simple that we will undertake all of our own testing and save money”*** (sic) The contractor likened the electrical surveying process to that of simply throwing a wire into a pond and wandering around, with the equipment locating any holes by itself This attitude of those uninformed contractors can be challenged by asking them if welding was simply a matter of putting metal together and glueing it with a machine. Ignorance is no excuse, as the likelihood of irreparable damage to the industry is high and the effect this can have on the industry as a whole is of great concern.

As geomembranes are applied to a growing variety of complex installations, which in turn have their own idiosyncratic requirements for performance owners and regulators are continually being challenged to ensure testing is appropriate and exhaustive.

In our consistently evolving world of scientific geomembrane testing, we are duty bound to ensure that the applied technology takes all complexities into consideration, and that Research and Development must include the knowledge and experience of those operators who are well aware that there is far more to their profession than throwing a wire into liquid and allowing a machine to do the rest.

2. CASE HISTORY

2.1 Background

Phillip Bennett is an Australian geomembrane consultant, with over 30 years experience in the design, construction and installation of liners and floating covers in the Asia Pacific region. He has been at the coal face of the geomembrane installation industry since its infancy and was responsible for the majority of pioneering design solutions throughout that period. For the past four years, he has worked as a geomembrane consultant, specialising in the electrical survey testing of lined containment installations. Part of his work in this field has involved the research and development of cutting edge survey equipment in Australia, Europe and the USA.

The focus of this paper is on one particular situation, wherein the client required verification of a pond's integrity in order to satisfy regulatory license conditions.

2.2 Site Description

The site, situated in remote northern Queensland, Australia, comprised a 35,000m² lined pond, which was a process storage pond for coal seam gas extraction, containing a saline solution of approximately 7000ppm. The pond's construction was a cut and fill with both a clay liner and 2.00mm HDPE liner, the latter being buried in an anchor trench. There were no perforations, appurtenances or liner incursions and all fill and discharge took place over the perimeter of the pond. The installation itself was similar to numerous other installations, all of which had been undertaken without any difficulty in locating potential holes. in the membrane..

The liner was installed by a reputable company, which has previous experience in the installation of the material. The specifications were written by a large consulting engineering company and were compliant with GRI Test Method GM 13⁴ and GRI Test Method GM19⁵ standards. Additionally, all appropriate CQA paperwork was in order.

2.3 Problematic Set-Up

Initial set-up for the survey was expected to be 'text book', in accordance with ASTM 7002 and ASTM.D 7007. Generally, the survey would consist of the application of a potential into the solution or onto the surface of geomembrane liner and, and mapping the electrical currents. A calibration puck was used to set the parameters and to represent the electrical fields that could be generated from a hole in the liner. Once the signals were established, standard procedure was to proceed in a methodical fashion to detect any anomalies or leaks in the geomembrane. Due to the exacting nature of the work and the size of the installation, it was realistic to expect the process to take approximately five days.

It became clear almost immediately that the survey equipment was unable to locate the calibration puck and could not maintain a stable voltage, thus disabling the entire process. Following a Standard Operating Procedure in the first instance, the survey equipment was checked to ensure it was in functioning order and that operator fault was not the cause.

2.4 Site Anomalies

Once it was established that the survey equipment was functioning within normal parameters, the site itself was considered as the most likely contributor to the situation, and the entire installation required forensic investigation to determine the solution. Methodical investigation revealed a number of abnormalities both in the installation and in the site conditions, each of which fell outside the parameters of what could be considered a 'text book' installation. Each of these abnormalities contributed to the overall problem, these being:

- The contained solution was of a high saline concentration (5500ppm);
- The contained solution also carried a high mineral content (Soil conductivity-1-2Ohms/m;
- Sedimentation in the base of the pond had a very high mineral content;
- The liner's sub grade contained a high mineral content;
- The combined high saline and mineral content in the pond as a whole produced an electrical potential of its own (acting as a battery);
- The configuration and assembly of the pond itself resulted in the installation acting as a capacitor, the result of the presence of conductive material on both sides, with insulation material between;
- Holes within the geomembrane;
- At the time of construction, liner installation technicians had discarded a roll remnant (which contained metal staples) under the liner itself which, when compounded by the pressure of the contained solution, resulted in 12 small holes.

3. SOLUTION

Initially the potential applied to the pond was relatively low approx 30 volts and at this level the voltage was relative stable but it was impossible to locate the artificial puck , the voltage was slowly increased in 10 volt DC increments and the calibration was attempted and in each instance location of the puck was impossible unless you were almost directly over the puck.

As the potential was increased the ability to locate the puck became better but not sufficient to allow a survey. When the potential reached just over 100 volts DC the voltage became very unstable.

The potential was increased through a range of voltages until just over 300 Volts DC which did allow better ability to see the calibration puck but the signals on the meters were also very unstable and not suitable to carry out a survey.

Once all contributing factors were identified, compensatable measures were taken with the survey equipment. The resistance on the earth return to the DC power supply was increased and the circuitry was altered to accommodate the capacitor effect created by the pond, thus achieving a stable voltage and current. At this point, it was possible to locate the artificial calibration puck and commence the survey.

Following the achievement of a stable voltage, surveyors discovered a relatively low voltage present with a high current, indicating the liner had been compromised with a number of small holes or a large hole. This was due to the presence of the abovementioned 12 staples in the discarded liner off cut. The metal staples under the liner were systematically located and subsequently sealed, thus negating their effect on the installation and making it possible to complete the survey and certify the liner's integrity.

4. CONCLUSION

The situation was brought about by a culmination of anomalies at the site, rather than one specific problem. Addressing the first anomaly identified and accepting it as the sole cause would have resulted in a failure to correctly diagnose and rectify the low voltage/high current situation. It was only through the systematic application of a logical, diagnostic procedure that the surveyors were able to arrive at both a conclusion and a solution to what may have been an insurmountable problem. The invaluable experience has subsequently led to the formulation of a procedural diagnostic regime that will assist in the field in future endeavours.

The Mechanics of Filter Cake Formation on a Geotextile

J. Richard Weggel, Ph.D., P.E., Department of Civil, Architectural and Environmental Engineering, Drexel University, USA, weggel@drexel.edu

Nicholas D. Ward, Ph.D., Otago Computational Modeling Group Ltd, New Zealand, nick@ocmo.co.nz

ABSTRACT

A numerical model describing the accumulation of suspended sediment on a geotextile is developed for both a colloidal suspension and for sediment that includes larger settleable particles. The model is solved using an Excel spreadsheet and is presented for a sediment comprised of 5 separate size components; however, the model can be easily expanded to more components. The time-varying rate of flow through the geotextile/sediment system is predicted along with the rate of accumulation of filter cake. The permeability of the two layer system is given as a function of time as it increases in thickness. The model has been verified experimentally using a settling tube by measuring the rate of discharge from the tube with time. Verification of the model is presented for three sediments: Ottawa sand, a fine sand and Plasti-grit, a low density plastic abrasive used for sand blasting. The model also allows the size distribution of the sediment at various levels in the filter cake layer to be estimated. A parametric analysis of the model investigates: (a) the occurrence of a clear water interface in the slurry, (b) the application of a vacuum to increase the rate of filtration and sediment deposition and dewatering, and (c) the effect of flocculants on the dewatering process. The relative importance of the geotextile vis-à-vis the sediment in the dewatering process indicates that sediment characteristics are usually more important than geotextile characteristics.

1. INTRODUCTION

Large geotextile bags are increasingly being used to dewater dredged material and mine tailings (Gaffney, et al., 1999; Gaffney & Wynn, 2004 and Weggel et al., 2010). As the water passes through the geotextile, solids in the slurry are retained on the surface of the geotextile. As the thickness of the accumulating filter cake increases the dewatering rate decreases. Thus, as time passes, the dewatering efficiency of the system decreases. The rate of flow through the filter cake depends on the permittivity of the geotextile, the permeability of the filter cake and its thickness. At the start of the dewatering process the permittivity of the geotextile can be important; however, as the filter cake's thickness increases, the permeability of the filter cake controls the dewatering rate. Weggel & Ward (2011) presented a numerical model that describes the accumulation of filter cake on a geotextile. The equations are solved numerically using an Excel spreadsheet to give the discharge through the geotextile-filter cake layers, the decrease in head, the cumulative discharge and the thickness of the filter cake, all as functions of time. In addition, the distribution of sediment grain size at various layers in the filter cake can be determined given the size distribution of the sediment in suspension at the start of the process. Thirty-four experiments were conducted with two geotextiles and three different sediments to verify the theory. The geotextiles used were Propex 135ST (Geotextile A) and Propex 315ST (Geotextile B), both with permittivities reported by the manufacturer as 0.05 s^{-1} . Table 1 presents the hydraulic properties of the geotextile as reported by the manufacturer. The sediments used were a well-sorted Ottawa sand, a fine sand and a well-graded, light weight plastic material (Plasti-grit).

2. THEORY

Details of the theory are presented in Weggel & Ward (2011). A summary is presented here along with the explicit numerical equations.

Application of Darcy's law to vertical flow through a two layer system gives the permeability of a geotextile/filter cake system, K_{system} , as,

$$K_{system} = \frac{z}{\left\{ \frac{1}{\Psi} + \frac{z}{K} \right\}} \quad [1]$$

in which z = the thickness of the filter cake, K = the permeability of the filter cake and Ψ = the permittivity of the geotextile. Hence the flow through the two layer system is,

$$q = \frac{h}{\left\{ \frac{1}{\Psi} + \frac{z}{K} \right\}} \quad [2]$$

where q = the flow through the geosynthetic/filter cake system per unit area and h = the head. See Figure 1 for a definition of terms. Note that the head is measured from the top of the filter cake and not from the top of the geotextile; therefore the head decreases because both the slurry level drops and because the filter cake thickness increases.

Table 1 Hydraulic Properties of Geotextiles

Figure 1 Definition of Terms

Filter cake thickness increases because of advection (the downward fluid flow carries sediment) and because the sediment settles. Advective transport depends on the rate of downward flow while the particle settlement rate depends on grain size. In the present numerical solution sediments have been characterized by six discrete size classes; however, the model can be expanded to accommodate any number of size classes. The six sizes used here include a "colloidal" component which does not settle but is transported only by the downward flow (advection) and five sizes which are transported by both advection and settlement. The solution progresses by stepping through time in Δt steps with successive values of the variables calculated from values at the preceding time step.

The flow through the system at the start of filtration is given by,

$$q_0 = \frac{h_0}{\left\{ \frac{1}{\Psi} + \frac{z_0}{K} \right\}} = \frac{y_0 - z_0}{\left\{ \frac{1}{\Psi} + \frac{z_0}{K} \right\}} \quad [3]$$

in which q_0 = the initial flow rate, h_0 = the initial head, y_0 is the initial height of the slurry level above the geotextile, z_0 = the initial thickness of the filter cake, Ψ = the permittivity of the geotextile and K = the permeability of the filter cake. The initial head is the height of the slurry surface above the top of the filter cake. The initial cumulative discharge is,

$$q_{cum0} = 0 \quad [4]$$

The initial water level in the tube is y_0 and the water level one time step, Δt , later is,

$$y_n = y_{n-1} - q_{n-1} \Delta t \quad [5]$$

The rate at which the thickness of the filter cake increases is given by,

$$\frac{dz}{dt} = \left\{ \frac{\alpha_o}{\varepsilon} + \sum_i \frac{\alpha_i}{\varepsilon} \right\} q + \sum_i \frac{v_i \alpha_i}{\varepsilon} \quad [6]$$

in which α_i = the volumetric solids concentration of the i^{th} component in the slurry, ε = the solids fraction of the accumulated filter cake (1 – porosity), v_i = the settling velocity of the i^{th} component of the slurry material. The first term on the right hand side of Eq. 6 is the advective transport while the second term is the particle settlement term. Taking a finite difference discretization, Eq. 6 becomes,

$$z_n = z_{n-1} + \left\{ \frac{\alpha_o}{\varepsilon} + \sum_i \frac{\alpha_i}{\varepsilon} \right\} q_{n-1} \Delta t + \sum_i \frac{v_i \alpha_i}{\varepsilon} \Delta t \quad [7]$$

where the subscript $n-1$ indicates a value at the previous time step and n the value Δt later. The flow rate is given by,

$$q_n = \frac{(h_n + h_{n-1})}{2} \left\{ \frac{1}{\frac{1}{\Psi} + \frac{(z_n + z_{n-1})}{2K}} \right\} \Delta t \quad [8]$$

where

$$h_{n-1} = y_{n-1} - z_{n-1} \quad [9]$$

and

$$h_n = y_n - z_n \quad [10]$$

which can be evaluated using values obtained from equations [5] and [7]. The cumulative discharge through the two-layer system is,

$$q_{cum(n)} = q_{cum(n-1)} + \frac{q_n + q_{n-1}}{2} \Delta t \quad [11]$$

The final thickness of the filter cake after all i components have accumulated is,

$$z_{\infty} = h_0 \sum_i \frac{\alpha_i}{\varepsilon} + z_0 \quad [12]$$

Given initial conditions for y_0 and z_0 (and thus h_0), equations [3] through [11] can be solved successively to yield the change in discharge and filter cake thickness with time. The dimensionless parameters, $\Psi y_0/K$, $g\Psi^2/y_0$ and the values of α_i/ε for the sediment components characterize the solution. $\Psi y_0/K$ is a measure of the relative importance of the geotextile's permittivity compared with the filter cake's permeability and $g\Psi^2/y_0$ is a dimensionless permittivity.

The model assumes that the size components comprising the slurry are completely mixed and uniformly distributed throughout the column at the start of the process.

3. EXPERIMENTS

3.1 Geotextiles

Two woven polypropylene geotextiles (Geotextile A and Geotextile B) were used for the experiments. They were selected for their low permittivities. Their hydraulic characteristics, as reported by the manufacturer, are given in Table 1.

3.2 Sediments

Three sediments were used in the experiments: Ottawa sand, a fine quartz sand and Plasti-grit. (Plasti-grit is a commercially available plastic material with a specific gravity of 1.17 used for sand blasting.) The Ottawa sand was characterized by a single size, the fine sand by four sizes and the Plasti-grit by five sizes. The size characteristics of the three sediments are given in Table 2. Of the three sediments, Plasti-grit most closely approximates the size and sedimentation rates characteristic of sediments being dewatered. The Plasti-grit size distribution is given in Figure 2 and the five sizes used to characterize it are shown in the histogram of Figure 3. Settling velocities were determined from the Rubey (1933) equation,

$$v_i = \left\{ \sqrt{\frac{2}{3} + \frac{36v^2}{gd_i^3(\rho_s/\rho - 1)}} - \sqrt{\frac{36v^2}{gd_i^3(\rho_s/\rho - 1)}} \right\} \sqrt{gd_i(\rho_s/\rho - 1)} \quad [13]$$

in which v_i = the settling velocity, d_i = the particle diameter, ρ_s = the density of the sediment, ρ = the fluid density and g = the acceleration of gravity. The equation is valid for any consistent set of units.

Figure 3 Histogram for Plasti-grit

3.3 Experiment Protocol

Details of the experiments are given in Weggel & Dortch (2011) and are summarized here. The experiments were conducted using a 4.46-cm (1.756-inch) inside diameter Plexiglas settling tube approximately 1.37 meters (4.5 feet) long. See Figures 4 and 5. A scale graduated in inches was taped to the side of the tube. The geotextile was fastened to the bottom of the tube with a hose clamp. Initial experiments were conducted without sediment in order to determine the permittivity of the geotextile. The bottom of the tube was placed on the floor on a large diameter rubber stopper and filled

with water. (The stopper diameter was larger than the outside diameter of the tube.) The stopper and tube were picked up and placed over a receiving basin, the stopper was removed and the time for the water surface to pass various levels on the graduated scale recorded. In effect, the system was a falling head permeameter. While this is not a standardized test for determining permittivity, it was deemed appropriate to determine the permittivity *in situ* rather than in a separate test. Permittivity was determined by plotting water level against time with water level on a logarithmic scale. An exponential curve was fitted to the data with the permittivity found from the exponent. Figure 6 presents a typical plot for Geotextile A for four tests. Permittivity values found for Geotextile A ranged from $\Psi = 0.0532$ to 0.0585 s^{-1} and from $\Psi = 0.1571$ to 0.1613 s^{-1} for Geotextile B.

Essentially the same procedure was used in subsequent experiments with sediment; however, an additional stopper with a hole was inserted into the top of the tube. The bottom of the tube was placed on the large stopper; a measured quantity of sediment placed in the tube and water added to fill the tube. The tube and stoppers were picked up and the system shaken until the sediment appeared to be evenly distributed throughout the water column. It was difficult to achieve a uniform distribution of sediment through the fluid for the Ottawa sand because of its high settling velocity. It was somewhat difficult for the fine sand but the distribution was observed to be more uniform than for the Ottawa sand. A uniform distribution was achievable with the Plasti-grit. The tube was placed over the receiving basin, the bottom stopper removed and the time for the water surface to pass various levels on the graduated scale measured. After water stopped draining from the system, the weight of water released was recorded and the thickness of the sediment in the bottom of the tube measured to the nearest 0.25 cm (0.1 inch). The thickness of the accumulated sediment filter layer was sensitive to any subsequent disturbance of the tube. If, following a test, the tube was disturbed, the sediment consolidated and its thickness decreased; consequently, for some tests, several sediment thicknesses were recorded. The basic data obtained from each test was: the water level as a function of time, the weight of the sediment introduced, the weight of the water released and the final thickness of the sediment layer. Some small amount of water was retained in the pores of the accumulated sediment at the end of a test; however, the amount of water remaining in the filter cake was small relative to the amount in the initial water column.

4. EXPERIMENTAL RESULTS

Thirty-four experiments were conducted, 18 with Geotextile A and 16 with Geotextile B. Of these, 13 were conducted with only water to determine the permittivity of the geotextile while 21 were conducted with sediment.

4.1 Permeability of the Geotextile/Filter Cake System

The permeability of the accumulating filter cake sediment was determined from the final permeability of the geotextile/filter cake system and the permittivity of the geotextile using the equation,

$$K = \frac{z}{\left\{ \frac{z}{K_{sys}} - \frac{1}{\Psi} \right\}} \quad [14]$$

which is the inverse of Eq. [1]. K_{sys} was determined from the rate of water level decline near the end of a test when all of the sediment had accumulated.

Figure 4 Experimental Setup

Figure 5 Settling Tube

Figure 6 Settling Tube Permittivity Measurements

Figures 7 through 9 present typical experimental results compared with theory for three tests. Figure 7 is for Ottawa sand and Geotextile A; Figure 8 is for the fine sand and Geotextile B while Figure 9 is for the Plasti-grit and Geotextile A. The figures show the variation with time of y = the water level in the tube, q = the flow through the system, q_{cum} = the cumulative volume of flow through the system and z = the thickness of the accumulating filter cake. Only theoretical values for z are given since only the final thickness of the filter cake was measured.

Agreement between theory and experiment is generally very good; however, the agreement for Ottawa sand is not as good as for the fine sand and Plasti-grit due to the speed at which the Ottawa sand settled during the experiments. Initially, comparisons were made assuming that the initial sediment thickness was zero; however, the rapidity with which the Ottawa sand settled and the likelihood that it was not completely mixed throughout the water column at the start of the experiment made it necessary to assume an initial sediment thickness. The Ottawa sand settled so quickly that a significant amount accumulated before the first timing interval - in some cases the entire amount in suspension. The fine sand also accumulated relatively quickly while the Plasti-grit, because of its low specific gravity and fine size distribution, accumulated slowest. In plotting the data and theory, several variables were adjusted to give the observed fit: (a) the permittivity of the geotextile (although it was close to the value reported by the manufacturer), (b) the permeability of the filter cake and (c) the initial thickness of the filter cake. For Figure 7 (Ottawa sand), $\Psi = 0.070 \text{ s}^{-1}$, $K = 0.610 \text{ cm/s}$ and $z_0 = 5.80 \text{ cm}$. For Figure 8 (fine sand), $\Psi = 0.05 \text{ s}^{-1}$, $K = 0.0290 \text{ cm/s}$ and $z_0 = 1.52 \text{ cm}$. For Figure 9 (Plasti-grit), $\Psi = 0.050 \text{ s}^{-1}$, $K = 0.0152 \text{ cm/s}$ and $z_0 = 2.13 \text{ cm}$.

Figure 7 Experimental Results for Ottawa Sand and Geotextile A, $\Psi = 0.07 \text{ s}^{-1}$, $K = 0.610 \text{ cm/s}$, $z_0 = 5.79 \text{ cm}$.

Figure 8 Experimental Results for Fine Sand and Geotextile B, $\Psi = 0.05 \text{ s}^{-1}$, $K = 0.029 \text{ cm/s}$, $z_0 = 1.52 \text{ cm}$.

Figure 9 Experimental Results for Plasti-grit and Geotextile A, $\Psi = 0.05 \text{ s}^{-1}$, $K = 0.0152 \text{ cm/s}$, $z_0 = 2.13 \text{ cm}$.

Figure 12 Effect of a Flocculant on Dewatering Rate

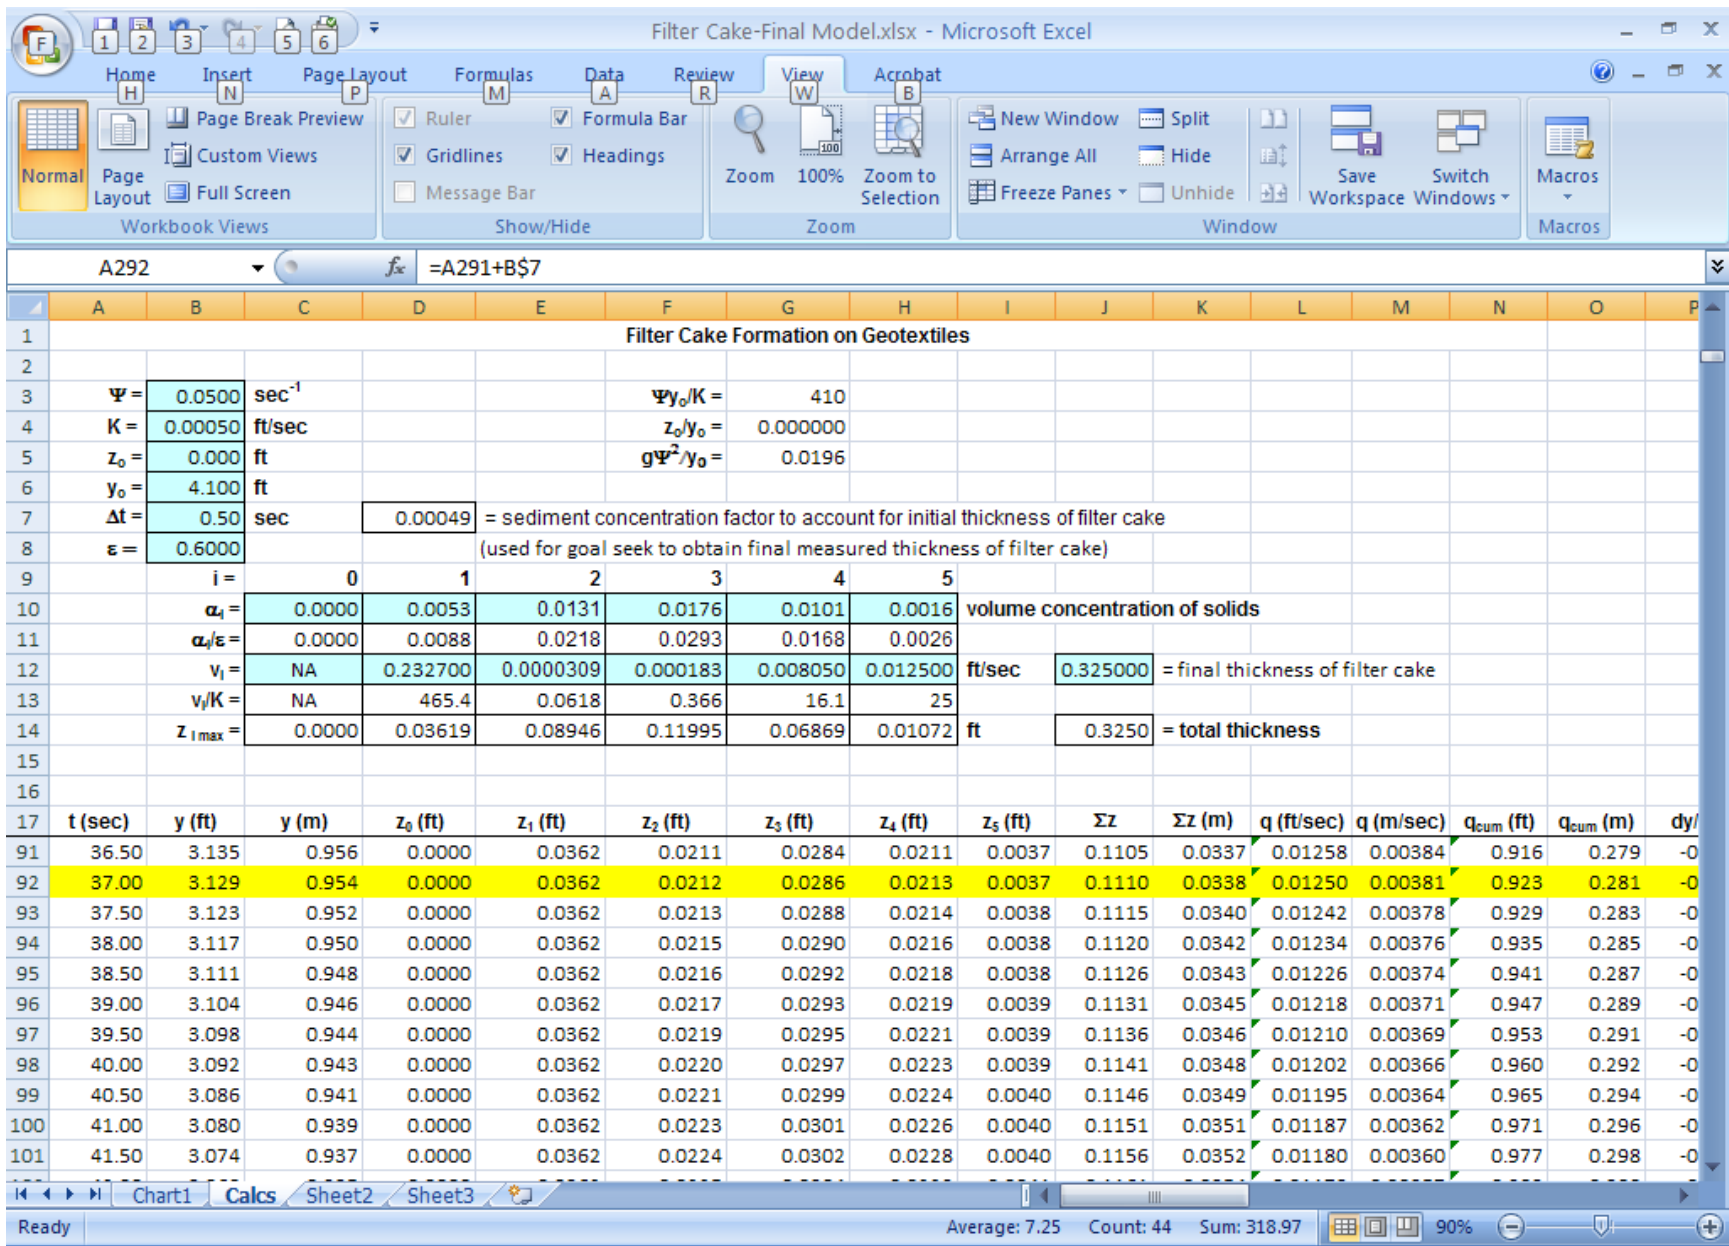

Figure 10 Screen Shot of Excel Program – Plasti-grit Example

5. PARAMETRIC STUDY OF PLASTI-GRIT RESULTS

The Excel model used for Plasti-grit is used here to demonstrate the capabilities of the model. Figure 10 presents a screen shot of the Excel spreadsheet for Plasti-grit. The shaded cells at the top of the sheet are input data. For the example, $\Psi = 0.005 \text{ s}^{-1}$, $K = 0.0005 \text{ ft/s}$ (0.000152 m/s) and $z_0 = 0$. (Figures 2 and 3 present the size distribution for the Plasti-grit and the five components used to characterize it.) Settling velocities shown in cells C12 through H12 were approximated using Eq. 13 (Rubey, 1933).

5.1 Size Distributions in Sediment Layers

The model allows the size distribution of sediments to be determined for various sediment layers. For example, with reference to Figure 10, the cumulative thickness of sediment is given in column J. Between $t = 37 \text{ s}$ and $t = 41.5 \text{ s}$ (rows 92 and 101 of the spreadsheet) the total accumulation of sediment is $0.0352 - 0.0338 = 0.0046 \text{ ft}$ (1.402 mm). The accumulation of size Class 1 (Column E) is $0.0362 - 0.0362 = 0 \text{ ft}$ (0 mm) since this entire size component settled in less than 30 s. The percent accumulation in size Class 2 (column F) is $0.0224 - 0.0212 = 0.0012 \text{ ft}$ (0.366 mm). Similarly the accumulation in size Class 3 (Column G) is $0.0302 - 0.0286 = 0.0016 \text{ ft}$ (0.488 mm), size Class 4 (Column H) is $0.0228 - 0.0213 = 0.0015 \text{ ft}$ (0.457 mm) and size Class 5 (Column I) is $0.0040 - 0.0037 = 0.0003 \text{ ft}$ (0.091 mm). Thus the percent of the total in size Class 1 is 0%, size Class 2 is $(0.0012/0.0046) \times 100 = 26\%$; size Class 3 is $(0.0016/0.0046) \times 100 = 35\%$; size Class 4 is $(0.0015/0.0046) \times 100 = 33\%$ and size Class 5 is $(0.0003/0.0046) \times 100 = 6\%$. These percentages can be compared with the original size distribution given in Table 2. (Class 1 is the coarsest fraction.) Note that the bottom layers of sediment are near the top of the spreadsheet since that accumulate first. For the example, the layer is 0.1110 ft (0.0338 m) above the geotextile.

5.2 Clear Water Interface

A clear water interface will occur in the slurry when the settling rate of the finest sediment component exceeds the rate at which the slurry level is declining. A clear water interface will generally occur for filter cakes with low permeabilities and/or high settling rates. The time when the clear water interface arises can be estimated by calculating the rate of the slurry surface decline, $q = dy/dt$, and comparing it with the settling rate of the finest component of the sediment. When q becomes less than v_i , where v_i is the settling velocity of the finest sediment, the clear water interface appears. The height of the clear water interface at any time can be calculated as the difference between the two velocities q and v_i times the elapsed time.

For the Plasti-grit example of Figure 10, the settling velocity of the finest component is 0.00381 m/s (0.0125 ft/s, cell H12). The rate of slurry level decline equals this velocity when $y = 0.953 \text{ m}$ (3.129 ft, cell B92) and $t = 37.0 \text{ s}$ (cell A92); hence the clear water interface arises at this time. One hundred seconds later, at $t = 137 \text{ s}$ the slurry surface has declined from 0.953 m (3.129 ft) to 0.708 m (2.323 ft) = 0.245 m (0.803 ft) while the clear water interface has declined $(0.00381 \text{ m/s}) \times (100 \text{ s}) = 0.381 \text{ m}$ (1.25 ft) giving the height of clear water as $0.953 - 0.245 = 0.708 \text{ m}$ (3.129 - 0.803 = 2.326 ft).

5.3 Vacuum Filtration

The model can be “tweaked” to yield results if a vacuum is applied downstream of the geotextile to increase the filtration rate. This can be done by artificially increasing the permeability of the system. The effect of applying a vacuum is to increase the head driving the flow without increasing the travel distance of the sediments through the slurry to the filter cake. The vacuum-induced rate of flow can be simulated by increasing the permeability of the geotextile/filter cake system. Since Darcy’s law is linear in head and permeability, the permeability can be increased to simulate an increase in head. Thus,

$$\frac{K_v}{K} = \frac{h_2}{h} \quad [15]$$

where K_v = the “artificial” permeability for the vacuum head (the increased head due to applying the vacuum), h = the actual head without the vacuum, and K = the actual permeability of the system. Letting $h_2 = h_v + h$ where h_v is the added head due to the vacuum,

$$K_v = K \left(1 + \frac{h_v}{h} \right) \quad [16]$$

It is not possible to allocate the increased permeability between geotextile and sediment without assigning a thickness to the geotextile. Fortunately, however, the greatest impedance to flow is usually due to the filter cake. Thus K can be increased assuming Ψ remains the same. This introduces some error at the start of the calculations until a small layer of filter cake

accumulates. (Note that if z/K_v approaches $1/\Psi$ for typical values of z , errors may be substantial. Normally this only occurs at the start of filtration.) For example, using the Plasti-grit model in Figure 10 and applying a vacuum head of 1 meter of water with an upstream head of 1.25 m (4.10 ft) and $K = 0.000152$ m/s (0.0005 ft/s). Applying Eq. 16, $K_v = 0.000152(1 + 1/1.25) = 0.000274$ m/s (0.0009 ft/s). The effect of the vacuum on the flow rate and cumulative flow is shown in Figure 11. The effect is to increase the dewatering rate, q_{cum} , shown as the light colored lines in the figure.

5.4 The Role of Flocculants in Dewatering

Chemical flocculants are often added to slurries to accelerate the dewatering process. Flocculants impact the process in several ways. The permeability of the accumulating floc is usually much greater than the slurry itself hence increasing the rate of flow (Koerner & Koerner, 2010). The rate at which the filter layer thickens increases and its final thickness is greater; however, its porosity and permeability are also greater. The settling velocity of the floc is greater than the original fine particles. Increased thickness decreases the rate of flow but this is compensated for by the increase in permeability. For successful flocculation, the benefit of increased permeability and porosity overcomes the increase in filter cake thickness and results in more rapid dewatering. Consequently, appropriately chosen flocculants accelerate the dewatering process. Figure 12 for the Plasti-grit example illustrates the effect of increasing the porosity from 0.4 to 0.7 (reducing ε from 0.6 to 0.3) and increasing the permeability by one order of magnitude from 0.0005 ft/s (0.000152 m/s) to 0.005 ft/s (0.00152 m/s). The thickness of the filter layer is doubled due to the increase in porosity which by itself would decrease the dewatering rate; however, the increase in permeability results in a net increase in the dewatering rate as shown by the light lines on Figure 12.

6. DISCUSSION & CONCLUSION

The equations describing the accumulation of filter cake on a geotextile were developed and solved numerically using an Excel spreadsheet with an explicit Euler finite difference scheme. The solution considers both a colloidal suspension that is transported to the geotextile by advection and sediments with finite settling velocities. The solution gives the head, discharge, cumulative discharge and filter cake thickness as a function of time. The dimensionless parameters that characterize a solution are $\Psi y_o/K$, a measure of the relative importance of the permittivity of the geotextile to the permeability of the accumulating filter cake, $g\Psi^2/y_o$, a dimensionless permittivity, and the values of α/ε , measures of the contribution of each size class to the filter cake's thickness per unit discharge. The rate of filter cake accumulation depends on the flow velocity (discharge) and the settling velocities of the various particles. The size distribution is considered by selecting a number of particle sizes with different settling velocities and different concentrations to approximate the actual size distribution. Coarser particles form the bottom layers of the filter cake while finer particles accumulate in the upper layers. The model allows the size distribution in the various layers of the filter cake to be determined. (Note that a Runge-Kutta numerical solution may also be used to solve the equations. Such an R-K solution has been developed using Matlab; however, the simpler finite difference Excel/Euler numerical version presented herein gives essentially the same results.)

The solution assumes that the colloidal filter cake material does not pass through the geotextile/filter cake but accumulates on it. Depending on the characteristics of the geotextile, it is likely that some or all colloidal material will pass through it at least initially. However, coarser settle-able components of the filter cake will accumulate first and subsequently retain any colloidal material. Thus, at the start of the process some colloidal and very fine sediment may escape through the geotextile while later the accumulating filter cake will retain the fines. Polymer additives are typically used to flocculate and capture colloidal materials. Experiments with various size materials including colloids are needed to further verify the model and establish its limitations. Furthermore, application of the model to the geometry of the geotextile tubes used for dewatering needs to be explored.

Agreement between the numerical theory and the experiments is very good and indicates the success of the theory and numerical model for describing filter cake accumulation on geotextiles. The experiments also indicate that for fine sediments, such as those usually dewatered using geotextile tubes, the model gives excellent results and indicates that the permittivity of the geotextile is normally of secondary importance; the permeability of the accumulating filter cake dominates the process. For coarse, rapidly settling, highly permeable sediments such as Ottawa sand, the permittivity of the geotextile plays a more significant role, at least at the beginning of the process.

In the experiments reported here, the Plasti-grit most closely approximates the type of sediments dewatered because of its relatively slow setting velocity; however, additional experiments need to be performed with finer, more slowly settling sediments to confirm the theory's validity for them. Also, experiments that measure where and when a clear water interface occurs should be conducted to verify the results of the model; experiments with flocculants and experiments with a vacuum application also need to be conducted.

In the present analysis the permeability of the filter cake has been assumed independent of z . It is likely that as filter cake accumulates its overall permeability will decrease. The upper layers of the filter will have a lower permeability since they will

be comprised of finer materials deposited later in the process. Consequently, K will be a function of z and the size distribution of the materials. Also, the solids fraction, ε , or equivalently the porosity, $1 - \varepsilon$, of the accumulating filter cake has been assumed constant in the present analysis with $\varepsilon = 0.6$. However, the solids fraction will vary somewhat depending on grain shape and grain size distribution. It is, however, independent of sediment size.

Upper Chiquita Reservoir Floating Cover and Liner

Andrew Mills, Layfield Environmental Systems Corp, USA, amills@layfieldgroup.com
Sven Falk, Layfield Environmental Systems Corp, USA, sfalk@layfieldgroup.com

ABSTRACT

The Upper Chiquita Reservoir is a large potable water reservoir located in Rancho Santa Margarita in Orange County California. The reservoir contains 244 million gallons of domestic water and covers an area of 18 acres. The reservoir was constructed on the western slope of the Chiquita Canyon by creating an earthen dam across the canyon. The reservoir is lined and covered with geosynthetic barrier materials with a defined-sump style cover. This case history details the construction of the reservoir lining and cover system including some of the unusual design details caused by the shape and size of the project. The paper also covers the difficulties caused by the excessive rainfall and the solutions to a leakage issue that developed after construction.

1. INTRODUCTION

1.1 Background

The Upper Chiquita Reservoir is a large reservoir that is part of the Santa Margarita Water District in Southern California. The Santa Margarita Water District (SMWD) is the second largest water district in Orange County covering 52,000 acres of land just east of Mission Viejo and San Juan Capistrano. The SMWD provides water to about 155,000 residents and businesses in Mission Viejo, Rancho Santa Margarita, Coto de Caza, Las Flores, Ladera Ranch, and Talega.

All domestic water supplied to the SMWD has to be purchased from outside sources as there are no local water sources. Most of the region's water is piped from the Diemer Filtration Plant in Yorba Linda. In the past few years the district has experienced major supply disruptions with the unplanned break in the district supply pipeline in 1999, and the additional planned outages of the Diemer Filtration Plant in several recent years. Any disruption in water supply was requiring immediate and severe water conservation measures in the district.

Figure 1: Aerial view of the Upper Chiquita Reservoir under construction.

The main purpose of the Upper Chiquita Reservoir was to increase reserve storage capacity to ensure water security to the customers served by the SMWD. The total installed cost for the investigation, design, and construction of the reservoir was \$53 million and was a shared project between a number of local agencies. These agencies included the SMWD, the City of San Clemente, San Juan Capistrano, Moulton Niguel Water District (Laguna Niguel), and South Coast Water District (Dana Point). The reservoir is operated by the SMWD.

2. THE RESERVOIR

Figure 2: Site visit during the construction of the dam.

the lengthy slopes and contained a drain system to monitor leakage for dam safety purposes.

The Upper Chiquita Reservoir is one of the first large emergency potable water reservoirs to be built in Orange County in decades. It has a design capacity of 244 million gallons (750 acre-feet) and has a surface area of approximately 18 acres. The reservoir is of new construction being built into the side slopes of the Chiquita Canyon. The reservoir was formed by constructing an earthen dam across the mouth of a section of the canyon to create a roughly triangular containment. At its deepest point it is 120 feet deep with side slopes ranging from 3 to 1 up to about 2 to 1. The construction of the reservoir began in June of 2009 and was put into service in October of 2011.

The reservoir has a number of interesting details. The first is the depth and the steepness of the slopes. This led to safety concerns during construction and led to problems in removing rainwater during an exceptionally rainy season.

The second issue was the irregular shape of the containment. Designing a defined-sump floating cover on an unusual shape requires some different techniques. In this case a bench was built into the side slopes at the half-way point. This earthen bench provided a flat surface on which to construct the floats and weights that tensioned the cover. The bench also acted as an intermediate anchor for

3. THE GEOSYNTHETICS

3.1 Geosynthetic Under Drain

A geosynthetic under drain was placed as the first layer of material underneath the entire reservoir. This underdrain was placed to monitor the performance of the lining system and to provide drainage during construction. The underdrain also provided drainage for the earthen dam section. The underdrain consisted of a tri-planar double-sided geocomposite. The core of the geocomposite was 300 mil (7.6mm) thick and was sandwiched between two layers of 8 oz/yd² (270 g/m²) non-woven polypropylene geotextile.

3.2 Geomembrane Lining System

The original specification for the primary geosynthetic barrier system (geomembrane) called for the use of a three-ply 60 mil (1.5mm) Chlorosulphonated Polyethylene (CSPE) geomembrane. During the time of construction there were challenges in the supply of CSPE materials and the lining was changed to a flexible polypropylene material in order to get both the lining and the cover materials delivered on time. The final liner material selected was a 60 mil (1.5mm) thick three-ply fabric-reinforced flexible polypropylene geomembrane (fRPP).

Figure 3: Placement of the geocomposite underdrain.

The fRPP materials for the liner were prefabricated prior to installation according to a detailed panel layout. All seams were welded using a 3" wide wedge welder that bonded the materials together edge to edge without leaving a flap of

material at the seams. In order to reduce creases in the lining material the fabricator on this project used a 36' wide winder to create rolls of fabricated materials that did not require any folds in the material. There is some thought that creases in fRPP materials can lead to stress concentrations that can initiate failures. This is especially problematic in thicker materials such as a 60 mil material. By fabricating without folds this particular fabricator was eliminating this area of potential problems.

Figure 4: 36 ft wide prefabricated liner panels

The liner was anchored to the perimeter of the containment using a concrete stub wall and steel battens. This concrete wall went around the entire perimeter.

Once the lining system was in place the entire area was surveyed using an electrical leak location method. Weather problems prevented the reservoir from being installed in a straight-forward fashion and earthworks, lining installation, and cover installation all took place at the same time in different parts of the reservoir. In order to test areas that couldn't be filled with water the leak location survey was performed with the Water Puddle Method (ASTM D7002). In this method a flow of water is delivered to the survey probe which is directed at the liner. The water is swept across the liner surface and penetrates any defects that are present. Contact with the ground below the liner generates a signal that the operator can use to locate the defect.

3.3 Floating Cover System

The Upper Chiquita Reservoir is one of the larger covered reservoirs in California and also one of the most irregular. The irregular shape is a challenge when designing the method in which the cover will rise and fall in response to water level changes. The design of this cover used the "defined sump" method of construction as first described in US Patent 3,991,900 (1976). A defined sump floating cover uses a series of weighted sumps and floats to maintain tension on the cover material as it changes elevation with water movement. The design of the cover layout needs to maintain continuous tension on the cover at all times to prevent wind damage.

The material used for the cover was a Chlorosulphonated Polyethylene (CSPE) three-ply fabric-reinforced 60 mil (1.5mm). During the construction period for this project the primary supplier of CSPE resins chose to close their plant and supplies of the CSPE resin were restricted. This resulted in allocations of resin which would have impacted the construction schedule. There was sufficient available material for the cover but not for the cover and the liner. That led to the change in the liner from a CSPE to an fRPP material. Note that since the time of this project the secondary manufacturers of CSPE resin have increased capacity to meet demand. CSPE has been used for many floating covers in the California area and has a strong performance record. The CSPE for this project was issued with a 30-year weathering warranty.

The cover system was factory prefabricated to match a detailed panel layout prior to deployment in the field. The normal sequence of operations for cover construction is to complete the liner installation and then to start placing the cover. The cover is usually installed over the entire area of the containment before floats, sump weights, and other details are added. In this project the excessive rain forced changes to this sequence. Since the base of the containment could not be kept free of water the liner and then the cover were advanced down the side slopes with the base remaining open. Only when the base was finally dried out could the liner, and then the cover, be completed.

Layout and location of floats and sump weights is usually accomplished on site once the cover panels are installed and tested. A special bench was included in the earthworks of this project to provide a flat area about half-way down the slopes where the main floats and sump weights for the cover could be constructed. Much of the detail work on the cover took place on this bench while the base of the containment was still too wet for construction. Another adaptation to the weather was to transfer the construction of appurtenances back to the factory. This moved a significant amount of the field labor inside when the weather was poor.

The final cover design covered an area of 900,000 ft² (84,000 m²) and included 18 hatches, 71 air vents, and 40 rainwater removal pumps. Once the cover was completed it was inflated with air using fans on the access hatches. Because of the size of this cover it was inspected in sections. Sand bags were used to isolate sections so that each area was inflated in turn. This reduced the risk of damage in the event of unexpected winds. The cover was 100% inspected from the inside for any defects (defects show as pinholes light). Once the cover inspection was completed the air was released and the cover was ready for service.

Figure 5: Plan view of cover system showing location of sump channels. Vents are indicated by black squares.

4. THE PROJECT

The Upper Chiquita Reservoir project had actually been started nearly 20 years earlier as part of the long range plans for the water district. There were a number of sites located that were deemed suitable for a large reservoir and environmental studies were begun. These environmental and planning studies started in the 80's and took many years to work their way through the system until this site was selected and approved for a reservoir.

The design of the reservoir has a number of interesting features. The first is the large earth-fill dam that encloses the canyon to create the containment. This dam is designed for stability in the strong earthquake environment of California. The other noticeable detail is the bench about half-way down the slopes. This bench and a road to access the bench was a design feature to improve access for maintenance. The bench lets the operators reach much of the reservoir surface without having to drain the reservoir completely. Part of the design was a concrete trough over 400 feet long from the top of the slope to the toe of the slope. This trough held the pneumatic lines that were used to operate the valves in the bottom of the reservoir. A final feature of the project was consideration given to the construction of the berms so that the reservoir is not normally visible from the nearby busy highway.

The construction of the reservoir started in the summer of 2009 and progressed well until the winter of that year. The winter of 2009/2010 was very rainy and there were many project delays. The large volumes of water kept the base of the reservoir very wet so that the earthworks could not be completed and the lining could not cover the base of the reservoir. The winter of 2010/2011 was even wetter with one particular week seeing over 10 inches of rain. "The rain gauges overflowed three days in a row" said Bart Lantz, project manager for SMWD. This rain event washed out a portion of the

subgrade underneath the liner and a large section of liner had to be removed and the subgrade repaired. Over 200,000 ft² of liner was pulled back to access this repair area. It took more than a month for the earthworks contractor to dry out the site after this rain event.

Finally after many weather delays and significant effort in repairs the liner and cover were complete. The reservoir went into service in October 2011.

5. LEAKAGE

As soon as the reservoir started to fill there was leakage observed in the leak detection system. The leakage started as soon as the reservoir had been filled to the 2 ft level and increased in intensity as the water head increased. The leak was approximately 90 gallons a minute which was higher than the specified leakage rate for this structure. The reservoir was put into service while the leak was evaluated.

The first steps were to send divers into the reservoir to see if they could spot any obvious leakage. Immediately they detected leakage in the concrete trough area that carried the pneumatic lines to the base of the pond. Using underwater epoxy the divers attempted to stop the leaks however there appeared to be too many leaks to stop effectively with this technique.

Figure 7: Pneumatic tubing in concrete trough

Figure 6: Subgrade damage after a significant rainfall event.

At this point the reservoir was needed in service and the leakage repairs had to wait for a suitable opportunity.

6. REPAIR

The opportunity to repair the reservoir occurred in 2012 when the Metropolitan Water District did a week-long shut-down of the Diemer Filtration Plant. This type of shut-down is precisely why the Upper Chiquita Reservoir was built and it supplied water to the region throughout this time. Once the shut-down was completed the reservoir was at a very low level so this was the opportunity to make repairs.

The reservoir was drained and the cover and the liner were cut back to expose the concrete trough. The trough was completely filled with additional concrete and then matched to the surrounding the subgrade. The geocomposite and liner materials were then extended over this sealed trench. The operators of the facility were concerned about the maintenance implications of sealing the pneumatic lines in concrete so a secondary set of pneumatic lines were placed on top of the liner in case they are needed in the future. The facility will operate with the encapsulated pneumatic lines until they malfunction and then a diver can switch the lines over to the newer lines on top of the liner using valves in the reservoir. Once the new lines were completed the cover was repaired and the reservoir brought back into service.

Since the repair the leakage rate fallen to between 9 and 10 gallons per minute which is within the design limits for a project of this size.

7. CONCLUSION

The Upper Chiquita Reservoir is the culmination of a long range plan to ensure water security to Santa Margarita Water District and area users. The reservoir is operating as designed and is not experiencing any further issues. The reservoir is an excellent example of a large covered potable water reservoir typical of the California area.

The Use of a Concrete Composite for a Boat Ramp Extension

John Paulson, P.E. – DISON C & S, LLC, Alpharetta, GA USA, Johnp@rediengineering.com
Rich Pilston - Milliken & Company, Spartanburg, SC USA, Rich.Pilston@Milliken.com

ABSTRACT:

A boat ramp for a recreational lake had outlived its useful life. Constructed in the 1970s this ramp was no longer adequate for the larger and longer boats and recreational craft using the facility in the 21st century. Longer boat trailers would drop off the end of the ramp, requiring specialized equipment to lift and remove trapped trailers. Additionally, the recent drought had magnified the problem with the resulting lower lake levels.

The City had addressed the problem in past years by simply dumping gravel at the ramp end. This solution was temporary, as the gravel would eventually be pushed away from the end of the ramp and build up down below the ramp end. This required frequent maintenance (re-grading the gravel and filling with additional gravel) on an ongoing basis.

As a result, the City began investigating permanent alternatives to solve this problem. The City intended to perform this extension effort using a portion of a state grant. A Geosynthetic Concrete Composite Mat (GCCM) was used to extend the ramp without dewatering.

1. BACKGROUND:

The East Fork Lake in the City of Olney, IL, is a significant recreational draw for boating and fishing enthusiasts. The lake has only one public access boat ramp, which was built in the 1970's to accommodate small fishing boats and recreational watercraft. Over time, as recreational and fishing boat sizes increased, the city found that the ramp was not long enough to accommodate longer boat trailers, especially when water levels in the lake dropped. (Figure 1)

A Conventional solution considered required the construction of a temporary dewatering cofferdam, then construction in the dry. Bids from contractors revealed the cost was in excess of the grant funds provided by the State of Illinois. Faced with a spiraling cost above the grant amount, the city searched for an alternative solution that could be constructed within the budgeted amount. The Geosynthetic Concrete Composite Mat option was identified as an alternative to the conventional approach.

Figure 1 – Boat ramp

2. LITERATURE REVIEW

The published literature was searched to determine past practices in boat ramp construction and enhancement. The following was found.

- a. Design of recreational areas and Facilities – Access and circulation – This engineering manual was developed by the US Army Corps of Engineers and discusses boat ramp construction. Section 4.1 refers to ramps for Existing impoundments stating: “Where additional ramps are required for existing impoundments and it is not feasible or economical to permit construction in the dry, ramps may be constructed on a bank and shoved into the water on a temporary base course.” A figure follows with details of this cast then shoved into place solution. This option was not considered during the evaluation phase.
- b. Extension kits are also a solution, but primarily for temporary extensions that were not considered. Several companies offer these, which consist mainly of parallel rails that are deployed so the boat may be deployed. (Roll N Go website)
- c. Mississippi Agricultural and Forestry Equipment Station publication – describes several means of boat ramp extension including the use of both cast in place and push slabs options. Little detail is provided.

The city of Olney selected two alternatives for further consideration as detailed below.

3. RAMP EXTENSION OPTIONS CONSIDERED:

3.1 Extend the Ramp with Additional Poured Concrete (Dewatering and Casting in the Dry Condition).

The City solicited bids for extending the ramp with poured concrete. This approach required that the contractor build a cofferdam, dewater the area around the ramp, build forms and pour the concrete in the dry, and then allow the concrete to cure for 1-2 weeks. The result would close the lake for 2-3 weeks at a minimum (with the potential for a one-month closure). Bids for this work ran approximately \$58,000, far exceeding the grant budget.

3.2 Extend the Ramp with a GCCM (Construct in the “Wet”).

An alternative approach was to extend the ramp with a prepared gravel bed, capped by a layer of GCCM to provide the hard, trafficking surface, and to protect the prepared gravel subgrade. This approach was estimated to take ~1-2 days to place the composite with the direct material costs expected to be ~\$7,000. With two days of surface contractor (excavator) work and one day of underwater contractor work, the approach appeared to be less costly than extending the ramp with poured concrete, especially since the work could be done under water. In addition, it was expected that the lake would be open within ~1 week of starting the project.

4. DECISION:

The City of Olney chose to extend the ramp using the Geosynthetic Concrete Composite Mat. This would reduce the time the ramp had to be closed, and was estimated to be less costly. The comparison of the two alternatives is listed below.

APPROACH USING COFFERDAM - DEWATERING, FORMING & POURING CONCRETE IN THE DRY	APPROACH USING CONCRETE CLOTH COMPOSITE ALTERNATIVE PERFORMED UNDERWATER
Time the ramp would be closed: 2 weeks	Time the ramp would be closed: 1 week
Cost of dewatering and construction in the dry: \$58,000	Cost of dewatering and construction in the wet: \$27,000

The attached figures 5 and 6 presented after the conclusions show the cross section and plan view of the existing ramp.

5. DESIGN CONSIDERATIONS:

Design considerations were driven by the need to provide a flat, hard underwater surface for the far end of boat trailers when dropping and retrieving boats launched. Note that the beginning of the GCCM extension occurred when the existing boat ramp was under about 1.2m of water. As such, high loads from the trailers were not expected. Regardless, the use of the CC13 material, the thickest of the GCCM product offerings was deemed sufficient to support the required loads.

Properties of concrete cloth composite, CC13				
<i>Thickness</i>	<i>Compressive Strength</i>	<i>Weight (unset)</i>	<i>Roll Width</i>	<i>Roll Length</i>
13 mm	>40 MPa	19kg/sm	1.1 m	6.7 m

6. THE GEOSYNTHETIC CONCRETE COMPOSITE MAT PRODUCT:

The GCCM material is a three dimensional fiber matrix into which specially formulated dry concrete mix is placed. This material hardens upon hydration to form a high strength fiber reinforced protection layer. Product compressive strengths of over 40 MPa are achieved once hydration is complete. (See Figure 2)

Figure 2 - Samples of Hardened 5mm, 8mm and 13mm thick GCCM, with fabric side showing (side with PVC attached is down).

7. CONSTRUCTION PLANNING:

The project consisted of three elements:

- the earthwork contractor and earthwork construction (including the divers),
- the Geosynthetic Concrete Composite Mat supplier, Milliken & Company, and
- design and drawings by the city engineer, Roger Charleston, P.E., of Charleston Engineering.
-

The Olney City engineer and Milliken staff developed this unique installation plan which is depicted in the attached figures.

8. INSTALLATION:

Day 1 - Site Preparation took one day to complete, and consisted of excavation and removal of the old stone and muck from past the end of the ramp, and grading to the final grades determined for the new extension. This excavation was performed in the wet, with the excavated material removed from the site. This was followed by deposition of stone backfill beyond the end of the ramp, out to the fullest extent of the new ramp extension, about 6 meters. The contractor used a long reach backhoe for this preparation work, necessitated by the need to reach some 12 meters into the lake.

Day 2- Divers arrived in the morning and inspected the underwater grading. They directed the contractor to place and spread additional stone to achieve a reasonably smooth, consistent surface. Concurrently, the GCCM, prefabricated into 6.5 meter long custom-length rolls, was fastened side by side to form two 5 meter wide panels. Panel fabrication consisted of hog ringing adjacent panels at approximately .5 meter centers down the 6.7 meter length of roll. The completed panels were then clamped at the leading edge with C clamps using 5 by 50 cm lumber on each side of the leading edge for support, and attached to the bucket for deployment (See Figure 3).

Figure 3 – Leading Edge Fabrication Concrete Cloth Composite

The backhoe then walked down the ramp dragging the panel with it and out into the lake for final placement (Figure 4). Divers assisted in the panel placement and guided the operator. Once the panel was positioned in the correct location with .3 meter of overlap with the existing concrete ramp, a second roll of GCCM was laid transverse to the ramp direction, bridging the junction between the existing concrete and the stone base. This was another support layer for this location.

Finally, a galvanized hold down bar was bolted underwater to the existing concrete ramp effectively holding down the two layers of GCCM and affixing them to the existing slab.

Once the installation was completed, sandbags were placed along the edges to confine the roll edge during the curing process. The sandbags were removed the following day. This process was repeated for the two sides of the boat ramp. Complete installation of both sides was accomplished by about 3:00 pm on day two.

Figure 4– Panel Installation Concrete Cloth Composite Mat

9. CONCLUSIONS:

The challenge of extending an old boat ramp was met using a Geosynthetic Concrete Composite Mat solution. The ability to fabricate a panel and then install it underwater without the cost and construction time that a dewatering construction required drove the decision by the city staff.

This option utilized a Geosynthetic Concrete Composite Mat product that cured underwater and accomplished the objective of ramp extension in two days using conventional construction equipment at half the cost of the conventional alternative.

ABSTRACT

Polyacrylamide-based (PAM) conditioners have become an essential component of the geotextile tube dewatering processes. These conditioners act as flocculants, binding fine sediments through charge neutralization and particle bridging, resulting in faster dewatering rates and greater retention of fines and contaminants. Recently, however, momentum has begun to shift towards the use of sustainable materials. Natural polymers, such as starch and chitosan, are increasingly being tested as an attractive alternative to synthetic polymers. Researchers have identified a number of natural flocculants, polysaccharides and polysaccharide derivatives in particular, as candidates for dewatering applications. In this study, the dewatering performance of four cationic starch-based polymers with degrees of substitution ranging from 0.3% to 0.9% and molecular weights ranging from 4.6×10^4 to 6.9×10^4 g/mole were compared with four cationic acryl-amide based polymers. The synthetic polymers were selected among several synthetic cationic polymers and proved to be very effective in flocculating Tully fines. The optimum dose for each polymer was determined and compared and pressure filtration tests (PFT) were used to determine and compare retention and dewatering indices, such as dewatering rate and filter cake solids content. Furthermore, centrifuge tests were performed to determine the compressibility of the filter cakes. The test results showed that the dewatering properties of the slurries conditioned with starch based polymers are comparable to those conditioned by synthetic polymers. Further, the degree of substitution in starch polymers plays a significant role in minimizing the optimum dose. The optimum dose of starch polymers (~500 ppm for 33% solids) was about 5 times that of the synthetic polymer (~100 ppm for 33% solids). These findings were echoed in the centrifuge tests, the results of which were found to be in agreement with the PFT results.

1. INTRODUCTION

Polyacrylamide-based flocculants have become an essential component of the geotextile tube dewatering process. Depending on their molecular weights and the charge densities, the critical characteristics of polyacryl-amide (McLaughlin and Bartholomew 2007), flocculation of fine particles may occur by polymer bridging, charge neutralization, polymer-particle surface complex formation and depletion flocculation, or by a combination of these mechanisms (Nasser and James 2006). This can result in faster dewatering rates and better retention of fines and contaminants (Maurer et al. 2012).

Flocculants can be categorized according to their charge type. Positive charge carrying polymers are cationic, negative charge polymers are anionic, and polymers with no charge are non-ionic. Cationic polymers are more commonly used as flocculants for a wide variety of soils when compared to anionic and the non-ionic polymers due to the negative nature of soils and colloids. However, several studies (Satyamurthy and Bhatia 2009, Koerner and Koerner 2010, Maurer et al. 2012) have shown that anionic and cationic polyacryl-amide based polymers can be successfully used in geotextile tube dewatering projects. Further, these studies showed that polymer conditioning yielded significant improvements in dewatering time and fines retention. Moreover, additional studies have shown that polyacrylamide polymers are also very effective in dewatering wastes other than soils, such as municipal wastes (Fowler et al. 2005) and fly ash wastes (Maurer et al. 2012, Khachan et al. 2012). Although PAM based polymers have succeeded in dewatering high water content slurries, concerns regarding the safety of synthetic polymers, including their non-biodegradability, aquatic toxicity (Letterman and Pero 1990), and the potential risks associated with toxic residual monomers due to additives and incomplete synthesis (Semsar et al. 2007), should be addressed. By contrast, starch-based polymer derivatives are biodegradable and their degradation intermediates are harmless to humans and the environment. Additionally, cationic starch polymers are believed to be effective flocculants over a wide range of pH (Brostow et al. 2009); they are non-toxic and can be used to treat organic and inorganic matter in negatively charged wastewater (Heinze et al. 2004; Pal et al. 2005). Furthermore, natural polymers are

less expensive and do not depend on non-renewable resources (Sharma et al 2006). Therefore, this research investigates natural polymers, such as starch, as an alternative for dewatering applications.

The current study builds on previous studies that demonstrate the viability of using starches for flocculation. For example, Oelmeyer et al. (2002) studied the systematic optimization of dual flocculant systems using cationic starches and various polymers on dredged sediments and found that the starches were economically competitive with synthetic alternatives. Further, Semsar et al. (2007) compared cationic starch to synthetic PAM polymers as flocculants for harbor sludge. Five different cationic starches were characterized by their flocculation and turbidity measurements, in addition to conducting zeta potential measurements. The flocculation and dewatering measurements demonstrated that synthetic cationic flocculant PAM can be substituted by cationic starches. Finally, Wang et al (2010) used starch-based cationic copolymer flocculant to flocculate wastes obtained from gas and oil exploration projects. According to Wang et al., starch-based polymer yielded better flocculation results than several commercially available synthetic polymers. Although these studies showed that starch-based polymers were successfully used as flocculants, studies in this field are still limited; none of the studies explored the behavior of starch polymers in geotextile tube environments. Moreover, the effect of starch polymers on dewatering time, floc structure, and filter cake strength has not been addressed.

Geotextile tube researchers (e.g., Moo-Young et al., 2002; Liao and Bhatia, 2005; Satyamurthy and Bhatia, 2009, Khachan et al. 2012) have found that filter cake properties such as floc structure and compressibility, not the geotextile properties alone, ultimately control dewatering performance. They have thus concluded that understanding the filter cake structure is critical to improving performance. Given these findings, it is believed that changes to the floc structure and related changes to the filter cake will positively impact the overall success of geotextile tube dewatering, including improvements in the dewatering rate, final solids content, retention of fines, and total volume of retained material in the geotextile tube.

This study evaluated the effects of differing polymer molecular weights, charge densities, and dosage variations on dewatering performance. Four cationic polyacryl-amide based polymers and four cationic starch based polymers were used to evaluate the dewatering performance of Tully fines along with a high strength woven geotextile typically used in geotextile tube dewatering projects. The optimum doses were determined by jar tests and preliminary pressure filtration tests. Determining optimum doses is important due to the negative effect of over-dosing and under-dosing for dewatering projects (Satyamurthy and Bhatia 2009, Khachan et al. 2010). Furthermore, centrifuge tests were performed to determine the effect of polymer properties on the compressibility of the filter cakes. The compressibility of the filter cake is a major concern in this study due to its direct impact on dewatering time and the final volume of solids in the geotextile tubes. Pressure filtration tests (PFT) were also performed to determine and compare dewatering indices, such as filtration efficiency (FE), dewatering efficiency (DE), fines retention, dewatering rate, and filter cake solids content (PS). The dewatering indices were determined for slurries conditioned with polyacryl-amide, starch- based polymers, and for unconditioned slurries.

2. MATERIALS

2.1 Tully Fines

Tully fines were obtained from Clarks Gravel Pit in Tully, NY. The soil is wet sieved through No. 200 standard US sieve. The fine fraction ($d_{85} = 0.062$ mm) is collected and oven dried. Hydrometer analysis showed that Tully fines have about 7% clay size particles and 93 percent silt size particles. Tully silt fines classify as silt (ML), as per ASTM D2487. Tully fines have a liquid limit (LL) of 23.6, plastic limit (PL) of 21.2, and Plasticity Index of 2.4. Figure 1 shows the particle size distribution of Tully silt fines.

Figure 1. Particle size distribution.

2.2 Geotextile

High strength monofilament woven geotextile (W1) made of polypropylene (PP) was used in this study, a geotextile commonly used in geotextile tube dewatering applications. W1 has an apparent opening size (AOS) of 0.25 mm. Table 1 shows the physical and hydraulic properties of the geotextile.

Table 1. Geotextile physical and hydraulic properties as obtained from the manufacturer.

Geotextile Properties	W1
Polymer Type	PP ¹
Fabric Structure	W ² , MF ³
AOS ⁴ (mm)	0.42 (0.25 ⁵)
Permittivity (s ⁻¹)	0.37
Mass per Unit Area (g/m ²)	585
Thickness (mm)	1.04
Tensile Strength (kN/m)	96x70

¹PP: polypropylene; ²W: woven; ³MF: monofilament; ⁴AOS: apparent opening size; ⁵According to Khachan et al. 2012

2.3 Polymers

Four commercially available cationic polyacryl-amide polymers with varying charge densities and molecular weights were selected from sixteen different cationic polymers known to be the most effective flocculants for Tully fines based on turbidity analysis. Additionally, four commercially available starch-based cationic polymers were also selected to compare their flocculation efficiency to synthetic polymers. The cationic starch polymers have varying charge densities, but similar molecular weights. Polymacryl-amide based polymers are dry powders that need to be dissolved in de-ionized water in order to be used for flocculation. The synthetic polymer concentration in this study is 0.25% polymers by mass. Starch-based polymers are prepared by placing the starch in a boiling water bath at 3% concentration by mass, except for N1, which is prepared by mixing in cold water. Table 2 shows a list of the polymers used in this study along with their properties.

Table 2. Polymers types and properties.

3. TEST METHODS

3.1 Supernatant Turbidity Test

The optimum doses of polymers were determined through turbidity tests. In this test, 500 ml of slurry at concentration of 5% by mass is added to a 500 ml graduated cylinder. 5% concentration by mass was selected to allow for visual observation of the flocculation of the fine particles. Polymers are then added in increments and the cylinder is manually inverted and rotated to assure the complete mixing of polymers and slurry. The turbidity of supernatant at each dose is measured using a turbidity meter (Hach 2100N Turbidimeter). The turbidity was measured for samples that were taken from the middle of the cylinder after allowing 2 min of settling time. The dose versus turbidity is then plotted and analyzed, and the optimum dose is estimated to be the lowest possible dose that yields minimum turbidity.

3.2 Centrifuge Test

The strength and compressibility of the filter cake can have significant effects on dewatering time and the geotextile tube solids content. Filter cakes with high compressibility are susceptible to decrease in their dewatering ability due to the decrease in void volume. In this study, filter cake compressive yield stress measurements were made using a batch centrifuge (Ample Scientific S-50D) with 4 x 50 ml swinging bucket rotor. The polycarbonate centrifuge tubes used in these measurements held 50 ml and had a diameter of 29.3 mm. The diameter of the tube was maximized to limit side friction in accordance with the findings of Green and Boger (1997). Rotational speeds in the range of 300-1000 rpm were used in

accordance with Glover et al. (2004), giving centrifugal accelerations of 10-140g. Centrifuge tests were conducted at slurry samples with 33% solids content by mass (15.8 % by volume) in order to determine the change in solids volume fraction (ϕ) and the compressive yield strength ($P_y(\phi)$). The solids volume fraction represents the packing of solids under the effect of applied pressure (centrifugal force), and the compressive yield strength ($P_y(\phi)$) is the force needed for a certain volume fraction to be compressed into a denser network. Therefore, when the applied pressure exceeds the yield stress of the network at the original volume fraction, the network collapses to a denser concentration that has sufficient strength to carry the applied load (Eckert et al. 1996). Buscall et al. (1987) defined $P_y(\phi)$ and ϕ and as follows:

$$P_y(\phi) = (\rho_p - \rho_f) h_0 \left(1 - \frac{h}{2R}\right) \quad [1]$$

and

$$\phi = \frac{\rho_f h_0 \left[1 - \left(\frac{h + s}{2R}\right)\right]}{(h + s) \left(1 - \frac{h}{R}\right) + \frac{h^2}{2R}} \quad [2]$$

Where:

P_y	=	Compressive Yield Strength (kPa)
ϕ	=	solid volume fraction
ϕ_0	=	initial solid volume fraction
$\rho_p - \rho_f$	=	difference in density between the particle and fluid (g/cm^3)
g	=	centrifugal acceleration ($g = \omega^2 R$)
h_0	=	initial sediment bed height (cm)
h	=	equilibrium sediment bed height (cm)
R	=	distance between the center of the centrifuge and bottom of sediment bed (cm)
s	=	$\frac{dh}{d \ln(g)}$

3.3 Pressure Filtration Test

The Pressure Filtration Tests (PFTs) were used to simulate geotextile tube dewatering in the lab. The PFT consists of a cylindrical reservoir (72 mm diameter and 170 mm tall) holding 600 mL of slurry and a threaded base plate that secures the geotextile specimen and directs effluent flow. For the test, 575 mL of 33% by mass solids slurry was mixed using a jar test apparatus for 180s; optimum doses were then added to the slurry mix. The slurry was mixed in manual rotational movement to assure flocculation of the soil. The flocculated slurry was then immediately transferred into the testing apparatus. A top cap with pressure inlet was secured atop the testing chamber with pressure applied at 34.5 kPa using a lab supply of compressed air. This pressure is representative of the internal pressure during geotextile tube dewatering (Gaffney 2001; Moo-Young et al. 2002). Volume measurements of the effluent were taken frequently for the first 10 to 15 minutes and additional readings were taken at 5 minute intervals. Upon completion of the test, percent solids retained, flow rate, filter cake strength, and the soil piping were evaluated. A photograph and schematic of the PFT apparatus are shown in Fig. 2.

Figure 2. Pressure filtration test setup.

4. RESULTS AND DISCUSSION

4.1 Optimum Dose Analysis

The optimum doses needed to flocculate Tully fines were determined from the supernatant turbidity versus polymer dose curves of the synthetic and natural polymers. Figure 3 (a, b) presents the turbidity versus dose curves for the eight polymers used in this study. Figure 3(a) shows that the four synthetic polymers yielded relatively similar behaviors and reached turbidities as low as 15 NTU at doses between 20 and 40 ppm for slurries with 5% solids content. On the other hand, the starch-based polymers, as shown in Figure 3(b), were also able to yield turbidity values as low as 15 NTU. However, it required a minimum of 40 to 120 ppm dose, which is two to three times higher than the dose obtained from the synthetic polymers. Moreover, Figure 3(a, b) shows that over-dosing of synthetic and of starch-based polymers leads to an increase in turbidity, which is demonstrated by the U-shape curves in the figure. Therefore, the optimum dose from the supernatant turbidity method does not give a clear cut result for the optimum dose value, but it gives a dose range where polymers are yielding minimum turbidity values.

Figure 3: Turbidity versus dosage.

The dosing results obtained from the turbidity tests were used to determine the optimum dose needed in dewatering applications. Since this method yielded varying dosage ranges for the two types of polymer groups, preliminary pressure filtration test were conducted to determine the required dose for successful soil retention in a dewatering performance test. The initial doses were selected to correspond with a turbidity value of 15 NTU for all the polymers. The doses were determined for soil slurry at 5% and 33% solids concentrations, where a linear relationship is found between polymer dose and slurry solids concentration. The determined doses at 33% fines concentration were used to flocculate soil slurries; the test was then repeated with higher doses until successful soil retention (minimum soil loss) was obtained. For most of the tests, the optimum doses were higher than the minimum dose that gives a turbidity of 15 NTU. Table 3 shows the comparison between the minimum doses that yielded low turbidity and the optimum doses obtained from preliminary PFT.

Table 3. Optimum doses determined from different tests at 5% and 33% solids concentration.

Polymer Type	Turbidity method (concentration = 5%) (ppm)	Turbidity method (Concentration = 33%) (ppm)	Optimum dose from PFT (Concentration = 33%) (ppm)

N3	100	660	1180
N4	36	240	530

As can be seen in Table 3, the optimum doses determined from PFT were generally higher than the minimum dose that yielded low turbidity values. This indicates that performance tests are necessary to determine the optimum doses needed in application. Furthermore, Table 3 shows that synthetic polymers S1 (very low charge density and high molecular weight), and S4 (very high charge density and low molecular weight) yielded similar and the highest optimum doses, while S2 (high charge density and high molecular weight) and S3 (high charge density and medium molecular weight) yielded the lowest optimum dose. For the natural polymers that have almost equal molecular weights to each other (see Table 2), the increase in charge density helped in decreasing the optimum dose needed for dewatering tests. Therefore, such comparisons show that polymers properties play an important role in determining the dose necessary for successful fines flocculation and retention.

4.2 Compressive Yield Strength of Filter Cakes

The previously determined optimum doses from PFT were used to perform centrifuge test on Tully fines slurries at 33% fines concentration in order to measure filter cake compressibility and compressive yield strength. Since the permeability of the filter cakes decreases with the increase in compressibility of filter cake, performing the centrifuge test allowed for better understanding of filter cake strength and dewatering behavior in geotextile tube dewatering applications. Equations 1 and 2 were used to determine the compressive yield strength $P_y(\phi)$ and the solid volume fraction (ϕ). Figure 4 presents the soil volume fraction (ϕ) versus compressive yield strength of the filter cake $P_y(\phi)$ results.

Figure 4: Volume fraction versus compressive yield strength.

Figure 4 shows that the centrifugal pressure that was applied to unconditioned (control) and polymer conditioned slurries yielded varying resistance to compressibility for all the tested samples. For example, the control sample needed a pressure as low as 2 kPa to yield and reach solid volume fraction of 0.47, while at the same pressure the slurries conditioned with synthetic polymers had solids volume fraction ranging from 0.27 to 0.33 only. On the other hand, the samples conditioned with starch polymers reached volume fraction ranging from 0.35 to 0.40. This indicates that the samples conditioned with synthetic polymers are more resistant to compression than natural polymers. However, both synthetic and natural polymers were more resistant to the external compressive pressures than the control sample. The same trend was noticed for all $P_y(\phi)$ values that ranged from 2 to 35 kPa. Therefore, synthetic and natural polymers filter cakes were able to resist applied loads as high as 35 kPa while they still have less packed floc structure than the control sample. This indicates that they can attain larger void ratios which allows for higher permeability in the filter cake. The results obtained of centrifuge test can be further studied by comparing them with the dewatering indices obtained from pressure performance tests.

4.3 Dewatering Indices

The dewatering performance of Tully fines conditioned with synthetic and starch based polymers were evaluated by performing PFT. The dewatering rate, dewatering indices such as filtration efficiency (FE) and dewatering efficiency (DE),

and filter cake properties such as the solids content, water content, and height can also be determined from PFT. Figure 5 shows the dewatering time versus effluent volume obtained from the eight polymers in this study.

Figure 5: Dewatering time versus effluent volume

The PFT tests results showed that all starch-based polymers resulted in slower dewatering rate than the synthetic polymers, but the difference was not significant except for polymer N1, which has a very low charge density and medium molecular weight. Synthetic polymers yielded a dewatering rate that was 12 times faster than the unconditioned sample, and the starch based polymers had a dewatering rate six times faster than the unconditioned sample. These conclusions agree with the results obtained from centrifuge testing. Centrifuge test results showed that all tested slurries that were conditioned with synthetic polymers are more resistant to compression because they have smaller solid volume fraction and larger void ratios than all the ones conditioned with starch polymers and the control sample. This trend can be observed in Figure 5, where synthetic polymers yielded the lowest dewatering time (~15 min), starch-based polymers allows for relatively close dewatering time (~35 min) to that of the synthetic polymers, and the control sample shows significantly higher dewatering time (~150 min). Therefore, it is believed that the centrifuge test can be a useful tool to assess the effect of polymers on filter cake properties and dewatering performance.

Moreover, PFT results were used to determine filter cake properties and dewatering indices for the eight polymers as shown in Table 4. Filter cake properties such as filter cake height and water content were determined after the completion of the PFT, and dewatering indices include FE, DE, and PS and can be defined as follows.

$$FE = \frac{TS_i - TSS_f}{TS_i} \times 100(\%) \quad [3]$$

$$DE = \frac{PS_f - PS_i}{PS_i} \times 100(\%) \quad [4]$$

$$PS = \frac{W_s}{W_T} \quad [5]$$

Where:

TS_i : initial total solids (g/l)

TSS_f : final total suspended solids in the filtrate (g/l)

PS_i : initial percent solids of the slurry by weight (%)

PS_f : final percent solids of the retained material by weight (%)

W_s : weight of retained solids (g)

W_T : total weight of the filter cake before drying.

Table 4. Filter cake properties and dewatering indices.

Polymer	Ch ¹ (mm)	Cw ² %	Piping g/m ²	FE	DE	PS
S1	55	52.5	118	99.8	100.7	66.2
S2	58	55.1	95	99.9	101.2	66.4
S3	65	62.9	450	99.1	91.3	63.1
S4	68	71.1	780	98.8	87.3	61.8
N1	41	36.1	651	98.9	134.4	78.1
N2	49	41.5	677	98.8	115.9	71.2
N3	44	39.2	1040	98.3	125.6	74.7
N4	43	37.8	651	98.9	128.3	76.3
No Polymer (Control)	40	28.2	6238	78.9	125.3	83.2

¹Ch: Filter cake height; ²Cw: Filter cake water content

As is shown in Table 4, the filter cake heights for the samples conditioned with synthetic polymers were 35% to 65% higher than those conditioned with starch-based polymers. The same conclusion can be applied to the water content of the filter cakes. These results are in agreement with the results obtained from centrifuge test showing that the filter cakes conditioned with synthetic polymers are less compressible than those conditioned with starch polymers and the control sample, yielding larger filter cake heights and higher water contents. Moreover, starch-based polymers allowed for higher DE values indicating that the filter cakes with higher DE hold less water and have higher solids content (PS) and thinner filter cakes. Therefore, starch-based polymers allow for more fillings of the geotextile tubes, which can help in decreasing dewatering costs. Piping, on the other hand, was not significant in any of the conditioned samples where the maximum piping amount of 1040 g/m² was only 1.5% of the initially tested solid amount. For FE, it was almost equal for all the tested polymers, which indicates that both the natural and the synthetic polymers successfully retained the soil particles.

The PFT results indicate that cationic starch polymer is comparable to synthetic polymers for use in dewatering high water content slurries. Furthermore, although synthetic polymers yield faster dewatering rate, the cationic starches allowed for more compressible filter cakes, higher dewatering efficiency, and higher filter cake solids content.

To further assess the validity of starch polymers in dewatering applications, this study will be extended to include flocculation and dewatering properties of soils that have high organics and clay contents. Furthermore, due to the significant effect of polymers properties on dewatering performance, future work will include testing starches with varying ranges of molecular weights and charge densities.

5. CONCLUSIONS

A total of 72 turbidity, centrifuge, and PFT tests were conducted using four PAM-based polymers, four starch-based polymers, Tully fines, and woven geotextile (W1). The tests were conducted to determine polymers optimum dosage, filter cake strength and compressibility, and dewatering properties. The optimum dose was verified by performing centrifuge tests and PFTs. Based on the results of this study on Tully fines, the following conclusions can be drawn:

- Polymers properties such as molecular weights and charge densities have significant effects on the dose amounts and on overall dewatering performance.
- The supernatant turbidity test allows for determining the minimum dose for separating fine soils from water. However, such doses were found to be slightly less than the optimum dose needed for dewatering applications.
- Centrifuge tests allows for determining the compressibility and strength of the filter cake which cannot be determined from PFT. Moreover, centrifuge test proved to be successful in predicting the filter cake behavior in dewatering applications, where less compressible filter cake allowed for higher dewatering rate and vice versa.
- Tests results showed that cationic starch polymers yielded a thinner filter cake and higher solids content. Additionally, PFT results showed that the dewatering time decreased from 150 minutes for the unconditioned sediments to about 15 minutes and 35 minutes for the synthetic and natural polymers respectively.
- Generally, the performance of the cationic starch polymer was comparable to that of the synthetic polyacrylamide polymer, indicating good potential for future use in geotextile tube dewatering applications.

ACKNOWLEDGEMENTS

This study was supported by the National Science Foundation (NSF) (CMMI 1100131), Geosynthetic Institute (GSI), and Wen-Hsiung and Kuan-Ming Li Graduate Fellowship of Syracuse University. The authors would like to thank P. Kaye and V. Ginter of TenCate for providing geotextiles, D. Hunter of BASF Corporation for providing the synthetic polymers flocculant, and National Starch Company for providing the cationic starch-based polymers. The authors would also like to thank Prof. Bandaru V. Ramarao for his contribution to this paper.

Time-dependent Impact of RECPs on Surface Water Quality

J.L. Smith, Sustainable Construction Management and Engineering, SUNY College of Environmental Science and Forestry, Syracuse, NY, USA

S.K. Bhatia, Civil and Environmental Engineering, Syracuse University, Syracuse, NY, USA

ABSTRACT

Geosynthetic rolled erosion control products (RECPs) are often used by engineers to manage and protect surface water quality by providing ground cover protection for bare soil slopes and channels. Although many studies have been published documenting the successful use of RECPs in reducing soil losses, few studies have considered the contributions of RECPs to protecting surface water quality in terms of the turbidity of runoff over time. Knowledge of runoff turbidity is important because it is commonly used by regulators to assess the effectiveness of best management practices (BMPs) and downstream surface water quality. This paper presents the results of a laboratory rainsplash study that compares runoff turbidity for three different RECPs (coconut, straw, and wood excelsior) over time. This paper demonstrates that turbidity can be used as a measure to assess the performance of RECPs and that RECPs can have an immediate positive impact on downstream surface water quality.

1. INTRODUCTION

Soil erosion from construction sites is a significant concern to downstream surface water quality. Soil erosion can lead to high sediment loads, decreased water clarity, and increased levels of contaminants, such as nitrogen and phosphorus, in surface waters. These effects can negatively impact the health and survival of fish, wildlife, and their habitat, the cost to treat surface waters for industrial and domestic uses, and the recreational value of downstream water bodies.

State and federal regulations have been enacted to regulate construction sites in efforts to protect downstream surface water quality. Regulations, such as the United States Environmental Protection Agency (USEPA) National Pollutant Discharge Elimination System (NPDES) program, typically require engineers and contractors working on construction sites to obtain permits, implement best management practices (BMPs), and monitor downstream water quality to prevent storm water pollution (USEPA 2007). The effectiveness of BMPs is typically based on downstream measurement of turbidity, similar to Safe Drinking Water Act (SDWA) standards which specify turbidity limits (USEPA 2012a).

Turbidity is a measure of the cloudiness of water that is caused by the presence of suspended solids, measured as the amount of light that is scattered by suspended particles in a sample as compared to a clear sample (USEPA 2009). Turbidity is commonly used because it is easy to measure, is relatively inexpensive, and can be continuously measured, unlike time-consuming laboratory total suspended solids (TSS) or suspended sediment concentration (SSC) tests. Relationships have been found between turbidity, measured in nephelometric turbidity units (NTUs), and TSS (e.g. Sims and Cotching 2000, Packman et al. 2002, Holliday et al. 2003.) Work by Holliday et al. (2003) suggests that NTU measurements can be used to estimate sediment concentrations of fine soil fractions, but underestimate total sediment concentrations when sand-size fractions are present. This is because sand and silt-clay particles rapidly fall from suspension, substantially decreasing NTU values within the first 12 hours; clay-sized particles stay in suspension for longer periods, typically more than 24 hours (Holliday et al. 2003.)

Recently, the USEPA has expressed interest in specifying turbidity limits in their NPDES permits to limit downstream impacts from construction site erosion (USEPA 2012b). However, the establishment of absolute turbidity limits has been difficult due to the lack of turbidity data from commonly used BMPs (USEPA 2012b). Rather than specifying an upper turbidity limit, many states evaluate turbidity violations by comparing turbidity increases relative to absolute or relative background levels. Background turbidities typically range from 25 to 75 NTUs; whereas, surface water turbidity downstream from construction sites can exceed several hundred to several thousand NTUs, even with the effective use of BMPs (Minton and Benedict 1999.)

Geosynthetic rolled erosion control products (RECPs) are BMPs that are broadly used by engineers and contractors to minimize soil erosion from bare soil slopes and channels. RECPs are temporary degradable or long-term non-degradable materials manufactured or fabricated into rolls designed to reduce soil erosion and assist in the growth, establishment, and protection of vegetation (ECTC 1998.) RECPs work by providing immediate ground cover protection against raindrop impact and stabilizing seed and soil within their structures, allowing vegetation to grow. Many field (e.g. Bhatia et al. 2002, Smith et al. 2005, Sutherland and Ziegler 2006), large-scale (e.g. Clopper et al. 2001, Kelsey et al. 2004), and bench-scale laboratory (e.g. Rickson 2002, Smith and Bhatia 2006, 2009, Smith et al. 2007) studies have

been conducted, documenting the successful use of RECPs in minimizing soil erosion. The majority of these studies, however, focus on RECP performance in terms of total soil losses measured by gravimetric methods. Although gravimetric methods are accurate, they are time-consuming and tedious. Regulators are typically more interested in evaluating downstream water quality, where turbidity can be quickly and inexpensively monitored, so that problems can be readily identified and addressed.

Few studies have been conducted that focus on downstream measurements of water quality from RECPs. One study by Babcock and McLaughlin (2011) evaluated the runoff water quality from three different erosion control methods (excelsior blankets, straw, and straw with polyacrylamide (PAM)) on four different sites with two horizontal to one vertical (2H:1V) bare slopes. The soils at the sites were mostly sand, with some silt and a trace of clay. Runoff was collected at the base of 10- to 30-ft wide by 29.5-ft long plots and analyzed for turbidity and TSS. Based on average data, the straw with PAM reduced mean runoff turbidity at three of the four sites by a maximum of 81% and TSS at two of the four sites by a maximum of 56%, in comparison to straw alone. Slopes covered with excelsior blankets had significantly lower turbidity and TSS than straw alone in one of the three sites; however, had significantly higher turbidity at two of the three sites in comparison to straw with PAM.

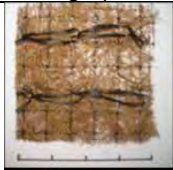

This paper presents the results of a laboratory rainsplash study that evaluates the contributions of RECPs to protecting downstream surface water quality in terms of turbidity. This paper demonstrates that turbidity can be used as a measure to assess the performance of RECPs and vegetative cover and that RECPs can have an immediate impact on downstream surface water quality. Attempts are also made to correlate turbidity, based on subsamples, with SSCs, based on whole samples from rainsplash tests. The role and contribution of RECPs to managing and protecting surface water quality are assessed.

2. MATERIALS AND METHODS

2.1 RECPs

This study, which is part of a larger study that included thirteen different RECPs, focuses on the performance of three different RECPs. The selected RECPs are erosion control blankets (ECBs), temporary degradable RECPs composed of processed natural or polymer fibers mechanically, structurally, or chemically bound to form a continuous matrix (ECTC 2001). The ECBs are made of three different fiber types: coconut (C2), straw (S1), and wood excelsior (W1). The ECBs range in light penetration from 20.5% to 41.5% and water absorption from 228% to 1218%, properties noted by several researchers (e.g. Ziegler et al. 1997, Rickson 2002, Smith et al. 2010) to be important to their rainsplash erosion performance. A summary of the RECPs and their average measured physical properties is given in Table 1.

Table 1. RECP properties.

RECP	Fiber type	Properties	Photograph ⁵
C2	Coconut	Mass/Area Thickness Light penetration Water absorption	
S1	Straw	Mass/Area Thickness Light penetration Water absorption	
W1	Wood excelsior	Mass/Area ¹ Thickness ² Light penetration ³ Water absorption ⁴	

¹ASTM D6475; ²ASTM D6525; ³ASTM D6567; ⁴ASTM D1117; ⁵4-in by 4-in specimens

2.2 Rainsplash Erosion

A laboratory rainsplash simulator was used to simulate rainfall events over different combinations of RECPs, soil, vegetated soil, and vegetated RECPs. The simulator was constructed in accordance with ASTM D7101. The simulator is approximately 2-m tall and produces 2.2-mm diameter raindrops that fall onto a 3 horizontal to 1 vertical (3H:1V) slope table, simulating a 15.24 cm/hr rainfall intensity. The slope table consists of three channels 89-cm long by 25-cm wide. Soil containers, 20-cm diameter and 10-cm deep, were placed in recessed holes at the base of the outside channels. Only the outside channels were used so that consistent rainfall conditions could be produced. Bare soil was compacted in the containers to $90\pm 3\%$ of standard dry density at an optimum moisture content of $\pm 2\%$. RECP specimens were placed along the length of the channels and covered the prepared soil containers. Runoff and eroded sediment were collected in buckets at the base of the channels. Photographs of the rainsplash simulator and examples of vegetated soil tests and RECP tests are shown on Figure 1.

Figure 1. (a) Rainsplash simulator and testing with (b) vegetated soil containers and (c) RECP-covered soil containers.

Soil. A well-graded silty sand (SM) consisting of 27% non-plastic fines and 73% sand (ASTM D2487) was used for the tests. The soil has an average organic matter content of 4.66%, based on the Loss-on-Ignition (LOI) method (Nelson and Sommers 1996). The maximum dry density of the soil is 1670 kg/m^3 at an optimum moisture content of 19.6% (ASTM D698).

Vegetation. For the vegetated tests, the soil was sown with Kentucky 31 tall fescue grass seeds and watered. For the vegetated RECP tests, RECP was then placed above the seeded soil. Seeds were placed at a rate of 0.75 g per container, which is equal to approximately 350 seeds. This amount of grass seed is twice the rate specified in ASTM D7322 for encouraging seed germination and plant growth under bench-scale conditions to ensure that an adequate stand of grass would be established after 21 days. The soil containers were placed in an environmental chamber capable of sustaining conditions at $27\pm 2^\circ\text{C}$, $45\pm 5\%$ relative humidity, and $9687 \text{ lumens/m}^2 \pm 1076 \text{ lumens/m}^2$. The soil containers were watered twice per week with 100 ml of water. The vegetated specimens were tested for rainsplash performance after 21 days of growth.

Turbidity. The mass of eroded soil, runoff volume, and turbidity were measured every 5 minutes through 30 minutes and at 45 and 60 minutes for each rainsplash test. A 30-ml grab sample of the runoff water was collected for each time increment and measured for turbidity using a laboratory turbidity meter (HF Scientific, Inc., HF - Micro 100 Laboratory Turbidimeter). The turbidity meter was calibrated with 0.02 and 10 NTU calibration standards and had an accuracy of $\pm 2\%$ of the reading plus 0.01 NTU. Once the eroded soil was dry, its weight was determined. SSCs of whole samples were calculated based on measured weights of eroded soil divided by runoff volume for each time increment. Five tests were performed for the bare soil and each RECP. Three tests were performed for the bare soil with vegetation and each RECP with vegetation tests.

3. RESULTS AND DISCUSSION

Runoff SSC and turbidity results are presented for the bare soil and soil with vegetation tests on Figure 2. As shown on Figure 2a, SSCs were relatively high over a large range (approximately 0.007 to 0.014 g/ml) within the first 5 minutes of the bare soil tests, but decreased and leveled off 10 minutes into the tests, to an average SSC of around 0.007 g/ml for the remainder of the tested time. Turbidity results (Figure 2b) also varied over a relatively wide range initially, from 487 to 790 NTUs for the bare soils tested; however, unlike the SSC results, the turbidity results continued to increase for 10 minutes then leveled off at an average turbidity of 815 NTUs. This level of turbidity is within the range of values given by Minton and Benedict (1999) of typical surface water turbidity downstream from construction sites.

a) Suspended soil concentration results

b) Turbidity results

Figure 2. Runoff water quality results for bare and vegetated soil.

It is believed that during the initial 5 to 10 minutes of the tests, loose coarse and fine soil particles present on the soil surface were dislodged and transported with the runoff. The coarse soil particles rapidly fell out of suspension and did not significantly contribute to the turbidity of the runoff (Figure 2b), similar to observations by Holliday et al. (2003), who found that higher concentrations of eroded sediment did not necessarily translate into increased turbidity. After 10 minutes, both the SSC and turbidity results stabilized, with SSCs decreasing and turbidity increasing then leveling off. This indicates that once the coarse soil particles eroded from the soil surface, it was the eroded fine soil fraction along with organics that dominated runoff water quality results, eroding at a fairly constant rate, for the remainder of the tests. The eroded soil surface is shown on Figure 3a.

Figure 3. Comparison of eroded soil surfaces (20-cm diameter containers).

The SSC results for the vegetated soils fell within a relatively narrow range of 0.00248 and 0.0028 g/ml for the initial 5 minutes, then slightly increased and leveled off to an average of 0.00295 g/ml within 10 minutes (Figure 2a). Although the average initial vegetated SSC was 78% less than the bare soil SSC, turbidity results (Figure 2b) for the vegetated tests (404 to 793 NTUs) were initially similar to the bare soil tests (487 to 790 NTUs), with turbidity sharply increasing to bare soil levels at 10 minutes. After 10 minutes, however, the turbidity of the vegetated samples decreased to an average of 590 NTUs, approximately 28% less than bare soil turbidity levels. The effectiveness of the vegetation continued to increase as the tests progressed, due to the shoots falling down from vertical to horizontal, providing increased ground cover protection (Figure 3b), stabilizing within 20 to 30 minutes. The vegetation also provided root reinforcement, which minimized the detachment of soil particles. The relatively wide range in turbidity results can be attributed to the varying densities of ground cover provided by the vegetation. Table 2 shows the wide range of biomass results that can be obtained under controlled conditions (ASTM D7322).

Table 2. Vegetation results at 21 days (ASTM D7322).

RECP	No. of Shoots	Plant Height (cm)	Biomass (mg)
Vegetation alone	0-42	0-13	0-42
W1	36-44	1-16	65-70
S1	34-46	1-16	30-70
C2	31-36	2-14	45-65

Establishing vegetation is a common BMP for stabilizing bare soil slopes. Although the vegetation was effective in reducing the turbidity of the runoff in comparison to the bare soil tests, the turbidity levels were still higher than typically acceptable limits (typically 5 to 10 NTUs above background levels of 25 to 75 NTUs). The vegetation also provided a delayed response in minimizing turbidity. In these tests, turbidity did not start to decrease relative to bare soil conditions until 10 minutes into the tests (Figure 2a.) The quality and density of vegetation can also vary significantly, even under controlled conditions. Difficulties establishing vegetation in the field have been noted by several researchers (e.g. Fifield et al. 1988; Rickson and Morgan 1988.)

RECPs were developed to address some of the limitations of seeding or mulching alone. RECPs are manufactured into rolls that can be easily installed on a slope to provide immediate ground cover protection. RECPs also stabilize soil and seed within their structures, allowing seeds to germinate quickly and vegetation to grow, reinforcing vegetation once it is established. Figure 4 presents photographs of the three ECBs included in this study, coconut fiber C2 (Figure 4a), straw fiber S1 (Figure 4b), and wood excelsior fiber W1 (Figure 4c) during a rainsplash test.

The runoff SSC and turbidity results for the coconut (C2), straw (S1), and wood excelsior (W1) ECBs are given on Figure 5. The coconut ECB SSCs (Figure 5a) were in a relatively narrow range (between 0.00026 and 0.0029 g/ml) within the first 5 minutes, and leveled off to an average of 0.000511 g/ml within 15 to 20 minutes, approximately 92% lower than bare soil and 82% lower than the vegetated tests. Turbidity (Figure 5b) ranged between 186 and 500 NTUs within the first 5 minutes. Turbidity continued to decrease and leveled off at an average of 131 NTUs, 84% less than bare soil and 78% less than vegetated soil. It is believed that the long, randomly placed, dense fibers of the coconut ECB, coupled with its high ground cover percentage of 79.5% (light penetration of 20.5%), allowed the ECB to effectively intercept and reduce the kinetic energy of the majority of raindrops. The high water absorption value of 1218% also allowed the ECB to uptake water, increasing the weight of the ECB, allowing it to conform to the soil surface, reducing the energy of the runoff beneath the ECB. Vegetating the ECB further increased its effectiveness. Once the coconut ECB was vegetated, turbidity decreased to an average of 95 NTUs. This value is within 20 NTUs of typical upper limit background values.

Figure 4. Photographs of the ECBs (C2, S1, W1) during a rainsplash test.

The straw ECB SSCs (Figure 5c) ranged from 0.00238 to 0.00482 g/ml and decreased to an average of 0.00125 g/ml, approximately 82% less than bare soil and 58% less than vegetated soil SSCs. Turbidity (Figure 5d) varied within a relatively wide range within the first 5 minutes of the tests (between 556 and 929 NTUs.) Turbidity was actually higher for one straw ECB test than the bare soil tests (Figure 2b). However, unlike bare soil and vegetated tests, turbidity did continually decrease beyond this point, and stabilized to an average turbidity of 314 NTUs, 61.5% lower than bare soils and 47% lower than vegetated soil turbidity. Once the straw ECB was vegetated, turbidity decreased to an average of 94 NTUs, similar to C2.

The wood excelsior fiber ECB SSCs (Figure 5e) ranged from 0.00301 to 0.00504 g/ml and decreased to an average of 0.00111 g/ml, approximately 84% less than bare soil and 62% less than vegetated soil SSCs. Turbidity (Figure 5f) varied from 534 to 759 NTUs during the first 5 minutes, again similar to the bare soil tests (Figure 2b). However, as with the straw ECB, turbidity continued to decrease beyond 5 minutes and leveled off at an average value of 289 NTUs, 65% lower than bare soils and 52% lower than vegetated soil turbidity. Once the wood excelsior ECB was vegetated, turbidity decreased to an average of 73 NTUs, slightly lower than C2 and S1.

As with the coconut fiber ECB (C2), both the straw (S1) and wood fiber (W1) ECBs work by providing ground cover and conforming to the underlying soil surface. Although the wood fiber ECBs contained relatively long wood fibers, visible openings were observed in the ECB. Similar observations were made for the straw ECBs, which contained loose fibers between two nets. The straw fibers easily moved during the tests, creating clear openings through the ECB. The straw and wood fiber ECBs provided ground cover of 73% and 59%, respectively. The wood fiber and the straw fiber ECBs also have relatively low water absorption capacities, 228% and 556%, respectively, in comparison to the coconut fiber ECB (1218%). Although the fibers absorbed some water, the contribution of water by the straw and wood ECBs did not seem to make a significant contribution to the ability of the ECBs to conform to the underlying soil surface. RECPs are particularly effective when they are vegetated. The vegetation provides a second layer of defense, further reducing the impact of raindrops and runoff on the soil surfaces.

4. CONCLUSIONS AND RECOMMENDATIONS

This paper demonstrates that turbidity can be used as a measure to assess the performance of RECPs and that RECPs can have an immediate positive impact on downstream surface water quality. Although vegetation alone is commonly used to stabilize slopes, results from this study indicate that the use of vegetation alone may not be sufficient in meeting downstream water quality requirements, only reducing turbidity levels by 28% in comparison to bare soil turbidity. Although turbidity results for some RECPs were initially high, in the range of bare soil levels, turbidity continued to decrease and reached an average of 70% below turbidity levels for bare soil and 60% lower than vegetated turbidity levels, for the RECPs. This behavior was unlike that for the bare and vegetated soil, where turbidity levels increased before leveling off. Overall, fiber type plays an important role in an RECP's ability to absorb water, which assists RECPs in conforming to and adhering to the soil surface. RECPs are particularly effective in reducing downstream water quality once vegetated, providing downstream turbidities in the range of 73 to 95 NTUs, as compared to 815 NTUs for bare soil and 590 NTUs for vegetated soil.

Trending Applications in Landfill Closure: Case Studies and Data on Exposed, Trenchless Covers

C.A. Eichelberger, American Environmental Group Ltd., USA
C.S. Kelsey, Geosynthetica, USA

ABSTRACT

This presentation will profile the United States' first large-scale designs and installations of exposed geomembrane covers that utilize a non-traditional, trenchless ballast approach. Four case histories and data from these sites will provide practical but forward-thinking design information on this new concept in geosynthetics and the solid waste industry. Data from these sites indicate that the design offers cost savings when compared to a ballast trench method, and provides a system that is more aesthetically pleasing and UV resistant than current ballast alternatives, such as ropes and sandbags. Cost savings are realized through construction methods and increased efficiencies, required equipment on-site, productivity of geosynthetic installation, and geosynthetic material quantities. Significant project schedule efficiencies are offered and provide a methodology that allows late-season construction and even construction during winter months in cooler climates.

1.0 INTRODUCTION: EMBRACING NEW TECHNOLOGY

The waste management field in the United States has routinely received the highest infrastructure grades in the American Society of Civil Engineers' (ASCE) *Report Card for America's Infrastructure*. The industry has benefited from deep interaction between all its key partners, resulting in dependable regulation, refined design, better construction, advanced waste stream management, beneficial reuse of former waste cells, improved operations and management practices on site, and the incorporation of renewable energy technologies. One thing that connects all aspects of the industry's consistent performance is an openness to new technologies and approaches that can improve environmental performance and the economic health of waste management facilities.

A new wave of exposed geomembrane covers (EGC) is one such technology that is giving numerous buried waste facilities a more flexible design and operational approach to save money on construction, create long term site value, and even reduce the carbon footprint of waste cell/closure construction practices.

Two types of EGC systems of note have emerged in the past few years:

- Exposed, trenchless ballast covers that utilize percussive driven earth anchors
- "Solar" EGCs, in which flexible thin-film photovoltaic laminates are adhered to the exposed geomembrane and provide long-term renewable energy generation that may be combined with landfill gas (LFG) to energy collection systems

The solar EGC systems have been well-publicized and discussed at major waste management engineering conferences; but the trenchless approach is a new and complementary process. Exposed, trenchless ballast systems will be the focus of this paper.

2.0 EGC ADVANTAGES

Exposed geomembrane cover systems offer a number of advantages over traditional, thick soil-covered systems. Of note:

- Greater cover stability
- No establishment / maintenance of vegetation above the cover soil (O & M advantages for the site)
- Reduction of hydraulic head
- Easier to spot/handle repairs
- Shorter construction time
- Much lower cap construction cost
- Potential for increased air space for waste after years of expected settlement

- Efficient stormwater control
- Improved odor/gas containment performance

Traditional thick soil cover layers, which already must have a geosynthetic system beneath them, are heavy and present a number of potential engineering problems, such as sliding of the soil along the membrane on a saturated slope or due to landfill gas pressure from beneath the cap. Slipping soil can tear the membrane as well, forcing not just a rebuild of the slope's vegetated soil-cover system but significant repair of the membrane cover and any affiliated system that might be affected (landfill gas, leachate management, etc.).

Removing the soil cover component and using only the geosynthetic membrane eliminates these types of cover stability concerns. Also, without soil to hold precipitation, potential hydraulic head acting upon the membrane has been neutralized. Stormwater runoff is cleaner and easier to manage in terms of sedimentation concerns. A tear in the geosynthetic cover, no matter the cause, is far easier to identify because it is on the surface and the repairs can be handled quickly.

In terms of cost, the absence of the earthworks necessary for thick cover soil placement and vegetation establishment is avoided. Furthermore, there are no long-term maintenance costs for mowing and re-seeding. Significant cost savings are also recognized due to the lack of trenching required to ballast the membrane system. (See section "ADVANTAGES OF TRENCHLESS BALLAST DESIGNS.")

3.0 EXPOSED COVER CHALLENGES

Exposed geomembrane caps, like all engineered systems, do have challenges that need to be overcome. Challenges have been addressed in various ways as the designs have advanced through lessons learned in the field. Exposed membrane challenges include:

- Wind uplift risk / membrane movement
- Landfill gas (LFG) system uplift
- UV exposure and thermal oxidation
- Less natural appearance
- Run-off volume management
- Animal/human traffic damage

Wind uplift and membrane movement concerns can be mitigated through proper selection of the geomembrane and anchoring systems (e.g., traditional anchor trenches and soil berms or the newer trenchless, geosynthetically anchored methods).

While exposed cover projects are gaining popularity as "voluntary closures" by landfill owners, many are still constructed in response to a site condition, such as odor, extreme leachate generation, etc. Therefore, a landfill gas collection system and more importantly a surface gas collection system, installed directly under the exposed cover membrane, is necessary for construction and performance of the system. The surface collection systems are not similar to the highly engineered primary gas collection systems, in that they typically consist of perforated plastic pipe in very shallow trenches beneath the membrane. Other examples include strips of geocomposite material that lead to the top of the closure with gas extraction ports where vacuum can be applied to the areas along the top of the cap.

Runoff management can be handled through normal bench, channel, and swale design and through other standard runoff controls on waste management sites. Sites with exposed covers generate more stormwater runoff, but the additional water is typically sediment free.

Most geosynthetic membrane formulations are tailored to specific performance goals, including UV resistance and protection against oxidation. Proper membrane selection can match the correct membrane to the site's conditions and the client's performance expectations of the system. Membrane material choice will vary based upon the expected lifetime of the exposed cover.

Standard landfill site security—such as fencing—can reduce, as much as possible, animal and human access onto the exposed membrane. Sites with exposed covers typically report little animal traffic on the membrane, as previous food and water sources are sealed with a membrane product that is not attractive to most wildlife.

And in terms of the site's aesthetics, the pigment of a membrane can be adjusted to take on visual characteristics of the area. There have been "camouflage" floating covers installed on reservoirs, for example, and green tinted membranes installed as an exposed cover on landfills (Figure 1).

Figure 1. The 40-mil textured high-density polyethylene (HDPE) exposed cap on the first use of the trenchless ballast approach in the United States used a green-tinted membrane to help the cap blend into the surrounding environment.

Figure 2. “Solar” exposed geomembrane cap on Hickory Ridge Landfill, Georgia.

4.0 EVOLUTION OF THE EXPOSED COVER DESIGN

Exposed geomembrane covers are not new solutions for landfill cell closure (see, for example, Gleason et. al), but they have not been utilized widely. Aesthetics (bare membrane vs. grass and vegetation) and questions about susceptibility to wind uplift and overall durability across a standard 30-year post-closure monitoring period have slowed both the acceptance of this application and innovation within this sector of design. But recent high-profile exposed cover systems (e.g., the “solar” membranes on the Tessman Road Landfill in San Antonio, Texas and Hickory Ridge Landfill, Atlanta, GA – Figure 2) and a new wave of R&D support have helped demonstrate the engineering, aesthetic, environmental and economic benefits of exposed geomembrane caps.

Adhering thin-film photovoltaic cells to the surface of exposed membranes has quickly moved from pilot projects to full-scale integration. A system that joins a surface layer of synthetic grass to the capping membrane has been developed. And, as this paper focuses on, a trenchless ballast system has been developed.

The trenchless system design has grown out of standard geotechnical anchoring solutions. At the four landfills cited in the case studies below, a percussive driven earth anchor installation system has been used—an approach commonly used for anchoring with sheet piles, gabions, tunnel liners, rockfall retention netting, bridges and in other applications. Applying them securely to membrane has been quickly successful.

Figure 3. The anchor installation requires only a small penetration of the membrane. Lightweight, common equipment is used to drive the corrosion-resistant anchors.

The anchors being used on these landfill covers are percussive driven earth anchors as used in other geotechnical applications. Corrosion-resistant steel cables are used and produce an overall 907KG load rated system, though they are not stressed to that level. The anchors are installed at typical depths of 1.2 – 1.8m and driven into the waste through a small penetration in the exposed membrane (Figure 3). While flexible membranes rated for long-term exposure (e.g., 45-mil EPDM) have been used for the cover membrane, the plates are connected to the membrane via a membrane patch (that matches the installed membrane, much as a normal penetration, such as a gas pipe penetration, would be dealt with) and an additional scrim-reinforced patch has been placed beneath the percussive anchors so that while the membrane may flex slightly the anchor point remains firmly in place.

IN PLACE LOAD TESTING OF EACH ANCHOR INSTALLED

The two-patch approach has resolved questions of resealing the geomembrane after driving in the anchor and securing the anchor plate to the geomembrane. The logical next question has concerned the waste, and it has quickly been confirmed that standard waste compaction practices have made the waste an ample medium for the anchor head to lock into inside of a few feet. The anchor installation equipment is lightweight, so it has not impacted equipment usage specifications on site, and allows easy readings of the load resistance of the installed anchor.

For HDPE geomembranes, the anchor load plate is adhered directly to the membrane surface.

Spacing of the anchors has varied based upon site characteristics (e.g., slope angle, expected wind/precipitation runoff conditions) and the specified material type (e.g., 40-mil HDPE, 45-mil EPDM, etc.).

5.0 ADVANTAGES OF TRENCHLESS BALLAST DESIGNS

The advantages of a trenchless approach include all of the advantages of an exposed geosynthetic cover as well as additional and considerable time and material-saving expense during installation. In the author's experience, traditional ballast trenches cost \$3.00 – \$4.50/m. The discussed ballast trenches should not be confused with typical landfill anchor trenches around the perimeter of new cell construction. Ballast trench excavation will encounter previously placed solid waste. The excavation of the solid waste produces odor and is typically constrained to daytime working hours of the site. The removed waste then needs to be replaced with suitable backfill materials that can be compacted to a specified density required for ballast of the exposed membrane cover. The excavated solid waste must then be transported to the active workface or to an offsite disposal location if the site is closed for waste acceptance. Additional hauling efforts are then required to supply suitable backfill material to be compacted into the excavated trenches. Offsite borrow material may be required for backfill of trenches if material of adequate quality and quantity is not available onsite.

Consider that standard ballast trench design requires the exposed membrane to be buried down and through the bottom of the trench, thus adding additional material to the order quantity. A ballast trench will require 1.5 – 2.1 meters of additional membrane (on a plan sheet detail), per LF of trench. Experience shows that excavating a defined trench through solid waste materials is difficult given the variations in solid waste. Therefore, trenches are usually much larger in the field and will utilize more material than anticipated. A 2.02 hectare exposed cover closure will contain approximately 2,285 – 3,050 meters of ballast trenching. When you add that to standard overlapping of membrane panels on site, overlap of trench-covering membrane welded to the previously installed membrane, and the oversized trenches caused by irregular waste materials, you then may be installing close to 3.6 hectares of membrane on that 2.2

hectare cell—with the lionshare of material “waste” being in the ballast trenches. This is a significant source of cost and carbon footprint increase due to materials used, labor, CQA and inspection, equipment, time, etc.

Trenches must be closed at the conclusion of every day, and liner material may not be left exposed without being anchored. As such, it is common to find liner installation crews waiting for trench crews to finish backfilling the most recently installed and seamed liner panels. Waiting on trench construction and backfilling adds to construction costs by forcing slower construction. A final item of significant cost / labor / and schedule associated with the trench ballast design includes the need to seam installed geomembrane to the geomembrane that was buried in a ballast trench. An extrusion seam is necessary in this application and is performed with hand welding equipment. Costs range between \$1.65 - \$2.25 / m and would be necessary for each meter of ballast trench, or \$55,000 - \$75,000 in the above 2.2 hectare example.

Excavation through cover soil / solid waste materials can also create additional factors to consider. The materials encountered when trenching through a landfill are not consistent and make a consistently sized trench difficult to impossible to construct. The irregular shapes of sidewalls and varying widths of trenches will create wrinkles in the geomembrane after backfilling of the trenches. Geomembrane wrinkles resulting from trenching activities are not a new concept to the landfill industry, but they can cause concern in exposed applications (such as when power generation from adhered photovoltaic cells is involved).

Table 1. Koerner’s (2011) analysis shows an exceptional advantage for exposed cap designs.

	Total Cost	Total CO₂ Footprint
Traditional Cap	\$916,000 / ha	652,400 Kg CO ₂ /ha
Exposed Geomembrane Cap	\$273,000 / ha	131,200 Kg Co ₂ /ha
Exposed Cap Savings	\$643,000 / ha	521,200 Kg Co₂/ha

The quick installation record for a trenchless ballast system reduces time spent running trucks and equipment on site. (In one of the case studies below, for example, the work window was reduced from 4-5 months to 1.5 months). While the carbon footprint reduction here is not on the scale that will make or break a project, it is a very healthy step for the construction field and another benefit for the waste management industry, which already invests considerable resources in environmental performance, R&D, and documentation. As such, whenever CO₂ issues can be reduced, they should be—especially when these strategies do not cost more and, in fact, save money.

For a detailed examination of the larger cost and sustainability benefits of exposed geomembrane caps, see Koerner (2011) and Ramsey (2011) (Table 1).

The following case studies summarize some of the project details, data and benefits the author has found at four early uses of the trenchless ballast EGC engineering strategy in the US waste management industry.

6.0 CASE STUDY #1: THE FIRST INSTALLATION

A large, municipal solid waste landfill needed to reduce landfill odors and chose to install an exposed geomembrane cover and landfill gas (LFG) collection system to manage this odor issue. Community complaints about the site’s odors and a desire to preserve their positive image had heightened the time-sensitivity of response to the odor and gas management issues. A seven-day work week program was established, but meeting all of the project’s fast-tracked goals, and finishing the work within budget, was made possible largely by two factors:

- The project utilized the first soil anchor ballast geomembrane cover design in the United States
- The contract used a single provider for all essential services (installation of geosynthetics, LFG design and construction, and primary operations and maintenance [O&M] services)
-

The trenchless, anchored ballast approach allowed for faster installation and lower job costs because it did not require nearly as large of a crew or suffer the delays commonly associated with trenching. The installation schedule was decreased dramatically, and the job cost was decreased. In this case, an installation of this size may have taken roughly

4 months, but ultimately took only 1.5 months due to using this geosynthetically anchored system. The owner selected to utilize a non-traditional approach in hopes of completing the work prior to winter, which would not have been achievable utilizing a trenching option, but also in hopes of creating a case study for the new technology and advancing the use of exposed covers to additional sites. The time savings, lesser need for heavy equipment, decreased quantity of geosynthetic material required, translated roughly to a 35% cost reduction for the project when compared to a trenched exposed cover design. In addition to the gas system installation and calibrating, only the liner then needed to be installed, anchored and inspected; versus, the trench-ballast approach which would have called for alternating stages of earthworks, liner installation, ballast trench excavation/backfill and inspection/compaction testing of the trenches. Also, if trenches had been used, open trenches during non-work hours would have been forbidden due to the sensitivity of odor emissions and safety concerns. All which would have led to a much longer construction schedule.

The installation involved roughly 186,000 m2 of 40-mil textured high-density polyethylene (HDPE) geomembrane. Because it was to be an exposed geomembrane, the material was tinted green by the manufacturer to better blend the special cover into the surrounding landscape. More than 4,290 meters of tie-in to the existing HDPE lined area was installed with 1,975 anchors installed to secure the liner in place without a need for the traditional trench. Some portions of the liner did not require anchors.

Additionally, more than 186,000 m2 of nonwoven geotextiles were installed for protection, drainage, and collection of gas beneath the geomembrane.

The trenchless ballast system approach allowed the LFG system to be installed with the liner installation and anchoring crews following close behind. This coordination was key to finishing the project quickly and successfully.

The odor issues were controlled by the combination of the covering anchored-membrane and the LFG system. Subsequent analysis has confirmed heightened performance of the gas collection system (Table 2). Off-site odor complaints ceased and the issue was controlled using the cover and operations and maintenance of the LFG collection system.

Table 2. Prior to the installation of Case Study #1's exposed cap (January 2010), the site gas flow was measured at 5228 CFM. As cap installation began (July 2010), gas capture increased, spiking in October 2010 (8150 CFM) when the last section of cap was installed.

7.0 CASE STUDY #2: RAPID RESPONSE TO ODOR CONCERNS

A municipal solid waste landfill in the southeastern United States installed a 40-mil high-density polyethylene (HDPE) exposed geomembrane cap with a trenchless ballast system that was tied into the existing HDPE cover system. The solid waste facility involved here was proactively addressing an odor concern from the site's landfill gas. The cover needed to be installed as quickly as possible and the geosynthetically anchored option provided a schedule of two weeks. A traditional trench-ballast response would have necessitated a two-month schedule.

As this work was ordered in October, the two-month schedule (associated with the ballast trench design) would have pushed construction too far into the winter/high moisture months to guarantee project completion.

The “trenchless anchor method” was chosen and the project was completed in two weeks. Work accomplished by the crew in those two weeks included the installation of:

- 81,290 m² of 40-mil textured HDPE over subgrade
- 10,405 m² of geocomposite with a 200-mil net
- 730 meters of tie-in seam to the existing HDPE-lined area
- Approximately 750 geomembrane anchors
- (15) 15 cm to 25 cm pipe penetrations
- 66 additional pipe penetrations

The scope of this work helped the site immediately address the landfill gas concerns, and the site operators have since reported (July 2012) nearing 100% on gas collection as estimated by their twice-daily gas readings.

The site operators have not attempted to quantify the leachate reduction, but when surveyed they estimated it to be “sizable.”

Importantly, they note that one of the greatest impacts of the exposed cap on their site has been in regards to their relationship with the community they serve. It has historically been a well-regarded site; the installation of the cap in a rapid-response manner has helped the operators quickly and economically maintain their community position while gaining additional long-term benefits to the site’s operations.

8.0 CASE STUDY #3: MORE EFFICIENT & ECONOMICAL

When a northern Midwestern landfill began an expansion plan simultaneously with relocating 1,000,000 ft.³ of waste from its original cell, the site operators looked to more efficiently manage stormwater runoff, control erosion, and reduce maintenance costs.

The site’s multiple cells have taken primarily municipal solid waste, though one ash pile—with a separated leachate and water management stream—is located on site.

Figure 4. 45-mil EPDM exposed cover installed in northern Midwest, with Phase I completed in November 2011 and Phase II in June 2012.

Figure 5. Percussion anchor installed on 45-mil EPDM exposed cap. An additional reinforced scrim patch is installed over the non-reinforced geomembrane to provide a significantly stronger attachment and pull-through resistance of the anchor to the geomembrane.

Two sections have recently been closed with an exposed interim cap. Totalling more than 46,500 m² of space, the choice to go with an exposed geomembrane cap and a trenchless ballast approach has replaced more than 3,000 m of ballast trench with roughly 1,000 percussion anchors. Both phases use 45-mil EPDM geomembrane with a 20+ year exposed service life.

A June 2012 installation secured roughly 0.4 ha of exposed membrane per day (Figure 4). Combined with other site activities (such as additional LFG pipe installation and maintenance checks) and a slight weather delay, the construction team was on site for only one week. A reinforced EPDM material was utilized in the areas of anchor attachment to provide a significant increase in strength of the anchor / geomembrane attachment (Figure 5).

The site does not currently convert landfill gas to energy, but the increased retention of LFG with the cap in place has drawn the interest of a developer with whom the site owner plans to work in 2013 on upgrading the gas collection system to an energy-generating operation. New gas header pipe is already being installed (July 2012). The site owner also reports an interest in converting another section of the landfill to an exposed cap in 2013.

9.0 CASE STUDY #4: USE OF NON-TRADITIONAL LANDFILL CLOSURE GEOMEMBRANE

For a northwest United States municipal solid waste landfill, more than 8 ha were secured with a 45-mil EPDM exposed geomembrane cap (79,000 m²). The site also incorporated a small amount of 40-mil green-tinted HDPE geomembrane (4,925 m²), to an existing exposed closure (Figure 6). Prior to this project, the site had installed previous exposed covers with varying degrees of success in terms of material performance and ballast option performance. The high amounts of precipitation allow for the financial expenditure on an exposed cover, given the cost savings on leachate treatment and the benefit of increased LFG collection.

Figure 6. Picture of Northwestern US exposed cap (Case History #4)

Various other geosynthetics were also incorporated into the construction, such as geomembrane for a rain flap and berms, geocomposite for gas collection and subgrade cushion, and geosynthetic clay liners for a tie-in anchor trench impermeable layer. The use of EPDM geomembrane provides the Owner the opportunity to make repairs / modifications to the liner given the ease of seaming and lack of specialty equipment required. The seaming supplies and techniques are shown below (Figure 7).

The trenchless ballast approach—the first of its type in the region—involved the installation of just under 2,000 geosynthetic anchors (Figure 8). These anchors replaced what would have been more than 6,000 m of ballast trenches. When considering the wider extent of work on the site, that trenching would have added a considerable amount of time and expense to the contract.

Figure 7. EPDM seaming procedure

Figure 8. Anchor installed to EPDM Geomembrane

In summary, the geosynthetically anchored ballast solution for exposed geomembrane covers offers a cost effective and “schedule enhancing” alternative to conventional ballast trenching of the geomembrane. A project can be completed in less than half the time and offer an additional advantages to those already recognized by exposed membrane covers.

Unconfined Compressive Strength Behaviors of Fiber-fly Ash-soil Mixtures

Yuksel Yilmaz, Ph.D., Gazi University, Turkey, yyuksel@gazi.edu.tr

ABSTRACT

An experimental program was undertaken to investigate the effects of discrete polypropylene fibers and class C fly ash on the unconfined compressive strength (UCS) behaviors of the clayey soil. Two types of polypropylene fiber (fibrillated and multifilament) in two different lengths and two fiber dosages were utilized. The effect of the fly ash content on the UCS is superior compared to the effect of fibers. Inclusion of fiber without fly ash decreases the UCS of the compacted fiber-clay mixtures. On the other hand, when combined with the fly ash, the fiber inclusion increases the UCS depending on fiber type, length and dosage, and the higher the dosage of fiber the higher the UCS for both fiber types and fiber lengths are. At the end of 28 days curing period, the increase in UCS is up to 218% for 30% fly ash content and 1.0% 19 mm long fibrillated polypropylene fiber.

1. INTRODUCTION

Fine grained soils with high plasticity are not desirable for use as a structural support unless their engineering properties are improved significantly in an economic manner. For many years, extensive research has been carried out on the usability of some additives (lime, cement, fly ash, cement kiln dust, chemicals, fibers, etc.) to improve the engineering properties of fine grained soils.

The modification of fine grained soils with fly ash to improve their engineering properties is well recognized and widely practiced. Through stabilization, the plasticity of soil is reduced, and its compressive strength properties are improved. Several factors such as plasticity of soil, types and amounts of fly ash, mixing and compaction methods, curing conditions, gradation and pulverization, etc., affect the performance of stabilized soil. These issues have been previously discussed by several authors (Goktepe et al., 2008; Buhler and Cerato, 2007; Kate, 2005; Aydilek and Arora, 2004; Kumar and Sharma, 2004; Prabakar et al., 2004; Cokca, 2001; Misra, 1998; Sivapullaiah et al., 1996; Chu and Kao, 1993; Ferguson, 1993; Keshawarx et al., 1993).

In addition, a number of studies have been conducted for several years to investigate the influence of randomly oriented discrete fibers on the engineering behavior of mainly coarse grained or cohesionless soils. Discrete fibers are simply added and mixed with soil, similar to traditional additives.

Several studies have been carried out on the effect of randomly oriented discrete fibers on the geotechnical behavior of fine grained or cohesive soils. In these attempts, various types of discrete fibers are used (Jadhao and Nagarnaik, 2008; Kumar et al., 2007; Ozkul and Baykal, 2007; Rafalko et al., 2007; Ozkul and Baykal, 2006; Heineck et al., 2005; Loehr et al., 2005; Ang and Erik Loehr, 2003; Iasbik et al., 2002; Nataraj and McManis, 1997; Maher and Ho, 1994; Freitag, 1986).

In the present investigation, the effect of various fly ash contents, fiber types, fiber lengths and fiber dosages on UCS behavior has been investigated.

2. PROPERTIES OF MATERIALS

Various types of material (the Ankara clay, the Cayirhan fly ash and polypropylene fibers) used in the present study have been described below.

2.1 Clay

The soil used in this study was obtained from an open-cut excavation in Ankara, the capital of Turkey. The particle size distribution curves of the clay and the fly ash are shown in Fig. 1. Some of the basic characteristics of the Ankara clay and the Cayirhan fly ash are also summarized in Fig. 1.

Figure 1. Particle size distribution curves and basic characteristics of Ankara clay and Cayirhan fly ash.

2.2 Fly Ash

The fly ash used for this study was obtained from Cayirhan thermal power plant in Ankara and it is referred to as the Cayirhan fly ash throughout the text. The chemical composition of the Cayirhan fly ash is presented in Table 1. Cayirhan fly ash classified as Class C fly ash (ASTM C 618-05).

Table 1. Chemical compositions of the Cayirhan fly ash and the chemical requirements for Class C fly ash according to ASTM C 618 standard.

Chemical Composition	Content (%)	Chemical Requirements for Class C fly ash, (%)
SiO ₂	49.72	-
Al ₂ O ₃	15.15	-
Fe ₂ O ₃	9.30	-
SiO ₂ + Al ₂ O ₃ + Fe ₂ O ₃	74.17	min. 50.0
CaO	13.1	-
MgO	2.97	-
SO ₃	2.60	max. 5.0
K ₂ O	2.00	-
Na ₂ O	2.37	-
Free CaO	0.74	-
Loss on ignition	1.00	max. 6.0

2.3 Fiber

Two different types of polypropylene fibers, namely fibrillated polypropylene fibers and multifilament polypropylene fibers, with two different lengths (6 mm and 19 mm) were used in the study. The fibrillated polypropylene fibers in length of 6.0 mm and 19.0 mm are denoted as F06 and F19, respectively. In a similar manner, the 6.0 mm and 19.0 mm long multifilament polypropylene fibers are denoted as M06 and M19, respectively. Table 2 shows some of physical characteristics of the polypropylene fibers provided by the manufacturer.

Table 2. The physical characteristics of the fibres (Ployfibres, 2009)

Properties	Fibrillated polypropylene fibre	Multifilament polypropylene fibre
Appearance	Fully oriented collated fibrillated (network) form	Fully oriented multifilament fibrous form
Content	100% virgin homopolymer Polypropylene(C ₃ H ₆)N	100% virgin homopolymer Polypropylene(C ₃ H ₆)N
Compliance	ASTM C 1116-1997 Type III	ASTM C 1116 1997 Type III
Density (g/cm ³)	0.91	0.91
Tensile strength (MPa)	400	700
Young Modulus (MPa)	2,600	3,500
Elongation at yield, %	15 %	20 %
Elongation at yield, %	15 %	20 %

3. COMPOSING FIBER-FLY ASH-CLAY MIXTURES

The design of fiber and/or fly ash mixtures was based on dry weight percentages of the fiber and the fly ash in the clay matrix. The proportions of dry mass of the fly ash to dry mass of the clay were predetermined as 0% (no fly ash) for the lower bound, 10% to representative for conventional range, and 30% for the upper bound. These three percentages of fly ash content were chosen to clearly reflect the effect of fly ash in a very wide range although the upper bound of 30% fly ash content is not practical in application. The proportions of dry mass of the fiber to dry mass of the clay were designated as 0.5% and 1.0%.

Standard Proctor compaction tests were conducted on 3 different fly ash-clay mixtures (0%, 10%, and 30% by dry mass of the fly ash to dry mass of the clay) without fiber inclusions according to ASTM D 698-00a standard. The maximum dry unit weight and the optimum moisture content of fiberless fly ash-clay mixtures were also used to prepare samples for strength tests of the fiber-fly ash-clay mixtures for all fiber inclusions.

The effect of polypropylene fiber type (fibrillated polypropylene fiber and multifilament polypropylene fiber), fiber length (6.0 mm and 19.0 mm) and fiber dosage (0.5% and 1.0% by dry weight of the clay) on the UCS was examined at the end of 28-days curing period.

4. PREPARATION OF FIBER-FLY ASH-CLAY SAMPLES FOR STRENGTH TESTS

A compaction mold was used to prepare cylindrical compacted samples of different fiber-fly ash-clay mixtures at optimum moisture content and maximum dry unit weight. The compaction mold was designed for specimens of the unconfined compression testing with a height-to-diameter ratio of 2.01 (50.0 mm in diameter and 100.50 mm in height).

5. UNCONFINED COMPRESSION TESTS

Unconfined compression tests were performed on the specimens using strain-controlled application of the axial load in accordance with ASTM D 2166-00 standard. In order to test all the mixtures under similar conditions and to isolate the effect of strain rate on the strength behavior, the strain rate was kept constant at 0.5 mm/min in the course of the testing program. Minimum three specimens were prepared for each combination of variables for the unconfined compression tests.

6. RESULTS AND DISCUSSION

6.1 Compaction Characteristics

The compaction curves of 3 different fly ash-clay mixtures (fly ash content from 0% to 30%) are shown in Fig. 2. With increasing fly ash content, the compaction curve shifted upward and toward the left, which indicates that the clay was stabilized by addition of the fly ash even at low water contents (Fig. 2). Furthermore, at given water content, the dry unit weight increases with increase in the fly ash content.

Figure 2. Standard Proctor compaction curves, maximum dry unit weight and the optimum moisture content of the fly ash-clay mixtures.

The maximum dry unit weight and the optimum moisture content of the mixtures are also shown in Fig. 2. As the fly ash content in the mixture increases from 0% to 30%, the maximum dry unit weight gradually increases from 14.3 kN/m³ to 14.7 kN/m³ while the optimum moisture content tends to decrease from 27.8% to 24.7% (Fig. 2).

6.2 Unconfined Compression Characteristics

The UCS of the compacted fiber-fly ash-clay samples was plotted with reference to fiber type and fiber length in Fig. 3 for each fly ash content and fiber dosage, separately. For determination of the UCS the failure deviator stress was taken as the peak deviator stress for the strain softening specimens and as the deviator stress at 15% axial strain for the strain hardening specimens. It is clearly seen from Fig. 3 that in spite of some exceptions, the higher the dosage of fiber the higher the UCS for both fiber types and fiber lengths is. For the mixtures with 10% and 30% fly ash contents (Fig. 3b and Fig 3.c) the effect of 0.5% M06 fibers on UCS is slightly greater than that of 1.0% M06.

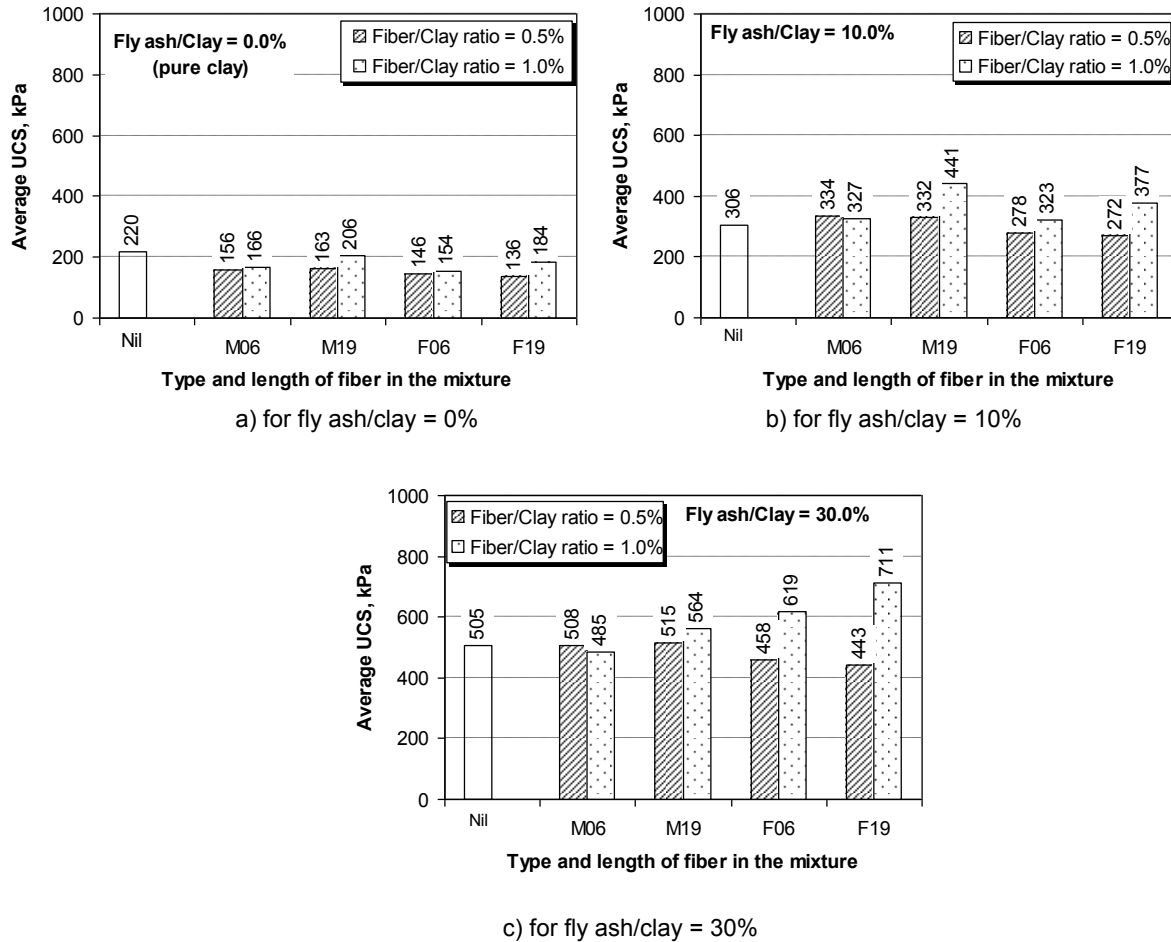

Figure 5. Variation of average UCS of 28 days cured fiber-fly ash-clay mixtures with respect to type and length of fiber in the mixtures

For the mixture with 10% fly ash content, the effect of multifilament polypropylene fibers (M06 and M19) is significantly higher than that of fibrillated polypropylene fibers (F06 and F19) at 1.0% fiber dosage. Moreover, the effect of 19 mm long fibers at 1.0% fiber dosage is slightly greater. Among the other fiber types, lengths and dosages, 1.0% M19 and 1.0% F19 give the highest increase and the second increase in the UCS, respectively. Addition of 1.0% M19 and 1.0% F19 further increased the UCS from 306.1 to 441.1 kPa (44%) and from 306.1 to 377.0 kPa (23%), respectively.

For the mixture with 30% fly ash content, the effect of the dosage on UCS is not significant for multifilament polypropylene fibers (M06 and M19) whereas the effect of fibrillated polypropylene fibers (F06 and F19) at 1.0% dosage significantly increases the UCS. While the 1.0% M19 gives the highest increase, 1.0% F06 and 1.0% M19 give the second and third highest increase in the UCS, respectively. Addition of 1.0% F19 and 1.0% F06, and 1.0% M19 further increased the UCS from 505.2 to 710.6 kPa (41%), 505.2 to 619.0 kPa (23%) and from 563.5 to 710.6 kPa (12%), respectively.

For the mixture with 0% fly ash content, inclusion of fiber reduces UCS except for 1.0% M19. Thus it may be concluded that addition of fiber alone does not improve the UCS of the clayey soil in fact it tends to decrease the UCS. Addition of fiber reduces the contact area of the clay-to-clay cohesive forces and increases the fiber-to-clay contact area at the failure plane. It is thought that depending on the soil plasticity, addition of fiber alone does not provide sufficient frictional resistance and addition of fiber tends not to improve the UCS. During shear, the fiber at the failure plane forced to orient in the direction of rupture in Fig. 4.

Figure 4. Typical failure surface for 0.5% F06 fiber-fly ash mixture a) parallel orientation of the fibers in the direction of rupture b) magnified photo of the failure surface.

7. CONCLUSIONS

An experimental study was conducted to investigate the influence of the fly ash (Class C) and randomly oriented polypropylene fiber (fibrillated and multifilament) inclusions on the stress-strain behavior and unconfined compressive strength (UCS) of high plasticity clay. The study results show that fibers have little effect on UCS for the soil tested. The conclusions of the study are as following.

1. This study showed that with an increase in the fly ash content the optimum moisture content decreases and the maximum dry density increases.
2. The frictional resistance between the fiber-to-clay contact areas is strongly improved by the fly ash inclusion and is proportional with fiber length and dosage. The effect of fiber type on the frictional resistance is less important.
3. Addition of the fly ash alone increased the UCS but inclusion of fiber alone (with no fly ash inclusion) negatively affects the UCS of clay. When combined with the fly ash, addition of the fiber increases the both UCS and residual strength considerably depending on fiber dosage, type and length. The effect of fiber type seems to be not significant on the UCS but the dosage and length of fiber considerably affect the UCS. The higher the dosage of the fiber and the longer the fiber length the higher the degree of improvement in UCS is.

Unique Approach to Dewatering of Mine Wastewater Residuals Using Geotextile Containers

Christopher Timpson, TenCate Water & Environment
Vicki Ginter, TenCate Water & Environment
TenCate Water & Environment, 3680 Mt. Olive Rd., Commerce, GA 30529

ABSTRACT

Mining and mineral processing is vast and complex industry. There are a variety of applications requiring the management of waste streams from the processing of raw coal, removal of tailings and fines from settling ponds, and treatment of thickened wastewater sludge. As in remediation projects, governmental regulations dictate what mines can and cannot do in terms of handling their waste streams. In some areas underground storage of process waste is allowed, in other states there is a moratorium on underground storage. Sometimes in states that allow underground storage, there may be temporary situations that require an alternative storage.

This paper will address how geotextile containers offer a unique high volume, low cost de-watering system to provide a very effective way of dewatering wastewater residuals in mining applications.

1. GEOTEXTILE CONTAINER DEWATERING TECHNOLOGY

Geotextile containers have been used since the 1960's as shoreline protection in marine and river structures such as breakwaters, dikes, artificial islands, and jetties. Over the years, this technology has transferred into the dewatering of wastewater with the aid of chemical conditioning. There are three basic stages to dewatering with geotextile containers which are confinement, dewatering, and consolidation (See Figure 1). The specially engineered textile which the geotextile containers are fabricated allows confinement of the fine solids inside the container but allows water to filter for dewatering. As the water drains, the solids continue to densify inside the geotextile container and the volume inside the container continues to consolidate over time.

Figure 1. Three basic stages of geotextile container dewatering.

A dewatering cell must be constructed to hold the geotextile containers (See Figure 2). In most cases the available area for construction of a dewatering cell is limited but geotextile containers can be manufactured in many configurations and sizes to maximize the available footprint. Creating a slight grade with the slope in the length direction of the geotextile containers promotes drainage of the filtrate for better collection. An advantage of geotextile containers is that they can be stacked in a pyramid configuration several layers high depending on the consolidated characteristics of the dewatered solids.

Figure 2. Geotextile containers inside dewatering cell

Generally this cell has an impermeable membrane installed to help control the volume of effluent which drains through the containers. Typically the effluent is returned back into a body of water, and in some instances can be directly discharged if the filtrate quality meets reporting limits. The wastewater can be dredged or pumped directly into geotextile containers.

If the flow of wastewater is extremely high, a manifold system can be installed which allows multiple containers to be filled at one time to maximize dredging output. The primary feature of a geotextile container is to retain solids and contaminants while permitting effluent to drain through the pores of the woven engineered filtration textile. During all phases of the dewatering process (filling, dewatering and consolidation), the filtration textile must provide excellent tensile properties, efficient effluent drainage, and effective retention of solids to guarantee optimum slurry dewatering. The filtration properties of the engineered textile permit the containers to capture the solids, while water drains out. The moisture will continue to filter out and solids will continue to dry over time promoting more volume consolidation. Using the appropriate polymer for chemical conditioning will allow for the solids in the wastewater stream to create an agglomeration and release free water for drainage. Figure 3 shows typical results of geotextile container dewatering with a depiction of filtered effluent, conditioned slurry, and in-situ slurry.

Figure 3. Results of dewatering with geotextile containers showing filtrate, conditioned slurry, and in-situ slurry.

Chemical conditioning optimizes the dewatering performance of geotextile containers, increasing the dewatering rate, improving effluent quality, and achieving higher dry mass. The chemical conditioning of the wastewater occurs before the slurry is pumped into geotextile containers to accelerate dewatering

Once the solids are fully consolidated or have met minimum requirements for transport, several options are available for disposal. Typically after consolidation, the geotextile containers can be cut open and solids transported to landfill or land applied. In some applications, the containers can be buried in place allowing the dewatering area to be reclaimed.

2. PROCESSING OF RAW COAL PROCESSING

Conventional disposal methods of surface impoundment or injection into abandoned underground mine workings is not always possible. Regulatory restrictions, available area, and construction scheduling can create possible interruptions to the primary disposal methods for mining refuse. Geotextile containers can offer an alternative disposal method for wastewater and allow for the coal processing to continue operation without disruption.

A coal processing plant faced an issue where it was facing a possible interruption of its operation which involved a waste stream of almost 1.5 million gallons of slurry per day. Continued production of coal was needed in order to meet shipment demands, and geotextile containers were chosen as an alternative to prevent any shutdown.

The plant's normal operation created two waste streams from the impurities of processing raw coal, which were composed of rock and fire clay. Both coarse rock and fine rock particles are produced during the process, the coarse rock is sent to a refuse disposal area by conveyor and fine rock particles are slurried and disposed.

Due to the volume of slurry to be processed, the coal mine needed a safe and efficient plan that would allow the containers to be reclaimed in place instead of opening them up and transporting the material to the coarse refuse disposal area. In order to maximize utilization of the available dewatering area, a stacked pyramid of four layers of geotextile containers was designed for one particular dewatering area. The additional layers were installed and stacked once the consolidated material reached 35% dry weight solids. The complete project required three dewatering cells. Figure 4 is an illustration of the dewatering cell and progression of the stacked containers.

Figure 4. Dewatering cell and stacking progression.

A manifold system, along with a polymer tank and pumps was implemented to fill and manage the flow to multiple containers at once. A swinging ladder 8-inch dredge was placed into the slurry pond to pump the slurry into the containers. The dredge was initially operated on a 24-hour basis with two 12-hour shifts. A crew of five to six men operated the dredge plus managed the filling and dewatering of the containers.

This set-up was capable of pumping 1,750 cubic yards per 24-hour day. The completed project utilized 240 geotextile containers, and a total of 200,000 cubic yards were pumped and dewatered. The average holding capacity of the geotextile containers was 5 cubic yards of solids per linear foot of container.

Once all the containers in the dewatering cell were fully dewatered, the site was then ready for reclamation. Eventually, the containers were covered with earth and then topsoil. Once reclamation was complete, the entire dewatering cell was mulched and seeded. All three dewatering cells were covered and reclaimed. During the reclamation process, a layer of

sand was first applied to cover the containers and provide a filter medium. Next a layer of limestone was installed for drainage, and then containers were covered with earth and topsoil.

3. REMOVAL OF TAILINGS & FINES FROM SETTLING PONDS

Many aggregate plants experience high equipment and manpower costs associated with the handling and removing of tailings and fines from settling ponds. The costs of maintaining pond operations can vary significantly from plant to plant. Not only is valuable space tied up during gravity settling and thickening the materials in the settling ponds, but the ability to calculate the overall costs for mechanical dewatering, removal, and disposal costs of fines can be difficult.

Smaller plants face a more difficult challenge since the capital, maintenance, and operating expense of mechanical dewatering equipment for the removal of clays and fines from plant effluent is beyond their budgetary means. Aggregate plants find it necessary to explore and evaluate other dewatering options.

Several states are revising permits aimed at protecting water quality from the pollution discharged by sand and gravel operations. These facilities can include sand and gravel mines, rock quarries, clay mines, concrete batch plants, and asphalt plants. Federal and state laws require a permit because these operations discharge water that may be polluted, such as sediment from gravel washing, oil and grease from trucks and heavy equipment, and alkaline wastewater from concrete plants. The permit requires companies to take steps to ensure that surface and ground waters are protected and to monitor water quality on a regular basis.

Dewatering with geotextile containers is a cost effective alternative to mechanical processes. Plant effluent can be pumped directly from the process or, if a clarifier/thickener is used, effluent from the underflow can be diverted through a geotextile container, eliminating the requirement for expensive mechanical dewatering units. Table 1 illustrates the effectiveness of dewatering aggregate tailings with geotextile tubes.

Table 1. Effectives of Dewatering with Geotextile Containers with Aggregate Tailings

<i>Material Type</i>	<i>% Solids During Pumping</i>	<i>Dry Solids after 1-Day</i>	<i>Dry Solids after 3-Days</i>	<i>Dry Solids after 15-Days</i>
Clarifier inflow with Polymer	8%	27%	45%	71%
Clarifier outflow with Polymer	31%	43%	55%	70%
Aggregate Tailings with Polymer	26%	42%	67%	86%
Pond Material with no polymer addition (high solids in filtrate)	26%	NA	36%	79%

Geotextile containers can be used to capture fines, silts, and clays from the tailings effluent prior to discharge into the ponds or directly into streams. The containers will separate and dewater the fines and allow disposal without expensive dredging and transporting operations.

4. DEWATERING OF ACID MINE DRAINAGE

A mining company was faced with a challenge to reopen a pit mine which had been converted into a tailings pond for nearly a decade. The mining company desired to extract zinc from the former pit mine, now a tailings pond since the value of zinc had increased. Restarting the operation also required refurbishment of the waste water treatment plant. Figure 5 shows the condition of the open pit mine at the start of the project.

Figure 5. Former pit mine converted into tailings pond.

The challenge of the operation required the removal of 392,000 cubic yards of zinc-contaminated water from the pit mine and dewatering 41,000 cubic yards of sludge. Of the potential options to either dewater the sludge with mechanical systems or build a storage pond on-site; geotextile containers were chosen for dewatering and temporary containment. The project began by adding lime to the tailings pond to raise the pH and precipitate metal ions. The addition of the lime to precipitate zinc created a need to inject CO₂ to balance the pH of the water during removal. This process left the need to dewater 41,000 cubic yards of sludge comprised tailings and addition of lime with geotextile containers. The limited area to construct a dewatering cell required two layers of containers in a pyramid stack to maximize the area, see Figure 6.

Figure 6. Two layer pyramid to maximize available area.

There was an additional benefit of the geotextile containers which allowed the mine to contain the sludge onsite for transport and disposal at a later time. Filtrate results showed that the geotextile containers in conjunction with proper chemical conditioning produced zinc leachate concentrations below the discharge limit of 250 ppb.

5. TREATMENT OF THICKENED WASTEWATER SLUDGE

Typically, thickened wastewater sludge from underground mines is pumped back underground. West Virginia has discontinued issuing new permits for underground wastewater storage. Geotextile containers can contain and dewater the thickened sludge and provide an efficient alternative to liquid hauling of the sludge to the refuse pile.

A particular coal mine produced approximately 2 million gallons of raw mine water per day which is pumped out of the underground mine. The wastewater containing coal fines, iron, and manganese salts is pumped to a neutralization tank where it is treated with hydrated lime and oxygen. The treated water in the neutralization tank overflows into the thickener. Flocculants are added in the overflow trough and thickened solids settle to the bottom of the tank, allowing clear water to overflow from the top to the discharge.

Rakes direct the solids at the bottom of the tank to a center well pump. From there, the solids at 15% by dry weight are pumped to geotextile containers. A dewatering cell was constructed near the wastewater treatment plant and containers were placed on an aggregate base for good drainage. Clean filtrate is collected in a pond and a submersible pump returns the filtrate to the thickener.

After one week the dewatered solids typically reach 33% dry weight solids and continue to consolidate over additional weeks to 67% dry weight solids.

6. CONCLUSIONS

As in remediation projects, governmental regulations dictate what mines can and cannot do in terms of handling their waste streams. In some areas, underground storage of process waste is allowed but in other states there is a moratorium on underground storage. Sometimes in states that allow underground storage there may be temporary situations that require an alternative storage. Likewise, the mines are accountable for contaminants in their waste streams. Case in point is a metals mine where a pond had to be closed pond. For several years wastewater had been stored in the pond due to nitrate contamination.

Acid mine drainage is heavily regulated in all mining areas and all these issues create opportunities for dewatering in geotextile containers. These opportunities may not have existed if not driven by regulations. Mining and mineral processing offer a variety of applications where geotextile containers offer a unique solution to dewatering of wastewater residuals.

Use of an Innovative Geocomposite to Construct a Reinforced Soil Slope using Marginal Fill Soils in Canada

Michael Simons, P.Eng., Maccaferri Canada Ltd., Canada, msimons@maccaferri.ca

ABSTRACT

The use of clayey and silty soils (marginal fill soils) in reinforced soil slopes and walls is usually avoided due to the low shear strength of these soils and the buildup of excessive pore pressures within the reinforced soil mass during compaction operations. On sites where these soils predominate and it is necessary to construct reinforced soil structures, it is not uncommon to import higher quality soils for use in the construction of these structures, usually at considerable cost to the project.

An innovative geocomposite reinforcement grid has been developed that combines reinforcement and drainage characteristics into a single geocomposite geogrid that allows for marginal fill soils to be used in reinforced soil applications. Significant cost savings were realized by using readily available marginal fill soil for the construction of an earth embankment in a large urban area in Southern Ontario. This paper will discuss the first use of this innovative geocomposite in North America.

1. INTRODUCTION

Many construction sites in urban areas are generators of excavated earth materials that may be unsuitable for reuse on site as structural backfill due to high fines and possible contamination. Some of this material may be used for general landscaping or other non-structural applications. Generally, most of these excavated soils are disposed of offsite. Increasingly, these soils are being exported to dump sites or new developments located at increasing distances from the source. This results in an increase in the amount of transit time for each load to be disposed, as well as a cost for disposal.

Reinforced soil structures consist of a series of planar tensile elements arranged in horizontal planes placed at a defined vertical spacing within a mass of engineered backfill. They are conventionally designed (FHWA 2009) and constructed using free draining granular soils. These soils have relatively high shear strength and are able to rapidly dissipate pore water pressures that develop in the reinforced soil mass. The use of high quality soils provides a material that is well understood, easily worked and minimizes post construction movement of the soil mass. When available at a reasonable cost, these high quality soils can provide a cost effective solution for the construction of soil retaining structures. Sources of high quality fill soils are increasing located at greater distances from urban construction site, resulting in longer transit times for truckloads of material.

A reinforced soil slope is a form of reinforced soil structure with an outward face of the reinforced soil mass that is typically inclined at greater than 26° from the horizontal, but usually no steeper than 70°. The facing is typically a flexible system that will tolerate movement and deformation, usually vegetation, but it may also consist of some form of flexible armor. With a flexible facing, these structures are capable of tolerating movement and deformations. The use of cohesive and marginal fill soils within reinforced soil slope is possible, but not commonly done in Canada.

Due to the high content of fine grained particles, cohesive and marginal fill soils are usually low permeability materials. When low permeability soils are subjected to loading, excess pore pressures can develop. This increase in excess pore pressure can lead to a reduction in the available shear strength of the soil. The bond between a soil reinforcement and the soil may also be reduced, requiring more reinforcement in order to provide adequate bond length. The dissipation of the excess pore pressure over a period of time will result in consolidation and settlement of the reinforced structure. This consolidation may result in unacceptable deformation of the reinforced soil structure.

Research (Zornberg & Mitchell 1994, Kempton et al 2000) has shown that cohesive and marginal soils can be used effectively in the construction of reinforced soil structures provided that adequate drainage has been incorporated into the design. With cohesive and marginal fill soils, the friction angle is generally lower than a high quality fill soil. A lower friction angle and the presence of pore pressures within the soil mass can significantly reduce the interaction between the soil and reinforcing elements. Dissipating the pore pressures locally around the soil reinforcement has been shown (Kempton et al 2000) to increase the interaction with the reinforcement and increasing the overall stability of the soil mass.

As long term post construction movement and deformations are a possibility with the use of lower quality soils, the use of cohesive and marginal fill soils is usually limited to reinforced soil slopes. Marginal or poor quality soils are usually defined as soil having more than 15% passing the 0.075mm sieve and with plasticity index of greater than 6 for walls, and greater than 20 for slopes (FHWA, 2009).

An innovative geocomposite has been developed that combines the functions of soil reinforcement and drainage for use in stabilizing steep slopes in conjunction with marginal and cohesive soils. This paper will discuss the first usage in North America of this innovative geocomposite, or draining geogrid, that has been designed solely for use as reinforcement for cohesive and marginal fill soils.

2. GEOCOMPOSITE REINFORCEMENT GEOGRID

2.1 Description of Innovative Geocomposite

The geocomposite soil reinforcement consists of high tenacity multifilament polyester yarns that are placed in tension and then co-extruded with a polyethylene sheath into strips. The combination of polyester and polyethylene polymers in a single strip provides high tensile strength and superior creep performance of the polyester while having the superior installation damage resistance of the polyethylene.

The polyethylene sheath is profiled to provide a shaped drainage channel. The drainage channel is oriented parallel to the load bearing axis of the polyester yarns, providing drainage along the direction of tensile loading in the reinforced soil zone. The profiled element has a thermally bonded nonwoven geotextile strip bonded on the shoulders of the drainage channel. The geotextile allows excess pore water pressure to dissipate while retaining the cohesive soil. The profiled strips are either 24mm or 33mm wide. The thickness of the strips varies from 2.1mm to 2.6mm, depending upon the strength of the strips.

Figure 1. Multiple extruded elements welded into geogrid roll (after Linear Composites)

Multiple polymeric strips are laid flat in the machine direction and a secondary member is laid in the cross direction and heat welded across the full width of the strip cross section at a 75mm centre to centre spacing. The geocomposite is available in a range of strengths from 50 kN/m up to 200kN/m (machine roll direction). The transverse strength of the material is constant at 15kN/m.

2.2 Geocomposite Concept

The laboratory performance of the geocomposite has been studied and reported by numerous authors (Kempton et al 2000, Naughton & Kempton 2004, Zornberg & Kang 2005, O'Kelly & Naughton 2008). A geogrid that is manufactured in a very similar manner to the geocomposite, but without a drainage profile, has been used for comparison purposes in these studies to quantify the improvement in interaction. Pullout resistance in testing improved 20% or more in various studies (Zornberg & Kang 2005, Clancy & Naughton 2010). Kempton *et al.* (2000) reported that when tested with English China Clay (coefficient of consolidation 1.3 to 2.3m²/year; permeability 1.07x10⁻¹⁰ to 2.43x10⁻¹⁰ m/s), excess pore water dissipated to 20% of the initial value in 32 hours, pore pressures measured at various distances from the geocomposite did not reach the applied confining stress, nor did there appear to be a difference in pore pressure dissipation above or below the geocomposite even though the drainage channel was only on one side. A good correlation between the volume of water displaced from the test cell and the measured dissipation of pore pressures was found. No clogging or washing through of fines into the drain was noted.

These studies have demonstrated that the geocomposite is effective in dissipating excess and increasing the shear strength of soils that would traditionally have been classified as cohesive or marginal fills and that would not have been normally used to construct a reinforced soil embankment.

Naughton et. al (2001) proposed a design methodology that incorporates dissipation times and settlements during the construction of reinforced slopes. The vertical spacing of geocomposite is determined based upon the consolidation behaviour of the fill soils. The goal of the design method is to dissipate any excess pore water pressures present in the slope during the construction stage to control vertical and horizontal deflections so as to occur during construction. A target of 80% as an average degree of consolidation is desirable at the end of construction of each lift. A vertical spacing of 0.5m between layers of the geocomposite is recommended as an initial starting spacing. A vertical spacing of 0.5m would facilitate construction of a maximum fill thickness in a period of approximately 24 hours. This time period would allow for the placement and compaction in one day of 0.5m of fill, making the construction of a reinforced marginal or cohesive soil embankment efficient.

2.3 Usage of Geocomposite

The use of geocomposite has been documented by Naughton & Kempton (2004) for the reconstruction of a slope failure in Taiwan in 1999, and by Veggi & Parla (2009) to construct part of the capping layer for a municipal solid waste landfill in Italy. The geocomposite has also been used to construct a berm in the United Kingdom (Maccaferri, 2001). These projects have used poor quality soils reclaimed from the site, or used imported cohesive soils.

3. NORTH AMERICAN USAGE

3.1 Site Location and History

The multi-phase conversion of a former industrial site within the City of Toronto, Ontario, Canada, into a residential infill development has been ongoing since 2005. The site is bounded along the north by Davenport Road, Lansdowne Road along the east and an active railway line along the western boundary. The three previous phases of redevelopment at the site required the staged construction of an earth berm aligned parallel to the railway line to act as a noise and crash berm. Reinforced soil embankment structures have been used for the construction of the berm in order to minimize the footprint of the berm. These reinforced soil berms were all constructed using imported fill soils that ranged from gravelly sands to silty sands, depending upon the type of material that was available during construction.

3.2 Phase IV Original Embankment Design

The fourth phase of development and the associated earthworks for the construction of the berm began in 2011. The berm was originally designed to be built as a 4.2m high, vegetated reinforced soil slope inclined at 60° from the horizontal. Imported gravelly sand fill was to be used to construct the berm. A PVC coated, double twisted galvanized woven wire mesh ($T_{ult}=50\text{kN/m}$) geogrid was to be used as the tensile reinforcement. The design of the reinforced slope used 6 layers of woven wire geogrid at 4m lengths, vertically spaced at 0.7m. The soil reinforcement was to be wrapped at the face of the slope. A synthetic turf reinforcement mat was used to secure a layer of topsoil at the face. The volume of fill required to construct the reinforced soil zone within the embankment was estimated to be 2,800m³ compacted, or 3,400m³ loose (1.225 bulking factor). The original embankment required a wooden sound fence to be installed at the crest of the embankment. This would require the installation of circular footing forms for the pouring of concrete footings for the fence during the construction of the reinforced embankment.

At the time of construction, the project Owner was developing another site located within close proximity to the project site. This site was generating significant quantities of sandy silt soils that had to be disposed of offsite, some of which was allocated for use for landscaping purposes on the project site. A contractor that had built two of the three previous reinforced berms was retained to construct the current phase. The project Owner requested that the contractor develop a method to use this sandy silt soil as structural fill within the reinforced soil zone of the berm. The reuse of the sandy silt soil as engineered fill on the project provided the Owner with a number of benefits: i.) A close disposal site (30 minute round trip); ii.) Elimination for the need to purchase and import high quality granular fill; iii.) Significant reduction in disposal fees (only costs associated with transportation between sites); and iv.) A reliable source of imported fill material for the construction of the Phase IV berm, thereby minimizing disruptions to the earthworks.

The sandy silt soil had a unit weight of 18 kN/m^3 and an angle of internal friction of 23° . The sandy silt soil had approximately 50% passing $75\mu\text{m}$. The optimum moisture content of the sandy silt fill was 11.3%. Figure 2 shows the gradation envelope of the gravelly sand fill compared to the gradation of the proposed sandy silt fill.

Figure 2. Comparison of backfill soil gradations

3.3 Redesign Embankment Using Draining Geogrid

After reviewing the limited soils information available for the project site and literature on the geocomposite, it was decided that the reinforced embankment could be redesigned to incorporate sandy silt fill. The redesign utilized 8 layers of the draining geogrid at 0.56m vertical spacing. The length of the geogrid was increased to 5m. The vertical spacing was selected based upon use of woven wire mesh forms at the slope face and the necessity to provide a reduced drainage path for the poor quality silt fill. Correspondence with authors of several reference papers (Naughton, pers. comm., 2011; Scotto, pers. comm., 2010) indicated that a vertical spacing of between 500mm and 600mm was typical of projects using different types of marginal and cohesive soils and no issues with performance had been observed.

The additional layers of geogrid in the redesigned structure did act to slightly decrease the speed at which the contractor could place reinforcement and fill. The increased installation time was offset by the efficiencies gained through the use of a steady, reliable source of imported fill material. The crew constructing the reinforced slope had extensive experience building similar structures using other types of geogrids and found no special accommodations were required to work with the draining geogrid. As per the original embankment design, the placement of circular forms for concrete fence post footings was required.

The placement and compaction of the sandy silt fill was monitored during the construction of the reinforced soil berm. The sandy silt fill was placed at 96% to 100% SPMDD. Moisture content of the fill ranged from 6.9% to 12.9%.

The circular forms were installed during the placement upper portion of the reinforced embankment. The footings were 1.5m deep, requiring adjustments in the 3 layers of reinforcement.

Figure 3. Geocomposite with woven wire mesh facing

Figure 4. Reinforced slope after 6 months

Figure 5. Circular forms for wooden fence

A visual inspection done one year after the start of construction showed no signs of tensile cracking along the crest of the berm or settlement. No bulging of the wire mesh facing panels was observed. A vegetated cover of primarily annual and perennial ryegrasses was present. The vegetation is estimated to cover approximately 85% to 90% of the area of the reinforced slope face.

The wooden fence was installed 10 to 11 months after completion of the reinforced berm. No signs of horizontal or vertical displacement were observed in the alignment of the fence.

3.4 Cost Comparison of Designs

It is possible to compare the cost of constructing the embankment as originally designed using imported granular fill against the redesigned embankment using marginal fill. The cost to supply the materials associated with the use of the geocomposite was approximately 10% higher than the material supply cost for the original reinforced slope design using the woven wire geogrid.

The embankment as original designed required approximately 2,200m³ of imported granular fill and 1,200m³ of marginal fill. The price presented to the owner to construct the embankment as originally designed was \$237,654, or \$486/m². This cost included the supply and installation of the woven wire mesh reinforcement. The costs associated with the disposal of 2,200m³ of the sandy silt soil were calculated to be \$62,700.

The embankment as constructed with the geocomposite utilized approximately 3,400m³ of marginal fill. The cost to build the redesigned embankment was \$160,881 or \$329/m². This cost included the supply and installation of the woven wire forms and geocomposite. There were no extra costs associated with the off-site disposal of the marginal fill.

4. CONCLUSION

Constructing reinforced soil structures using high quality granular fill soils is becoming increasingly difficult due to the high cost of these soils. Many construction sites in urban areas generate excavated spoil soils that are historically considered

as waste and transported off site. These exported soils are not normally considered for reuse in the construction of reinforced soil structures.

Soil reinforcement that is capable of dissipating excess pore pressure for cohesive and marginal fill soils may afford an opportunity on some projects to mitigate the off-site disposal these materials. The reduction and re-use of materials will have obvious economic benefits for the project.

The use of an innovative geocomposite geogrid in conjunction with sandy silt soil that was to be wasted from a nearby construction site allowed for the construction of a steep, reinforced soil slope using soils that would normally be used for landscaping purposes or bulk engineering fill. The reuse of the marginal soil in a reinforced soil slope resulted in a significant cost savings to the project owner.

Use of Bituminous Geomembranes in Harsh Conditions

Bertrand Breul, Montreal Canada, BBreul@axtercoeltancehe.com
Bernard Breul, Axter Coletanche, Irvine USA, Breul@eirnet.com

ABSTRACT

This paper presents two mining applications of bituminous geomembrane. At the Diavik Diamond Mine in the 'Lac de Gras' area in the Northwest Territories of Canada, the diamonds are extracted from the Kimberlite ore, and the rejected material is permanently stored in a diked containment facility lined with a geomembrane. The initial stages of the embankment construction used HDPE geomembrane, which meant that geomembrane lining could not be done for many months of the year. The design was changed to bituminous geomembrane, which can be installed at very low temperature. This increased the construction period by several months each year. At the Furioso Mine in the Chilean Patagonia region, the waste rock pile was closed using a bituminous geomembrane covered with 20 cm of soil. The driver for liner selection was the ability to install the bituminous geomembrane in winds up to 50 km/h.

1. INTRODUCTION

Over the past two decades the use of geosynthetics in the mining industry has grown. Geotextiles, geomembranes, geosynthetic clay liner, and geocomposite to name a few have been used to line dams, heap leach pads, tanking storage facilities, tailings ponds and water ponds and to cover mine waste facilities at closure. Bituminous geomembranes have been part of this growth and have been deployed in numerous mines worldwide over the past few years. Bituminous geomembrane offers specific advantages over other geomembrane that have led to their usage in parts of the world characterized by harsh weather and some very difficult access conditions. Bituminous geomembranes are manufactured by impregnating a non-woven geotextile with bitumen. The thickness of the bituminous geomembrane is controlled mostly by the thickness (mass) of the geotextile. Bituminous geomembrane exhibits the strength and deformation characteristics of the non-woven geotextile and the very low permeability of the bitumen. They are therefore well suited for applications that require strong geomembrane such as tailings facilities, mine waste rock piles, process water ponds, and areas where equipment must traffic over the lined area. Because of the high melting point of bitumen, asphalt can be laid on top of bituminous geomembranes to create hard impervious surfaces.

Bituminous geomembranes are:

- Heavier than most polymeric geomembranes, and can be installed in very windy conditions.
- Denser than water so they do not flood.
- Have a low coefficient of thermal expansion, and so do not expand and contract and develop wrinkles as the temperature changes daily after deployment.
- Thick (at least 3.5 mm) and therefore, extremely resistant to puncture.

The balance of this paper highlights two projects where bituminous geomembranes were used to address weather related constraints.

2. COLD WEATHER SITE

2.1 Location

The Diavik Diamond Mine (DDM) is located on East Island, a 17 km² island in Lac de Gras, NWT, approximately 300 km northeast of Yellowknife (64°31' North, 110°20' West) as shown in Figure 1.

2.2 Climate

The DDM site lies within the Arctic Climatic Region where daylight reaches a minimum of 4 hours per day in winter and a maximum of 20 hours per day in summer. The climate is extreme, with long, cold winters and very short, cool summers. The mean monthly temperature in July is 10 °C and that in January is -31 °C. The mean annual air temperature at the site is approximately -10 °C. On average, there are 260 days per year with temperatures below zero degrees Celsius. Snow falls every month, although rain generally only occurs between May and October.

Figure 1: Diavik Diamond Mine Location

2.3 Permafrost

The DDM site is located in the area of continuous permafrost, with permafrost depths confirmed to 150 m at the mine site. The active layer is about 1.5 m to 2.0 m deep in till deposits, 2.0 m to 3.0 m deep in well-drained granular deposits (eskers) and about 5 m in bedrock. In poorly drained areas including bogs, with thicker vegetation cover, the active layer is less than 1 m in depth. Thermistor data shows that the mean annual ground temperatures range from about -3°C to -6°C .

2.4 Water Management Ponds

Protection of the quality of water in Lake Lac de Gras is a priority for the mining company. Water management at the DDM site involves collecting all surface water runoff from areas affected by the mining operations. This water is used in the diamond processing operations or is treated and discharged to Lac de Gras. Water collection ponds are built as mining operations expand. During the initial construction of the mine facilities in 2001 and 2002, the water collection ponds were lined with using an HDPE geomembrane.

A new pond (Pond 14) was required for the spring-melt period in 2005 and two additional ponds (Ponds 2 and 13) were required for 2006. Due to other construction activities at the mine site, the construction of Pond 14 was scheduled for the second quarter of 2005, before the onset of the spring thaw and surface water runoff. This meant that construction would be carried out completely in freezing conditions. In addition, the locally borrowed fine sand that was used as liner bedding and cover would not be available during this time. Therefore, both the liner bedding and cover materials would be angular materials produced by crushing and screening granitic rock. Alternative designs of the dike section and pond liner system sections were evaluated to allow efficient cold weather construction and to minimize the amount of crushing and screening required. A section incorporating a bituminous geomembrane liner in the upstream section was selected.

The decision to use a bituminous geomembrane liner was based on the fact that the elastomeric bitumen in the geomembrane remains flexible at temperatures lower than -20°C and exhibits a low coefficient of thermal expansion ($1 \times 10^{-6} \text{ cm/cm/}^{\circ}\text{C}$). This meant that the material would be relatively insensitive to temperature changes during installation and service. In addition, the 4mm thick bituminous geomembrane is much heavier than the HDPE geomembrane previously used in these ponds (3.9 kg/m^2 vs 1.4 kg/m^2), and not is prone to being lifted by light winds during installation. This type of liner had been installed at other sites at temperatures down to about -20°C and productivity during installation at low temperatures was reported to be similar to productivity at temperature above zero degrees Celsius. A 50 mm minus crushed gravel was initially selected as the liner bedding and cover material. Tests during construction showed that a crushed 150 minus cobble, gravel and sand material could be used without damage to the liner, if surface

of the bedding was smoothed and raked to remove protrusions from the surface. The grain size distribution for the fine and coarse liner bedding materials are shown in Table 1.

Table 1. Liner bedding and cover grain size limits

Coarse Liner Bedding and Cover				Fine Liner Bedding and Cover			
Grain (mm)	Size	% Passing (Minimum)	% Passing (Maximum)	Grain (mm)	Size	% Passing (Minimum)	% Passing (Maximum)
200		100	100	50		100	100
75		45	100	19		80	100
19		24	56	9.5		60	90
4.75		13	34	4.75		40	70
2		7	28	0.85		18	38
0.42		0	16	0.075		3	15
0.075		0	12				

Pond 14 was constructed during April and May 2005, with 12,700 m² of liner installed in a 6 day period in early May 2005. During this period the temperature varied from -18 °C to -4 °C, winds were typically in the range of 10 km/hr to 20 km/hr and 1 to 2 cm of snow fell on a number of days. The rate of liner installed varied from 1,300 m²/day to 2,400 m²/day. Quality control testing and quality assurance testing involved vacuum box and ultrasound testing of seams to confirm the quality of the welds. Vacuum box testing proved to be more effective than ultrasound testing in the cold conditions during installation. Anti-freeze is required in the testing water to prevent the vacuum box from freezing to the liner.

To assess the performance of exposed bituminous geomembrane, and select a thickness for future design, a test pad was built with panels of 3.5, 4.0, and 4.8 mm thick bituminous geomembrane. The test pad was left uncovered and exposed to the elements (Figure 2). After exposure for four winters there were no changes in the appearance of any of the panels.

Figure 2: Bituminous geomembrane liner exposed for long term weathering assessment

Ponds 2 and 13 were designed with the same lining system as as Pond 14. Construction of Pond 2 was started in May 2005, but stopped in June 2005 when warm temperatures caused ice-rich permafrost exposed in the cut off trench excavations to melt and create unstable excavations. The construction of Pond 2 was finished in November and December 2005. Twenty-five thousand square meters of liner were installed in Pond 2, with 1,000 to 2,000 m² being installed per day. The temperature during installation in June 2005 ranged from about 3 °C to 14 °C, while the temperature during installation in November and December 2005 ranged from -4 °C to -32 °C. Some sections of the liner was successfully installed at a temperature of -25 °C, not including the effect of wind chill. Heavy snowfall occurred on a number of days, which required snow to be removed from the face of the dike on the already installed sections before installation could continue. The upper surface of the bituminous geomembrane has a sand coating, which provides good traction for the workers walking and working on the liner even in the presence of a thin cover of snow.

Pond 13 was constructed during April and May 2006. Ten thousand square meters of liner were installed. Temperatures during liner installation were in the range from -15 °C to -5 °C.

The water management ponds now have been in operation for 7 years. Each of the ponds has experienced some seepage. Investigations into the cause of each area of seepage have identified foundation issues, most likely melting of ice lenses in soil or ice within fractures in the bedrock beneath the cut-off level of the liner. The performance of the ponds indicate that after the dam and foundation re-establish a stable temperature regime, with the foundation refrozen, seepage does not occur. Planning for the construction of new ponds incorporates construction of a pond at least one year in advance of when the pond is required to allow the foundation to refreeze.

Figure 3: Snow clearing during bituminous geomembrane liner installation in Pond 2

2.5 Processed Kimberlite Containment Facility

The Processed Kimberlite (PK) that remains after diamond recovery is permanently stored in the Processed Kimberlite Containment (PKC). At DDM, the diamond recovery process results in two by-products, Coarse PK consisting of kimberlite particles with grain size between 1 mm and 6 mm, and Fine PK consisting of kimberlite particles with grain size less than 1 mm. The Coarse PK is trucked from the process plant to the PKC facility and the Fine PK is transported as low-density slurry in a pipeline to the PKC facility. The PKC facility design provides for storage of both streams of PK within geomembrane-lined rock fill perimeter dams. The perimeter dams now completely surround the PKC facility. The process water pond is maintained in the center of the facility by discharging fine PK from each of the perimeter dams. A rockfill berm constructed into the center of the facility is used to access the barge mounted pumps that recycle water to the process plant.

The perimeter dams are all wide rockfill embankments with the seepage control elements on the upstream face. Till and HDPE geomembranes were used on the initial stages of the dams, but this was changed to a bituminous geomembrane to allow lining to be carried out in colder temperatures. The bituminous geomembrane also allowed the use of coarser bedding material, which reduces the amount of crushing and screening required, and hence fuel consumption.

A typical section with bituminous geomembrane including the coarse liner bedding material, a sand liner cover material, and a layer of rock fill for erosion protection shown on Figure 4. Bedding materials used for various stages have been a coarse till material, the coarse material shown in Figure 4 and a 50 mm minus crushed material. Liner cover materials have been sand, and processed sand and gravel materials.

Figure 4: Typical dam section with coarse bedding and sand cover

Seepage has occurred from the PKC dams into the water management ponds located downstream of each dam. Investigations show three causes of the seepage. The first is related to winter construction and the difficulty of controlling the fine grained materials used in the liner anchor trench at the toe of the dams. If these fills freeze before or during placement and then subsequently thaw, soft and open zones can develop across the trench and allow seepage. This is a problem common to all winter construction. The second cause is melting of ice in the permafrost foundation. This either creates flow paths in the foundation, or creates voids in the foundation supporting the dam fills and liner bedding materials. Settlement of the fills into these voids results in liner damage. This is a foundation issue, and common to all liner types. The third cause is related to the discharge of the fine PK slurry into the facility. If the slurry erodes the liner cover and is directed against the liner, erosion of the liner occurs resulting in holes. Again, this mechanism is common to all liner types.

2.6 Joining Bituminous Geomembrane to HDPE

One of the technical aspects of the PKC Dam construction was joining the HDPE liner used in earlier stages of construction with the bituminous geomembrane liner. The process involved thoroughly cleaning the HDPE by sweeping and then washing with water (Figure 5). A primer was applied to the HDPE to enhance adhesion and then a peel and self-adhesive elastomeric membrane (commonly known as Flam Stick) was applied to the HDPE (Figure 6). Careful rolling of the Flam Stick was required to ensure a good bond. Sand and gravel liner bedding material was then placed over the HDPE to the edge of the Flam Stick to prevent excessive heating of the HDPE when the bituminous geomembrane was welded to the Flam Stick using the roofing torch. Tensile testing of samples taken of the joint showed that failure occurred within the Flam Stick and separation of the HDPE from the Flam Stick did not occur.

Figure 5: Primer being applied to HDPE

Figure 6: Flam Stick attached to HDPE

3. WINDY REGION SITE

3.1 Background

The Furioso Mine is approximately 46 miles (75 km) southwest of Chile Chico at an elevation of about 4,600 ft. (1,400m) above sea level in Chilean Patagonia and is essentially non-accessible during the winter months (between mid-March through December) due to the high snowfall and poor road conditions.

Following cessation of operation, the mine owner started closing the facilities including the waste rock facility which covers approximately 6.5 ha.

3.2 Weather

Daytime temperatures in the winter can be as low as -25°C with wind speed in excess of 80 km/h. Snow fall can occur just about any day of the year slowing down construction activities.

3.3 Closure Design

The closure plan called for a geomembrane protected by 1 meter of soil and an erosion protection layer consisting of 50 cm minus rock.

- Facing the potential of high wind and cold temperatures, the design team was looking for a geomembrane that:
- Could be installed when wind speed could in near 50 km/h;
- Would provide the contractor with flexibility in installation;
- Could sustain some vehicular traffic and could remain exposed to the element for a few weeks;
- Did not need a cushion geotextile or a fine grained subgrade; and
- Could be covered with a thinner soil cover than originally planned.

The designer selected a bituminous geomembrane because it could satisfy the needs expressed above, namely:

Weighting up to 3,900 g/m² the 4 mm bituminous geomembrane can sustain winds up to 60 km/h. Following deployment, minimum ballast was placed over the geomembrane that would remain exposed and subjected for the placement of the soil cover.

The installation and seaming process, similar to roofing material does not require a specialty subcontractor. A roofing torch is all that is need to weld the seam which consists of a 20 cm overlap of one panel over the other. This allowed the mine operator to use his own forces (local Patagonians resident) to do the closure work.

The 4 mm thick bituminous geomembrane could be deployed directly on the support that includes protrusion up to 2.5 cm in diameter as shown on Figure 7.

It was decided at design time that a 20 cm thick sand and gravel cover was enough to protect the geomembrane.

The design including the 4 mm bituminous geomembrane and the 20 cm cover was approved by the regulatory agencies and implemented.

Figure 7 Support for the bituminous geomembrane (note particle size of the support)

3.4 Construction

Work started on 11 January 2012, a mid-summer day in the Southern Hemisphere but a snow fall delayed construction for two days (Figure 8). The procedure followed was to prepare and line small areas as weather permitted. Because the bituminous geomembrane is heavier than most geomembrane with a low thermal coefficient it remains flat on the ground support with no wrinkles, waves, or kinks and therefore the cover soil can be pushed over without problem at any time during the day even when the temperature increases.

Figure 8: Snowy cold day in Chilean Patagonia

Nearly 65,000 m² of bituminous geomembrane including 12,000 m of welding and all the Construction Quality Assurance activities (Ultrasound and vacuum box) were installed and performed in 45 days. The bituminous geomembrane was then covered with 20 cm of sand and gravel as shown in Figure 9. The waste rock facility is now considered closed.

Figure 9: Placement of sand and gravel cover

4. CONCLUSION

Bituminous geomembranes have been successfully used at two sites with very harsh weather: extremely cold at the Diavik Diamond Mine in the Northwest Territory (Canada) and very windy and susceptible to quick changes in weather at the Furioso Mine in Chilean Patagonia. The use of bituminous geomembrane provided several benefits to the two mines namely:

- The possibility to install the geomembrane in difficult weather conditions: liner can be efficiently installed at nearly any time of the year. Only when temperatures dip below $-30\text{ }^{\circ}\text{C}$ is liner installation not possible.
- The installation does not require a specialty contractor so it offers employment opportunities for local workforces. The owner at Furioso mine was able used Patagonian residents whereas at Diavik first Nation People were employed.
- Economically viable when balancing the initial higher capital cost with the facts the cushion geotextile are not needed, not using a specialty contractor provide full schedule flexibility, and coarser bedding and cover material can be used.

Use of Chemically Modified Geotextiles to Selectively Remove Metallic Impurities from Potable Water

ABSTRACT

The paper provides an overview of the areas in which geosynthetics are traditionally employed for “Sustainable Water Management” and then goes on to shed light into a new application area of “Geotextiles based ion exchangers (GTIX)”. When compared to the conventional resinous form, GTIX offer comparative advantages such as high rate of sorption and osmotic stability, and the possibility of the textile being spun into various forms such as filters, cloth, moving bands etc. The paper also offers insights on research investigations that have been undertaken on how a geotextile could be modified to remove selective metal ions so as to provide clean potable water to everyone, especially the rural dwellers. The source of water could be open water sources or groundwater. Water treatment is done either in-situ, or ex-situ where groundwater can be pumped out and filtered through these chemically modified textiles before usage.

1. WATER AS A SCARCE COMMODITY

More than 1.1 billion people in the world do not have access to clean drinking water- this is one person in every six. There are 4 billion cases of diarrhea each year, causing 2.2 million deaths (5 000 every day), mostly of children under the age of five. (Coping with Water Scarcity, UN 2007) Over 260 river basins are shared by two or more countries mostly without adequate legal or institutional arrangements. (World Water Council, Marseille 2002) Many women, throughout the world and particularly in developing countries, suffer permanent skeletal damage from carrying heavy loads of water over long distances day after day.

While water scarcity is linked to obvious problems such as hunger, poverty and disease, its far reaching effects exacerbate such issues as gender inequality, denial of education to children, pollution and environmental sustainability, and even regional and global conflicts.

Fortunately, there is heightened awareness about the global water crises that confronts us today and threatens to risk our survival even more in near future. The incorporation of sustainable access to clean drinking water and sanitation in Millennium Development Goals of 2005 was a pointer to this increased realization. Even more encouraging are the reports that convey that the MDG on clean drinking water has been met, halving the proportion of the world's population without access to safe drinking water, five years before the deadline of 2015.

Before going any further however, a word of clarification and caution is important here. While defining water as a scarce commodity, it is important to note that the term ‘Scarcity’ does not imply shortage of water from global perspective. In fact, if all the freshwater resources of the world are divided equally among the global population, there would be 5 000–6 000 m³ of water available per year, per person. According to this per capita calculation, the volume of water lies quite above the threshold value of 1700 m³/person, giving an impression of excess rather than scarcity.

Therefore, from the global perspective, there is no water shortage at all. The World Health Organization and Unicef Joint Monitoring Programme admit this dilemma in their report on ‘Progress on drinking water and sanitation 2012’. Almost half of the 2 billion people who have gained access to drinking water since 1990 live in China or India. Meanwhile, many countries in Africa are not on track to meet the target by 2015, with some countries actually falling back to pre-1990 rates of coverage. More than 40% of all people globally who lack access to drinking water live in sub-Saharan Africa.

The appropriate scale to understand scarcity is, therefore, at the local or regional level. It is also the appropriate level to address the water scarcity issues. Comprehensive Assessment of Water Management in Agriculture, 2007 has listed ‘small-scale, individually managed water management technologies’ as one of the pathways for reducing poverty and vulnerability in rural areas. These technologies can provide water at lower unit costs than large-scale hydraulic infrastructures and can be easily implemented locally.

It is in this context that chemically active geotextiles offer promising potential to provide clean drinking water solutions to rural areas or other water stressed regions.

2. GEOTEXTILES FOR SUSTAINABLE WATER MANAGEMENT

Before embarking on this relatively new area of chemically active geotextiles, it is only befitting to review the traditional role of geotextiles and how they have been used extensively in various hydraulic applications for sustainable water management. Historically, geotextiles have been used in the following ways in water conservation and conveyance systems.

2.1 Canal Lining

Geotextiles and their composites are used for lining of canals. They are known to prevent water loss due to seepage. Additionally, canals can also be covered to reduce evaporation. Their efficiency is known to be as high as 95% in preventing seepage loss.

As a fabric layer, this system is extremely easy to install. Geo composites can be used, depending on the requirement of the project, either in membrane-grid-textile or grid-textile combinations. In these composites, while the grid eliminates the requirement of graded filter for drainage, the textile layer prevents the fines from interfering with the drainage path. The geo composites are used in canal lining system with the water proof membrane in contact with the cover (required to weigh down the geo composite on the slope) and the geo textile is laid against the well graded slope.

Geotextiles also serve to protect the membrane layer on top side walls of the canals. The exposed membranes are susceptible to being damaged either due to intentional or unintentional vandalism; birds that pick at the seams, or animal hoofs when animals approach canals for drinking water.

2.2 Dams

Geotextiles and their composites are employed in dams both for erosion control and reinforcement purposes. To prevent erosion caused by atmospheric agents such as rain, the entire downstream facing and the upper portion of the upstream facing are covered with geotextile; whereas erosion of the dam caused by overtopping can be prevented by protecting the downstream face of the dam. This is a more technically viable and economically feasible solution than protection using concrete slabs. Geotextiles are also used to reinforce dams to give them more stability; this is even more essential in areas prone to high seismic activity.

2.3 Coastal Protection

Geotextile Tubes are used to prevent coastal erosion by simply filling the bags or tubes with readily available fill material such as sand; and strategically placing these tubes on the banks or shores to dissipate or absorb wave energy. These tubes can either be left exposed, which can be a risk to its integrity, or incorporated into the environment as part of a manmade dune or riverbank. They can also be placed in the water to serve as jetties and groins.

2.4 Landfill Liners

In modern landfills, the waste is contained by a geotextile lining system which serves to prevent the movement of small soil and refuse particles into the leachate collection layers and to protect geomembranes from punctures. These materials allow the movement of water but trap particles to reduce clogging in the leachate collection system. In this way they help to protect the soil and ground water/ aquifers from pollution originating in the landfill.

3. CHEMICALLY MODIFIED GEOTEXTILES- A WAY FORWARD TO TACKLE WATER SCARCITY PROBLEMS

Textile materials made of polymers with chemically active functional groups have a unique combination of properties. On one hand, they can fulfill functions of conventional textile materials such as cloths, non-woven fabrics, filters etc., and on the other hand, they can function as chemical agents, such as ion exchangers, complexones, reductants or oxidants and catalysts.

This section will elaborate the function of textiles as ion exchangers to remove metallic impurities from potable water, the possibility of either using this technology as small scale water purification units or as active materials in groundwater barriers; and most importantly, the edge that the fibrous ion exchangers provide over conventional resinous ion exchangers. It is important to begin this subject by revisiting the basic definitions and concept of ion exchange.

3.1 Basic Concept of Ion Exchange

Ion-exchange is a chemical reaction between two substances (each consisting of positively and negatively charged species called ions) that involves an exchange of one or more ionic components. Ion exchange usually transpires between a material carrying a fixed ion and a solution carrying mobile ions. The solution must be permeable in the material in order to allow the exchange to take place.

Materials with fixed negative charges exchange positive ions, or cations, and the process is called cation exchange. Those having fixed positive charges correspondingly exchange negative charges, or anions, and are said to undergo anion exchange. Typical ion-exchange reactions can be written as follows:

Where Fix^- is an ion fixed in the resin or other type of exchanger, A^+ and B^+ are univalent cations and C^{2+} is a divalent cation.

3.2 Treatment of Water

Ion exchange technique is extensively used for purification of water from ionic impurities. These may include poisonous ions such as arsenic and silver or ions such as calcium and magnesium that are responsible for causing hardness in water. Hard water is a nuisance as it causes scaling and also forms insoluble precipitates with soaps. Excess calcium and magnesium in water also leads to increase chances of cardiovascular disease. Arsenic, on the other hand, is known for affecting the gastrointestinal tract (nausea, vomiting), and in more severe cases even the cardiovascular system (hypotension, shock).

In order to remove calcium and magnesium ions from water, hard water is made to pass through a column densely packed with resins such as natural aluminosilicates or synthetic resins. These resins have sodium ions fixed on the surface. As the water comes into contact with the resin, magnesium and calcium ions are exchanged by the sodium ions; and the water leaving the column is free from the Ca/Mg impurities. After the column has been in use for some time, calcium and magnesium begin to appear in the water leaving the column. The column must then be regenerated by passing a concentrated solution of brine slowly through the column.

Removal of other poisonous metallic ions such as silver and arsenic from water can also be explained using similar principles of ion exchange. However for every metal, different kinds of fixed ions are required based on the preference attraction of the resin for the particular mobile ion.

4. GTIX ADVANTAGES

Though resinous ion exchangers are extensively used all over the world for water purification, there are possibilities to make it even more efficient and easier to handle or operate. Inconvenience is particularly caused owing to its large size, especially if large quantity of water needs to be purified. Chemically active textiles, also known as geotextiles based ion exchangers (GTIX), offer promising alternative to resinous counterparts in this context. Some of their advantages over conventional ion-exchange beads include:

GTIX can be easily fabricated into various textile forms such as cloth, conveyer belts, non-woven materials, staples, nets, felts, papers, etc. This opens many possibilities for new configurations for mounting the materials. The increased surface area of textiles provides opportunity for better accessibility of the mobile ions to the active sites. This leads to shorter diffusion time and the sorption rates can be as much as a hundred times faster than that of the conventional granular resins. They also allow column designing with pressure drops much lower than in reactors using granular materials. Furthermore, GTIX do not lose their shapes on successive absorption and desorption of water, for example, during cyclic sorption/regeneration processes.

Figure 2 shows the comparison of typical behavior of fibrous and resinous ion exchangers with the same chemistry of ion exchange sites. As is seen in the figure, a considerable part of GTIX graph shows complete absence of metallic ions in the beginning, giving credence to the extremely high sorption rates of GTIX. This also implies that GTIX can be used for efficient purification in thin layer beds. Both these advantages make geotextiles based ion exchangers a suitable technology for small scale water purification systems.

Figure 01. Schematic of fibrous and granular ion exchangers' performance.

5. SYNTHESSES AND FABRICATION METHODS OF GEOTEXTILES BASED ION EXCHANGERS

Essentially, there are two steps for formation of textile based ion exchangers. The first is related to the formation of fiber itself, and the second to its functionalization. However, in more cases than not, the two steps are not discrete but may overlap in a variety of methods. Several researchers have experimented with innovative routes to obtain a chemically active textile. A general classification of these methods is given below. These methods are by no means exhaustive, but they serve to give some basic understanding of the principles of synthesis of GTIX.

5.1 Suspension of Resinous Beads into Fiber Forming Solutions or Melts

This can be done either directly by dispersing fine particles of resinous ion exchangers into an inert fiber forming solution, or indirectly when two polymer solutions are mixed whereupon the ionizable group is formed upon mixing of the two solutions.

This method is quite appealing because of its universality in which any form of resins can be incorporated into the fibers. However, its limitation lies in the size and quantity of the resin beads being dispersed. Particle size of more than 3-5 μm , and resin quantity more than 35% of the solution leads to deterioration in the mechanical strength of the resultant fiber.

5.2 Graft Polymerization via Radiation or Chemical Means

Grafting is the process of joining or incorporating a copolymer into the chains of a main or principal polymer. This requires activation of sites on the main polymer in the form of free radicals or ions. The stimulus for this activation can either be by means of chemicals or direct radiation.

5.2.1 Irradiation Technique

Irradiation technique can proceed in three different ways: preirradiation, peroxidation and simultaneous irradiation.

In the pre-irradiation technique, the principal polymer is first irradiated in vacuum or in the presence of an inert gas to form free radicals. The modified polymer is then grafted with the monomer. One limitation of this methodology is the formation of homopolymer, which results in the loss of chemicals, and involves tedious task of washing off the homopolymer from the final product.

Peroxidation technique is carried out in the presence of air, resulting in the formation of peroxides or hydroperoxides. These intermediate products are rather stable in ambient conditions and can be stored for days. When treated with monomer at higher temperature, the peroxides decay spontaneously to initiate grafting.

In the mutual irradiation technique, the polymer and the monomers are irradiated simultaneously, to form free radicals and subsequent graft. Since, the backbone polymer is not irradiated separately, this technique, unlike the preirradiation one, does not cause the problem of homopolymerization.

5.2.2 Chemical Technique

Chemical grafting is done by means of initiator, the type and quantity of which determines whether the reaction would proceed via free radicals or ions. In chemical method, unlike the irradiation method where the free radicals are formed directly on the polymer, the radicals are first formed on the initiator and then transferred to the monomer.

Both the chemical and irradiation grafting have their own pros and cons. From the process control aspect, irradiation grafting yields purer products. Higher degrees of penetration of radiation can be used to access the inside of polymers resulting in greater depths of grafting. Furthermore, it's easier to control the molecular weight of the polymer via irradiation grafting as opposed to chemical grafting. On the other hand, the biggest limitation of irradiation grafting lies in its feasibility on industrial scale; it also poses health hazards associated with exposure to radiation.

6. TRANSLATING THE SCIENCE INTO TECHNOLOGY

Textile materials can be functionalized either by means of radiation or chemicals to introduce ion exchange sites into their matrix. These sites can exchange the metallic impurities from water on the same principle as the resinous ion exchangers do. This, with the added advantages of overall simplification of the process and greater efficiency, makes GTIX a promising aspect to look into for research and development.

The science can either be incorporated into water purification filters (ex situ method) or become a part of underground permeable barriers (in situ method) to prevent groundwater from contamination.

6.1 Water Purification Filters

There are several water purification techniques available in the market and the degree of their sophistication varies from nanofiltration and reverse osmosis (RO) to ultra and micro filtration. By principle of filtration, only reverse osmosis and nanofiltration are capable of *filtering out* ionic impurities.

While nanofiltration blocks out multivalent ions, it is largely permeable to monovalent ionic impurities. On the other hand, reverse osmosis blocks out virtually all the dissolved ions. This, itself, is a disadvantage, since the process removes even the recommended level of certain minerals. Water purified by RO plants must be treated with calcium and magnesium beds, for example, to make them suitable for drinking purposes. Furthermore, both nanofiltration and RO are expensive processes and are particularly not feasible for small scale purification units in rural areas.

An alternative is to modify the ultra filtration technique (which in its basic form does not block out ionic impurities) by assisting it with geotextiles based ion exchangers. GTIX assisted membrane filtration can remove metallic species from water. Metallic species are retained after binding with the fixed ion on the textiles, and the replaced ions pass through the membranes. The process is depicted in Figure 02. The advantages of this process are the low energy requirement involved in UF processes and the high binding capacity of the water soluble polymers.

Figure 02. Schematic of GTIX assisted Ultra filtration

6.2 Permeable Reactive Barriers

Physical barriers constructed in a contaminated groundwater system that intercept and degrade or remove soluble pollutants yet allow groundwater to flow through are called permeable barriers. PRB is just one of the groundwater remediation techniques amongst other techniques such as containment of contaminants, removal of contaminated soil and its subsequent disposal or treatment, and removal of pollutants and their subsequent neutralization.

However, other remediation methods have several disadvantages over the PRBs. These include water supply disruptions for long time periods, producing undesirable by products such as contaminated soil or sludge, and institutional obstacles pertaining to pumping large volumes of groundwater such as requirements for discharge permits and possible purchase of ground water.

Nevertheless, in order for the PRB's to perform effectively there are several factors that should be taken into proper consideration. These include

- **Depth of groundwater:** This should be only as much as would make the aquifer feasibly accessible by trenching or boring equipments.
- **Contaminant transport:** The groundwater should flow through the barrier with sufficient velocity so as to enable the contaminants to come into contact with the activated barriers.
- **Barrier performance:** The barrier must be swift and effective in removal of the particular impurities of water. Chemically active geotextiles can be used as barriers to remove harmful metallic impurities by intercepting and exchanging the mobile ions with non hazardous ones. GTIX various advantages such as the ease with they can be made into any shape or form, their osmotic stability and swifter sorption rates make them a suitable candidate for PRBs.
- **Construction and operating cost:** The construction and operating cost should be reasonable when compared to other groundwater remediation techniques. Since most GTIX can be manufactured by cheap or recycled polymers or fibers as the backbone, and inexpensive copolymers; they are poised to give cost effective products for groundwater restoration.

Though chemically modified textiles are being manufactured and used, at least to a limited extent, for water purification in ex-situ situations; their applicability and usage in in-situ environments has not been touched upon by researchers as yet. The in-situ scenarios maybe difficult to explore in terms of logistics, but the successful incorporation of this technology in PRBs has the potential to solve myriad of groundwater contamination problems.

7. CONCLUSION

Geotextiles are used extensively in a variety of sustainable water management systems in the world. However, their traditional use is limited to their important but passive properties such as strength and permeability. The possibility of modifying their structures so that they play an active role in the purification of water presents exciting opportunities for further research and subsequent product development. The concept of GTIX introduced in this paper is a step in this direction. GTIX offers superior performance when compared to resinous counterparts; and the technology can be employed for either in-situ or ex-situ for water purification.

ABSTRACT:

In this study, the use of coir fiber reinforcement to improve the strength properties of black cotton soil subgrade stabilized with cement kiln dust (CKD) was investigated. Black cotton soil was mixed with optimum of CKD along with different proportions of discrete coir fibers (0%, 0.25%, 0.5%, 0.75% and 1.0% by dry weight of soil cut to 25mm size). Compaction properties and unconfined compressive strength (UCS) values were determined for soil mixtures compacted using British Standard Light (BSL) effort. Test results indicated that the inclusion of fiber in stabilized specimens resulted in reduced maximum dry unit weight, higher optimum moistures as well as UCS and therefore enhanced load carrying capacity of the subgrade. The results further demonstrated that randomly distributed coir fibers can be used to reduce the brittleness of stabilized soil which is the drawback associated with high lime content stabilizers. Thus, strength of black cotton soil can be successfully improved by the combined action of CKD and coir fiber.

Keywords: Black cotton soil, Cement kiln dust, Coir fiber reinforcement, unconfined compressive strength

1.0 INTRODUCTION

Black cotton soil is an expansive clay soil that constitutes a major group of soils found in tropical latitudes. It is however considered a problem soil due to its small load bearing capacity, high swelling characteristics, excessive shrinkage properties with the resultant large cracks and long term settlement under external load as moisture content fluctuates (Ola, 1983; Warren and Kirby, 2004; Osinubi, 2006). Consequently, roads running through regions covered with these clays are subjected to severe distress resulting in poor performance and increased maintenance cost. These behaviors are attributed to the presence of clay minerals with expanding lattice structure. Among them, montmorillonite, the most common of all the clay minerals in expansive clay soils. The mineral is made up of gibbsite sheet sandwiched between two silica sheets (Morin, 1971, NBBRI, 1983; Chen, 1988).

Thus, in natural states, the soil is not suitable for subgrade construction but can be used as subgrade material only after stabilization by means of admixtures.

Over the years, progress has been made as different types of stabilizers have achieved different levels of performance. Cement and lime are still among the most effective stabilizers in use, although many studies have been made for nontraditional stabilizers, such as fly ash, cement kiln dust, blast furnace slag, baggase ash, reinforcing fibers or the combination of these materials with varied degree of success (Osinubi and Medubi, 1997; Peethamparan and Olek, 2008; Liman, 2009; Oriola and Moses, 2011).

Unfortunately, the increase in compression resistance associated with lime or related stabilizers is always accompanied by brittle failure and consequently the possibility of hazardous failures under any unexpected load condition.

The technique of soil stabilization by admixtures and reinforcement in form of discrete fibers is known to cause significant improvement in strength characteristics of soils. The main reasons of using randomly oriented fibers as additional additive is to increase tensile strength, solve the problem of brittle failure of stabilized soils as well as to maintain strength isotropy (Gray and Ohasi, 1983; Al Refeai, 1991; Ranjan et al., 1996; Consoli, et al., 1998; Prabhakar and Sridhar, 2002; Kumar et al., 2005; Rafalko et al., 2006).

In the present study, the use of eco-friendly coir fiber with high initial tensile strength and excellent durability derived from yarns of coconut husk to improve strength properties of black cotton soil subgrade treated with cement kiln dust was investigated by measuring strength in terms of unconfined compression strength.

2.0 EXPERIMENTAL PROGRAM

2.1 Materials

The soil used in this study was collected at shallow depth from Adamawa state, Nigeria. It is a blackish grey clayey silt of intermediate plasticity normally classified as black cotton (BC) soil.

Fresh CKD sample used as primary stabilizer in this study was collected from Benue Cement Company, Gboko, Nigeria. The coir fiber which is abundantly available in some parts of south and coastal regions of Nigeria was used as secondary stabilizer. For the present study, brownish coir fiber obtained from processed coconut husk, was collected from Minna.

2.2 Method

2.2.1 Sample Preparation and Testing

British standards (BS 1990a, b) were used to determine the particle size distribution, Atterberg limits and specific gravity of black cotton soil as well as mixture of soil and CKD. The effect of fiber content was evaluated by testing specimens in which the fiber weight fraction related to dry weight of the soil was varied, but all other significant test variables were controlled. The fiber content selected were 0, 0.25, 0.5, 0.75 and 1% by dry weight of soil cut to 25mm size and were randomly mixed with soil. The maximum dosage rate was limited to 1% of dry weight of soil because of possible mixing difficulties at greater dosages. The composite soil specimens (soil, stabilizer and fiber) were prepared by dry blending soil and the optimum CKD content together with fiber for fiber reinforced mixtures. The samples were mixed manually with proper care to get homogeneous mix and then the required amount of water was added. Compaction test was conducted using British Standard Light (BSL) compactive effort as per BS 1377 (1990a, b) and unconfined compressive strength tests were conducted for various combinations of soil sample compacted to their optimum moisture content – maximum dry unit weight. Treated specimens for UCS tests were cured for 7 days before testing. A 7-day curing period was adopted to simulate the relatively short period between subgrade preparations to pavement construction activities in practice.

3.0 RESULTS AND DISCUSSION

3.1 Index Properties

The grain size distribution curve (Figure 1) indicates that the study soil was primarily fine grained with specific gravity of soil solids as 2.67. The index properties of the natural soil are summarized in Table 1. The soil is classified under the A – 7 – 6 subgroup of the AASHTO classification system and CH in accordance with USCS system. Liquid limit and plasticity index values of 52% and 37%, respectively were established and this indicates that the soil is highly plastic. The dominant clay mineral is montmorillonite which is consistent with results of previous research findings on black cotton soil samples from the region (Ola, 1983, Osinubi, 1999). From these results, the soil would not meet the standard specification for most geotechnical works including pavement subgrade construction.

On application of optimum CKD, the liquid limit and plasticity index of soil mixture were lowered to 49% and 34% respectively. The concentrations of the major detected oxides in the black cotton soil together with that of the CKD analyzed using X-ray fluorescence (XRF) are summarized in Table 2, while some properties of coir fiber used are reported in Table 3.

Table 1 Summary of study soil index properties

Property	Value
Natural moisture content	8
Liquid limit (%)	52
Plastic limit (%)	15
Plasticity index (%)	37
Linear shrinkage (%)	15
USCS classification	CH
AASHTO classification	A-7-6
Specific gravity	2.67
Maximum dry unit weight (kN/m ³)	13.7
Optimum moisture content (%)	33.6
Swelling potential	High
pH	7.2
Color	Blackish grey

Average diameter (mm)	0.25
Average length (mm)	25
Aspect ratio	100
Average tensile strength (N/mm ²)	405.9
Density (g/cm ³)	1.45
Young modulus (kN/m ²)	4.0x10 ⁶
Elongation (%)	15

3.2 Compaction Characteristics

The maximum dry unit weight (γ_{max}) decreased and the optimum moisture content (OMC) increased with the addition of optimum cement kiln dust. The decrease in the maximum dry unit weight of the treated soil mixtures is reflective of increased resistance offered by the flocculated soil structure while the increase in optimum moisture content is probably a consequence of additional water held within the flocculated soil structure resulting from CKD reactions (Osinubi, 2000). This trend did not change even after the addition of coir fiber. The optimum moisture content of soil - CKD mixtures reinforced with coir fiber varied between 1 to 6% above the OMC stabilized soil. Similarly, the variation in maximum dry unit weight of coir fiber reinforced soil – CKD mixtures is between 18.56kN/m^3 and 16.9kN/m^3 which again represents up to 10% that of stabilized soil. The reduction in dry unit weight of stabilized soil specimen reinforced with coir fiber is due to the fact that lighter material replaces heavy soil particles. The compaction characteristics of untreated and treated soils with CKD and different percentages of fibers are shown in figure 2.

Figure 2: Compaction characteristics of reinforced stabilized soil specimens

3.3 Strength of Stabilized Unreinforced and Stabilized Reinforced Specimens

The addition of optimum CKD increased the UCS nearly 2.5 times that recorded by the untreated soil. For reference, the maximum value of UCS (q_u) of the natural soil was 48 kN/m^2 , while that of stabilized soil was 118 kN/m^2 . The increase in strength of soils with CKD is well established (Liman, 2009; Oriola and Moses, 2011; Amadi and Eberemu, 2012). The increase in unconfined compressive strength after CKD application is as a result of flocculation, cation exchange and the formation of various cementitious compounds i.e., calcium silicate hydrates and calcium aluminate hydrates due to pozzolanic reaction between silica present in soil and lime in the CKD in the soil matrix.

Reinforcement of CKD-stabilized soil with varying fiber contents produced slightly higher strengths than exhibited by the chemically stabilized black cotton soil without fibers. Figure 3 reports the normalized UCS of composite soil. The normalization was by the unreinforced soil – CKD UCS of 118 kN/m^2 . In general, the UCS gain increased with an increase in fiber content achieving an increase of 1.3 times the value of unreinforced soil – CKD on addition of highest dosage level of 1% fiber.

In terms of the general relationship between UCS and the quality of the sub-grade soils used in pavement applications (Das, 1994), the natural soil was upgraded from soft subgrade to stiff subgrade by the integrated effects of the chemical stabilizer and coir fiber.

Fig. 3 Normalized UCS vs. fiber content of stabilized soil

In addition to increase in UCS, one of the main reasons for fiber inclusion to soils with chemical stabilizers is to increase their energy absorbing capacity or toughness, so that the composite materials (soil, stabilizer and fiber) will exhibit a more ductile post peak behavior. Toughness is important because chemically stabilized soils without fibers exhibit brittle stress-strain curves and have relatively little toughness, which may cause the treated soil to crack and fail suddenly (Consoli et al., 1998; Rafalko et al., 2006). At 0% fiber, the soil – CKD mixture was friable, although high strength was achieved. Figure 4 presents the normalized toughness index values for stabilized soil reinforced with the fiber dosage used in this study. As in UCS, toughness index was normalized by taking the ratio of the reinforced soil – CKD toughness index and the toughness index of mixtures with 0% fiber. From the figure, soil mixtures in reinforced state exhibits slightly higher toughness than in unreinforced condition. The results indicate that the toughness index increased by as much as 1.2, 1.9, 2.08 and 2.15 times due to the inclusion of 0.25, 0.5, 0.75 and 1% coir fiber respectively compared to unreinforced sample. Similar to UCS results, the soil stabilized with 8% CKD and 1% of the fiber produced the highest toughness index. It is likely that the bond strength and friction at the interface seem to be the dominant mechanism controlling the reinforcement benefit.

Fig. 4 Normalized toughness index vs. fiber content of stabilized soil

The increment in the peak stress and the corresponding decrease of the failure axial strain (ϵ_f) associated with the addition of optimum CKD content is also noteworthy. This brittle behavior of CKD stabilized soil was however reduced with the inclusion of randomly distributed coir fibers which increased the failure axial strain (ϵ_f) as reported in Table 4. It is observed that the soil alone attained a peak strength at about 9.52% axial strain while the stabilized soil reinforced with different coir fiber contents increased the axial strain and failure occurred at higher strains around 10% and above exhibiting a more ductile behavior of composite soil (Karimi et al., 2010; Ramesh et al., 2010).

Table 4: Peak stress and axial failure strain of unstabilized, stabilized and reinforced stabilized specimens

Mixture	Peak strength (kN/m ²)	Axial strain at failure (ϵ_f)
Unstabilized soil (Natural)	48	9.52
Stabilized soil (soil + 8% CKD)	118	5.7
Soil + 8% CKD + 0.25% fiber	128.62	6.4
Soil + 8% CKD + 0.5% fiber	133.27	8.6
Soil + 8% CKD + 0.75% fiber	148.67	9.5
Soil + 8% CKD + 1% fiber	152.42	11.66

4.0 SUMMARY

Black cotton soil has been identified as one of the major groups of soils found in the tropical latitudes. Roads running through regions covered with these clays are subjected to severe distress resulting in poor performance and high maintenance cost. Different stabilization techniques to achieve suitable performance and provide required service life for the expected traffic intensity have been adopted in the past.

In the present study, representative sample of black cotton soil chemically stabilized with optimum cement kiln dust content (8%) was reinforced with varying percentages of coir fiber (0, 0.25, 0.5, 0.75 and 1% by weight of soil) cut to 25mm size to evaluate its suitability for pavement subgrade construction. Laboratory tests carried out included Atterberg limit test, compaction test as well as unconfined compressive strength tests. All specimens for UCS tests were compacted at optimum moisture content using British Standard Light (BSL) compactive effort.

Test results indicated that the maximum dry unit weight decreased marginally while the optimum moisture content and UCS increased on application of optimum CKD content. Although, CKD treatment of soil improved the compressive strength but it imparted brittleness in soil specimens. Coir fiber inclusion in stabilized samples resulted in further reduction of maximum dry unit weight as well as higher optimum moistures together with the UCS and therefore the load carrying capacity of the subgrade. Evaluation of the toughness index established an increasing trend with higher fiber content. An increased toughness index is desirable, as the longevity of the pavement would be expected to increase with increasing toughness.

Overall, stabilization with the optimum stabilizer content and the fiber at the highest dosage of 1% increased the strength and toughness index of the study soil the most. Based on these results, it can be concluded that tropical black cotton soil can be successfully stabilized by the combined action of CKD and coir fiber.

Use of Electronic Leak Detection System in 24/7 On-line Mode to Control Construction and Operation of Lined CAL Lagoons

Vladimir Nosko, RNDr., PhD., Sensor spol. s r.o., Slovakia, nosko@sensorgroup.com
Petar Razdorov, MSc., Consultant, Canada, PetarRazdorov@gmail.com

ABSTRACT

The latest Covered Anaerobic Lagoon (CAL) equipped with Electronic Leak Detection System (ELDS), with permanently fixed position sensors (to monitor integrity of geomembrane) was built in 2011/2012 in UK. A new improved CAL design was implemented. Advancements incorporated into the new design were based on experiences from previous installations and operation of permanent ELDS, now incorporating sophisticated Continuous Monitoring Station (CMS), allowing real time monitoring of geomembrane integrity 24/7 and providing leak alarms and positioning of damage in the event of any leak. Special conductive geotextiles are used providing consistent current distribution and in the latest application a new conductive geotextile incorporating a unique signal layer was introduced. The presented article describes the use of ELDS to further perfect and continuously improve CAL construction. The 24/7 electronic monitoring and processing unit is described to help promulgate the understanding of the process of on-line geomembrane integrity testing of CAL facilities.

1. INTRODUCTION

The concept or requirement for leak detection monitoring of geomembrane lined tanks filled with liquid are as old as the use of geomembrane lining itself. The options for leak monitoring and detection of damage have historically been restricted to passive solutions. Such solutions have provided only indicative information that a tank or lagoon is 'probably' free of any damage. This unacceptable level of uncertainty is as a result of the nature of passive systems utilising drainage pipes or drainage composites. Prior to this indicative bore holes were used as integrity indicators, especially for tanks filled with toxic material or contaminants where the presence / absence of the stored material in a tank or lagoon was controlled. In both cases if the presence of the material in bore holes or the drainage system was positive, the leak was detected however it was never possible to detect the exact position of any geomembrane damage. In many cases having found that a tank was leaking, the only solution was the installation of an additional layer of the geomembrane. Unfortunately many lagoons were still found to be leaking even after a number of additional layers were installed.

The installation of five or more geomembrane layers has been seen on sites where there were still leakage problems. There have been many experiments using indication chemicals and similar tracing solutions, but none have adequately resolved the inherent problems.

2. DESCRIPTION OF APPLICATION

Resolution of the root cause of the problem (a leak through damaged geomembrane) required the use of an electronic monitoring system in order to mitigate the huge costs associated with unserviceable tanks, which could have resulted in the closure of a factory. The data from the electronic monitoring system was used to create a report of geomembrane integrity, which was issued to the inspection office at the Environmental Bureau in order to get approval to use the lagoon.

The cost of suspended production on the site was the dominant consideration and after consultations with the Client an ELDS off-line system was designed. As a result, when testing of the geomembrane was carried out with the installed system it was found that the impact of 'the electrical bridges' and ELDS electric signal formation itself, caused very complicated data analysis and their evaluation / interpretation, was practically impossible without the input of highly experienced engineers.

2.1 Europe

The first Covered Anaerobic Lagoon (CAL) to be equipped with permanently installed ELDS with sensors in fixed positions (to monitor integrity of geomembrane), was built in 2001 in Europe. Three different types of leak detection and location systems were applied prior to filling the lagoon with water. To enable function of the pre-filling tests a conductive geotextile was installed. The physical make up of the sealing layers (reading from bottom to top) were: HDPE

geomembrane; geosynthetic drainage layer; conductive geotextile; ELDS; upper HDPE geomembrane. Both HDPE geomembranes were tested prior to filling the lagoon using an electro acoustic test method as well as wading and water lance surveys. These techniques revealed a number of leaks, which were then repaired prior to the filling process. During the filling process the permanent ELDS was used to monitor the integrity of the lagoon. Data from the ELDS was recorded and analysed in-situ requiring the permanent presence of an engineer throughout the filling process. Since then over the period of 11 years service zero leakage has been recorded. This first application was published and presented by group of authors I.D.Peggs, V.Nosko, P.Razdorov and P.Galvin at Eurogeo 2004.

2.2 North America

Based on the abovementioned success, the Client wanted the system adapted in order to monitor the integrity of geomembrane layers automatically both during the construction and during the operational life of a lagoon. **The main requirement was to have information available 24/7 in the control centre for the site (via SCADA)** where all information about the function of a lagoon is coordinated (pumps, mixers, liquid levels, etc). At the time, the only system available was an off-line version, but driven by the client's desire for innovation and a culture of continuous improvements based on experiences since, a new type of system was developed. In 2008 in North America the iterative technical improvements made through continuous improvement allowed for a technological leap to a much more sophisticated electronic leak detection system which was installed complete with an on-line 24/7 testing mode. The photographs 1 and 2 below show the installation of sensors and cables to the geogrid that is to be contained along with the conductive geotextile between two layers of geomembrane.

Photo 1. Installation of ELDS.

Photo 2. Detail of sensor installation.

Photo 3. General view of the tested lagoon

Photo 4. ELDS remote analysing centre

Unlike previous experiences, earlier involvement in the design stage made it possible to influence the process. This allowed the client eliminate the impact of 'electrical bridges' and to eliminate false signals in data scanning. In this case

two geomembrane layers were installed with a conductive geotextile between in order to maintain consistent signal transfer from any damage. The sealing layers comprised (in order from bottom to top): a compacted clay base; thick protective geotextile; lower HDPE geomembrane; drainage geocomposite; conductive geotextile; ELDS; and finally the top layer of HDPE geomembrane.

2.3 Europe

After the successful implementation of ELDS incorporating the 24/7 monitoring concept in 2011 in Europe the same system was installed (Photo 3) but adapting the installation to work with only one geomembrane layer. 24/7 monitoring was included but **we also added a new 'Watchdog function' (a leak alarm)**. The sealing layers comprised (in order from bottom to top): clay subsoil; thick protective geotextile; drainage geocomposite; **new type of conductive geotextile with integrated the signal layer (for watchdog alarm function)**; ELDS; and on the top the HDPE geomembrane. There were 400 sensors installed for monitoring the integrity of lagoon, the area monitored is 10,200m². The aim of the project was achieved with 100% integrity in the construction phase of the lagoon. The main aims of the project in relation to the ELDS implementation was set out as:

1. Integrity testing of a geomembrane before filling;
2. 24/7 Integrity testing during the filling lagoon with water;
3. Integrity testing during the use of the lagoon.

In order to ensure that the ELDS was able to achieve aim 3 above it was necessary to develop a system that could filter the electrical noise generated by the production processes. The methodology adopted to test during the operational lifespan of the CAL was the use of the Watchdog system during periods of sustained production process 'noise', then to switch to scanning mode during low noise periods. This method enabled the elimination the false signals, or damaged data caused by 'noise' and was achieved by implementing a high level of data coordination through the client's SCADA system. This system and other similar systems installed around the world are monitored remotely from our monitoring (Photo 4 above). These developments took more than **10 years Research & Development** by teams of highly educated engineers.

It is very important to clearly state that the unambiguous aim was that 100% geomembrane integrity be maintained during lagoon construction process and its fluent transfer from construction to operational service. This aim was achieved by maintaining the team whose close coordination and shared experience of such installations enabled familiarity to be translated into success. Cooperation between the individual companies started on the earlier applications developing the collective intelligence as each project was completed. This intelligence is both built and capitalised by the repetitious deployment of the same installers, manufacturers and consultants on each project. The combined and thorough knowledge of all processes involved in the construction process resulted in a successfully delivered project.

The key measure of the success of the whole project was the coordination of all processes without the need to repair the geomembrane which would cause construction delay. In 2001 there were 7 anomalies; in 2007 there were only 3 anomalies; and in the year 2011 there were none (the functionality of the ELDS monitoring system was proven by successful detection of 2mm diameter test holes, shown in Photo 5 and Photo 6). This is the most important result validating the approach of learning from mistakes during the construction process and in order to achieve this the importance of maintaining the same team of companies cannot be overstated.

Photo 5. Position of test hole.

Photo 6. Detail of the test hole.

3. CONCLUSION

The latest installation was carried out during 2011/2012 where another improved CAL design was implemented to make ELDS more effective. The advancements incorporated into the design were based on the experiences from previous installations and the operation of the permanent ELDS, now incorporating the sophisticated Continuous Monitoring Station (CMS) which allows real time control of geomembrane integrity 24/7.

In each case special conductive geotextiles were used, the latest of these textiles enable CMS to provide a leak alarm in the event of a leak. The prescribed ELDS testing process has two modes:

- Watchdog monitoring mode to warn clients immediately that the integrity of the geomembrane is broken;
- Measuring mode when liner is scanned and the position of any damage / leak can be precisely located.

The abovementioned functions of the ELDS CMS system, provide 24/7 geomembrane integrity monitoring during each phase of the CAL's life, these phases are summarised as:

1. Construction Phase (pre-filling);
2. Water Filling Phase (up to maximum capacity);
3. Operational Phase.

Each of these phases present their own challenges as the dynamic forces applied to liner shift the installed system is continuously and automatically reporting to the client through their SCADA system, confirming the integrity of the protective geomembrane.

The presented article describes the use of ELDS with permanently installed sensors in fixed positions to assist in the further and continuous evolution of CAL construction perfection.

The full electronic monitoring and processing unit in 24/7 mode are described to help promulgate the understanding of the process of on-line testing of geomembrane integrity within a CAL facility.

ACKNOWLEDGEMENT

As authors we would like to thank Jon Crowther from Sensor UK for his valuable input.

ABSTRACT

The main objective of this paper is to investigate the performance of levee sections at the onset of flooding and subsequent seepage with the help of centrifuge model tests at 30 gravities. Three levee sections were modeled viz. levee section without drainage layer, with horizontal sand drain and with horizontal geotextile drainage layer. The flood was simulated with the help of remotely operated in-flight flood simulator. Levee section without any horizontal drain or clogged drain was observed to experience a catastrophic failure. Horizontal sand drainage layer was found to be very effective to dissipate pore water pressure leading to the stability of a levee. The analysis of centrifuge test results shows that horizontal geotextile drainage layer is effective in ensuring stability of the levee section at the onset of flooding and subsequent seepage. An attempt has also been made to compare results obtained from centrifuge studies with seepage and stability analyses using SEEP/W and SLOPE/W software. Finally, this paper concludes the use of geotextile horizontal drainage layer as an internal drain in place of conventional sand drainage layer as a viable option for imparting economy to construction projects.

1. INTRODUCTION

Levees are earthen embankments that run along the river or canal banks, which protect land side area containing agricultural, industrial, urban and rural areas. Any breach in levee section can trigger catastrophic consequences to cities situated in the vicinity of rivers. Construction material used in levees greatly varies from silty sand to clayey soil according to availability of borrow materials locally. Preferably, less permeable soil is used in hearting zone in order to contain water and relatively permeable soil is used in the casing zone of a levee section, which is not subjected to cracking in the case of direct exposure to atmosphere. One of the most acute problems in designing levees is to control seepage of the water. In the absence of appropriate seepage control measures, it may lead to various types of failures, such as: i) downstream side face/base failure, ii) piping, boiling failure, iii) excessive hydrostatic pressure below the hard stratum etc. An earthen embankment has various components such as cut-offs, trenches, drainage layers and reinforcement layers etc. All these components address numerous functions such as, drainage, resistance to piping and erosion control in order to maintain stability and facilitate the functionality of levee. Horizontal drains serve to dissipate pore water pressure in the downstream side. In this study internal drainage system in the form of horizontal drain embedded in downstream side was considered. BIS 9429(1990) suggests guidelines for drainage system for earth and rockfill dams where it is illustrated that geometry of drains are essentially affected by water level at upstream side, height of embankment both in upstream and downstream sides, permeability of embankment and drainage material, gradation of embankment and drainage materials and angle of discharge face. Additionally, several regulations recommend different thicknesses of horizontal drains. US Army Corps of Engineers EM 1110-2-1913 (2000) suggests a minimum thickness of horizontal drain layers of about 457.2mm for construction purposes. BIS 9429(1990) proposes a minimum 1.0 m thick horizontal drain in earthen dams. Geometry of horizontal drain is also affected with the availability of well graded material, as per filter requirements. Due to rapid expansion of infrastructure in developing countries in the world like India, lack of availability of suitable material for drainage imposes economic burden on projects. Hence, there is a need to explore avenues for replacing conventional drainage layer with an appropriate material, which can cater the basic requirements of internal drain.

Several researchers adopted different approaches for understanding the hydraulic behavior within the levee section, such as analytical, numerical, large-scale and small-scale studies. Iryo and Rowe (2003) studied the applicability of Van Genuchten equation for estimating unsaturated/ saturated water flow within soil-geotextile system and simulated the phenomenon using SEEP/W. Further, Iryo and Rowe (2004) examined the hydraulic response of a geotextile layer embedded in sandy soil subjected to 1-dimensional infiltration. Jia et al.(2009) evaluated the stability of the slope model constructed using sandy silt (12% sand, 80% silt, less than 5% clay) subjected to rising and lowering water level by conducting large-scale model tests at normal gravity. Ubilla et al. (2008) investigated the failure and non-failure conditions of levees subjected to Katrina hurricane with help of centrifuge studies on the London Avenue and Orleans Canal South. Das and Viswanadham (2010) proposed an experimental set up for examining the piping behavior of silty sand soil type with and without discrete and randomly distributed geofibers. Raisinghani and Viswanadham (2010) presented the effect of geosynthetic layers in enhancing the in-plane permeability of fine-grained soils in the laboratory by using custom made permeameter tests. It was reported that the use of a permeable geosynthetic layer in the form of

a geocomposite (which is combination of woven geotextile and non-woven geotextile or geogrid and non-woven geotextile) helps in lowering phreatic surface and reducing generated pore water pressures by draining water in the plane of geocomposite layers. Successful application of using geocomposite materials for pavement, behind retaining walls, reinforced soil walls and slopes was reported by Raisinghani and Viswanadham (2011).

However, very few attempts have been made to understand the stability and deformation behavior of levee sections without and with conventional or geocomposite drainage layer as internal drain using a centrifuge modeling technique. Hence this forms the research interest of the present study.

In this present study, hydraulic behavior of horizontal drainage layer of sand and geotextile at the toe of the embankment constructed with low permeable embankment material was evaluated using centrifuge tests at 30 gravities. For this purpose three levee model sections with and without horizontal drainage layers subjected to flooding were considered as shown in Table 1. Sand and geotextile were used as internal drain materials separately in the horizontal direction located at toe towards downstream side. A set-up has been developed to induce in-flight flooding at 30g. Material properties of levee section, upstream and downstream slopes, levee height, top width and base layer thickness were kept constant. The effect of inclusion of drainage layer and replacement of sand with a non-woven geotextile material on the stability and deformation behavior of levee, pore water pressure distribution, phreatic surface development has been evaluated. Further an attempt was made to compare observed centrifuge model test results with the help of finite element based SEEP/W and limit equilibrium based SLOPE/W (Geostudio, 2007).

Table 1. Details of centrifuge model tests

Test Legend	Drainage material	H (mm)	Upstream slope angle (α)	Downstream slope angle (β)	Drainage length (mm)	Thickness of drainage layer (mm)
RL-1	- ^a	200 (6000)	45 ⁰ (1V:1H)	56.3 ⁰ (1.5V:1H)	- ^a	- ^a
RL-2	Sand	200 (6000)	45 ⁰ (1V:1H)	56.3 ⁰ (1.5V:1H)	185 (5550)	20 (600)
RL-3	NW Geotextile	200 (6000)	45 ⁰ (1V:1H)	56.3 ⁰ (1.5V:1H)	185 (5550)	0.66

^a Not relevant; Prototype dimensions are given within parentheses; NW = Non-woven.

2. SCALING CONSIDERATIONS FOR MODELING NON-WOVEN GEOTEXTILE

In the present study, centrifuge modeling technique was adopted to achieve stress similarity at homologous points by subjecting a model reduced by 1/N times to N time's gravity. The use of centrifuge modeling technique was considered relevant because of the requirement of simulation of stress conditions and pore water pressure variation at the onset of flooding and subsequent seepage through a levee section as that of in the prototype. In addition, climatic events like simulation of flooding at full-scale are difficult.

In order to scale-down a geocomposite layer, three criteria are required to be satisfied: i) Scaling down of tensile-load strain characteristics, ii) Scaling of in-plane permeability characteristics, and iii) Soil-geocomposite interface friction. Detailed discussion on modeling of geocomposites in a centrifuge was reported by Raisinghani and Viswanadham (2011). Based on the scaling considerations, there is requirement of having a geocomposite layer with reduced thickness, tensile load and secant stiffness reduced by 1/N times that of the commercially available geocomposites and with identical soil-geocomposite interface friction. However, in order to satisfy scaling requirements from hydraulic properties point of view, the geocomposite shall have identical transmissivity as that of in the commercially available geocomposites and shall possess N times more in-plane permeability characteristics in the model. Although geocomposite can have reinforcement and drainage functions, considering the requirement of drainage function, only non-woven geotextile was considered and referred as geocomposite in the present study.

3. CENTRIFUGE MODEL TESTS ON LEVEES SUBJECTED TO FLOODING

3.1 Model Materials

Three types of model materials are involved. They are; i) Model soil for constructing a levee; ii) Sand as an internal drain; iii) Non-woven geotextile as an internal drain and as a replacement for conventional sand drainage layer. Generally, levees are constructed by using low to very low permeable materials. By blending 80% of locally available fine sand with 20% of commercially available kaolin (by dry weight), silty sand type model soil was formulated. The model soil was found to have maximum dry unit weight $\gamma_{d, \max}$ of 18.75 kN/m³ and optimum moisture content (OMC) of

8% according to standard Proctor compaction. The value of coefficient of permeability of the model soil moist-compacted at $\gamma_{d, \max}$ and OMC is 1.54×10^{-6} m/s. The model soil (moist-compacted at $\gamma_{d, \max}$ and OMC and saturated) was found to have a cohesion of 11.9 kN/m^2 and angle of internal friction of 27° obtained by conducting drained direct shear box test. The sand used in the present study is classified as SP according to Unified Soil Classification System and has an effective particle size $d_{10} = 0.10 \text{ mm}$. The sand was found to have a maximum void ratio of 0.89 and minimum void ratio of 0.58. The coefficient of permeability of sand placed at 85% relative density is 1.49×10^{-4} m/s.

Based on the above set scaling considerations for modeling non-woven geotextile, a non-woven geotextile having thickness of 0.66 mm, a mass per unit area of 46 g/m^2 , transmissivity θ of $0.38 \times 10^{-6} \text{ m}^2/\text{s}$ at 20 kPa normal stress, and coefficient of in-plane permeability of 5.757×10^{-4} m/s (ASTM D6574, 2006) was used.

3.2 Model Test Package

The 4.5 m radius large beam centrifuge facility having 2500 g-kN capacity available at Indian Institute of Technology Bombay was used in the present study. The specifications were discussed by Viswanadham and Mahajan (2007). Identical stress-strain behavior can be simulated by subjecting the scaled down model to N-times gravity level in controlled environment. Centrifuge models tests reported in this study were carried out at 30g. The internal dimensions of strong box were 760 mm in length, 200 mm in breadth and 410 mm in height. Model was constructed in strong box having three steel walls with honey-comb structure and one wall with thick Perspex glass sheet. Fig. 2 shows cross-section of a model test package. Plane strain conditions were maintained by applying white petroleum grease on inner surfaces of front and rear walls of strong box. Perspex sheet was used to ensure clear view of front elevation of the model to the digital photo camera mounted in front of the container. A rectangular grid of 430 mm x 210 mm with four permanent markers was glued on to the Perspex surface in contact with the soil to serve as reference points for image analysis. Movable markers were embedded in the soil at different elevations as along the downstream face to traced displacement vectors at the onset of flooding. Relative positions of movable markers were captured and recorded with help of high resolution digital photo camera. Four pore water pressure transducers (PPT) were embedded at the levee bottom to evaluate the variation in pore water pressure with respect to seepage time. Two linear variable differential transformers (LVDT) were housed at both side of crest to obtain crest deformations with respect to seepage time.

To induce in-flight flooding, a remotely operated DC-pump based flood simulator has been developed. As shown in Fig. 1, there are three main components of set-up: a) water reservoir b) Pump assembly and c) voltage controller. Water reservoir having dimensions (650 mm x 160 mm x 140 mm) was placed by the side of strong box. Firstly, this water reservoir constantly receives water supply from one of the slip rings provided in centrifuge. Thus, this reservoir acts as constant head reservoir catering a continuous source of water to the inlet of pump. Secondly, pump was housed vertically over the water reservoir. A mild-steel frame was used to fasten pump firmly to avoid any sort of damage to pump during flight. This frame was firmly attached to backside of the strong box. Finally, power supply to this pump was regulated remotely with help of DC-voltage controller. Thus, for a given g-level, voltage level and levee section, a particular flood rate could be generated. One PPT was also placed in upstream side of levee in order to monitor and evaluate flood level with seepage time.

3.3 Model Test Program and Test Procedure

Base layer was comprised of two layers viz. 60 mm thick with silty sand and 40 mm thick with kaolin. Kaolin layer was overlaid the base layer of silty sand (80:20 mix). Kaolin having very less permeability was intentionally selected as a model soil to be placed just beneath the levee section in order to induce potential seepage through levee section only. In model RL-2, Goa sand was placed as a horizontal drainage layer at downstream. The sand was placed at 85% relative density with a dry unit weight of 15.5 kN/m^3 . Angle of internal friction for the sand in dry sand placed at 85% relative density was found to be 32° . In Model RL-3, sand layer was replaced with a model needle punched nonwoven geotextile to serve as an internal drain.

Model Levee sections were constructed with a height of 200 mm, top width of 100 mm, upstream slope 1V:1H and downstream slope 1.5V:1H. Geometry of levee was selected such that factor of safety at the onset of seepage is close to one. In this paper, results of three centrifuge model tests are presented. They are: i) without drainage layer (RL-1), ii) with horizontal sand drainage (RL-2) and iii) with horizontal geotextile drainage layer (RL-3), as shown in Table 1. Levee models were constructed in layers of 30 mm thickness moist-compacted at $\gamma_{d, \max}$ and OMC according to standard Proctor compaction. L-shaped movable plastic markers were also placed at the top of each compacted layer horizontally at a centre to centre spacing of 20 mm from downstream slope face. External side of one leg of the movable markers was lubricated with grease in order to reduce friction between Perspex sheet and marker surfaces. Positions of the movable markers were traced with help of image analysis of front elevation images of levee section captured during the centrifuge test. At selected locations, food dye was placed to trace the movement of water at the onset of flooding through a levee section during centrifuge test.

In model RL-2, a 20 mm thick horizontal sand drainage layer was placed at toe of the levee section towards downstream side. The length of the sand drainage layer was maintained constant throughout the width of the levee and it was laid from vertical projection of midpoint of top width to the toe in the downstream side. The drainage layer was constructed by pluviating the sand in dry state and desired density was controlled by performing density checks. The sand layer was confined with a thin layer of geotextile fabric was wrapped with an anchor length of 20 mm at toe to prevent washing of sand particles at the onset of seepage. In model RL-3, horizontal drainage layer with sand was replaced with a model non-woven geotextile layer having same length and width as that of in model RL-2. It was positioned vertically 10 mm above the base layer, embedded in levee material to ensure no clogging of geotextile with kaolin particles from the base layer.

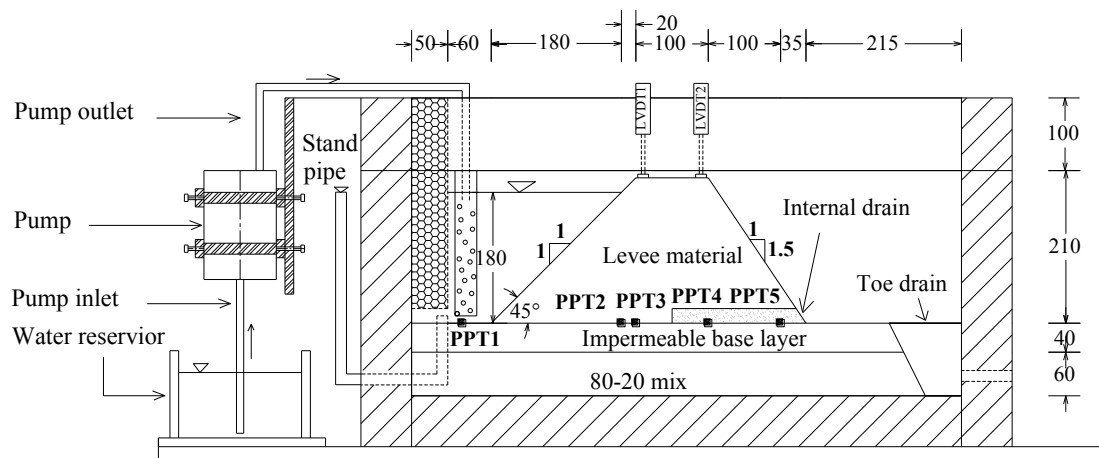

Figure 1. Schematic cross-section of model test package (All dimensions are in mm)

All levee models were instrumented with 5 no's PPTs and 2 no's LVDTs to evaluate variations in pore water pressure and settlement behavior of levee crest respectively. As shown in Fig. 1, PPT1 was placed above the base layer towards upstream to monitor the flood level and another four PPTs were embedded along the levee bottom at a distance of 180 mm (PPT2), 200 mm (PPT3), 300 mm (PPT4) and 400 mm (PPT5) from the upstream toe. PPT3 was placed at different position at 250 mm from upstream toe of levee in both model RL-2 and RL-3. In models RL-2 and RL-3, PPT3 was placed right below the mid-point of top width of the levee section to capture pore water pressure variations at the junction of levee material and horizontal drainage layer. LVDTs were housed at both left and right side of the crest at a horizontal distance 210 mm and 290 mm from upstream side toe. After completion of the model, in-flight simulator was mounted along with the model and initial checks were performed.

For all the models, 30 gravities was induced by rotating a model with 81 revolutions per minute. On reaching 30g, in-flight flood was commenced by activating pump remotely from the control room. Once the pump started, flood level kept on increasing due to constant pumping of water into the enclosure in front of the upstream face, as shown in Fig. 1. In order to prevent early seepage of water into levee section, the upstream side slope surface was coated with a thin layer of bentonite up to desired flood height. Constant High flood level could be maintained with the help of a stand pipe connected to the enclosure in front of the upstream slope face, as shown in Fig. 1. At the onset of flooding and subsequent seepage, seepage of water into levee section could be easily traced with help of diffused colored food dye. The seepage phenomenon through levee section was captured with the help photographs triggered at every 30 seconds from the time of commencement of flooding.

4. ANALYSIS AND INTERPRETATION OF CENTRIFUGE MODEL TESTS

4.1 General

Based on Pore water pressure data obtained from PPTs and corresponding variation of pore water pressures, head development and development of phreatic surfaces were calculated for all centrifuge models carried-out in the present study. Deformation behavior of levee sections was evaluated with the help of LVDTs data and image analysis. The following sections present analyses and interpretation of results of centrifuge tests.

4.2 Simulation of Flood

Figure 2 shows the variation of flood level with seepage time in prototype dimensions. This figure was plotted by considering the time in prototype dimensions, right after commencement of flooding at 30g. This was calculated by using $t_m/t_p = 1/30^2$ (where t_m = time in model dimensions and t_p = time in prototype dimensions). As shown in Fig. 2, maximum flood level could be achieved within four days for all the models. Efforts were made to simulate ideally identical flood levels for all the levee section, but due to limitation of pump capacity in high gravity environment water head slightly dipped and flood level fluctuations were observed. However, hydraulic response of levee sections in the form of pore water pressure and phreatic surfaces were evaluated with respect to function of flood level for individual levee sections.

Figure 2. Simulated flood function with respect to time in centrifuge models

4.3 Deformation Behavior of Levees

Crest deformations were measured with help of LVDTs placed at both sides of crest viz. landside crest and riverside crest, as shown in Fig. 1. Measured deformations of landside crest (i.e. towards downstream side) with respect to time in days for all the centrifuge tests are shown in Fig. 3. It can be seen from Fig. 3 that levee model RL-1 has undergone catastrophic failure right after attaining highest possible flood level. However, levee sections RL-2 and RL-3 with horizontal drainage layer were observed to experience only very negligible crest settlements. Values of normalized pore water pressures ($u/\gamma H$) are also marked in different stages of test in Fig. 3. Normalised pore water pressure is defined herein as a ratio of the measured pore water pressure with the help PPT3 to the product of bulk unit of the soil (γ) and height of levee section H. At the onset of seepage, normalized pore water pressure within levee section for model RL-1 was observed to increase up to 0.665 at 5 days after initiation of flood. In comparison, steady state seepage conditions were found to establish in models RL-2 and RL-3. This demonstrates the importance of un-clogged or proper drainage layer at the toe of levee section.

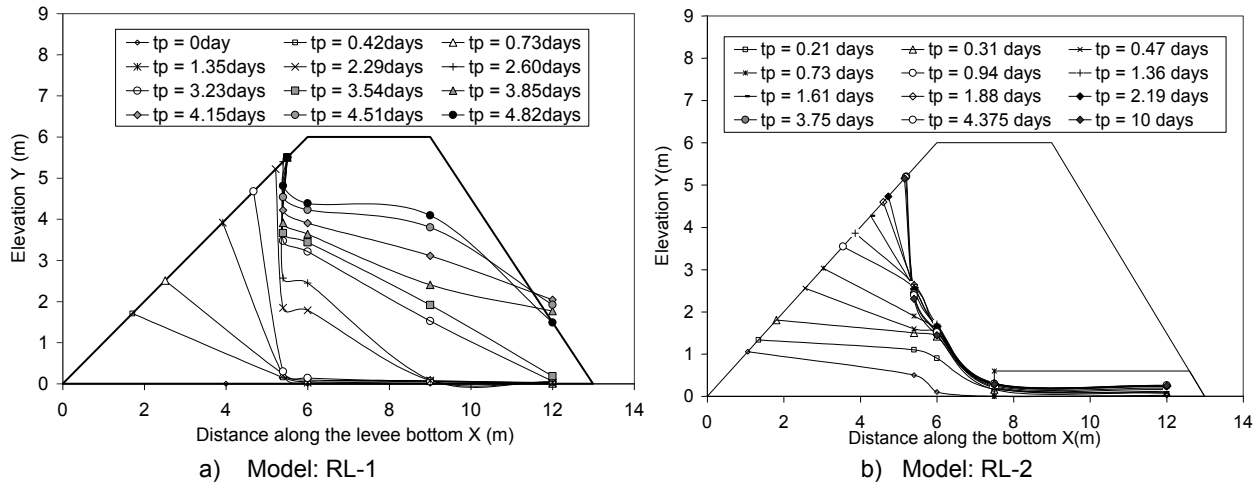

Figure 3. Measured variation in surface settlements of land side crest with respect to time

4.4 Development of Pore Water Pressure Within Levee Section

Phreatic surfaces during various stages of centrifuge after commencement of initiation of flooding were evaluated with the help of pore water pressure data obtained from PPTs embedded along the levee bottom. Figs. 4a-c present development of phreatic surfaces in levee sections with prototype time in days for models RL-1, RL-2 and RL-3 respectively. Three different types of phreatic surface development patterns can be observed for all the models presented in this paper. Relatively higher elevation of phreatic surfaces was observed in case of model RL-1. This is attributed to the absence of horizontal drainage layer at the toe or the presence of clogged drainage layer. In the case of model RL-2, the flow path of the water changed considerably and significant drop in pore water pressure drop within the levee section was observed. Depletion in the elevation of phreatic surfaces indicates efficiency of sand horizontal drainage layer in model RL-2. As depicted in Fig. 4c, a considerable dip in phreatic surfaces was observed for model RL-2 when compared with RL-1 without any drainage layer. However, development of pore water pressures in the drain zone for model RL-3 was found to be relatively higher than those in model RL-2.

Figure 4. Development of phreatic surface with seepage time within time (days)

Figs. 5a-b present variations in normalized pore water pressure with respect to prototype time for models RL-1, RL-2 and RL-3 respectively. In Fig. 5a, variation of $u/\gamma H$ obtained from PPT3 was used and in Fig. 5b, variation $u_{toe}/\gamma H$ obtained from PPT5 placed at the toe was presented. As shown in Fig. 5a, relatively high peaks of normalised pore water pressures both within the levee section and the toe were observed for model RL-1. These high values of pore-water pressures lead to the catastrophic failure immediately at the onset of maximum flood level for model RL-1. In comparison, lower values of $u/\gamma H$ and $u_{toe}/\gamma H$ were recorded for models RL-2 and RL-3 reflecting stability of levee models. Moreover, interestingly, distinct peaks were not observed for models RL-2 and RL-3 and this indicates the need of an appropriate internal drain in levee sections. The decrease in normalized pore water pressure values at the toe ($u_{toe}/\gamma H$) essentially depicts efficiency of drainage layer either in the form sand as well geotextile layer. In the case of RL-2 and RL-3, centrifuge tests were terminated after attaining steady state conditions in terms of pore water pressures. Long term hydraulic behavior of drainage measures is beyond the scope of this study.

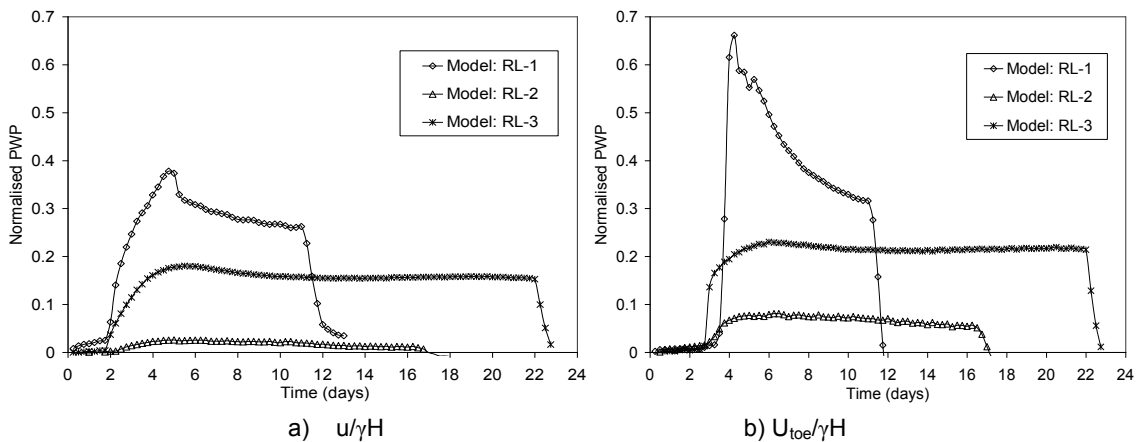

Figure 5. Variation of $u/\gamma H$ and $u_{toe}/\gamma H$ with time in days

4.5 Digital Image Analysis of Centrifuge Models

Images of front elevation of levee models captured with the help of on-board digital cameras at 30g for various stages of seepage were used to arrive at displacement vectors of markers embedded within the levee body and along with the downstream slope face. Image processing software, ImageJ (Version 1.44, 2011) was used for evaluation of relative positions of movable markers. For each image, global co-ordinates were fixed with reference to a grid of permanent markers. This was adopted for analyzing each and every image to prevent any error due to monitor resolution. After fixing global coordinates, positions of all the markers were registered for each image. Fig. 6 shows displacement vectors from the time of initiation of flooding and up to penultimate stage of the stage. Fig. 6 also depicts levee geometries of model RL-1 at both pre and at failure states. Levee model RL-1 was observed to experience a catastrophic failure at 5.1

days after initiation of flooding. A clear and distinct failure surface extending from the crest towards water side to the toe of the levee section can be observed. However, in case of levee models RL-2 and RL-3, negligible movements were recorded and hence digital image analysis was not performed.

Figure 6. Displacement vectors for model RL-1

Figure 7. Variation of face movements at the onset of seepage for model RL-1

Figure 7 presents variation of face movements for different durations of time (both in horizontal and vertical direction) with normalized height (which is defined as a ratio of height z from the top surface of impervious layer to the levee height in vertical direction) for model RL-1. The face movements could be obtained with the help of tracking movements of markers glued on to down stream slope surface. As can be noted from Fig. 7, downstream slope face was observed to move considerably immediately after completion of $t_p = 5.1$ days and experiencing a catastrophic failure. Further, relatively large movements at the toe (i.e. at $z/H = 0.2$) due to higher values of higher values of normalized pore water pressures at downstream slope lead to toe failure and is attributed mainly due to the absence of horizontal drainage layer or clogged drainage layer.

5. SEEPAGE AND STABILITY ANALYSIS OF CENTRIFUGE MODELS

Seepage analyses and stability analyses were also carried-out for all the three models with the help of finite element based software package SEEP/W and limit equilibrium method based SLOPE/W (GEO-SLOPE, 2007) softwares. For all models, dimensions of models were maintained in their corresponding prototypes having identical soil properties. As per the scaling considerations, hydraulic properties of geotextiles were scaled-up corresponding to 30 gravities. Geotextile tensile load characteristics were not considered while performing SLOPE/W analysis. Boundary conditions in numerical modeling were kept similar to those adopted in centrifuge model tests. Boundary conditions were assigned in the form of total head on the upstream side, total head on the downstream side and transient seepage time span. Flood functions were kept identical to simulated flood in a centrifuge test with the help of flood simulator, as shown in Fig. 2. Soil water characteristics curve (SWCC) was obtained with the help of grain size distribution curve to consider unsaturated-saturated properties of levee material (Geoslope, 2007). Drainage materials sand and geotextile were modeled as saturated materials and interface model respectively. Foundation layer was modeled as an impermeable material to ensure potential seepage through levee section only. For stability analyses, slip surfaces were specified to pass through toe at the downstream side. Special geometrical points were specified in numerical models to represent various PPT positions along the levee bottom of centrifuge models. Pore water pressure contours and phreatic surfaces were obtained from the seepage analysis. Variations in pore water pressure at levee bottom were plotted for the special geometrical points.

Figs. 8a-c present variations of pore water pressure for all centrifuge model tests. For comparison purposes, measured pore water pressure with seepage time for models RL-1, RL-2 and RL-3 is shown in Figs. 8a-c. Model RL-1 without any drainage measure registered high pore water pressures along levee bottom in comparison to RL-2 and RL-3. In all the levee sections the delay in pore water pressures built-up at levee bottom was found to be about by 2 days immediately after initiation of flooding, which can be attributed to unsaturated-saturated properties of levee material. PPT2 placed just vertically below the water level interacts with upstream levee face experienced highest pore water pressure. Measured pore water pressures by PPT2 in models RL-1, RL-2 and RL-3 were 48 kPa, 27 kPa and 32 kPa respectively. In comparison, computed pore water pressures from the seepage analysis of models RL-1, RL-2 and RL-3 at PP2 location were found to be 46 kPa, 27 kPa, and 32 kPa respectively. Measured pore water pressure at PPT5 (near toe) was found

to be 22 kPa in case of RL-1, whereas in the case of models RL-2 and RL-3, it was found to be the order of only 3 kPa and 7 kPa. Identical trend could be obtained from the seepage analysis of levee models. Relatively high pressures at the downstream toe in RL-1 caused instability to levee section. Whereas, proximity of reduced pore water pressure in models RL-2 and RL-3 at PPT5 indicates the efficiency of horizontal drainage layer to dissipate pore water pressure constructed with sand as well as non-woven geotextile as a drainage material.

Figs. 8a-c exhibit identical pattern of pore water pressure variation as obtained in centrifuge tests. Pore water pressure in model RL-2 near the downstream was found as 5 kPa from the centrifuge test and 4 kPa through SEEP/W respectively. In the case of model RL-3, it is 7 kPa and 11 kPa respectively. The consistencies in variations of pore water pressures demonstrate a good agreement with observed phenomenon in centrifuge model tests.

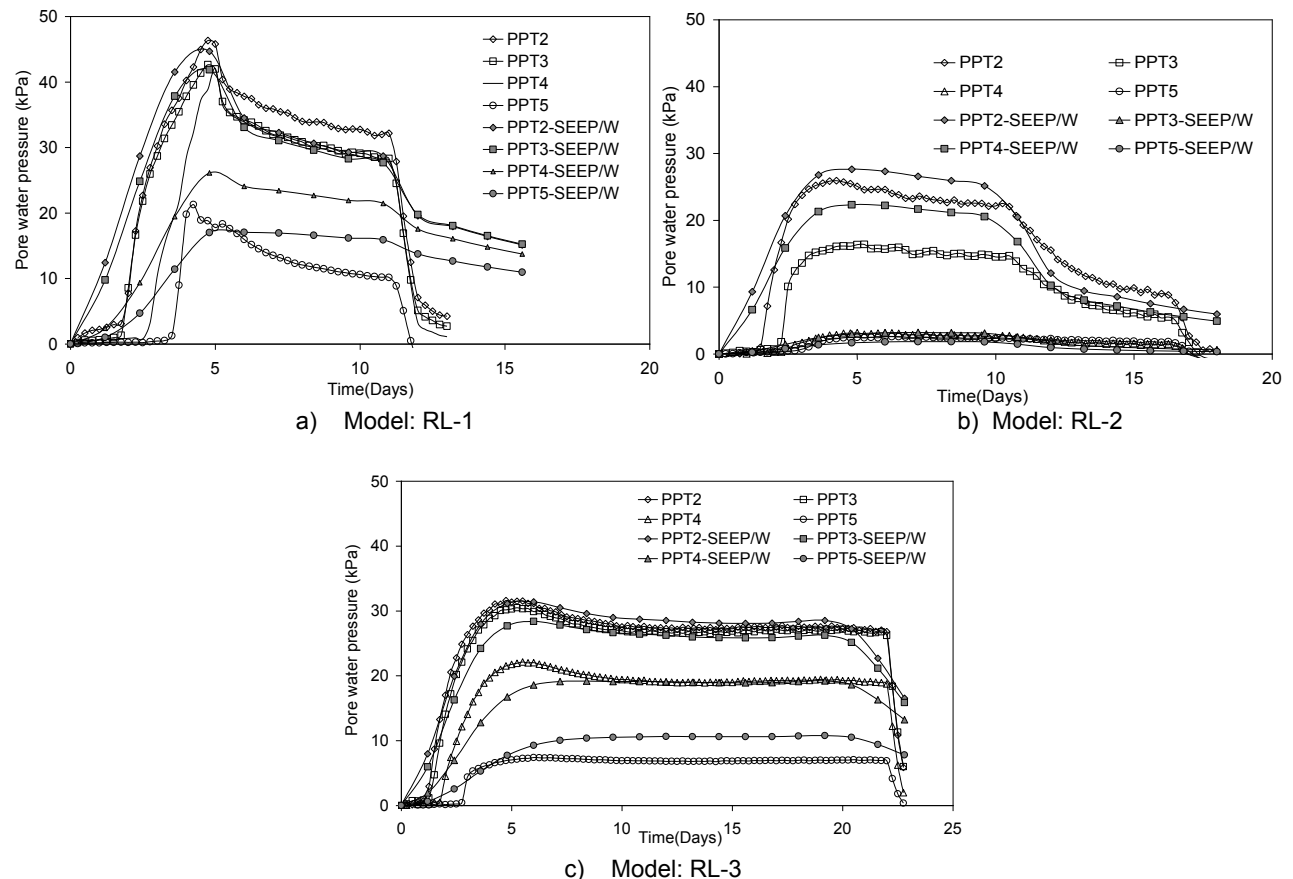

Figure 8. Comparison of pore water pressure variation in centrifuge tests and seepage analysis

Figs. 9a-c depict stability analyses carried out using Bishop's simplified method of slices with help of SLOPE/W (Geoslope, 2007) based on limit equilibrium analysis. While performing stability analysis, phreatic surfaces recorded during penultimate stages of centrifuge tests were used. As depicted in Fig. 9a model RL-1 was found to have a factor of safety 0.933. This is found to represent the observed failure for model RL-1 immediately after 5.1 days of seepage time. Whereas, for models RL-2 and RL-3, the computed factor of safeties were found to be of the order of 1.1 and 1.107 respectively. Marginal increase in factor of safety shows the efficiency of drainage layers to enhance stability of levee sections in high flood conditions.

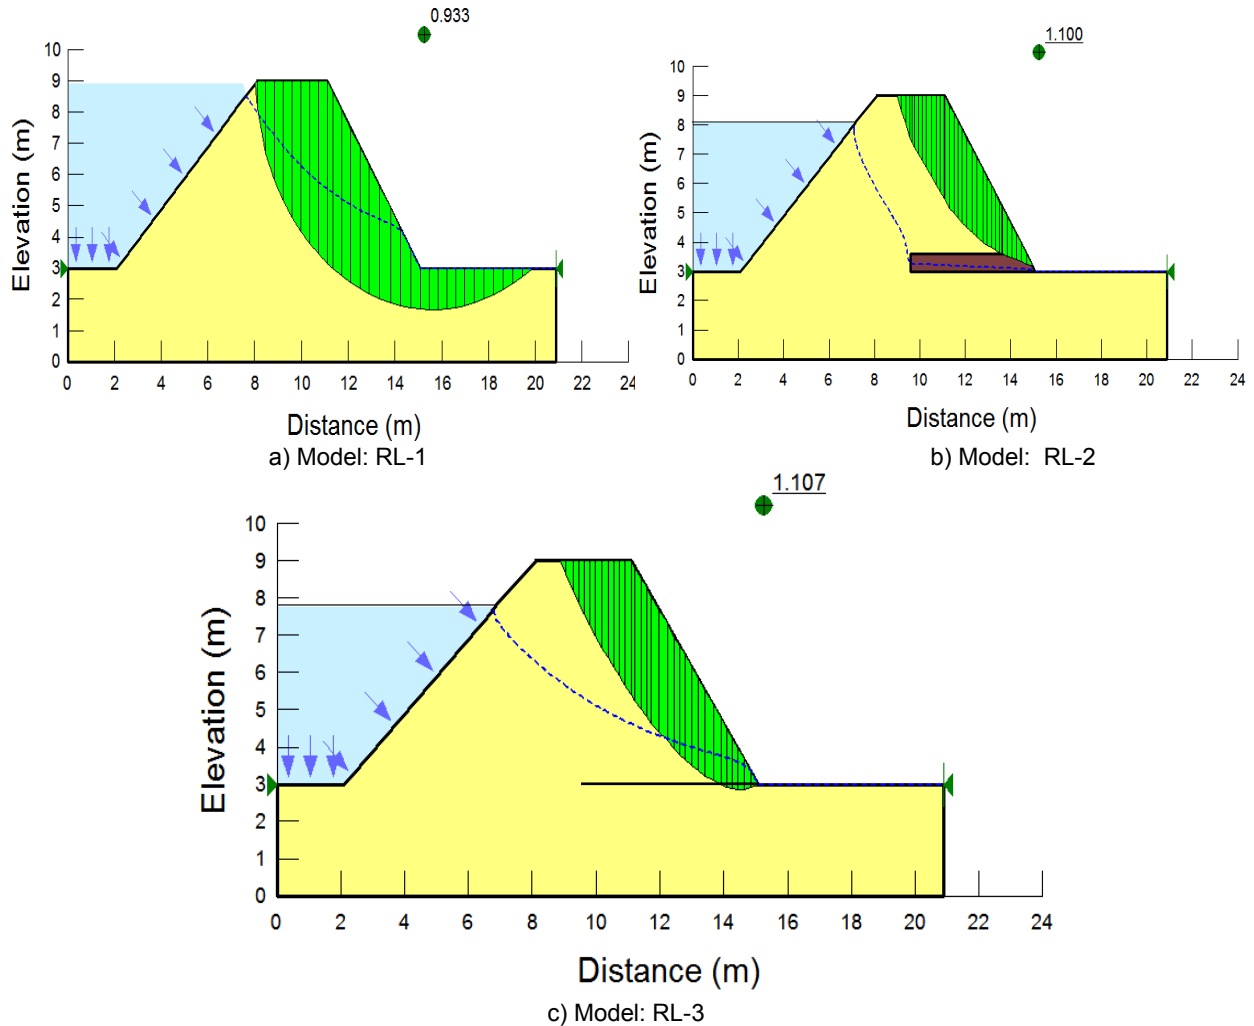

Figure 9. Stability analysis of centrifuge models using SLOPE/W.

6. CONCLUSIONS

This paper evaluates performance of an internal horizontal drainage layer (with sand or nonwoven geotextile) positioned at the levee bottom in the downstream side at the onset of flooding and subsequent seepage. For this purpose, three centrifuge model tests were performed. Furthermore, centrifuge model tests were also replicated with numerical experiments using finite element method based SEEP/W and limit equilibrium based SLOPE/W software. Finally, Influence of inclusion of drainage layer and replacement of sand with a non-woven geotextile layer was examined. Based on analyses and interpretation of centrifuge model tests and seepage and slope stability analyses, the following conclusions can be drawn:

1. Levee section without any horizontal drainage layer or clogged drainage layer experienced a catastrophic failure at the onset of flooding and subsequent seepage. The normalized water pressure ($u/\gamma H$) was registered as high as 0.665 and in the case of models with internal drain either in the form sand or non-woven geotextile, it is 0.08 and 0.24 respectively. Further, reduced values of maximum pore water pressures at the toe of the order of 3 kPa and 7 kPa were recorded for models with sand and non-woven geotextile as an internal drain. In comparison, the maximum pore water pressure recorded at the toe for the model without any drainage layer was 22 kPa. This indicates the efficacy of provision of drainage layer in the horizontal direction in levee sections.
2. Movement of displacement vectors from the time of initiation of flooding to penultimate stages of the test indicates a catastrophic failure for the levee section without any drainage layer. On the other hand, levee sections with sand and geotextile layers as an internal drain was not noticed experience any notable movements.

3. Results of transient seepage and stability analyses were found to be very consistent with those in physically observed centrifuge model test results.
4. Finally, hydraulic response of geotextile layer was found to be almost identical to sand drainage layer in order to improve the stability of levees. This study indicates that the conventional drainage layer constructed with sand as an internal drain can be replaced with a suitable geosynthetic layer which can impart economy in levee/earth dam construction projects.

However, further studies are warranted to have a better insight into the hydraulic behavior of geotextile embedded in levee sections, especially under long-term conditions.

Use of Geotextile Reinforced Slope for Containment Facility Dike

M. Surendra, Findling, Inc., 3401 Carlins Park Drive, Baltimore, MD 21215, USA,
surisurendra@findlinginc.com

ABSTRACT

Geotextiles have been used successfully in the construction of retaining structures and in order to make fill slopes steeper. This paper presents a case history where a reinforced slope section was incorporated into the design cross section of a dike around a dredged material containment facility (DMCF). The paper provides a brief discussion of the dike that was designed to retain dredged materials that will be pumped in to the containment facility periodically. The alignment of the dike was located in the area of previous shoreline and contained remnants of previous structures. This necessitated the need for a slope cross section that would remain stable in the event the existing previous remnants were to collapse and induce a ground loss condition. The dike that was constructed encompassing the stabilized portion of the slope and the overall stability of the dike is also briefly discussed.

1. INTRODUCTION

The site of the Masonville DMCF is located in Baltimore, Maryland, USA as shown on Figure 1: Site Vicinity Map. The dredged material that will be generated during the maintenance dredging operations by the Maryland Port Administration (MPA) will be placed inside the containment facility. The DMCF is about 38 ha in plan and is approximately rectangular in plan. The west and north sides of the facility consist of earthen dike constructed in water, the east side consists of a steel cellular cofferdam that will be used as a pier and the south side consists of existing shoreline.

The site is located to the south of the Patapsco River and consists of several existing piers on the east and a containment facility to the southwest and several previously used slips. Several barges and other vessels were also encountered at various parts of the site in the southeast portion. A layout of the proposed DMCF is shown on Figure 1.

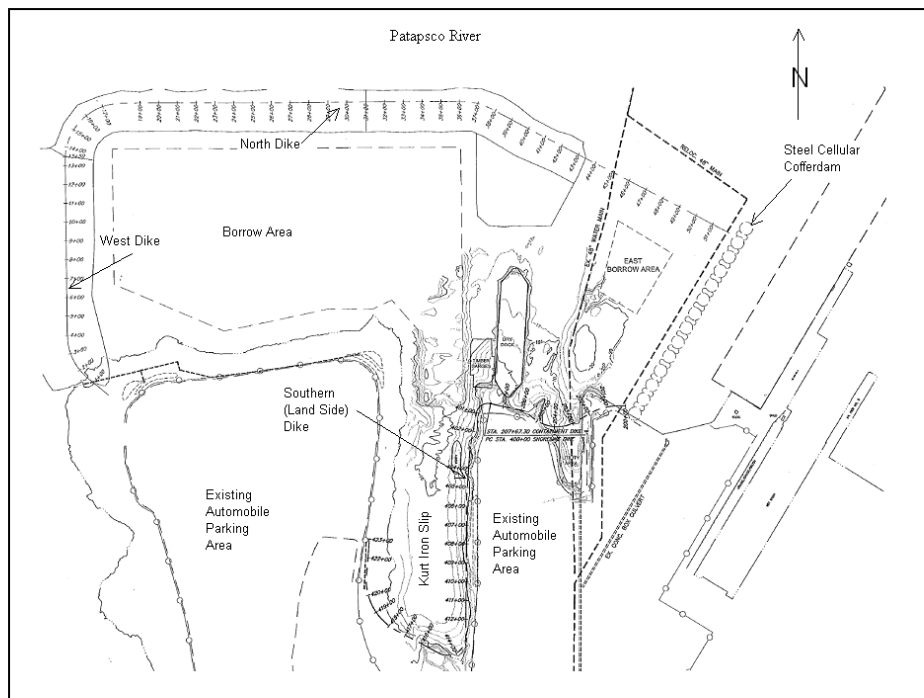

Figure 1. Layout of DMCF

2. SITE AND SUBSURFACE CONDITIONS

Geologically, the site is located in the Western Shore Lowland Region of the Atlantic Coastal Plain Province. The Coastal Plain Deposits generally consist of Sand, Silt and Clays that have been deposited by the receding seas. The site is located on the southern bank of Patapsco River and was previously used as a borrow area for sand and gravel. The area to the east of the site consists of active piers and remnants of old piers. During the past use, this portion of the site was used where ships were repaired and later was used as a salvage yard in the 1970's. Steel and wooden dry-docks and barges were abandoned in shallow waters along the then existing shoreline following the completion of the repair and salvage operations at the site. The site surrounding the subject DMCF has been developed for use by the port as a storage facility for automobiles by placing fill over the shallow portions along the previous shore line. During this process, many structures were buried underneath the currently used parking areas.

Test borings were drilled along the alignment using a truck-mounted drill rig from a barge. The depth to mud line (i.e., the depth of water) at the site ranges from 4.5 m to 6 m below Mean Lower Low Water (MLLW). The tidal change in water level is about -0.2 m to +1.2 m. The near surface soil beneath the water was Muck consisting of very loose and soft organic SILT. The Muck layer extends to a depth of 9 m to 12 m below MLLW. Below the Muck layer, relatively soft Silty CLAY stratum was encountered. Thickness of the clay layer ranged from 1 m to 3 m. Below the Silty CLAY stratum, a Silty SAND stratum with varying percentages of Gravel was encountered. This Sand stratum extended to a depth of 20 m to 23 m below MLLW. Below the Silty SAND stratum a hard CLAY or dense SAND and Gravel stratum was encountered to the maximum depths explored (i.e., to 30 m below MLLW).

A summary of the subsurface conditions and typical properties of the stratum encountered and design parameters used in the analysis of the dike (Findling, 2010) is summarized on the following table:

Table 1. Summary of Subsurface Conditions

Stratum	Elevation, m	USCS Classification	Natural Moisture Content, %	% Passing No 200 Sieve	Atterberg Limits (LL, PL, PI)	Undrained Shear Strength, kPa	Angle of internal Friction, degrees	Total Unit Weight, kN/m ³
Water	0 to -6	--						
Muck	-6 to -12	MH	>100	90	70, 40, 30	4.78	--	17.28
Silty CLAY	-12 to -15	CL	36	95	29, 20, 9	4.78 – 19.20	--	18.06
SAND	-13 to -23	SM	12	10 – 30	--	--	30	18.85
CLAY	-23 to -30	CH	20	95	50, 20, 30	95.6	--	19.63
SAND & Gravel	-23 to -30	GM-SM	12	10 – 30	--	--	35	19.63

3. DESIGN OF CONTAINMENT DIKE

The initial design of the dike was considered to extend to a height of El +3.66 m. The cross section of the dike consisted of a 6.1 m wide crest and side slopes of 3 Horizontal to 1 Vertical. The dike was planned to be constructed using SAND obtained from dredging the area inside the containment facility. The dike was designed to be constructed using the sand from the borrow area (within the containment facility) by hydraulic placement. The dike was also planned to be raised in the future to El +12.8 m in stages using the dried crust materials generated from the crust management program of the dredged materials within the containment facility.

Slope stability analysis was performed using PCSTABL computer program. The subsurface conditions and the cross section of the dike used in the analysis of the inside slope is shown on Figure 2 in the Appendix. Based on initial analysis of the cross section, it was determined that the muck layer will have to be displaced by the fill for the new dike or undercutting of the muck layer is required in order to obtain adequate factor of safety for the proposed dike cross section. The muck layer was replaced with Sand fill, and the analysis was repeated. The resulting factor of safety after the replacement of the muck is about 1.27.

In order to obtain an adequate factor of safety against global failure, undercutting (i.e., excavation and disposal) of the muck stratum was required. Therefore, during the construction operations, a pre-dredging program was used to excavate and remove the muck stratum along the proposed footprint of the dike on the west and north sides of the proposed dike.

Figure 2. Slope Stability Analysis of landside Dikes

3.1 Landside Dike

The landside dikes are located in the southern portion of the site as shown on Figure 3. In the area of the southern portion, the shoreline adjacent to the previous slips had been previously filled to create the parking lot that is currently being used to park automobiles. The containment dike in this area is located along the current shoreline. The existing parking lot is near El +7 and the dike is designed to extend towards the water. Due to the limited access and to minimize disturbance to the operations of the existing parking lot, undercutting of the muck stratum was not performed. The dike was constructed in this portion of the site by displacing the muck by placing sand over the existing muck stratum.

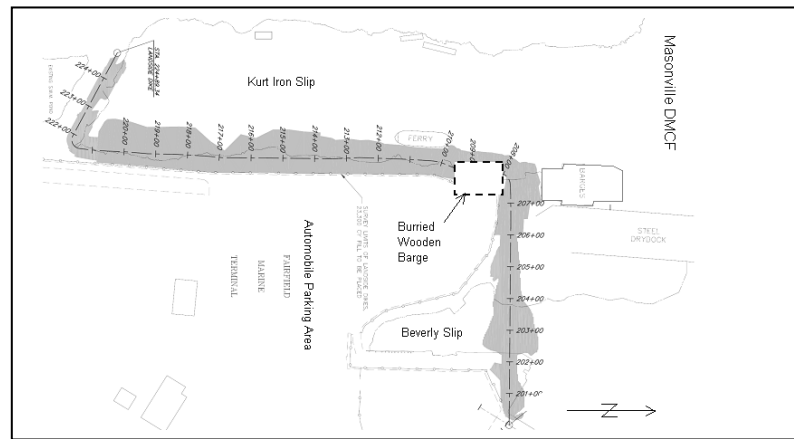

Figure 3. Location of Landside Dike

During the subgrade preparation operations, prior to the placement of the sand for the construction of the dike, the existing subgrade was cleared of surface vegetation and remnants of previous construction (such as concrete slabs, asphalt pavement, etc.). During this subgrade preparation, remnants of a previous barge structure were encountered near the northern portion of the Kurt-Iron Slip. Approximate limits of the buried barge in relation to the cross section of the proposed dike are shown on Figure 4.

After clearing the surficial materials, the timber planks and beams that constituted the barge were encountered. A portion of this wooden barge structure was removed and disposed of off-site. The excavation and removal was stopped at the property line and the structure was noted to extend under the active parking lot. The dimensions of the barge structure and the limits of the structure under the existing parking lot are not known.

Slope stability analysis was performed using PCSTABL computer program (Achilleos, 1988). A typical cross section that was used in the slope stability analysis is shown on Figure 5. The results of the slope stability analysis indicated that the stability of the new dike constructed on top of the remnant of the wooden barge structure was marginal. In order to

increase the factor of safety of the dike, the barge structure that is empty (i.e., filled with water and not soil) would have to be grouted with flowable fill (that consists of a Sand, fly ash and cement mix). However, due to cost associated with grouting the barge with flowable fill and other project constrains it was decided by the owner that the grouting would not be performed at this time.

Figure 4. Typical Cross Section of Dike at the location of the Buried barge

Figure 5. Slope Stability Analysis at Location of Barge

3.2 Geotextile Reinforced Slope within the Dike

The wooden barge structure that extends under the current parking lot and that will be incorporated into the body of the containment dike in this area extends from EI +0 to EI -3.66 m. A dewatering operation was performed to lower the water inside the containment facility to facilitate the first inflow of the dredged materials into the containment facility. At the time the site preparation was performed, the water inside the containment facility had been lowered to about EI -4.0 m. The dike in this area had to be completed before the first inflow of the dredged material was scheduled for placement

into the containment facility. A view of the wooden barge structure that was encountered along the alignment of the proposed landside dike is shown on Figure 6.

Figure 6. Slope Stability Analysis at Location of Barge

The barge structure extends from El +0 to El -3.66 m and about 45 m along the alignment of the dike. The exposed vertical face of the barge structure along the property boundary is an interior partition of the barge. The vertical exposed face contained several openings in to the interior compartments that are located beneath the active parking lot. The construction of the dike along its planned alignment would require placement of Sand fill against the vertical face of the remnants of the barge structure. The sand fill could migrate into the open voids of the interior compartments (beneath the parking lot). Also the wooden structure could collapse under the lateral load of the new sand fill of the dike and thus create a ground loss condition. The ground loss condition will cause the dike to become unstable.

The geotextile reinforced slope was designed to meet the following requirements:

- a. Prevent Fill material from being infiltrating into the open voids of the barge
- b. Confine the fill materials in front of the remnant of the barge
- c. Reduce lateral pressures on the walls of the remnant of barge structure

In order to prevent the migration of sand into the open voids and to reduce the lateral earth pressures on the exposed face of the wooden barge structure, a Geotextile reinforced slope was designed (DM7.2, 1982). Active earth pressure of sand backfill was used in computing the horizontal design load and surcharge load from the fill above the reinforced zone was used in the design of geotextile required for the slope. The Geotextile used consisted of Mirafi 600x and the sand material used consisted of Silty SAND with about 20 % of fines. Typical properties of Geotextiel Mirafi 600x are summarized on Table 2 below. This Geotextile was selected based on its adequate strength to retain the fill behind it and also prevent migration of the sand material into the voids of the adjacent barge structure. In addition, this Geotextile had been used at the site for other purposes and was readily available for use for this application (Koerner, 1986).

Table 2. Physical Properties of Geotextile Mirafi 600X

Mechanical Properties	Test Method	Unit	Minimum Average Roll Value	
			MD	CD
Grab Tensile Strength	ASTM D4632	lbs (N)	315 (1402)	315 (1402)
Grab Tensile Elongation	ASTM D4632	%	12	
Trapezoid Tear Strength	ASTM D4533	lbs (N)	113 (503)	113 (503)
CBR Puncture Strength	ASTM D6241	lbs (N)	900 (4005)	

¹ ASTM D4751, AOS is a Maximum Opening Diameter Value

The Geotextile was extended to a distance of 3.05 m from the face and consisted of 0.46 m to 0.30 m lifts. The face consisted of wrapping the Geotextile back for a distance of 1.22 m. The annular space between the Geotextile reinforced earth structure and the vertical face of the wooden barge structure was filled with crushed stone aggregate (of

ASTM gradation No. 57). A typical cross section of the Geotextile reinforced slope is shown on Figure 7. The geotextile reinforced slope was incorporated into the cross section of the dike in this area. This enabled the completion of the dike in time for the first inflow of the dredged material into the containment facility. The performance of the dike will be monitored by surveying the crest elevation during the operation of the facility.

4. CONCLUSION

The paper provides a brief discussion of the background information that required the need for a stabilized slope within a dike section. The dike was designed to retain dredged materials that will be pumped periodically in to the containment facility. The alignment of the dike was located in the area of previous shoreline and contained various obstructions. This necessitated the need for a slope cross section that would remain stable in the event the existing previous remnants were to collapse and induce a ground loss condition. The design methodology used for the construction of a Geotextile stabilized slope cross section adjacent to the previous remnants at the site is discussed. The dike was constructed to encompass the stabilized portion of the slope.

The construction operation was completed in September 2011. Based on the performance of the dike in the last 6-months, it appears that there is no measurable settlement or loss of ground condition that has occurred in the vicinity of the Geotextile stabilized portion of the dike adjacent to the buried barge. Field observations will continue on a periodic basis. The use of the Geotextile reinforced slope within the dike cross section enabled the completion of the containment dike to receive the placement of dredged materials in time.

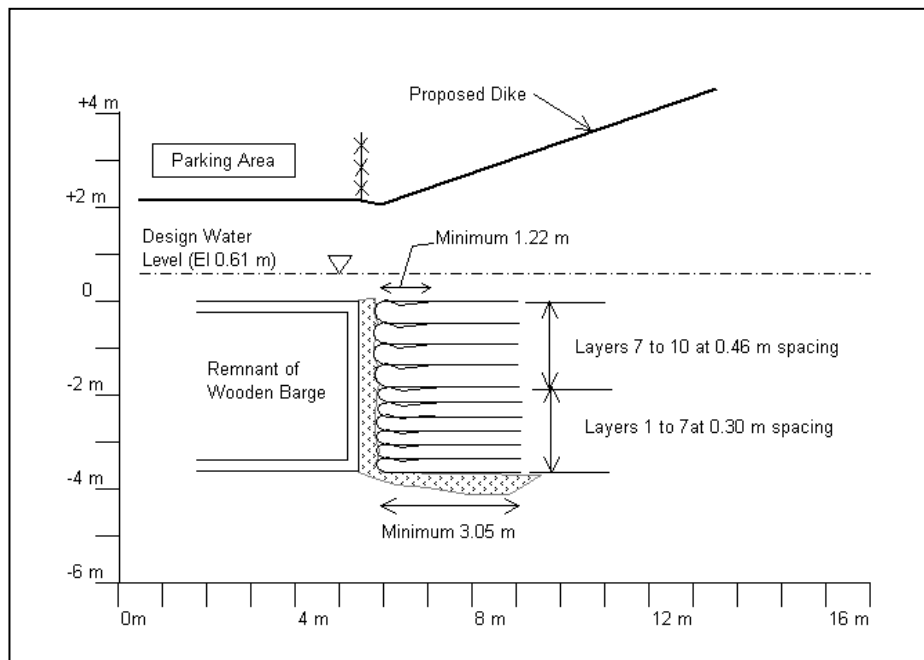

Figure 7. Typical Cross Section of Geotextile Reinforced Slope

ACKNOWLEDGEMENT

The author would like to thank Mr. Steve Storm with the Maryland Port Administration for allowing use of the data from which this paper is prepared. Mr. Dennis Urso and Mr. Tim Donegan with Gahagan, Bryant and Associates provided the design of the containment facility. Mr. Mike Miller with Maryland Environmental Services, Inc. provided the assistance in the implementation of the Geotextile reinforced section into the dike. Mr. Amsalu Duressa and Mr. John Tallman with Findling, Inc. provided assistance in the preparation of this paper.

What Value of Interface Friction to Select for Geosynthetic Liner on Landfill Slopes?

ABSTRACT

To characterize the geosynthetic friction, the Inclined Plane is recognized as a very suitable and versatile device, since it allows to test large samples with variable relative tangential displacements under low normal stress. According to different studies carried out in France, the procedure proposed by the European Standard could provide non-conservative results. For this reason, two alternative procedures are proposed: the "Displacement Procedure" and the "Force Procedure". In this study a full description of the two procedures is presented and an application to a typical landfill barrier interface is carried out. Furthermore, several values of the interface friction angles are determined from the two methods and a comparison with the "standard" value is provided.

1. INTRODUCTION

Geosynthetics barriers in landfill are frequently arranged on slopes. Consequently, the stability of these systems is a key issue. Despite a lot of research on this topic, quite often sliding of the barriers is observed on slope (Girard et al. 1990). This kind of dramatic event could be attributed in many cases to a not proper assessment of the friction at the different interfaces.

As different studies demonstrated (Izgin & Wasti 1998, Lalarakotoson et al. 1999, Wasti & Özdüzgün 2001, Palmeira et al. 2002, Palmeira 2009, Reyes Ramirez & Gourc 2003, Wu et al. 2008, Brianchon et al. 2011), the main advantage of the Inclined Plane test is to allow testing the materials with variable relative tangential displacements under low normal stress (<10 kPa) typically present during the construction of the lateral barriers and in the landfill covers.

The test procedure is ruled by the European Standard EN ISO 12957-2 (2005); since it is not rigorous method as other researches underlined (Gourc & Reyes Ramirez 2004, Pitanga et al. 2009, Brianchon et al. 2011), Gourc and Reyes Ramirez (2004) and Brianchon et al. (2011) proposed two alternative test procedures in order to improve the evaluation of the interface friction angles.

The three test procedures are carried out to assess and to compare the friction angles of a typical landfill cover interface. In particular, the present study investigates, as an example, the behavior of the geocomposite drain (GCD) in contact with a geomembrane (GMB) which is likely to be a critical interface in the geocomposite systems. Furthermore, the influence of the two geosynthetics (geotextile (GTX) and geonet (GNT)) which constitute the GCD, are separately tested in direct contact with the geomembrane in order to assess their influence in the geocomposite drain performance.

2. THE INCLINED PLANE TEST

2.1 Generalities

The Inclined Plane Test permits to determine the friction angle between soil-geosynthetic and geosynthetic-geosynthetic interface at very low normal stress (5.0 ± 0.1 kPa). The test is ruled by the European Standard EN ISO 12957-2 (2005), that describes both the apparatus and test procedure.

The normal stress must be applied to obtain a regular distribution on the entire surface of the specimen and the plane tilts slowly and at a constant rate, i.e. $d\beta/dt = 3.0 \pm 0.5^\circ/\text{min}$ where β is the plane angle related to the longitudinal position.

According to EN ISO 12957-2 (2005), the device is composed by two boxes for the upper and the lower layer respectively. The minimum dimensions of the boxes are: $l_u = 0.3$ m in length along the displacement direction, and $b_u =$

0.3 m in width for the upper box; while $l_1 = 0.4$ m, $b_1 = 0.325$ m for the lower box. In the case of geosynthetic – geosynthetic contact, the upper geosynthetic is fastened to the upper box while the lower is fixed to the inclined support in order to limit any relative movement between the layer and the plane.

The techniques used to fix the lower geosynthetic are: sewing, gluing, using a rough support to increase the adherence between the geosynthetic and the plane, or anchoring the layer outside the contact area.

2.2 Standard Procedure

The European Standard proposes a specific interpretation of test results, here called “Standard Procedure”. According to this interpretation, the interface friction angle is a plane inclination angle β corresponding to a conventional displacement of the upper box $u = 50$ mm. The relative friction angle ϕ_{stan} is calculated considering a static equilibrium along the plane direction, as follows:

$$W \cdot \sin\beta_{50} - N \cdot \tan\phi_{\text{stan}} = 0 \quad [1a]$$

$$W \cdot \cos\beta_{50} = N \quad [1b]$$

where, N is the reactive force balancing the normal component of the weight, W , of the upper box.

The value of the standard interface friction angle, ϕ_{stan} , is obtained combining Equations 1a and 1b to yield the following:

$$\tan\phi_{\text{stan}} = \tan\beta_{50} \quad [2]$$

2.3 Displacement Procedure

The interface friction angle ϕ_{stan} calculated following Equation 2, is obtained from a static approach. Gourc & Reyes Ramirez (2004), modifying the standard inclined plane device (Figure 1), demonstrated that during the sliding the uniformly accelerated movement takes place and the equilibrium equations should take into account this dynamic condition.

For this purpose, the modified apparatus presents a sufficient length in the slope direction ($l_1 = 1.3$ m, $b_1 = 0.8$ m) to measure the acceleration of the upper box during the motion. The initial normal stress is applied using metal plates as overload.

Using this modified setup, Gourc & Reyes Ramirez (2004) proposed a new interpretation, here called “Displacement Procedure” where the sliding behavior could be divided into three characteristic phases (Figure 2), as follows:

- Phase 1 (Static Phase): The upper box is practically motionless (the displacement of the upper box equals zero) over the inclined plane until a critical angle, β_0 , is reached,
- Phase 2 (Transitory Phase): With increasing inclination beyond β_0 , the upper box moves gradually downward, and the acceleration γ of the upper box is not constant, and
- Phase 3 (Stabilized - Sliding Phase): At $\beta = \beta_s$, the upper box undergoes stabilized sliding with constant acceleration γ_c , and the speed progressively increases.

Figure 1. Inclined Plane apparatus geosynthetic – geosynthetic configuration.

Figure 2. Different phases of the "Displacement Procedure" Test.

Here, β_0 is defined as the plane inclination angle before the initialization of the sliding corresponding to the static interface friction angle, ϕ_0 , at the end of the Phase 1 and β_s is the plane inclination angle when the acceleration γ of the upper box could be considered constant for the stabilized sliding.

As already found by (Pitanga et al. 2009), Phase 2 may be of two types:

- Sudden sliding: abrupt displacement of the upper box with $\beta_0 \sim \beta_s$, and
- Gradual sliding: displacement u increases with inclination β , progressively or as a stick-slip mode.

The Phase 3 starts when the acceleration reaches a constant value γ_c ; under this condition, the relations (Equations 1a and 1b) should be replaced by the Equations 3a and 3b:

$$W \cdot \sin\beta_s - N \cdot \tan\phi_s = W \cdot \frac{\gamma_c}{g} \quad [3a]$$

$$W \cdot \cos\beta_s = N \quad [3b]$$

The value of the actual friction angle, ϕ_s , in place of ϕ_{stan} , is similarly obtained by combining Equations 3a and 3b to give:

$$\tan\phi_s = \tan\beta_s - \frac{1}{\cos\beta_s} \cdot \frac{\gamma_c}{g} \quad [4]$$

where γ_c is the constant acceleration of the upper geosynthetic component of the interface during the stabilized-sliding phase.

2.4 Force Procedure

The “Force Procedure” was recently proposed by Briançon et al. (2011) since evaluating the acceleration during the motion in the “Displacement procedure” could be very complex for some interfaces.

This method consists in determining the interface friction angle, here denoted as δ , through the inclined plane apparatus by measuring the force required to restrain the upper box after reaching a limiting value of the sliding displacement u_{lim} .

To perform the Force Procedure, the inclined plane device is modified linking the upper box by means of a loose cable (Figure 1) to a force sensor fixed to the device frame.

After reaching a predetermined displacement value, u_{lim} , corresponding to an inclination $\beta = \beta_{lim}$, the cable is stretched and the force $F(\beta)$ required to hold back the upper box is measured (Briançon et al. 2011).

Figure 3. Schematization of the different steps during the “Force Procedure” test.

The test consists of three steps (Figure 3):

- Step 1: corresponds to the static state of the upper box with respect to the lower plane during the tilting process ($\beta < \beta_0$),
- Step 2: corresponds to the transitory state where the upper box slides, gradually or suddenly, it is in the dynamic state until the cable is stretched for a displacement u_{lim} ($\beta_0 \leq \beta \leq \beta_{lim}$), and
- Step 3: the upper box reaches the end of the slide ($u = u_{lim}$) and it could be considered in a static state because the only possible movement is due to the elongation of the cable that could be neglected. Here, the variation of F is monitored during the test, in particular it increases with the continuous tilting process of the plane ($\beta > \beta_{lim}$).

During the Step 1 (where $F(\beta) = 0$) and the Step 3 ($F(\beta) > 0$) the equilibrium analysis is achieved by the following equations:

$$W \cdot \sin\beta - N \cdot \tan\delta - F(\beta) = 0 \quad [5a]$$

$$W \cdot \cos\beta = N \quad [5b]$$

$$\tan\delta = \frac{W \cdot \sin\beta - F(\beta)}{W \cdot \cos\beta} \quad [6]$$

where W is the total weight of the upper box and $F(\beta)$ is the force required to hold back the upper box.

During Step 2, the equilibrium should take into account the acceleration during the sliding and it is not considered in this method.

Thus, for convenience the whole test may be represented in terms of the parameter λ as follows:

$$\tan\lambda = \frac{W \cdot \sin\beta - F(\beta)}{W \cdot \cos\beta} \quad [7]$$

In particular, $\tan \lambda$ could be characterized during all the test as follows:

During Step 1:

$$\tan \lambda_0 = \tan \bar{\delta}_0 = \tan \beta_0 \quad [8]$$

During Step 2:

$$\tan \lambda = \tan \bar{\delta} - \frac{\gamma}{g \cos \beta} \quad [9]$$

During Step 3:

$$\tan \lambda_{\text{lim}} = \tan \bar{\delta}_{\text{lim}} = \tan \beta - \frac{F(\beta)}{W \cdot \cos \beta} \quad [10]$$

If the acceleration γ is not measured during the Step 2, in the analysis of test results, it is possible to calculate only two different values of the interface friction angles corresponding to the Step 1 and Step 3. In particular, as found by Briançon et al. (2011), $\bar{\delta}_{\text{lim}}$, is considered the key parameter of this method because it is not sensitive to the test conditions.

3. TESTING PROGRAM

The study is carried out on a wide range of geosynthetic interfaces typically present in landfill liners. In particular, the present work investigates the behavior of the geocomposite drain – geomembrane interface since its use is very widespread in the composite systems.

The geocomposite for drainage (GCD) consists of a thermobonding rhomboidal shape HDPE geonet (GNT) with two nonwoven geotextiles (GTX) on both sides, working as separation, filtration and protection layers. The geomembrane is a smooth high density polyethylene (HDPE) geomembrane (GMB) representing, in all the tests, the lower layer (here denoted as Geos^L) while the other geosynthetics are glued to the upper box (Geos^U). The physical properties of the materials are given in Table1 and all the tests are performed using specimens obtained from virgin samples, in the machine direction.

To examine the geocomposite drain–geomembrane interface, the influence of the different materials which constitute the geocomposite system is also assessed; thus, during the experimental program the three different interfaces are tested:

- geotextile (GTX^U) – geomembrane (GMB^L);
- geonet (GNT^U) – geomembrane (GMB^L);
- geocomposite drain (GCD^U) – geomembrane (GMB^L).

For the Inclined Plane tests program, the Standard Procedure, the Displacement Procedure and the Force Procedure are carried out in order to compare the results.

It is worth noting that, the behavior of each interface is standard and replicable; the friction results are determined as an average value of at least three tests where the deviation is less than 0.5°.

Table 1. Characteristics of tested geosynthetics.

Type of geosynthetic	Material	Thickness (mm)	Mass per Unit Area (g/m ²)
Geotextile (GTX)	Thermally bonded nonwoven	1	130
Geonet (GNT)	Thermobonding rhomboidal shape High Density Polyethylene	3.5	520
Geocomposite drain (GCD)	External filter + Drainage core	5.5	780
Geomembrane (GMB)	High Density Polyethylene	2	/

4. RESULTS AND DISCUSSION

The Figure 4a shows the displacement (u) versus time for the three different interfaces, according to the “Displacement Procedure”.

In the case of the GTX^U-GMB^L interface, the upper box starts to slide for a plane inclination β_0 corresponding to 15.8°. In this case, the upper box moves gradually downward with a very low velocity.

Considering test results about GNT^U – GMB^L interface, it could be seen that the interface shows a stick-slip behavior characterized by an abrupt initial displacement ($\phi_0 = 15.2^\circ$) followed by a braking phase where the upper box slides slowly, up to a very fast sliding until the end of the plane. In this case, determining the dynamic interface friction angle is not simple because it changes during the sliding.

Finally, the GCD^U - GMB^L interface is tested; the direct contact is between the geotextile GTX^U and the geomembrane GMB^L but, as it could be noticed by the Figure 4b, the influence of the geonet core is clearly highlighted.

In fact, the sliding remains gradual and constant until the end of the test as in the case of GTX^U -GMB^L interface even if there is a sudden initial displacement as for GNT^U – GMB^L interface.

Regarding the Displacement Procedure, ϕ_s is calculated in the range of the displacement curve (Figure 4b) where the velocity increases linearly. It could be noticed that all the interfaces are characterized by a gradual sliding of the upper box at a very low velocity. This kind of behavior indicates that the resisting force (friction) gradually increases respect the value at rest during the slide. Consequently, in all the cases the dynamic friction angle ϕ_s is greater than the ϕ_0 corresponding to the beginning of the movement.

In the Force Procedure the force $F(\beta)$, the displacement, u , of the upper box and the plane inclination angle, β , are measured. In Figure 5a, the force F mobilized during the entire test procedure is presented and, subsequently the parameter λ is calculated (Equation 7) and plotted versus the plane inclination β (Figure 5b).

At the beginning of the test, during Step 1, ($\beta < \beta_0$) the mobilization of static friction is partial and, the value of λ increases linearly according to the Equation 8.

At the end of Step 1, at the initialization of the sliding for $\beta = \beta_0$, the corresponding measured friction angle is δ_0 that corresponds to the interface friction angle also determined in the Displacement Procedure ϕ_0 . Subsequently, the force F increases fast (Figure 5a) and β rises from β_0 to β_{lim} . During this transitory state (Step 2), as the interface friction angle depends on the acceleration of the upper box (Equation 9), its representation is only qualitative. Finally, at the end of the sliding ($u = u_{lim}$ and $\beta = \beta_{lim}$) Step 3 begins; the driving forces are higher than the friction resistant forces and there is a full mobilization of the friction corresponding to a displacement u_{lim} .

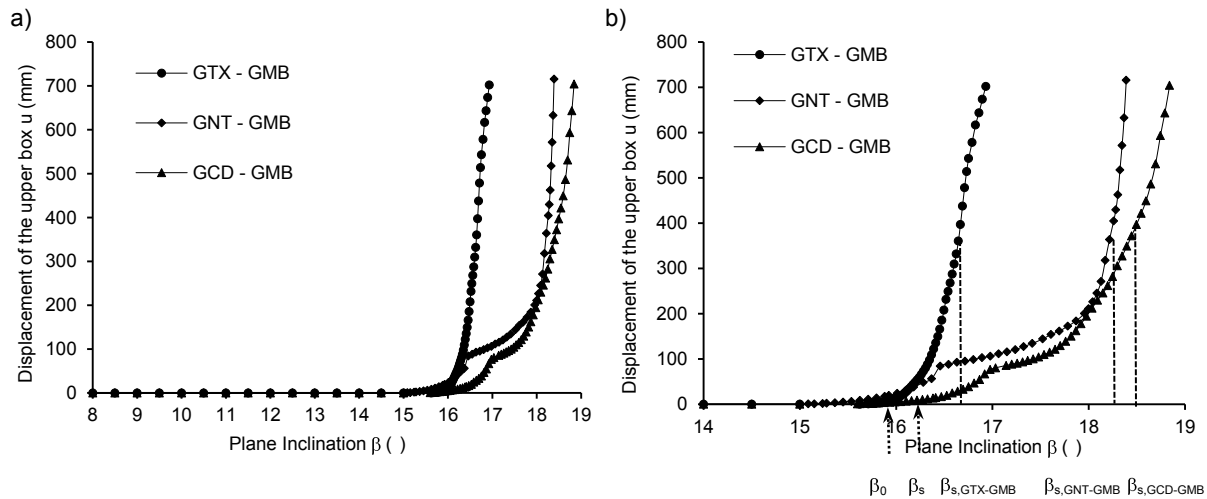

Figure 4. Inclined Plane test according to the “Displacement Procedure”: a) Displacement of the upper box against the plane inclination angle β ; b) Zoom on the initial sliding phase of GTX-GMB, GNT-GMB and GCD-GMB interfaces, plotting all the characteristic plane inclination angles used for the “Standard” and the “Displacement” procedures interpretations.

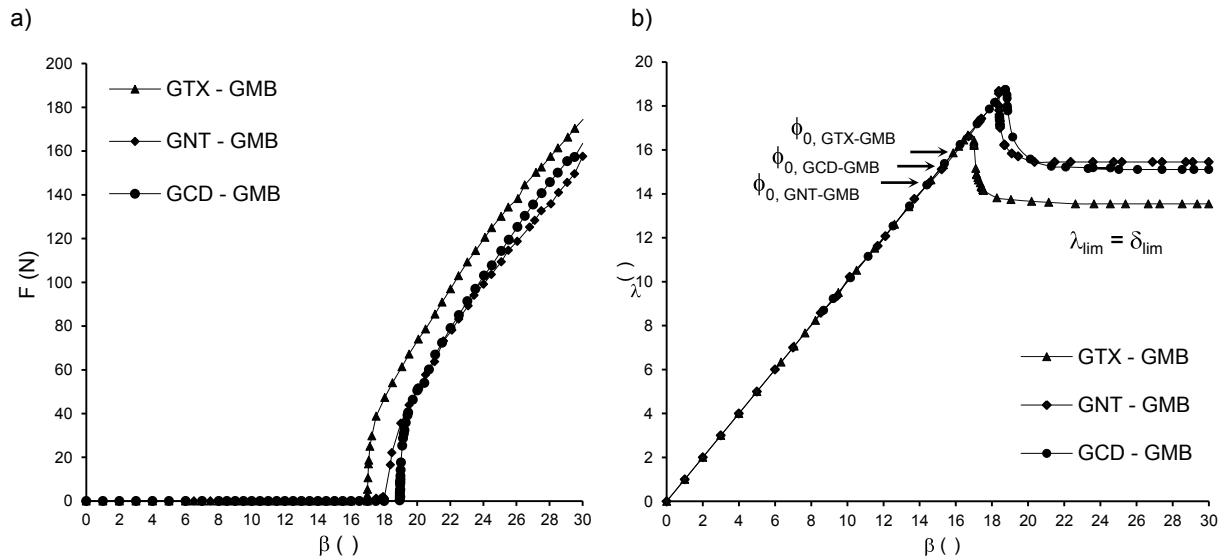

Figure 5. Force Procedure test results: a) The force F mobilized against the plane inclination angle β during the entire test; b) The parameter λ versus β plotted during the three steps.

At this stage, as it could be noticed in Figure 5b, λ versus β reaches a constant value and the characteristic parameter corresponding to the static phase, can be determined after the stabilization of the system ($\delta_{lim} = \lambda_{lim}$ for $\beta > \beta_{lim}$). Thus, the limit interface friction angle, δ_{lim} is the only parameter of the interface that could be determined according to the Force Procedure.

In this experimental program, the length of the cable is adjusted to perform the test at large displacement before the cable stretching, $u_{lim} = 715$ mm.

It is worth noting that, also in this method, the performance of GCD^U-GMB^L interface is influenced by the combination of the geotextile and the geonet and the resulting limit interface friction angle is between the two values: $\delta_{lim}^{GTX} < \delta_{lim}^{GCD} < \delta_{lim}^{GNT}$.

The results of the interface friction angles determined with the three different approaches are presented in Table 2.

From test results it could be noticed that the Standard Interpretation is not consistent with the real friction mobilization because a static approach is proposed for a kinematic condition. Furthermore, the conventional reference displacement $u = 50\text{mm}$ could lead to an overestimation of the interface friction compared to the static angles ϕ_0 and δ_{lim} as also found in other studies concerning other geosynthetic interfaces (Brianchon et al. 2011; Pitanga et al. 2009).

Thanks to the Displacement Procedure results, it is possible to understand the evolution of the interface friction if a slip occurs. In particular, in the studied cases, the dynamic friction angle increases ($\phi_s > \phi_0$) as soon as the stabilized sliding is attained.

Table 2. Friction angles at the Inclined Plane test applying the Standard, the Displacement and the Force Procedures.

INTERFACE TESTED	STANDARD PROCEDURE	DISPLACEMENT PROCEDURE		FORCE PROCEDURE
	ϕ_{stan} (°)	ϕ_0 (°)	ϕ_s (°)	δ_{lim} (°)
GTX^U - GMB^L	16.3	15.8	16.3	13.5
GNT^U - GMB^L	16.3	15.2	18.3	15.4
GCD^U - GMB^L	16.8	15.7	18.0	15.1

The static interface friction angle δ_{lim} could represent the minimum mobilized friction after a large relative displacement between the two layers in contact.

At last, regarding the ϕ_s and δ_{lim} angles, a similar trend of test results is found in other studies (Pitanga et al. 2011; Brianchon et al. 2011) even if the friction angles could be different depending on the materials properties.

However a question is still pending: what kind of the interface friction value should be selected to represent appropriately the interface behaviour? Additional tests program on many different interfaces are in progress in order to fit test results belonged to different kinematics conditions with the actual field situations.

5. CONCLUSIONS

Nowadays, the use of geosynthetics is a common practice in landfill barriers. Since the landfill liner systems are even steeper, an appropriate characterization of the mechanical properties of the interfaces is required for their stability analysis. In this contest, the appropriate determination of the interfacial frictional properties is necessary.

In this work, the mechanical characterization of a typical interface found in landfill barriers is presented and discussed. In fact, the experimental assessment of geocomposite drain (GCD) – geomembrane (GMB) interface is particularly important since its use is become even more widespread. To assess its performance, also the effect of the two different materials which form the composite layer (geonet and geotextile) is examined separately. For this purpose, the three procedures “Standard”, “Displacement” and “Force” are carried out.

The results shown in Figure 4a and 4b, indicate that all combinations of geosynthetics tested with HDPE smooth geomembrane, exhibit a typical behavior of gradual sliding and, in particular, a stick-slip behavior for GNT - GMB and GCD - GMB interfaces.

Following the test sets on GNT-GMB and GTX-GMB, it could be deduced that the behavior of GCD-GMB interface, where the Geotextile GTX is in direct contact with the Geomembrane GMB, is influenced by the Geonet GNT support. In conclusion, based on test results, it could be noticed that:

- “Standard Procedure” is not rigorous because a static approach is proposed for kinematic conditions. Moreover, this interpretation overestimates the interface friction angle, overall in the case of gradual sliding, compared to the static ones.
- Thanks to the “Displacement” and the “Force” Procedures it is possible to study accurately the interface friction during different phases of the test. Anyway, it is worth noting that the corresponding friction angles are calculated in different kinematics conditions. In particular, the interface friction angle ϕ_s is determined taking into account the acceleration during the slide (dynamic conditions of the upper box) while δ_{lim} corresponds to a static

state of the upper box after large displacements. Test results show that the kinematic conditions could influence the interface friction angles. For this purpose it is important to relate the conditions found during the laboratory tests with the existing situations on site. Finally, it is necessary to answer to the outstanding question about the selection of the interface friction angle that could lead to an appropriate value for a safe design.
